During proestrus serotonergic uptake in the median eminence and suprachiasmatic regions reaches peak values ($p < .05$) at the beginning of the critical period for luteinizing hormone release. This peak of serotonergic uptake in the suprachiasmatic region confirms previous data on cycling females and is probably related to photoneuroendocrine control mechanisms.

Diestrus serotonergic uptake in the median eminence shows maximum values during the mid light period and minimum values during the late light-early dark period ($p < .05$). These results in conjunction with the diestrus serotonergic uptake changes in the amygdala, suggest a role for these regions in ovulation control mechanisms prior to the critical period for luteinizing hormone release.

152.33 OPPOSING ACTIONS OF TWO NOREPINEPHRINE (NE) CNS STRUCTURES IN THE REGULATION OF RHYTHMIC GROWTH HORMONE (GH) SECRETION. T.A. Day* and J.O. Willoughby. Centre for Neuroscience, Flinders University of South Australia, Bedford Park, South Australia 5042

Pituitary GH secretion is regulated by somatostatin (SRIF) and a postulated GH releasing factor (GRF) which are released from tubero-infundibular (TI) nerve terminals at the median eminence (ME) into the hypothalamo-pituitary portal circulation. Cell bodies of SRIF TI neurons are located in the preoptic/anterior hypothalamic area (PO/AHA). Hypothalamic deafferentation studies suggest that GRF TI neurons are located in the medio-basal hypothalamus. Previous studies have shown that NE is important in the regulation of GH secretion but have not specified its site of action. NE may act directly on SRIF or GRF cell bodies or on SRIF or GRF terminals in the ME. The present study examined the effects on GH secretion of 6 hydroxydopamine (6OHDA) destruction of catecholamine (CA) structures within the CNS, generally, or in the ME or PO/AHA, specifically. A CA-fluorescence technique was used to confirm destruction of CA structures in the respective studies.

Male Porton albino rats chronically implanted with right atrial cannulae were used. Radioimmunoassay of GH (NIAMDD materials) in plasma samples obtained by serial blood sampling of these undisturbed animals permitted construction of hormone profiles before and after treatments of the animals with (a) 6OHDA 600 µg intracerebroventricularly (icv) (b) 6OHDA 2 µg intracerebrally in the PO/AHA and (c) intravenous (iv) 6OHDA 50 mg/kg, a treatment which selectively destroys ME NE terminals because 6OHDA fails to penetrate the blood-brain barrier, which is absent at the ME, and ME DA neurons are resistant to this treatment.

One day after treatment GH secretion was almost completely suppressed by icv and PO/AHA 6OHDA but iv 6OHDA dramatically increased the frequency of GH secretory bursts. Recovery of GH secretory rhythms occurred in all groups within 1-3 weeks.

As DA is thought to have only a minor role in the regulation of GH release, suppression of GH following icv 6OHDA treatment favours the accepted facilitatory action of NE in GH secretion. GH suppression by PO/AHA 6OHDA indicates that it is NE in the PO/AHA which is facilitatory for GH, presumably by an inhibitory action on SRIF neurons. The increased frequency of GH peaks after iv 6OHDA indicates that ME NE is inhibitory to GH secretion. Others have shown that NE stimulates SRIF release from ME terminals incubated in vitro, suggesting that ME NE inhibits GH through an excitatory action on SRIF terminals.

152.34 DIFFERENCES IN THE PROLACTIN-INDUCED ACTIVATION OF TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS IN MALE AND FEMALE RATS. K.T. Demarest and K.E. Moore. Dept. of Pharmacology and Toxicology, Michigan State University, East Lansing, MI 48824.

Studies were undertaken to investigate factors responsible for the previously observed differences in the activity of tuberoinfundibular dopaminergic (TIDA) neurons in male and female rats (Demarest et al., Fed. Proc. 39(3): 980, 1980). The in vivo rate of dopamine (DA) synthesis, estimated by the accumulation of DOPA in the median eminence 30 min after the administration of a DOPA decarboxylase inhibitor (NSD 1015; 100 mg/kg, ip), was used as a biochemical index of TIDA neuronal activity. The rate of DOPA accumulation in the median eminence of female rats (16.8±0.9 ng/mg protein/30 min) was greater than that in male rats (5.6± 0.4). Previous reports indicate that increased concentrations of prolactin in serum or CSF cause a delayed activation of TIDA. Estradiol benzoate (25 µg/kg sc x 3 days), which increases serum prolactin, increased the rate of DOPA accumulation in the median eminence of both male and female rats. Since this effect was not observed in hypophysectomized rats it is probably not the result of a direct action of estrogen on TIDA neurons, but rather the result of the estrogen-induced increase in serum concentrations of prolactin. These results demonstrate that prolactin stimulates TIDA nerves in the female. It was unexpectedly found, however, that hypophysectomy per se dramatically reduced the rate of DOPA accumulation in the median eminence of female rats but not in male rats. TIDA neurons in the hypophysectomized female rats retain the capacity to respond to prolactin since the intracerebroventricular administration of this hormone (1 µg/10 µl) increased DOPA accumulation in the median eminence of hypophysectomized animals in the same way as it does in intact animals. The greater basal rate of DOPA accumulation in the median eminence of the female rat and the marked decrease in this rate following hypophysectomy may be due to the greater sensitivity of TIDA neurons to circulating prolactin in the female. To test this possibility the capacity of prolactin to stimulate TIDA neuronal activity was compared in male and female rats. Rat prolactin (0.1-10 µg) was infused into the lateral cerebroventricles of conscious castrate male and female rats via previously implanted cannulas. When measured 12 hr after prolactin administration DOPA accumulation in the median eminence was significantly increased at a lower dose in the female than in the male (minimal effective doses were 0.1 µg and 1 µg, respectively). These results indicate there is a marked difference in the sensitivity of TIDA to prolactin in male and female rats. (Supported by USPHS grant NS9174.)

152.35 EFFECT OF DEHYDRATION AND REHYDRATION ON TUBEROHYPOPHYSEAL DOPAMINERGIC NEURONS. R.H. Alper and K.E. Moore. Dept. of Pharmacology and Toxicology, Michigan State University, East Lansing, MI 48824.

Tuberohypophyseal dopamine (DA) neurons originate in the arcuate nucleus of the hypothalamus and project to the neural and intermediate lobes of the pituitary (posterior pituitary). The purpose of the present study was to characterize some of the factors that regulate the activities of these neurons in the rat. For this purpose the rate of synthesis of dopamine was quantified by measuring the accumulation of DOPA 30 min after the inhibition of DOPA decarboxylase with NSD 1015 (100 mg/kg, ip). Three days of water deprivation did not alter the concentrations of DA or norepinephrine (NE) but selectively increased the rate of DOPA accumulation in the posterior pituitary (2.4 versus 1.3 ng DOPA/mg protein/30 min). Water deprivation did not alter DOPA accumulation in the striatum or median eminence, regions containing terminals of nigrostriatal and tuberoinfundibular DA nerves, respectively. The rate of DA and NE synthesis in the posterior pituitary was also calculated from the rate of decline of these amines following the administration of α-methyltyrosine (250 mg/kg, ip). Three days of water deprivation increased the rate of DA synthesis in the posterior pituitary (1.9 versus 1.1 ng DA/mg protein/hr) whereas NE synthesis was unaltered (0.2 ng NE/mg protein/hr for water deprived and control rats). Thus, the increased DOPA accumulation in the posterior pituitary of water deprived rats represents an increase in DA and not NE synthesis. The water deprivation-induced increase in tuberohypophyseal DA nerve activity was partially reversed in animals provided access to water for 12 hr and completely reversed in animals rehydrated for 24 or 48 hr.

Subcutaneous injections of polyethylene glycol (PEG) cause similar but more rapid increases in hematocrit and plasma vasopressin concentrations than those observed during water deprivation (Dunn et al., J. Clin. Invest. 52: 3212, 1973). Hypovolemia, as evidenced by an increase in hematocrit, was observed 3, 6 and 12 hr after PEG 4000 (4 g/kg, sc). At 12 hr, but not at 3 or 6 hr, after PEG 4000 DOPA accumulation was increased in the posterior pituitary but not in the striatum or median eminence. These results demonstrate that PEG 4000 and water deprivation selectively stimulate DA synthesis in tuberohypophyseal neurons and the effect of water deprivation is reversible by rehydration. (Supported by USPHS grants NS9174 and NS15911.)

152.36 LACTATION ALTERS THE ACTIVITY OF TUBEROINFUNDIBULAR DOPAMINERGIC NEURONS. D.W. McKay*, K.T. Demarest, G.D. Riegle* and K.E. Moore (SPON: W.H. Lyness). Depts. of Animal Husbandry, Physiology, and Pharmacology and Toxicology, Michigan State University, E.Lansing, MI 48824.

Alterations in tuberoinfundibular dopaminergic (TIDA) neuronal activity may play a role in the regulation of prolactin secretion during lactation. Studies were undertaken to determine the activity of TIDA neurons, estimated by the accumulation of DOPA in the median eminence 30 min after the administration of a decarboxylase inhibitor (NSD 1015, 100 mg/kg, i.p.), in female rats during diestrus and lactation. All lactating animals were used 12 days post-partum and litters equalized to 8 pups at 7 days post-partum. After 4 hr of pup deprivation, the activity of TIDA neurons was determined in the following groups of lactating female rats: 1) pups were returned and allowed to suckle for 30 min during which time DOPA accumulation was measured (suckled), 2) pups were returned, allowed to suckle for 30 min and then removed for 30 min during which time DOPA accumulation was measured (post-suckled), 3) pups were not returned and DOPA accumulation was measured for 30 min (non-suckled).

In the lactating animals, suckling significantly reduced the rate of DOPA accumulation (6.3±0.5 ng DOPA/mg protein/30 min) when compared to the nonsuckled (9.9±0.5) or post-suckled groups (8.0±0.9). This suckling-induced decrease in TIDA neuronal activity may play a role in the mediation of the increased prolactin secretion during suckling. The rate of DOPA accumulation observed in the diestrous group (18.5±1.4) was significantly greater than that in any of the lactating groups. There were no significant differences in the rates of DOPA accumulation in brain regions (striatum, nucleus accumbens, olfactory tubercle) containing terminals of mesotelencephalic DA neurons. Since results of previous studies have demonstrated that TIDA neurons are activated during periods of increased serum concentrations of prolactin (see review Moore and Wuerthele, Prog. Neurobiol. 13: 325, 1979), the low rate of DOPA accumulation observed in the median eminence of lactating animals was unexpected. It would appear that TIDA neurons are somehow inhibited during lactation to allow the serum prolactin concentrations to increase. (Supported by USPHS grants HD 10521 and NS 9174.)

153.1 EXTRANUCLEAR INPUT TO NEURONS OF THE CAUDAL NEUROSECRETORY SYSTEM. R.M. Kriebel* and J.P. O'Brien* (SPON: J. Wells). Dept. of Anatomy & Neurobiology, University of Vermont, College of Medicine. Burlington, VT 05405

The caudal neurosecretory system provides a favorable structure in which to study the synaptic control of neurosecretory mechanisms. The neurosecretory neurons in the caudal system of the black molly are an isolated population of cells in the terminal aspect of the spinal cord. This group of neurosecretory cells can be deafferented from extranuclear input to examine the relationship of extranuclear and intranuclear synaptic control of neurosecretion. To identify the extranuclear synaptic input, surgical deafferentation was performed on sixteen animals by transection of the spinal cord rostral to the caudal system. Animals were allowed to survive 12, 24, 40 hours, and 7 days after the lesion. At each postlesion time, four animals were anesthetized in MS-222 and killed by decapitation. Five animals provided control data on the synaptic organization of the caudal neurosecretory system. The caudal system was fixed in vivo by a 2.5% glutaraldehyde, 2% paraformaldehyde, phosphate buffered solution (0.06M) and subsequently prepared for electron microscopy. In control tissue, synaptic terminals were observed on cell bodies and dendrites of the neurosecretory cells. Identification of the extranuclear synaptic input was determined by the dark reaction of synaptic boutons, preterminals, and axon bundles in the lesioned animals. Degeneration of small myelinated axon bundles was seen in the dorsolateral portion of the spinal cord at seven days after transection. At forty hours, degenerating synaptic boutons were found primarily in the vicinity of the neuronal soma and engulfed in thin glial processes. These results suggest that control of neurosecretory mechanisms by extranuclear input is at the level of the somal membrane. HRP tracer studies are currently being undertaken to determine the specific source of these terminals. (Supported by PHS 5429-16-19)

153.2 DYE-COUPLING BY GAP JUNCTIONS IN MAGNOCELLULAR NEUROENDOCRINE CELLS OF RAT HYPOTHALAMUS: EVIDENCE FOR ELECTROTONIC COUPLING. R. David Andrew, Brian A. MacVicar, F. Edward Dudek and Glenn I. Hatton. Dept. Zool., Univ. Toronto, Toronto, Ontario M5S 1A1, and Dept. Psychol. and Neuroscience Program, Michigan State University, East Lansing, MI 48824.

Electrotonic coupling has been demonstrated between endocrine cells and between some neurons of the vertebrate brain. The morphological substrate of communication is gap junctions, channels which allow molecules of MW <1000 to pass between cells. It is not known if vertebrate neuroendocrine cells or hypothalamic neurons in general are coupled. We have examined, by two independent means, the possibility of electrotonic coupling in neuroendocrine cells of the rat paraventricular nucleus (PVN) and supraoptic nucleus (SON).

Coronal hypothalamic slices (500 μm) were cut and single cells in PVN and SON impaled with micropipettes containing 5% Lucifer Yellow (MW=453) in .33 M Li Citrate. Dye was injected with hyperpolarizing currents (7nA, 30-180 sec). Ten dye ejections (7nA, 180 sec) into extracellular space served as controls. Injected magnocellular neurosecretory cells (MNC's) of PVN or SON were identified by a minimum diameter of 15 × 15 μm and a large cytoplasm-to-nucleus ratio. Of 32 well-filled MNC's, 14 were dye-coupled to a second MNC (9 of 19 in PVN, 5 of 13 in SON). The majority of coupling appeared to be dendro-dendritic. In two cases, a third MNC was faintly stained. No intracellular uptake of dye was observed following extracellular ejections.

For electron microscopy, tissue blocks containing PVN or SON were dissected from fresh brains and immediately fixed. Freeze-fracture replicas displayed particle aggregates on P-face membrane of cells with cytoplasm containing 170-220 nm diameter neurosecretory vesicles. Furthermore, these aggregates were comprised of from 15 to 400 small diameter particles surrounded by a halo of non-particulate membrane, thus having a typical gap junction morphology.

We conclude that gap junctions provide the channels that dye-couple MNC's in PVN and SON and that, as such, these cells are probably electrotonically coupled. Coupling may facilitate the recruiting or synchronizing of peptidergic neurons which release neurohormone in a pulsatile fashion. Lucifer Yellow injections together with immunohistochemistry should identify the peptide contents of coupled MNC's.

153.3 HYPOTHALAMIC ACCESSORY MAGNOCELLULAR VASOPRESSIN, OXYTOCIN AND NEUROPHYSIN NEURONS PROJECTING TO THE NEUROHYPOPHYSIS IN THE RAT. M. V. Sofroniew, U. Schrell*, W. Glasmann*, A. Weindl* and R. Wetzstein*. Dept. of Anatomy, Ludwig-Maximilians University, Pettenkoferstr. 11, 8000 Munich 2, FRG.

It is commonly known that vasopressin (VP), oxytocin (OT) and neurophysin (Nph) are produced by hypothalamic magnocellular neurons located in the supraoptic and paraventricular nuclei. However, in many mammalian species there is a large population of magnocellular VP, OT and Nph neurons outside of these nuclei, located in various groups in different parts of the hypothalamus. In this study we have examined the topography of these groups, as well as the extent of their projections to the neural lobe, using a new procedure allowing the parallel demonstration of the horseradish peroxidase (HRP) retrogradely transported by, and the peptide produced by, the same neurons. For topographical analysis, endogenous VP, OT and Nph were visualized using the immunoperoxidase technique. To analyze peptide-specific projections, HRP (0.4 μl, 15%) was injected into the neural lobe; after 48 hr, rats were sacrificied and hypothalami processed for 1.5 μm sections; HRP, VP, OT and Nph were then detected immunohistochemically in neighboring serial sections. In the rat hypothalamus, accessory magnocellular neurons can be divided into more than 8 separate groups. The groups are located in the medial preoptic area and medial anterior hypothalamus, behind the anterior commissure, near the rostral end of the stria terminalis, along the third ventricle, at several levels of the lateral hypothalamus, and in the posterior hypothalamus lateral to the fornix. Most groups contain both VP and OT neurons. The group just caudal to the anterior commissure consists of only OT neurons. The neighboring serial 1.5 μm sections showed that a large number of VP, OT and Nph neurons in the various groups had retrogradely transported HRP from the neural lobe. The presence of VP, OT and Nph neurons not transporting HRP may have been due to injection sites which did not always include the entire neural lobe. At present all magnocellular neurons in the accessory groups (or in the supraoptic and paraventricular nuclei) identified as transporting HRP from the neural lobe, have also stained positively for Nph and either VP or OT in the neighboring 1.5 μm sections. No neurons stained for both VP or OT. These findings indicate that there is an extensive network of magnocellular accessory neurons in the rat, and that a large portion of these neurons project to the neurohypophysis. These neurons may also contribute to the extrahypophyseal VP, OT and Nph projections. Past descriptions of their topography are incomplete, and a new and simpler nomenclature is warranted. Supported by the Deutsche Forschungsgemeinschaft (We 608/5).

153.4 THE HYPOTHALAMIC ARCUATE NUCLEUS OF RAT: A QUANTITATIVE GOLGI ANALYSIS. Anthony N. van den Pol and John R. Cassidy*. Sect. Neurosurgery, Yale Univ. Sch. Med., New Haven, Conn. 06510.

The arcuate nucleus (ARC) has classically been considered a loosely organized net of relatively simple neurons. To better understand the intrinsic organization of this nucleus, a computer-assisted analysis of Golgi impregnated material was undertaken. From our series of several hundred Golgi impregnated hypothalami, 11 brains from 8-10 day old rats were selected. High magnification camera lucida drawings were made of 1,686 neurons in ARC and additional cells in the adjacent hypothalamus for comparative purposes; coronal and horizontal sections were used. Neurons and their 3-dimensional position in the ARC were digitized (Summagraphics Digitizer) for computer storage and quantitative analysis. Neurons had one to four primary dendrites. The mean number of primary dendrites from 487 neurons drawn from coronal sections was 2.1±0.8 (SD). Medially, on horizontal sections, dendrites of arcuate neurons tended to run orthogonal to the tanycytes projecting from the wall of the third ventricle into ARC. The center of dendritic mass (in two dimensions) relative to the perikaryon of origin was examined; averaged over all areas of ARC, the percent of cells with the center of mass dorsolateral to the soma was 28%, dorsomedial 21%, ventromedial 17%, and ventrolateral 34%. When these data were grouped on the basis of perikaryal location, differences between ARC subpopulations were found: for instance dorsomedial cells were more likely to send dendrites dorsomedially (28%) than ventrolateral cells (14%) were. When the total length of a cell's dendritic arbor in single coronal sections was examined, neurons in the rostral 30% of ARC had 56% larger total dendritic length than cells in the caudal 30% of the nucleus. Axons originated from perikarya and primary dendrites; locally terminating collaterals, projections lateral and outside ARC, and projections ventrolateral into the median eminence were found. The initial trajectory of 249 axons originating from ARC cells was in a medial direction (62%). Impregnated axons were found in coronal sections which proceeded horizontally through the dorsal median eminence and gave off ventrally directed collaterals at regular intervals parallel to ventral tanycytes. Tanycytes represent a significant factor in the overall cellular organization of ARC. The height of the tanycyte cell body above the base of the brain was highly correlated (r=.95) with the position of the terminal process of the same tanycyte measured laterally from the ventricular wall. Taken together with additional analyses not described above the arcuate nucleus is found to have a significant organization which is revealed by quantitative assessment of large number of cells.

Supported by NIH Grant NS16296 and NS10174.

153.5 SUCKLING INCREASES DIRECT CELL-CELL APPOSITION BETWEEN NEUROSECRETORY NEURONS IN THE RAT SUPRAOPTIC NUCLEUS. Glenn I. Hatton and Charles D. Tweedle, Neuroscience Program and Department of Anatomy, Michigan State University, East Lansing, MI 48824

Water deprivation for short periods of time (4-24 h) has been shown to increase the amount of direct soma-somatic contact between magnocellular neurosecretory cells (MNC's) of the supraoptic (SON) and circularis nuclei (Cell Tiss. Res. 1977, 181, 59-72). This increased contact was apparently due to withdrawal of fine glial processes from between the MNC somata. Rehydration reversed this effect, re-establishing control levels of cell-cell contact presumably by glial re-insertion.

Lactating rats were studied to determine whether another, naturally occurring stimulus complex known to physiologically activate hypothalamic MNC's would lead to similar changes in cell contact characteristics. Thin sections of SON from lactating and non-lactating rats (Holtzman strain) were quantitatively examined at the ultrastructural level. Lactating rats were allowed to nurse their young for 2 weeks prior to perfusion fixation with buffered aldehydes. To date, we have measured the % of cells in direct soma-somatic contact and the % total membrane in contact for samples of thin sections from these two treatment groups. In non-lactating rats the cells in contact = 4.6% and the amount of membrane in contact = 0.09% of total. These values in lactating rats were 42.8% and 7.2%, respectively. Thus, there was a 10-fold increase during lactation in the number of cells and a 70-fold increase in the amount of membrane involved in making soma-somatic appositions. The large increase in direct cell contact may be related to the fact that in lactating rats not only are oxytocin containing neurosecretory cells being activated by suckling, but other neurosecretory cells containing other peptides (e.g., vasopressin, enkephalin) may also be activated by dehydration which results from lactation.

This research was supported by NIH grant NS 09140 and by the College of Osteopathic Medicine of Michigan State University.

153.6 BRAIN CELLS OF THE MALE RHESUS MONKEY ACCUMULATE ^{3}H-TESTOSTERONE OR ITS METABOLITES. H.D. Rees and R.P. Michael. Dept. of Psychiatry, Emory Univ. Sch. of Med., Atlanta, GA 30322 and Georgia Mental Health Institute, Atlanta, Georgia 30306.

Androgens restore the potency of castrated male rhesus monkeys, and may also stimulate aggressive behavior. To help elucidate the neural mechanisms for the behavioral actions of testosterone in the primate, the distribution of testosterone target cells in the rhesus brain was studied by autoradiography. Two days after castration, a mature male rhesus monkey, weighing 9.6 kg, was tranquilized with ketamine (10 mg/kg) and injected intravenously with 2 mCi of ^{3}H-testosterone (5.8 µg) (New England Nuclear, 98.8 Ci/mmol). An hour later, the monkey was killed by an intravenous injection of Nembutal, and its brain was removed and frozen in liquified propane at -180°C. Frozen sections, 4 µm thick, were cut in a cryostat, thaw mounted on Kodak NTB3 emulsion-coated slides, and photographically developed after exposure for 10 months.

Radioactivity, representing ^{3}H-testosterone or its labelled matabolites, was concentrated in nuclei of neurons in several areas of the brain, including the medial and cortical amygdaloid nuclei, the accessory part of the basal amygdaloid nucleus, periamygdaloid cortex, suprachiasmatic preoptic nucleus, medial preoptic nucleus, anterior hypothalamic area, bed nucleus of the stria terminalis, ventromedial hypothalamic nucleus, and periaqueductal gray. All of these structures are known targets for testosterone in male rats (M. Sar and W.E. Stumpf, in Anatomical neuroendocrinology, Stumpf and Grant, eds, Karger: Basel, 1975), but androgen localization has not previously been reported for the brain of any primate species.

Since the brain of the rhesus monkey has the enzymatic capacity for the aromatization of androgens to estrogens (F. Flores et al., Neuroendocrinol., 11:177, 1973), as well as for 5α-reduction and 17β-dehydrogenation (L.J. Sholiton et al., Steroids, 24:537, 1974), further studies are necessary to characterize the chemical identity of the nuclear radioactivity visualized autoradiographically in the present study.

Supported by grant number MH 19506, U.S. Public Health Service, and by Georgia Dept. of Human Resources.

153.7 THE EFFECT OF KAINIC ACID ON AROMATIZATION AND 5α-REDUCTION IN EMBRYONIC RAT HYPOTHALAMIC CULTURES. E.G. Livingston*, J.A. Canick*, D.E. Vaccaro*, K.J. Ryan*, and T.O. Fox, (SPON: S.Wieland), Depts. of Obstetrics and Gynecology, and Neuropathology, and Laboratory of Human Reproduction and Reproductive Biology, Harvard Medical School, and Dept. of Neuroscience, Children's Hospital Medical Center, Boston, MA 02115.

Kainic acid, a potent neurotoxic agent (Olney et al, Brain Res. 77:507, 1974), was used in the investigation of cell classes responsible for aromatization and 5α-reduction of androgen in the hypothalamus. The conversions of [6,7-^{3}H]19-hydroxyandrostenedione to [^{3}H]estrone (aromatization) and [1β,2β-^{3}H]testosterone to [^{3}H]5α-dihydrotestosterone (5α-reduction) were studied in intact primary cell cultures of embryonic rat hypothalamus (Vaccaro & Messer, TCA Manual 3:361, 1977). To determine the effect of kainic acid on a non-neuronal class of cells, glutamine synthetase activity, localized to glial cells in the brain (Martinez-Hernandez et al, Science 195:1356, 1977), was measured in extracts of the cultured cells. All cultures were treated initially with 1β-D-arabinofuranosylcytosine (ara-C), which results in increased neuritic elongation and inhibition of the proliferation of non-neuronal cells. Seven days after plating, the cultures were exposed to kainic acid for an additional 8 days. The neuronal population was low in number and some of the remaining neurons had disintegrating processes in the kainic acid-treated cultures. The effect of kainic acid (K.A.) on enzyme activity was:

	Aromatase (pmol/culture/24hr) (mean±SEM, n=6)	5α-reductase	Glutamine synthetase (µg GHA/culture/hr) (mean, n=2)
Control	0.25±0.03	1.69±0.06	10.3
10^{-4}M K.A.	0.14±0.01	1.75±0.05	9.8
10^{-3}M K.A.	0.02±0.002	1.75±0.03	10.3

A time course experiment indicated that kainic acid (10^{-3}M) affects neuronal morphology and aromatization as early as two days after treatment. Kainic acid preferentially decreases aromatization without measureably affecting 5α-reductase. This is consistent with a predominant localization of aromatase in neurones.
(Supported by NIH grants HD 12337 to J.A.C. and HD 10818 to T.O. F.; a postdoctoral N.R.S.A., NINCDS, to D.E.V.; facilities of the Mental Retardation Res. Ctr., NICHD, at Children's Hospital Med. Ctr.)

153.8 EFFECT OF A POLYPEPTIDE (E_5) EXTRACTED FROM BOVINE PINEAL GLANDS ON PLASMA AND PITUITARY LEVELS OF LUTEINIZING HORMONE (LH) AND PROLACTIN IN NORMAL AND CASTRATED ADULT MALE RATS. M.K. Vaughan, L.Y. Johnson, P. Pevet*, C. Neacsu*, and R.J. Reiter. Department of Anatomy, University of Texas Health Science Center at San Antonio, San Antonio, TX 78284, The Netherlands Institute for Brain Research, Amsterdam, The Netherlands, and Oncological Institute, Bucharest, Romania.

A highly purified polypeptide (E_5) from the bovine pineal gland blocks spermatogenesis in gonadotropin-treated male frogs (Rana esculenta) and inhibits uterine weight and P^{32} incorporation in gonadotropin-treated female mice (Neacsu, Rev. Roum. Physiol. 9: 161-169, 1972). In the present experiment, the effects of E_5 on plasma and pituitary levels of LH and prolactin in intact and castrated adult male rats were assessed. Forty-three adult male rats (225-275 g) were housed in a temperature and light-controlled room (14L:10D; lights on 0600) and provided with food and water ad libitum. Twenty-three rats were castrated using ether anesthesia; 20 rats were left intact. One hour following castration, the intact and castrated rats were divided into 4 treatment groups: intact + diluent (11 rats), intact + 5 µg E_5 (9 rats), castrate + diluent (12 rats) and castrate + 5 µg E_5 (11 rats). E_5 was diluted in 0.5% bovine serum albumin (BSA)-Ringers lactate diluent. Subcutaneous injections of 5 µg E_5 or diluent were administered every 12 hours for 5 injections. One hour following the last injection, the rats were rapidly decapitated and a trunk blood sample obtained. Anterior pituitaries were weighed and disrupted by sonication in 1% BSA-0.05M phosphate buffer. Plasma and pituitary samples were stored frozen until radioimmunoassay (RIA). RIA kits were provided by NIAMDD. As expected, castration caused a significant elevation in plasma LH ($p < 0.001$) and a concomitant decrease in pituitary LH ($p < 0.001$) when compared to the levels of diluent-treated intact rats. Both plasma ($p < 0.05$) and pituitary ($p < 0.01$) levels of LH were significantly depressed in E_5-treated intact rats compared to intact controls; E_5, however, had no effect on plasma or pituitary levels of LH in castrated rats. E_5-treated intact rats had a significantly lower ($p < 0.001$) level of pituitary prolactin than the corresponding diluent-treated intact animals; no effect was observed on plasma prolactin levels. In conclusion, the effects of E_5 administration are most evident on pituitary levels of LH and prolactin in intact rats; the exact mechanism by which this phenomeon is accomplished remains to be elucidated.
Supported by NSF grant PCM-77-05374 and NIH Center for Reproductive Biology (Bioassay Core) #P 30 HD 10202.

153.9 EFFECTS OF NEONATAL ALTERATIONS IN GONADAL STEROIDS ON CA1 HIPPOCAMPAL PYRAMIDAL CELLS: CHALLENGE WITH SEX HORMONES TO IN VITRO SLICE PREPARATIONS FROM ADULT RATS. Richard M. Vardaris, Timothy J. Teyler, and Craig T. Reiheld. Neurosci. Lab., Kent State U. and N.E.O.U.C.O.M., Kent, OH 44242.

In previous studies we have found that 17-beta-estradiol enhances throughput of the Shaffer collateral-CA1 synapse in slices from male hippocampus. Slices from females, however, show this response to testosterone. The female CA1 response to gonadal steroids varies with stage of estrous cycle. In addition we have found similar relationships for hippocampal CA1 cells with intact preparations.

In an effort to determine whether these gender-specific hippocampal response patterns are attributable to CNS differentiation or to circulating sex steroids, we are comparing the effects of gonadectomy at birth and in adulthood. For the present study, male and female rats were gonadectomized on Day 1 of life and then were injected with testosterone, 17-beta-estradiol, or a vehicle control solution. Both genders received each treatment.

Monosynaptic population responses were recorded from the CA1 cell body region of slices from the adult castrates. Control responses were obtained from slices that had equilibrated in steroid-free Ringer (Earle's medium). Responses following challenge with 10pM 17-beta-estradiol or testosterone were expressed as a percent of control amplitudes. Effects were evaluated 10 and 20 minutes after the administration of steroids.

The major result was that, after gonadectomy at birth, slices from both male and female adult hippocampus responded with increased synaptic throughput to challenge from either hormone. Steroid injections on Day 1 had inconsistent effects on responding. Studies involving different dosages and methods of hormone replacement are in progress as further attempts to investigate this problem.

153.10 IMMUNOHISTOCHEMICAL MAPPING OF NEUROACTIVE PEPTIDES IN THE CAT MEDIAN EMINENCE. Paul E Micevych and Robert P. Elde, Dept. of Anatomy, Univ. of Minnesota Medical School, Minneapolis, MN 55455

The effects of both exogenous and endogenous opiates on the neuroendocrine axis have been extensively documented by many authors. The localization of the enkephalins and opiate receptors to the median eminence (ME), as well as physiologic evidence support the concept that enkephalin is apparently acting at the level of terminals in the median eminence or the posterior pituitary. We had reported an extensive enkephalinergic system which overlapped the vasopressin-oxytocinergic system in the cat median eminence and posterior pituitary (Micevych, P. and Elde, R., J. Comp. Neurol., in press). We now expand these earlier immunohistochemical studies of the cat median eminence to demonstrate further areas of enkephalin-neuropeptide overlap and potential interaction in the median eminence.

Normal and colchicine treated cats (500 μg in the third ventricle, 48 hour survival) were perfused with 4% paraformaldehyde. Serial 10 μ cryostat sections were taken of the cat hypothalamus at 22 levels and stained with the indirect immunofluorescence method. Primary antisera directed against bovine neurophysin (NP), met-enkephalin (M-ENK), β-endorphin (β-END), α-MSH, somatostatin (SOM), luteinizing hormone releasing hormone (LHRH), and substance P (SP) were applied to adjacent sections and the pattern of staining for each antiserum was mapped.

Within the cat ME, very dense NP-like immunoreactivity was found in the internal layer and moderate to dense immunoreactivity was localized in the external layer abutting portal capillaries. The distribution of SOM and LHRH terminals and fibers in the ME appeared as a discrete band in the external layer of the lateral wings of the ME. Bright, punctate structures were scattered in the internal layer of the ME with anti-SOM sera. In contrast to the rat, scattered SP-like fibers and terminals were localized in the ME in the external layer near portal capillaries. No α-MSH or β-END was detected with antisera against these substances in the ME.

This overlap of neuropeptides may suggest physiologic interactions in the ME which may regulate hypophyseal function.

Supported in part by the Graduate School at the University of Minnesota.

153.11 PEPTIDE HORMONES AND THEIR PRECURSORS IN EXTRACTS OF BOVINE AND SHEEP PINEAL GLANDS. Jerry Vriend*, Patricia M. Hinkle*, Karl M. Knigge and Shirley A. Joseph* (SPON: L.A. Sternberger). The Neuroendocrine Unit and Department of Pharmacology, University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

Extracts of bovine and sheep pineal glands were fractionated on a Sephadex G-25 column (5 x 150 cm). Aliquots of lyophilized fractions were prepared for radioimmunoassay of LRF, TRF, and SRIF, for bioassay in an in vitro system of dispersed pituitary cells, and for further purification. Three 'peaks' of LRF immunoreactivity were detected and tested in bioassay. LH releasing activity was detected in only one peak. A second peak of material containing LRF immunoreactivity migrated on G-25 as if it contained an LRF-like peptide larger than LRF; a third peak of material migrated as if it contained an LRF-like peptide smaller than LRF. Evidence for two TRF-like substances was obtained using bioassay, radioimmunoassay, and radioreceptor assay. The two substances, apparently TRF and a TRF antagonist, were separated on the G-25 column. The material containing TRF antagonist activity displaced ^{3}H-TRF from pituitary cell membrane preparations in the TRF radioreceptor assay and inhibited TRF induced TSH release in cell culture. The TRF inhibitory factor (TRF-IF) was further purified on Sephadex G-10 and carboxymethylcellulose ion exchange columns. Copurification of anti-TRF bioactivity (in the dispersed pituitary cell system) and anti-TRF binding activity (in the radioreceptor assay) suggests that the inhibitory activity results from the binding of a TRF antagonist to receptors. TRF-IF did not copurify with SRIF or LRF, but did copurify with prolactin release inhibitory activity. Two peaks of SRIF immunoreactivity were detected by radioimmunoassay of G-25 fractions. Growth hormone releasing activity was detected in material obtained by subfractionation of G-25 fractions on LH-20. These results are interpreted as evidence for peptide hormones in the pineal gland. Larger molecular weight substances related to these hormones may be precursors with either no bioactivity or inhibitory activity.

153.12 EFFECTS OF CENTRALLY AND PERIPHERALLY ADMINISTERED MAO INHIBITORS ON SEXUAL BEHAVIOR, MONOAMINES AND MAO ACTIVITY. V. Luine, E. Schmitt*, C. Paden*. The Rockefeller University, New York NY 10021.

The effects of inhibition of monoamine oxidase (MAO) on female sexual behavior was investigated. Adult female rats were given pargyline or clorgyline i.v., tested for lordosis responding, and then levels of serotonin (5HT), norepinephrine (NE), MAO A and MAO B were measured in the preoptic-hypothalamic area.

Rats were ovariectomized-adrenalectomized, and one week later they received 2.5μg of estradiol benzoate for 2 days. On the 3rd day, MAO inhibitors were given, followed 2h later by progesterone. Sexual behavior (lordosis quotient (LQ) and quality score (QS)) was tested 3-5h later. Dose-dependent decreases in LQ and QS were observed after MAO inhibitors. Inhibition of behavior was most closely correlated with the extent of MAO inhibition and with increases in levels of 5HT in the preoptic-hypothalamic area. A significant lowering of LQ and QS occurred when both forms of MAO were inhibited by approximately 90% and/or when levels of 5HT were increased twofold. When only the A form was inhibited, the QS was lowered but the LQ was not. These levels of MAO inhibition were associated with increases in 5HT levels which were less than twofold. Increases in NE levels after MAO inhibition did not correlate well with decreases in behavior. The same increases in NE levels were found in treated females which did and which did not show decreased lordosis.

In order to localize more precisely the sites within the preoptic-hypothalamic area which may be involved in MAO inhibitor dependent decreases in sexual behavior, double barrel cannulas were stereotaxically implanted within this area. One week later, estrogen + progesterone (E+P) dependent lordosis responding was measured. The following day inner cannulas containing 2mm of crystalline pargyline were inserted, P was given 2h later, and lordosis behavior was tested 3-5h after P. Placements dorsal to the lateral aspect of the ventromedial nucleus led to decreases in LQ and QS 5-7 and 29-31h after pargyline. Placements at a greater distance above the ventromedial nucleus (within or dorsal to dorsomedial nucleus) led to decreases in LQ and QS only at the longer time interval suggesting further that diffusion of the drug to the ventromedial nucleus area might be critical for inhibiting behavior. The LQ and QS of all females recovered to pre-pargyline values 53-55h after pargyline administration.

Results suggest that serotonin containing systems projecting into the vicinity of the ventromedial nucleus may exert regulatory control of female sexual receptivity in rats.

154.1 VISUAL PROJECTIONS TO LIMBIC CORTEX. Richard T. Robertson, Scott M. Thompson*, and Martine J. RoBards. Department of Anatomy, College of Medicine, University of California, Irvine, CA 92717.

A neural substrate for visual projections to limbic cortex has been demonstrated in the rat by the combined use of anterograde transneuronal and retrograde transport techniques. Retrograde transport of horseradish peroxidase was demonstrated in 6μm cryostat sections by conventional histochemical techniques using 3-3' -diaminobenzidine or the Hanker-Yates reagents. These sections were then processed for autoradiography to demonstrate anterograde transneuronal transport of ^{3}H-adenosine and/or ^{3}H-uridine. Neurons that were labelled both with intracellular peroxidase reaction product and with overlying silver grains were interpreted as receiving an afferent projection from the region injected with ^{3}H-adenosine/uridine, and sending an efferent projection to the region injected with peroxidase.

Intraocular injections of ^{3}H-adenosine/uridine combined with pressure or iontophoretic injections of peroxidase into the lateral dorsal nucleus of the thalamus resulted in double labelled cells in the pretectal complex. Double labelled cells were found in the nucleus of the optic tract, the posterior pretectal nucleus, and the pretectal olivary nucleus.

Pressure injections of ^{3}H-adenosine/uridine were made in the pretectal complex, involving the nucleus of the optic tract and the posterior pretectal nucleus. When these injections were combined with pressure injections of peroxidase into the retrosplenial cortex or the presubiculum, double labelled cells were seen throughout much of the lateral dorsal nucleus of the thalamus.

Two conclusions can be made from these studies. First, the combined use of anterograde transneuronal transport and retrograde transport techniques offers a unique approach to determining functional neural connections with the light microscope. Second, these data indicate a functional series of connections that could convey visual information to the limbic system. The system includes retinal projections to the pretectal complex, pretectal projections to the lateral dorsal nucleus of the thalamus, and lateral dorsal projections to limbic cortex.

154.2 FUNCTIONAL CONNECTIONS OF THE AMYGDALA IN THE RAT DEMONSTRATED WITH THE (^{14}C)2-DEOXYGLUCOSE TECHNIQUE. B.S. Layton, S. David*, R.S. Poulsen*, C.J. Thompson* and Leo P. Renaud. Dept. of Neurology, Montreal General Hospital, Montreal, Canada.

A variety of morphological and electrophysiological techniques have been utilized to determine central connections of the amygdala from a structural and functional viewpoint. In the present experiments we have combined electrical stimulation in the rat amygdala with the (^{14}C)2-deoxyglucose (2-DG) autoradiographic method so as to trace its functional connections to various brain regions. Specific emphasis was directed to those connections of the amygdala with basal forebrain structures that have been examined with electrophysiological techniques. Pentobarbital anaesthetized Male Sprague-Dawley rats were implanted with monopolar or bipolar nichrome electrodes stereotaxically positioned in various amygdaloid nuclei and stimulated with current pulses (0.05msec duration 0.1-1.0mA) at frequencies of 2.0, 7.5, 10 and 20Hz. for 45 minutes. At the onset of stimulation, 150μCu/Kg body weight of 2-DG in 0.4 ml of normal saline was injected intravenously. After 45 minutes, the animals were sacrificed by decapitation and the brains were sectioned for autoradiographic and histological analysis. Our results indicate that electrical stimulation in the amygdala at frequencies greater than 2Hz enhanced 2-DG uptake in several areas ipsilateral to the stimulation site including the bed nucleus of the stria terminalis, preoptic area, ventromedial hypothalamus, head of the caudate nucleus and piriform cortex. Uptake was particularly dense over the stria terminalis pathway itself. These observations are in accord with known anatomical data on amygdalofugal projections to basal forebrain regions and provide information on changes in metabolic activity induced by electrical stimulation that can be correlated with the activity of single neurons evoked in these areas by stimulation in the amygdala. 154.3 Thalamic projections to the cingulate cortex of rabbits: Robert W. Sikes and Jon F. DeFrance, Dept. Anatomy & Neurobiology, Univ. of Texas Medical School, Houston, TX 77025

In their study of the cingulate cortex in rabbits, Rose and Woolsey (1948) described a topographical pattern of projection from the anterior thalamus in which the anterior medial nucleus (AM) projected to the anterior cingulate (LA), the anterior ventral nucleus projected to the posterior cingulate (CING), while the anterior dorsal nucleus (AD) projected to the retrosplenial cortex (RS). Recent studies in rats and cats have shown more overlap in the cortical projections of anterior thalamic nuclei and have described projections from thalamic nuclei not described in the Rose and Woolsey paper. This paper will reevaluate the thalamic projections to the cingulate cortex in rabbits using the retrograde horseradish peroxidase technique.

Adult New Zealand rabbits received small injections (10-100nL) of 25% horseradish peroxidase through micropipettes with a tip size of 10-50 mu. Injections were placed in the cortical fields defined by Rose and Woolsey. The tissue was processed by the tetramethylbenzidine technique (Mesulam, 1976).

Although the scheme of cortical projections by the anterior nuclei described by Rose and Woolsey was generally supported, important overlap was found. The projection from AM did terminate primarily in LA, but many neurons were labeled in this nucleus after injections into CING. Conversely, cells in AV were heavily labeled after injections into the CING and RS. These neurons were concentrated in the ventral part of the nucleus. Cells in the dorsal part of AV were labeled only by injections into the presubiculum or injections which entered the cingulum bundle. The AD had projections to much of the medial cortex caudal to the septal area, but appeared to have no projection to the dorso-lateral CING.

A major projection to the cingulate cortex also originated in the lateral thalamus (LP,LD). Neurons were heavily labeled in LP following all injections except for the most anterior ones. Neurons were also seen in LD, but in greatly reduced numbers.

Projections from the ventral thalamus (VA,VL,VM) terminate in LA. The primary projection field of VA may lie anterior to that of VL and VM which have a strong projection to the caudal LA.

Finally, neurons were labeled in the midline thalamic nuclei, especially in the mediodorsal nucleus (MD). Injections into LA produced labeled neurons in the lateral part of MD, and injections into the infralimbic area labeled neurons in the medial MD. The central and reunions nuclei also were occasionally labeled, but the topographical distribution is at this time uncertain.

154.4 ALTERED LH RESPONSE TO ESTROGEN PLUS PROGESTERONE TREATMENT IN FEMALE RATS WITH DUAL LIMBIC SYSTEM LESIONS. Julia L.Tyler, Valer Csernus* and Roger A. Gorski. Departments of Psychology and Anatomy, UCLA, Los Angeles, California 90024.

Extrahypothalamic structures appear to modulate luteinizing hormone (LH) release. In this study we examined the potential functional interaction of 3 limbic structures: olfactory bulbs, amygdala, and septum, in the release of LH in response to estradiol benzoate (EB) and progesterone (P). Ovariectomized rats received 1 or 2 of these bilateral procedures: sham surgery (SHAM), bulbectomy (OB), amygdala lesions (AL) or septal lesions (SL). Operations were performed simultaneously or 10 weeks apart. Ten to 12 weeks after the second operation the influence of EB and P on LH titers was tested. Jugular blood samples (0.5ml) were removed from etherized rats at 1600-1700 h (lights on 0500-1900 h) on 5 consecutive days. The first sample was taken the day before EB injection. EB (20 ug) was injected sc at 1300 h and P (2 mg) was injected 72 h later. Analyses of variance were applied to the data, followed by Neuman-Keuls tests. Relative to their pre-EB levels, all rats showed negative feedback 5 h post-EB. There were no differences among groups in LH levels prior to EB or 5 h or 29 h post-EB. Rats given OB first and SL 10 weeks later showed higher LH levels 53 h post-EB compared to those of several other groups, but were not different from SHAM rat values. Thus, few lesion effects were detected prior to P injection. Lesions did significantly alter the magnitude of the P-induced LH surge. LH values 5 h post-P are listed below:

SHAM:	2623 ± 471 ng/ml	OB/SL:	2803 ± 378 ng/ml
OB:	1374 ± 393*	OB+SL:	2870 ± 426
AL:	1379 ± 427*	SL+OB:	2170 ± 489*
SL:	2739 ± 352	AL/SL:	3209 ± 288
OB/AL:	1366 ± 474*	AL+SL:	2763 ± 420
OB+AL:	1747 ± 304*	SL+AL:	1910 ± 183*
AL+OB:	1398 ± 304*		

*= significantly different from SHAM value. A "/" signifies simultaneous dual lesions of the types indicated; a "+" signifies that the indicated lesions were produced sequentially. It is clear that OB or AL decrease P-induced LH release in the EB-primed rat while SL alone does not. SL before OB (SL+OB group) or SL before AL (SL+AL group) does not prevent the OB or AL-induced deficit in the magnitude of the P-induced LH surge. However, SL could counteract the effects of OB or AL if it occurred after OB or AL or simultaneous to OB or AL. Thus, it is clear that the sequence of lesioning is a critical parameter although the mechanisms involved in lesion-induced alterations in LH control remain to be elucidated.

Supported by the Ford Foundation and NIH Grant # HD 01182.

154.5 NON-FORNIX SPREAD OF HIPPOCAMPAL AFTERDISCHARGES DEMONSTRATED BY THE 14C DEOXYGLUCOSE TECHNIQUE. Michel Kliot*, Mark Boytim*, and Charles E. Poletti* (SPON: E.I. Knudsen). Department of Neuro-Surgery, Massachusetts General Hospital, Boston, MA. 02114.

Non-fornix hippocampal efferent projections were investigated using the 14C Deoxyglucose (DG) technique in rats. In a previous study (Science 204:641-643,1979) we showed that only after-discharges (AD's) electrically initiated (.2-.4mA, 1-msec pulses, 16 per sec) in the ventral subicular cortex increased metabolism in the amygdala, hypothalamus, and basal forebrain. In the present series of experiments, AD's were triggered in the ventral subicular cortex of rats with either bilateral lesions of the fornix or fornix and stria terminalis combined.

Rats with complete lesions of the fornix displayed increased DG uptake in the ipsilateral hippocampal formation, amygdala, hypothalamus, and basal forebrain. This pattern differed from that found in unlesioned rats in three respects. First, the AD's did not spread to the contralateral side. Second, increased activity in the hypothalamus was confined primarily to the preoptic, ventromedial, and premammillary nuclei whereas in intact rats marked increases were also found in the anterior, lateral, dorsal, and posterior hypothalamic nuclei. And third, increased metabolism was not present in the dorsal portion of the lateral septum. As in unlesioned rats, increases were found in the ventral portion of the lateral septum and the nucleus accumbens, ventral putamen, nucleus of the lateral olfactory tract, and bed nucleus of the stria terminalis.

Rats with combined lesions of both the fornix and stria terminalis showed a similar pattern of increased glucose consumption in the ipsilateral hippocampal formation and amygdala. In contrast, the basal diencephalon showed only modest increases in activity restricted to the ipsilateral lateral preoptic region, nucleus accumbens, ventral putamen, nucleus of the lateral olfactory tract, and bed nucleus of the stria terminalis.

In controls with lesions but no electrical stimulation, only tissue injured by the surgery showed DG levels above those levels seen in nonstimulated intact animals.

These results demonstrate that AD's initiated in the rodent ventral hippocampal formation can spread to the amygdala, hypothalamus, and basal forebrain in the absence of the fornix. They also support the proposal that ventral hippocampal activity is relayed to the hypothalamus and basal forebrain via the amygdala and its efferent projections, the stria terminalis and ventral amygdalofugal pathway (Poletti and Sujatanond, J. Neurophysiol., in press; Morrison and Poletti, Brain Res., in press).

This research was supported by the NeuroResearch Foundation and BioMedical Research Support Grant 05486-16 of the Massachusetts General Hospital.

154.7 AMYGDALOID EFFERENTS TO THE BED NUCLEUS OF THE STRIA TERMINALIS AND THE MEDIAL PREOPTIC AREA CONTROLLING MALE HAMSTER SEXUAL BEHAVIOR: COMBINED HRP AND BEHAVIORAL ANALYSES. Michael N. Lehman and Sarah S. Winans. Neurosci. Prog. and Dept. Anat., Univ. Mich., Ann Arbor, MI 48109.

Recent evidence suggests that olfactory and vomeronasal information critical to male hamster mating behavior is processed in the medial nucleus of the amygdala, an androgen-binding brain area. This nucleus is a major source of efferents, via the stria terminalis (ST), to the bed nucleus of the stria terminalis (BNST) and the medial preoptic area (MPOA), two additional androgen-binding brain areas important in the control of male copulatory behavior. Because medial nucleus lesions but not ST destruction eliminates male hamster mating behavior (Neurosci. Abstr., 4:88), we hypothesized the existence of a non-strial route by which the medial nucleus influences the BNST or MPOA. To test this, we iontophoretically applied horseradish peroxidase (HRP) in the BNST or MPOA of male hamsters in which we surgically interrupted the ST, and control males with the ST intact. After 48 hours survival, the hamsters were perfused and the brains were processed using the tetramethylbenzidine procedure.

Histological analysis of HRP labelled brain sections demonstrated the existence of a ventral non-strial projection from the medial nucleus to the BNST, but not to MPOA. To test the functional significance of this pathway, we observed the mating behavior of male hamsters before and after either: a) bilateral parasagittal knife cuts placed between the amygdala and the BNST (n=8); b) a unilateral parasagittal knife cut with a contralateral medial nucleus lesion (n=7); or c) control knife cuts (n=5). After postoperative testing, we iontophoretically applied HRP in the BNST of these animals.

Procedures a) and b) completely eliminated mating behavior in 10 out of 15 animals. The remaining males showed impaired or absent mating in at least two of the three postoperative tests. Males with control knife cuts continued to mate normally. HRP analysis confirmed that the parasagittal knife cuts had interrupted the ventral pathway, and showed that the ST was intact in at least four of those males that displayed severe mating deficits. These results suggest the importance of the ventral pathway from the medial amygdaloid nucleus to the BNST as a route by which chemosensory information influences the display of male copulatory behavior.

(Supported by NIH grant NS 14071 and NIMH National Research Service Award 5 T32 MH14279-05.)

154.6 CYCLIC CHANGES IN HIPPOCAMPAL EVOKED RESPONSES DURING THE OVULATORY CYCLE IN RATS. L. F. Mercer, Jr. and N. Hagino. Dept. of Anatomy, University of Texas Health Science Center, San Antonio, Texas 78284.

Experiments were undertaken to examine the characteristics of hippocampal responses evoked by medial forebrain bundle (MFB) stimulation during stages of the ovulatory cycle of rats. In ten female rats (Timco Simonson), stimulating and recording electrodes were surgically implanted in the MFB at the level of the lateral preoptic area and dorsal hippocampus (area CA2), respectively, and were connected to an Amphenol connector to allow recording with unanesthetized preparations. An ovulatory sequence was determined for each animal by daily inspection of vaginal smears. Evoked response patterns were determined during metestrous, diestrous, proestrous, and estrous. Stimulation voltages were slowly increased until a reliable pattern was obtained from the hippocampus. In the evoked response, three peaks were identified having latencies of 8-12 msec (P_1), 18-24 msec (P_2) and 30-40 msec (P_3). P_1 showed the most reliable correlation with the vaginal status. P_1 was of lowest amplitude during metestrous and progressively increased during diestrous and proestrous with a subsequent decrease on estrous. Since the pattern of changes in P_1 paralleled the pattern of estrogen levels during the cycle, Experiment 2 examined the effect of exogenous estrogen during metestrous when the amplitude of P_1 was found to be lowest. Administration of 1 µg estradiol benzoate in oil, IM, on the day prior to metestrous produces a 45% greater amplitude of P_1 during metestrous than occurred in noninjucted controls. The findings of Experiment 2 supported the suggestion of an excitatory effect of estrogen on MFB-Septal-hippocampal system. The possibility of catecholamine involvement in the observed changes was investigated in Experiment 3 in which the evoked response pattern was observed after depletion of catecholamines with alpha methyl tyrosine (AMT 250 mg/kg, IM) on proestrous when the P_1 component is at its maximum. Injection of AMT eliminated the expected proestrous rise in emplitude of P_1 resulting in no significant difference from the amplitude during metestrous. The overall results of the study suggest that the excitability of the MFB-septal-hippocampal system is lowered by estrogen and requires the integrity of catecholamines for the process to occur. (Supported by NIH HD 10071)

155.1 NEURAL CONTROL OF CARDIOVASCULAR RESPONSES DURING FOOD AROUSAL IN APLYSIA. U. T. Koch,* J. Koester, and K.R. Weiss (SPON: W.L. Nastuk). Div. of Neurobiology and Behavior, Depts. of Anatomy, Physiology and Psychiatry, Columbia University, New York, N.Y. 10032.

Exposure of Aplysia to food stimuli produces an arousal state that is reflected in parallel increases in heart rate (30% above baseline) and in biting rate. Two-thirds of the heart rate increase is eliminated by cutting either the pericardial nerve (J. Comp. Physiol., 123:11) or the pleural-abdominal connectives, suggesting that this effect is primarily neurally mediated. With chronic recordings from intact animals we have found that blood pressure also increases during food arousal.

We have developed a preparation to study the cellular basis of the cardiovascular components of food arousal. The anterior region of the head, connected to the abdominal ganglion by the pleuro-abdominal connectives, was dissected free. The pericardial nerve connections to the heart and the abdominal aorta were also maintained. The animal was kept at 0 to 2° C. throughout the dissection. During experiments the head was held by a soft, inflatable collar, and perfused through the anterior aorta with culture medium. The lips and tentacles protruded into a separate chamber, filled with artificial seawater. Seaweed extract was introduced into this chamber to elicit food arousal. Biting movements were monitored with a strain gauge attached to the buccal mass. We recorded intracellularly the activity of the LB_{VC} vasoconstrictor motorneurons, and the RB_{HE} heart excitor neuron. Activity of the LB_{VC} cells reduces blood flow to the visceral organs, and firing RB_{HE} increases the strength and frequency of heart beat.

During arousal biting movements were elicited, and the firing rates of both cell types increased significantly. The mean spike rate increase was 35% for RB_{HE} ($N=5$, $p < .05$) and 105% ($N=7$, $p < .01$) for LB_{VC} during stimulation. The firing pattern of the LB_{VC} cells changed from a steady rate to a pronounced bursting pattern that was phase-locked to the biting movements. The increase in RB_{HE} firing rate during arousal was a tonic change with no link to the biting cycle.

These results are consistent with the hypothesis that LB_{VC} and RB_{HE} cells contribute to the changes in heart rate and blood pressure that occur during food arousal. If so, the overall effects of this neural activity may be to increase blood flow, with a shift in distribution from the viscera to the head. Such a response may be required to increase O_2 supply and support the hydrostatic skeleton of the animal during the head extension and biting movements that occur during food arousal.

As in the case of the biting component of food arousal, it appears that the phasic cardiovascular changes during arousal are mediated primarily by cholinergic cells (LB_{VC}), whereas the tonic effects are primarily mediated by an increase in cyclic AMP produced by a serotonergic modulatory cell (RB_{HE}) (Br. Res., 177:388; J. Neurophysiol., 42:791).

155.2 MORPHOLOGY AND TONIC ACTIVITY OF THE LASHING VENTRAL NERVE CORD IN A SATURNIID MOTH. James J. Cole and Frances V. McCann. Dept. of Physiology, Dartmouth Med. School, Hanover, NH 03755.

Hyalophora cecropia is a moth having a flexible ventral nerve cord (vnc) which is constantly in left-right oscillation at 1 cm intervals along its length, with an amplitude of 2-4 mm and a frequency of 1-3 Hz at physiological temperatures.

The abdominal vnc is a series of four ganglia communicating by paired interganglionic connectives having unmyelinated axons. It is profusely invested with branching tracheae, and sends out ganglionic roots that innervate the abdominal body walls and viscera. The contractile cells directly responsible for vnc motility are bilateral sheets of muscle fibers attached dorsally to connective tissue overlying the neural elements. The lashing fibers comprise the muscular component of the ventral diaphragm. The fibers on left and right sides of the vnc contract alternately. Each ganglion has its locally coordinated pair of fiber sheets whose combined activity pulls the segments of the vnc from side to side in a serpentine fashion. Putative functions of lashing include facilitation of gas exchange between tracheal air and neural tissue, and generation of a caudal flow of hemolymph in the ventral sinus (Hessel,J.H., Ann.Ent.Soc.Am.62:353, 1969).

The fibers of the lashing muscle resemble at a histological level the alary muscle fibers of the heart. The rate of oscillation of the vnc approximates the rate of the heartbeat. Histology and ultrastructure, however, have not provided evidence of synapses onto the heart or alary muscles. Tonic units exist in the vnc which have firing frequencies similar to the heartbeat, but the heart will continue to beat in isolation.

Supported by the National Science Foundation and the New Hampshire Heart Association.

155.3 NEURAL CARDIAC MODULATION IN A PULMONATE GASTROPOD LIMAX MAXIMUS. D.S.Grega and D.J.Prior. School of Biol. Sciences, Univ. of Kentucky, Lexington, KY 40506.

The myogenic heart of the garden slug Limax maximus is innervated via the visceral nerve (VN) by neurons in the visceral ganglion. Stimulation of the intact VN with a suction electrode has both chronotropic and inotropic effects on the heart. Heart activity was monitored with a force transducer; the parameters measured were heart (HR), contraction amplitude (Amp) and inter-contraction interval (ICI) to determine immediate inhibition due to stimulation. A single stimulus pulse of 1 ms duration evokes a brief immediate inhibition of heart contraction indicated by a 68% increase in ICI followed by reestablishment of the control HR with a 55% increase in Amp. With trains of pulses at various frequencies (0.5 to 100 Hz) low frequency stimulation (0.5 to 10 Hz) was most effective in increasing Amp and evoking immediate inhibition of heart contraction. Moderate increases in ventricular pressure were achieved in two ways. Increasing peripheral resistance with a ligature of the aorta and increasing heart volume with an injection of saline via the cut aorta both result in a slight 1 to 3% decrease in Amp and HR which returned to control values when the pressure was eliminated. Thus, the increase in Amp after initial inhibition of heart contraction is probably neuronally mediated and not due to volume stress associated with accumulation of blood in the heart. Unlike VN stimulation, topical stimulation of discrete areas of the visceral ganglion with fine-tipped suction electrodes cause both cardiac inhibition and excitation (increase in HR and Amp). Thresholds for cardiac excitation were observed to be higher than those for inhibition in accord with that reported for other pulmonates. Cobalt backfills of VN toward the ganglion reveal the position of possible cardioregulatory neuron cell bodies. These soma generally were located toward the periphery of the dorsal surface of the ganglion in areas which,when topically stimulated excite or inhibit heart activity. Preliminary pharmacological studies were done by drug application on the isolated,beating heart with the central nervous system removed. A low concentration (10^{-7}M) of serotonin results in an immediate,transient decrease in Amp followed by a decrease in HR. Application of acetylcholine (10^{-7}M) evokes an immediate inhibition of heart contraction followed by an increase in HR and Amp.

155.4 MOTONEURONS INNERVATING ANTERIOR AORTA OF APLYSIA. J.E. Blankenship, M. Sawada* and D.H. McAdoo. Marine Biomedical Institute, Univ. Tx. Med. Br., Galveston, TX 77550.

Three new motoneurons in the abdominal ganglion of Aplysia californica have been identified which make monosynaptic connections with muscle fibers in the wall of the anterior aorta but not in other aortic vessels. Two of these cells, designated RD_{AAI}, are inhibitory, and one is excitatory, RD_{AAE}. The cell bodies lie near cell R2 and send their axons to the aorta via the vulvar nerve. Neurons and muscle fibers were impaled with microelectrodes, the vulvar nerve was recorded or stimulated with suction electrodes, and muscle tension in the aortic wall was recorded by a micro-strain gauge. Various transmitters or pharmacologic blocking agents were applied to the bathing solution, and in some experiments the ionic composition of the bath was altered to determine which ions were involved in junctional current. Muscle fibers of the aorta had a mean resting potential of -62 mV. Muscle fibers could have any combination of at least three spontaneous junctional potentials (diffuse, polyneuronal innervation): a very brief ejp, a slower ejp, and an ijp. The motoneuron producing the fast ejp is unidentified, but these responses are blocked by 10^{-4} M d-tubocurarine (dTC). The other ejp is produced directly by cell RD_{AAE}. This response could be mimicked by μM amounts of serotonin (5HT) and was almost completely blocked by 10^{-7} to 10^{-5} M bromo-D-lysergic acid. It was also partially blocked by atropine, but unaffected by dTC. The amplitude of this ejp was reduced when extracellular Na was reduced to 80% of normal. The ijp was produced by either of the two cells RD_{AAI} which are larger than RD_{AAE} and have lower thresholds to extracellular stimulation of the vulvar nerve. The ijp's are completely and reversibly blocked by 10^{-4} M dTC and are mimicked by acetylcholine (ACh). The ijp is reduced in 1/10 normal Cl and increased in 1/10 normal K and is believed to be due to an increase in conductance to both ions. RD_{AAE} firing or bath applied 5HT cause muscle depolarization and increased contractions, while RD_{AAI} activity or bath applied ACh produce muscle hyperpolarization and relaxation. Motoneuron activity partly underlies spontaneous oscillatory contractions of the aortic wall. Muscle fibers only rarely show spike-like responses; these do not overshoot the zero potential but do have a small afterhyperpolarization. Both types of motoneuron-induced jp's show moderate facilitation with repetitive firing. The motoneurons do not synaptically interact with one another, but bursts of activity in interneuron II drive RD_{AAI} and cause pronounced muscle relaxation while RD_{AAE} is simultaneously inhibited.

156.1 PREMOVEMENT POSTURAL MUSCLE ACTIVITY DURING RAPID UNILATERAL ARM FLEXION IN CEREBRAL PALSIED AND NORMAL PERSONS. W.A. Lee, Neuromuscular Laboratory, University of Texas, Austin, Texas, 78712

Activity in postural (posterior thigh: biceps femoris) muscles has been reported to precede arm movement in a rapid unilateral arm flexion task in neurologically unimpaired persons (1,2). The pattern of neuromuscular activity which has been described in normal subjects consists of: onset of biceps femoris activity ipsilateral to the arm raised; onset of the primary agonist (anterior deltoid); onset of contralateral biceps femoris; and finally arm movement (reaction time, RT). It has been hypothesized that the premovement biceps femoris activity may preset stiffness of the trunk support system to counteract perturbations of balance expected to accompany the voluntary arm flexion. Were this the case, persons with some neurological dysfunction like cerebral palsy who have imbalance as one motoric symptom might be predicted to produce neuromuscular patterns with reduced or delayed biceps femoris activity, as compared with the pattern from normal subjects.

In the present report, data on the complex neuromuscular patternof rapid arm flexion are described for three adult, ambulatory cerebral palsied (CP) persons; these are compared with previously reported data (2) on normal subjects' behavior. Each subject performed 30 left and 30 right rapid flexions of one arm from hip to shoulder level while in a standing posture, under simple RT conditions. Means and standard deviations of response component latencies (ipsilateral biceps, anterior deltoid, contralateral biceps, and RT) and intercomponent correlation coefficients for individual subjects are reported. Correlations among components were high and significant for CP subjects, in a manner similar to those for normal subjects, indicating a similarly tight linkage of postural and task components for the two groups. However, the temporal order of the pattern differed for the CP subjects, with a delay observed in either contralateral or ipsilateral biceps femoris (or both) relative to anterior deltoid onset. The data are consistent with the hypothesis that premovement biceps femoris activity observed in standing subjects for the rapid arm flexion task may serve some function in controlling balance. Because the delays were specific to biceps femoris, it is plausible that the postural and task components are controlled via parallel pathways although both components are part of the voluntary response of rapid arm flexion.

156.2 THE ORGANIZATION AND REORGANIZATION OF SPEECH MOVEMENTS. R. Netsell, R.Kent* and J. Abbs*. Boys Town Institute, Omaha, NE 68131 and University of Wisconsin, Madison, 53706.

X-ray motion pictures from three subjects were used to study lip and tongue movements during speaking conditions in which the jaw was held in a fixed position (the upper and lower incisors being separated by 8, 16, and 24 mm) or was free to assume its normal movement pattern. The data on movement reorganization in the lips and tongue were drawn from the jaw-fixed conditions, where, in some cases, the lips and tongue were required to more than double their range of movement in order to produce normal speech.

For the most part, the subjects successfully reorganized the lip and tongue movements to closely approximate the temporal and spatial targets achieved in the control (jaw-free) condition. These precise adjustments were made without conscious mediation, i.e., subjects reported no awareness of the movement reorganization. For productions of single vowel sounds, the tongue adjustments were made before vocalization, i.e., before the subject had auditory feedback about the adequacy of the adjustment. In jaw-fixed sentence productions, subjects maintained the temporal organization of the control condition by increasing the velocity of movements. For example, to achieve lip closure for p in the word heap for the 24 mm. jaw-fixed condition, the lower lip more than doubled its velocity over the control condition. Other data displays demonstrate which aspects of these temporal/spatial goals are achieved with high accuracy and which are more variable.

Two hypotheses could explain the reorganization of these speech movements. With the jaw held in the fixed positions, subjects may have (1) selected different muscles to achieve the observed vocal tract adjustments, or (2) increased contractile force to the same muscles used in the control (jaw-free) condition which, in turn, increased the observed range and velocities of movement. In the absence of EMG data on individual muscle activity, the latter hypothesis is more parsimonious and consistent with recent modelling approaches to tongue movements during speech.

From the vowel data, it is hypothesized that spatial representations for these vocal tract shapes exist in the brain and can be reconstructed through intero- and exteroceptive feedback of tongue and oral cavity contacts. Auditory feedback is not necessary in these instances. The use of auditory feedback in the ongoing control of speech movements might be clarified by observing the reorganization task under the conditions of auditory masking.

156.3 REDUCTION OF THE LENGTH-THRESHOLD OF THE MYOTATIC REFLEX BY VOLUNTARY MUSCLE CONTRACTION. Gyan C. Agarwal, Gerald L. Gottlieb and Robert J. Jaeger. Department of Physiology, Rush College of Health Sciences, 1753 W. Congress Parkway. Chicago, Illinois 60612.

Torques were applied to the human ankle joint to first plantarflex the foot and, after a specified delay of 50 ms to 750 ms, rapidly dorsiflex it. The initial plantarflexion shortened the soleus muscle and the subsequent dorsiflexion restretched it, evoking a myotatic reflex.

The latency of the soleus myotatic reflex is not sensitive to the rate of muscle stretch under many circumstances (Gottlieb & Agarwal, J. Neurophysiol., 1979) but under conditions where the muscle is shortened before stretching, an increase in latency is observed which can be accounted for by the existence of a threshold process within the reflex arc of the form of equation 1.

$$f(x) = x + \tau \dot{x} \;;\; f(x) > \Delta \qquad = 0 \;;\; f(x) < \Delta \qquad \text{eq. 1}$$

In this equation, no reflex output occurs until the function f(x), where x is the change in muscle length, exceeds Δ. This model predicts that reflex latency (t_r) during constant velocity stretch (γ) will be described by equation 2 and the stretch (x_t) during that subthreshold period by equation 3.

$$t_r = t_c + \left(\frac{\Delta}{\gamma} - \tau\right) \qquad \text{eq. 2}$$

$$x_t = \Delta - \gamma\tau \qquad \text{eq. 3}$$

(t_c is conduction time for a tendon-jerk reflex)
These predictions were verified experimentally. The hypothesized site of the threshold is the muscle spindle membrane where length changes are transduced to action potentials.

Voluntary plantarflexion reduces the reflex threshold. This suggests that coactivation of skeletomotor and fusimotor pathways prevents spindle unloading during voluntary muscle shortening and thereby maintains the integrity of the reflex pathway during voluntary movements. 156.4 INFLUENCE OF TONIC LABYRINTHINE REFLEX UPON SOLEUS MOTONEURON EXCITABILITY IN MAN. C.W.Y. Chan, K.E. Kearney, and I. Levine. School of Physical and Occupational Therapy, Biomechanican Engineering and Aviation Medical Research Units, McGill University, Montreal, Quebec, Canada.

Although animal studies have demonstrated that vestibulospinal influences can reach the lumbar cord, and through their modulation of spinal mechanisms, contribute in a systematic way to the control of posture, such effects have not been examined in man. The objective of the present study was therefore to determine how tonic labyrinthine reflexes, evoked by changes in the static position of the head and body relative to gravity, modulate the excitability of human soleus motoneurons.

Subjects were blindfolded and fixed to a circular bed in supine position by means of body straps, as well as partial casts at the neck and legs. Extreme care was taken to ensure a constant angle between head and body to eliminate neck afferent inputs. The excitability of soleus motoneurons, as reflected by the H reflex, was then measured as a function or orientation of the head with respect to gravity, by rotating the bed over a range of 180° in steps of 15° or 30°. Stimulus intensity for the H reflex was carefully adjusted to elicit a small m response and an H reflex usually no larger than 70% of the maximum m response. At each orientation, 25 responses were recorded and later analysed to determine the "mean" and "standard deviation" of the peak-to-peak amplitude of H and m components. Responses were rejected if there was a significant variation in m response indicating a change in stimulus conditions.

Seven subjects were examined to date. In one subject, the H reflex was facilitated when the head was tilted forward and backward from the vertical position. The opposite was found in another subject. However, in 5 out of 7 subjects, there was no significant difference in the amplitude of the H reflex as a function of changes in static head orientation with respect to gravity. This consistent finding indicates that tonic labyrinthine reflexes probably exert negligible influence on the excitability of human soleus motoneurons. The two exceptions mentioned earlier could presumable be explained on the basis of different cutaneous inputs, a possibility being currently investigated.

156.5 VOLUNTARILY INDUCED DIFFERENTIAL ALTERATION IN FORCE THRESHOLD OF SINGLE MOTOR UNITS OF THE HUMAN VASTUS LATERALIS. S. A. Cremer*, R. J. Gregor*, M. Mirsky*, and V. R. Edgerton (SPON: J. Keesey). Neuromotor Control Laboratory, University of California, Los Angeles, California 90024.

It has been shown that the force threshold (FT) of single motor units within a muscle can be differentially activated via skin afferents (Datta and Stephens, Neuroscience Abstracts, 1979). The possibility of differentially altering the force thresholds of single motor units (SMUs) by voluntarily modifying the type of muscle effort was investigated in this study.

Bipolar fine wire (50μm) electrodes were inserted into the vastus lateralis muscle (VL) for recording of SMU action potentials. Surface EMGs of the biceps femoris and vastus lateralis were also recorded. The subject's knee remained at a 90° angle with the ankle fixed at 110° and the foot secured to a force platform to record the three components of the isometric force produced by contraction of the knee extensors. The subject received auditory and visual feedback of the action potentials and visual feedback of the resultant vector of the forces produced in the X-Y plane of the force platform. The force thresholds of the SMUs were determined for a slow (approx. 10N/s) smooth ascending and descending force ramp and for the same ramp rate, but with voluntary oscillations (alternating contraction-relaxation of the knee extensors). These oscillations produced at a rate of about 6-12 Hz, resulted in a fluctuation in force of 2.5-5.0 N at the platform. Firing frequencies both with and without voluntary oscillations were determined at maintained force levels.

Thirty-one SMUs were studied in three healthy subjects. The SMUs had force thresholds in the smooth ramps up to approximately 25% of maximum voluntary contraction (MVC). During oscillation, the FT increased more than 5% of MVC in 22% of the SMUs, while 6.5% had a lower FT during oscillatory efforts. The largest increase in the FT of a SMU was 40% of MVC. Two pairs of SMUs were observed to exchange rank in the recruitment order. Thirteen per cent of the SMUs varied in FT by greater than 5% of MVC on the ascending vs. descending portion of the ramps with oscillations. At a maintained steady force level 42% of the SMUs decreased firing frequency by 20% (e.g. from 10 to 8 Hz) to 100% (cessation of firing) during oscillation. These data suggest that the input to the motoneuronal pool can be selectively influenced voluntarily during a rapid but low amplitude oscillating movement.

156.6 SPEED OF TENSION DEVELOPMENT IN ISOMETRIC CONTRACTIONS OF A HUMAN HAND MUSCLE, R. G. Miller, A. Mirka and M. Maxfield*. Department of Neurology, University of Oregon Health Sciences Center, Portland, Oregon 97201.

This study compares the amplitude and rate of tension development during both electrical stimulation and voluntary activation of a human hand muscle. The contractile responses from the first dorsal interosseous muscle of 14 normal human subjects were studied to provide the experimental data.

Under each experimental condition, there was a linear relationship between force generation and speed of contraction over the force range studied. This linear relationship between the speed and force of contraction, as the proportion of active motor units varied, implies that these two parameters are similarly related in motor units of various sizes.

In fast voluntary contractions, the rate of rise of tension at any given force level was higher than that observed in response to repetitive stimuli delivered to the motor nerve. Even at 200 and 500 impulses per second at maximal intensity, the speed of tension development was less than that found in fast voluntary contractions. The importance of asynchronous impulses and optimum discharge sequencing in generating a faster speed of tension development in fast voluntary contractions is underscored by these findings.

156.7 MODIFIABILITY OF HUMAN LONG LATENCY (90-100 ms) MUSCLE RESPONSES TO POSTURAL PERTURBATIONS BY EXPECTANCY. M. Woollacott, O. Marin and L. Nashner. Neurological Sci. Inst., Good Samaritan Hosp., Portland, OR 97209.

The EMG activity of four leg muscles [gastrocnemius (G), tibialis anterior (T), hamstrings (H) and quadriceps (Q)] was recorded while freely standing humans were subjected to anterior or posterior horizontal displacements of the platform on which they stood.

In order to determine the effects of expectancy on postural responses, latencies of rectified and integrated EMGs were compared for trials in which a) the perturbation was unexpected and unidentified, b) the perturbation was preceeded by a tone cue (500 ms in advance) but information on the direction of the perturbation was not given, and c) the perturbation was preceeded by a tone cue (500 msec in advance) which identified the perturbation direction by its pitch. EMG response latencies to unexpected anterior platform translations (causing posterior sway and stretch of T) were 88 ± 4 msec in the tibialis anterior. With a 500 msec advance warning cue, latencies were reduced to 74 ± 12 msec for anterior translations. With 500 msec advanced warning and identification of the direction of movement the latencies were reduced further to 61 ± 9 msec.

In order to determine the effects of repetition on postural responses, a series of 20 posterior platform displacements was given (intertrial intervals were 15 sec). In the subjects tested, the long latency EMG response in the stretched G muscle decreased in latency from 100 msec to 71 msec and decreased in amplitude to 50% of initial values. After 20 trials, an unexpected anterior translation was given. The subject was thrown off balance and required assistance for postural support.

These results indicate that long latency postural responses can be reduced in amplitude and latency by preparatory processes, and that these processes may reduce the effectiveness of antagonist postural pathways.

156.8 SYNCHRONIZATION OF HUMAN MOTOR UNITS DURING STATIC AND RAMP-FORCE ISOMETRIC CONTRACTIONS. Carl G. Kukulka* and Brenda Bigland-Ritchie*. (Spon: Charles F. Stevens). John B. Pierce Foundation, New Haven, CT. 06519 and Quinnipiac College, Hamden, CT. 06518.

It is generally accepted that motor neurons discharge asynchronously in voluntary contractions of unfatigued muscle. We have found, however, that at the time of first recruitment, pairs of units recorded from a single intramuscular electrode frequently demonstrate quite high degrees of synchrony even at low force levels.

Bipolar, fine wire recordings of single motor units were obtained during both static force and ramp isometric contractions of human biceps brachii and first dorsal interosseus muscles. Units were recruited between 1 and 30% maximum voluntary contraction (MVC), and each was identified by its characteristic recruitment force, spike shape and amplitude. All pairs of units which were clearly identifiable for sufficient time (5-60 sec.) were tested for cross-correlation of their firing rates. Of 10 pairs from biceps brachii, 3 showed prominent synchronization which could generally be detected visually in the raw data as well as by clearly defined peaks in their cross correlograms; 3 showed less well defined peaks; and 4 were clearly asynchronous. Of the 4 pairs analyzed from first dorsal interosseus, 2 displayed similar prominent peaks. As a measure of this synchronization the area of each peak was expressed as a percentage of the total area of the correlogram (ie. 100% = total synchrony). For well synchronized units, these varied from 20-60% (mean = 38%), with lower values for the rest. Firing frequencies varied from 8-12/sec. Some pairs of highly synchronized units had nearly identical frequencies, while others did not. For well synchronized pairs the difference between the recruitment forces for each unit was less than 5% MVC. This suggested that synchrony might result from a common excitatory input to neurons of similar size and excitability, yet asynchronous pairs with similarly close recruitment threshold were also observed. Several pairs of units, well synchronized when first recruited, remained so when responding to increasing excitatory drive during slow force ramps, but lost their synchrony during subsequent static contractions at constant force.

156.9 VELOCITY DEPENDENT CENTRALLY PROGRAMMED HUMAN VOLUNTARY ACTIVITY. B. T. Shahani, R. R. Young, and J. L. Harrison*. Clinical Neurophysiology Laboratories, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114.

The central programmes subserving the execution of fast voluntary flexion and extension movements of human limbs during a visual matching task produce a triphasic EMG pattern (Ag1: the initial agonist burst, Ag2: the second agonist burst with a silent period Ag1-Ag2 interposed between them and An1: the antagonist burst) in a pair of antagonist muscles whereas slower "smooth" movements are produced by continuous EMG activity only in the agonist. The present study was undertaken to determine whether or not the transition from continuous EMG activity to a discrete "burst" pattern is velocity dependent. Gradual changes in linear velocity were studied using 5 healthy subjects, 22-34 years old. In different individuals, continuous agonist EMG activity seen with slower velocities (< 30 cm/sec.) was transformed into a two-burst pattern at a velocity of 35-50 cm/sec. An1 appeared only with even greater velocity (greater than 55 cm/sec.) Durations of Ag1 and Ag1-Ag2 interval both decreased with increasing velocity, reaching, at approximately 120 cm/sec., the normal range (Ag1 = 86 $\pm$ 19 msec., Ag1-Ag2 = 66 $\pm$ 29 msec., N = 32). The triphasic EMG pattern seen with human ballistic movements appears to be velocity dependent. Changes in these EMG parameters produced by increasing angular velocity at a joint are appropriate for bringing the distal limb to the target with speed and precision.

156.10 TWO TYPES OF POSTURAL ADJUSTMENT TO LIMB FLEXION IN THE CAT. J.M. Macpherson*, M. Dufossé* and J. Massion* (SPON: J.H.J. Allum) Dépt. Neurophysiol. Générale, C.N.R.S., 13274 Marseille, FRANCE.

Previous studies in the cat have shown that the postural adjustment to flexion of a limb can differ, depending on how the limb flexion is elicited.[1] By dropping the platform supporting one forelimb, or by perturbing that limb to cause loss of support, a diagonal pattern of support is elicited such that the pressure exerted by the contralateral forelimb and ipsilateral hindlimb is increased, while that exerted by the contralateral hindlimb is decreased. In contrast, the postural adjustment to a conditioned raising of the forelimb is non-diagonal, with increased pressure exerted by the contralateral forelimb but no reciprocal type of change for the hindlimbs.

This study was undertaken to elaborate the biomechanical and electromyographic (EMG) differences between these two patterns of postural adjustment. The cats were unrestrained, and stood with each limb on a small platform. The pressure exerted by each limb in a vertical direction was recorded on-line. To measure movements of the vertebral column, fine rods were implanted in the spines of vertebrae at three levels (approx. T1, T12 and L5). Movements of the cat as well as the video display of limb forces were recorded on film. In another series of experiments with the same cats, the EMGs of limb extensors were recorded on-line along with the forces.

When postural adjustment was diagonal, the vertebral column remained relatively rigid, i.e. no lateral displacement in space, and very little or no torsion or rotation. The triceps surae muscles of the hindlimbs responded in a reciprocal manner: the muscle of the hindlimb which increased its pressure was activated whereas the other was inhibited. Both muscles responded before the onset of force change in the corresponding limb.

During conditioned movement of a forelimb with a non-diagonal force pattern, there was a marked lateral flexion of the forequarters of the cat toward the side of the supporting forelimb. The triceps muscles of the hindlimbs showed no reciprocal response, corresponding to the lack of reciprocal change in pressure exerted by the hindlimbs.

The diagonal pattern is closer to that seen during locomotion (e.g. trotting), however the non-diagonal pattern appears to be the more stable one for single limb flexion. The elaboration of these different mechanisms of adjustment to limb flexion provides an important basis for studying the central control of postural change.

156.11 AGONIST-ANTAGONIST COUPLING IN RAPID LIMB MOVEMENT. C. Ghez and J. Martin*. Div. of Neurobiol. & Behav., Depts. of Physiology & Neurology, Columbia P&S, New York, N.Y. 10032.

EMG activity associated with rapid limb movements exhibits a characteristic "three burst pattern". The first burst is in the agonist muscle (AG1) and accelerates the limb. Next, during the dynamic phase of movement, a burst of activity occurs in the antagonist (ANT) which may decelerate the limb. Finally, a burst of unknown significance is observed in the agonist (AG2). The present study was undertaken to determine if ANT and AG2 reflect the action of a central program or if they represent stretch reflexes evoked during the evolving movement. To answer these questions it is necessary to dissociate the intended force produced by the subjects from the ensuing limb displacement.

Cats were trained (using a compensatory display) to apply force isometrically or to position the lever of a torque motor controlled manipulandum to match a target level which was stepped at random times. Under isometric conditions, angular displacement of the limb was prevented by an electromechanical brake which could be released on random trials during the animal's response (when dF/dt exceeded a threshold corresponding with the end of the first agonist burst). The torque motor was used to generate elastic and viscous loads to control limb trajectory. Thus, we could dissociate centrally programmed muscular events from their intended mechanical consequences.

Whereas AG1 was present under both isometric and isotonic conditions, ANT and AG2 required limb displacement and were time locked to movement parameters. ANT occurred within 15 msec following the onset of acceleration; its magnitude varied linearly with this parameter and inversely with AG1. Thus, passive displacements stretching the antagonist elicited responses with similar latencies but of greatest magnitude. AG2 was only present in underdamped movements with terminal oscillations and typically occurred at the initial position overshoot as the velocity recrossed zero. Its magnitude was a function of both limb deceleration and of the intended force.

These data suggest that both ANT and AG2 represent stretch reflexes whose amplitudes are modulated by descending commands. Reciprocal mechanisms operating at a spinal level could account for the transient reduction of the antagonist stretch reflex as a function of the intended force. The increased sensitivity of the agonist stretch reflex, compatible with alpha gamma co-activation, suggests that acceleration sensitivity of muscle spindles can provide a predictive signal to dampen mechanical oscillations which ensue from rapid movement of a mass against elastic forces.

156.12 LUMBAR BACK MUSCLE ACTIVITY DURING WALKING AND GALLOPING IN DECEREBRATE CATS. Zomlefer, M. and Rossignol, S. Centre de recherche en sciences neurologiques, département de physiologie, Université de Montréal, Montréal, Québec, Canada, H3C 3J7.

Electromyograms (EMG's) were recorded from trunk muscles in pre-collicularly decerebrated cats moving on a treadmill during stimulation of the mesencephalic locomotor region. Bipolar intramuscular electrodes were introduced bilaterally into the Multifidi (Mf) and Longissimus (Lo) muscles along the lumbar spine, as well as into the hindlimb extensors vasti lateralii (VL). During slow and fast walking, at speeds ranging from 0.55 to 1.15 m/s, all the lumbar back muscles exhibited two separate bursts in each step cycle. These bursts occurred within periods of overlapping activity in the two VL's, with burst duration decreasing and mean amplitude increasing as the cat walked faster. In general, the larger of the two bursts in the back muscle on one side was linked to the onset of the VL on the same side. These EMG patterns from decerebrate walking cats are consistent with those reported earlier (Carlson et al., Acta physiol. scand., 165: 251-253, 1979) from chronic cats during treadmill and overground walking. In several animals, it was also possible to elicit good sequences of galloping at belt speeds from about 2.0 m/s to 2.9 m/s. Angular movements of the spine are clearly much more pronounced in galloping than in walking (Goslow et al., J. Morphol., 141: 1-42, 1973). During galloping, the lumbar back musculature underwent a dramatic shift in its activation pattern, to yield only a single large burst in each step cycle. All back EMG's were synchronously initiated about 50 ms before the co-contraction of the VL's, with burst durations of the order of 150-225 ms. Hence, the Mf and Lo become active prior to the hindlimb stance phase and remain active for about the first third of this phase. Whereas in the above cited studies it was apparent that the back muscles mainly serve to control trunk stiffness during slow and fast walking, the present work indicates that during gallop the back muscles may also be used to extend the spine prior to and during the initial part of the stance phase.

156.13 EFFECTS OF THE GLOBUS PALLIDUS ON RAPID ARM MOVEMENT IN MONKEYS
Fay B. Horak and Marjorie E. Anderson, Depts. of Physiol. and Biophys. and Rehab. Med. and Regional Primate Research Center, Univ. of Wash., Seattle, WA 98195

The role of basal ganglia output via the globus pallidus was examined in monkeys trained to elevate the arm in a forced reaction time task. Normal pallidal output was disrupted using either microstimulation or a kainic acid-produced lesion.

Microstimulation in the globus pallidus contralateral to arm movement with currents as low as 25 μA during random trials resulted in an increase in the movement duration. As stimulus intensity was increased up to 100 μA, there was a graded prolongation of movement duration, which finally exceeded control values by up to 100 msec. The reaction time following the target light onset, however, was minimally affected. Stimulus trains as short as 25 msec initiated at varying times during the task were most effective if applied 50-150 msec prior to movement onset. Stimulation early during the reaction time or late during movement execution did not lengthen movement times. Stimulation was effective only when applied in the area where typical high frequency pallidal unit activity was recorded, and the firing of many pallidal units in these same tracks covaried with task execution. Prolongation of movement was not caused by stimulation in areas surrounding the globus pallidus.

EMG activity recorded in six arm and paraspinal muscles was depressed and prolonged by the stimulation. Details of somatotopic and temporal effects of stimulation on EMG patterns are being investigated.

A lesion of the globus pallidus produced by injecting kainic acid during contralateral task execution also resulted in profound slowing of the arm movement with little effect on the reaction time. This effect persisted during the ten day survival period following the lesion. The changes in EMG activity underlying the prolonged movements, however, appeared to be different when the slowing was caused by a lesion, instead of by microstimulation.

156.14 HOW IS THE DIRECTION OF A BALLISTIC WRIST MOVEMENT PROGRAMMED?
D. S. Hoffman* and P. L. Strick. V. A. Med. Ctr. and Depts. of Neurosurg. and Physiol., SUNY-Upstate, Syracuse, NY 13210.

The wrist joint is capable of movements along two axes: flexion-extension and radial-ulnar deviation. How does a single muscle which acts across this complex joint participate in generating ballistic movements in different directions? In order to answer this question, we monitored the activity of extensor carpi radialis (ECR) with intramuscular electrodes while human subjects performed 20 degree ballistic wrist movements in 8-12 different directions. When subjects performed a ballistic movement which required equal combinations of radial deviation and extension, there was a single, >60 msec. long, burst of ECR activity beginning prior to movement onset (=agonist burst). Later phases of ECR activity were observed, but will not be described here. When subjects performed a movement in the opposite direction (equal combinations of ulnar deviation and flexion), there was a single, >50 msec. long, burst of ECR activity at or just after movement onset (=antagonist burst). The antagonist burst was present only when subjects were required to terminate their movements accurately.

ECR displayed two initial phases of activity when subjects performed movements orthogonal to those described above (ulnar deviation + extension or radial deviation + flexion). One burst of activity occurred prior to movement onset and the second occurred at or just after movement onset. These two bursts occurred at time intervals similar to the agonist and antagonist bursts described above. In addition, the second burst, like the antagonist burst, was present only when accurate termination of movement was required. Furthermore, the amplitude of the two bursts in ECR varied with the direction of movement. The first burst increased and the second burst decreased in amplitude as the subject moved in directions approaching radial deviation-extension (agonist burst direction). Opposite changes in burst amplitude were observed as the subject moved in directions approaching ulnar deviation-flexion (antagonist burst direction). Therefore, we believe that these two bursts are equivalent to the agonist and antagonist bursts described above. We conclude that the trajectory of an accurate ballistic movement of the wrist is determined by modulating the amplitude of agonist and antagonist bursts in single muscles.

156.15 COMPUTER SIMULATION OF THE PERFORMANCE OF A WEIGHT-LIFTING TASK BY NORMAL AND DEAFFERENTED MONKEYS.
R.M. Wylie. Dept. Med. Neurosci., Walter Reed Army Inst. of Res., Washington, DC 20012.

Performance on a weight-lifting task of deafferented monkeys approaches that of normal monkeys (Wylie and Tyner, Soc.Neurosci. Abstr. 4:308, 1978). Among the possible interpretations of these results is the possibility that the mechanical properties of the muscle-joint system are such that to perform the task at the observed levels, the animal need not modulate the neural signals driving the muscles in response to the external load. To assess this possibility, I have developed a mathematical model embodying the mechanics of the physical apparatus and the muscle-limb system. The model is based on a model of horizontal rotation of the head (Bizzi, Dev, Morasso and Polit, J. Neurophysiol. 41:542-556, 1978) with terms added to reflect the action of gravity on the system.

In the experimental paradigm, flexion of the forearm in the vertical plane rotated an arm restraint and lifted different test weights vertically. The model is the equation of motion of the system in which an applied torque is equated to the sum of a series of terms representing each of the resistances to movement along any specified trajectory. The resistances incorporated in the model are the rotational inertia of the monkey's arm and of the arm restraint, the translational inertia of the test mass, the gravitational forces acting on the test mass and the monkey's arm, and the internal viscous and elastic resistances of the muscles acting across the elbow. The model is a lumped parameter model in which the resistance of each component is idealized as a constant multiplied by the appropriate variable of motion.

To explore the potential role of the non-linear properties of muscle, in particular the viscous-like dependence of force on the velocity of shortening and the spring-like dependence of force on the length of the muscle, the parameters reflecting these two properties were independently varied to study their effects on the behavior of the system. This is a heuristic exercise in that both the viscosity and elasticity of muscle are dependent upon the level of activation of the muscle which is a time dependent function. Therefore, viscosity and elasticity are neither independent of each other nor constant. Nevertheless, results from the model focus attention on the importance of these properties in movement and the dangers of drawing inferences about compensatory responses without taking these properties into account.

Results from computer simulations indicate that the entire range of observed performances by monkeys can be simulated using a command signal which does not change with the imposed load. EMG recordings from both groups indicate active compensation contributes to the performance of monkeys.

156.16 THE PAW SHAKE REFLEX IN CHRONIC CAT.
J.L. Smith, L.A. Smith*, V.P. Stokes,* R.F. Zernicke* and C. Sabin*. Neuromotor Control Lab., UCLA,Los Angeles, CA 90024.

Chronic spinal cats transected at T_{12}, at a young age, exhibit several normal reflexes (Forssberg, Acta Physiol. Scand. Suppl. 474, 1979). Using cats which were spinalized at 2 or 12 wks, and allowed to recover for 6 mth, we studied hindlimb shakes elicited by sticking tape to the plantar pads. This cutaneous reflex is abolished when the pads are made insentient with xylocaine (0.2%) injections. EMG from soleus (SOL), lateral gastrocnemius (LG) and tibialis anterior (TA) was coordinated with 16 mm high speed film (100 fr/s), and 63 records from 6 spinal cats were analyzed.

A shake record consisted of 12 cycles, on average, with alternating ankle flexion-extension (F-E) occuring at 11 c/s, or with a paw shake interval of 88 ms. The average displacement at the ankle was 42 deg for both F and E, while peak velocities of 25 rad/s were common for both movements.

LG-EMG bursts,initiated at least 35 ms prior to peak F, had burst duration times (BDT) of 22 ms and interburst intervals of 66 ms. Neither the cycles times, ankle kinematics, nor LG-EMG differed significantly from normal cats (Smith, et al, J. Neurophysiol. 43: 612, 1980). The EMG of the SOL and LG coincided when both were active; however, the BDT of the SOL was slightly longer (31 ms). In normal cats the SOL is not recruited during paw shaking; however, in those spinal cats with a fast-contracting SOL (CT: <50 ms), the SOL was active (see Smith, et al, Neuroscience Abst. #1304, 1979).

The TA exhibited the longest BDT (38 ms), being initiated prior to peak extension and terminating 20 ms after. When the LG acted to decelerate ankle flexion, its EMG activity appeared, on average, 10 ms before the EMG activity of the TA ceased. When the TA acted to decelerate extension, no such coactivation was observed. Others have reported coactivation of antagonistic muscles during rapid movements (Lestienne, Exp. Brain Res. 35: 407, 1979), as well as asymmetrical co-contraction during reciprocal E-F movements (Norman & Komi, Acta Physiol. Scand. 106: 241, 1979).

Although the ankle kinematics and EMG during paw shaking are relatively normal, differences do exist. For instance, the reflex cannot always be elicited in chronic spinal cats, and the failure rate is about 20%. In addition, rather than abduction preceding the movement, the hip is fully extended at the beginning and then fully flexed at the termination of the reflex. With the hip in flexion, the knee and ankle are held rigidly in extension with the digits abducted. Also the reflex can be obtained with spinal cat held suspended; this position is not conducive to eliciting the reflex in intact cats. NIH Grant 10423.

156.17 "FATIGUE PROPERTIES" OF HINDLIMB MOTONEURONS OF THE CAT. D. Kernell* and A.W. Monster☒. Dept. of Neurophysiology, Jan Swammerdam Institute, University of Amsterdam, The Netherlands.

It is well known that the motor units of a mixed hindlimb muscle may differ markedly from each other with respect to their resistance to contractile fatigue. We have investigated whether the motoneurons innervating muscle fibers with different fatigue resistance would show any consistent differences with respect to their ability to produce a steady discharge in response to constant stimulation. The experiments were performed on cats anesthetized with pentobarbitone. M.gastrocnemius medialis (GM) was attached to an isometric force transducer. GM motoneurons were penetrated with single-barrelled micro-electrodes filled with potassium citrate. For measurements of the twitch and the fatigue resistance (ref.1) of a muscle unit, its motoneuron was directly activated by 1 ms pulses of injected current. The "late adaptation" (ref.2) of the motoneuron was determined by measuring the decline of firing rate during direct stimulation with a step of steady injected current which lasted 240 sec. Earlier studies have indicated that damage inflicted by the microelectrode may make motoneurons unable to produce a maintained discharge in response to steady stimulation (ref.2). For the present investigation, we only used neurons that possessed healthy-looking spikes of > 55 mV, and which were capable of tonic firing during at least a few seconds of constant stimulation. Thus far, we have measured the "motoneuronal fatigue"(late adaptation) in response to various stimulus intensities in a total of 24 GM motoneurons. In 18 of these cells we applied a test current of 5 nA above the threshold for rhythmic firing. The resulting discharge lasted for 124±95 sec ($\bar{x}$±SD; range 10 - 240 sec); its duration showed no significant correlation to the "fatigue index" (ref.1) of the muscle unit (r=0.14, n=16). Among cells capable of firing during > 2 min of constant stimulation, adaptation was faster during the first minute of maintained firing than later on. During an initial period of the discharge (typically some tens of seconds) the decline of discharge rate could usually be approximated by an exponential function. Preliminary results suggest that the time constant of this initial neuronal rate decrease tends to be longer for units with a slow twitch and a high fatigue resistance than for faster and more fatiguable ones.

156.18 THE EFFECT OF UNILATERAL FASTIGIAL LESIONS ON STATIC AND DYNAMIC RESPONSES OF MUSCLE SPINDLE PRIMARY AFFERENTS IN THE CAT. D. Kornhauser*, M.B. Bromberg and S. Gilman. Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI 48109 and Neurosurgery Section, V.A. Medical Center, East Orange, NJ 07019.

The responses of single gastrocneimus muscle spindle primary afferents to static and dynamic extension of the gastrocneimus muscle were recorded before and after lesions of the fastigial nucleus. Sixty-five units were recorded in 15 cats. In all animals, the lesion involved the rostral pole of the fastigial nucleus on the side of the recording. The fastigial lesions depressed significantly the responses to static extension of the spindle primaries and the extent of the lesion was a significant factor in this effect. Lesions involving 15 to 50% of the nucleus had no significant effect but when the lesion involved 51% or more of the fastigial nucleus, a significant decrease of response occurred. The lesion interrupted projections from both the ipsilateral and contralateral fastigial nucleus since efferent fibers from the caudal pole of the contralateral fastigial nucleus pass through the rostral pole of the ipsilateral fastigial nucleus en route to the brainstem.

The dynamic sensitivity of the muscle spindle primaries was assessed by measuring the afferent response at the immediate termination of a ramp stretch performed at 5, 30 and 100 mm per second. Even lesions damaging 76% or more of the fastigial nucleus resulted only in a slight and non-significant decrease in the peak frequency of the response at all three velocities of stretch in comparison to control levels. De-efferentation by ventral root section had a pronounced effect on the peak frequency response to stretching at 5 and 30 mm per second and no effect on the response to stretching at 100 mm per second.

Thus, lesions involving at least 51% of the fastigial nucleus, including its rostral pole, decrease the responses to static extension but not to dynamic extension of muscle spindle afferents in an extensor muscle on the ipsilateral side of the body. The lesion includes projections from the caudal pole of the contralateral fastigial nucleus. We conclude that the fastigial nuclei maintain a tonic facilitatory influence upon muscle spindle primary afferents for their responses to static extension. This influence is probably mediated to the spinal cord via the spinal projections of the vestibular and reticular nuclei. The vestibulo spinal projections make contact primarily with static fusimotor neurons which are responsible for the spindle afferent responses. Supported in part by USPHS Grant NS 10612.

156.19 REGIONAL GLUCOSE METABOLISM IN THE DECEREBRATE CAT. R. Watts*, E. B. Montgomery, Jr.*, W. Landau and R. C. Collins. Dept. of Neurology, Washington Univ. Sch. of Med., St. Louis, MO 63110.

[^{14}C]-2-deoxyglucose (2-DG) autoradiography was used to study changes in functional metabolism in the brainstem and cerebellum of cats in response to decerebration. Two cats were decerebrated by blunt intercollicular transection and 2 by the anemic method (ligation of both carotid arteries and the basilar artery at mid-pontine level). The decerebrate cats were maintained in a resting prone position with the extremities and head held extended during the injection of 2-DG two hours after recovery from ether anesthesia. Two control cats were maintained in a resting prone position with their extremities casted in extension, head freely movable and were injected with 2-DG two hours after recovery from ether anesthesia. Arterial blood gases and blood pressure were maintained within physiological ranges.

Cats anemically decerebrated (AD) differed behaviorally from cats decerebrated by transection (TD). The AD cats displayed lability of blood pressure and respirations, more "running" and other atypical behavior, and more vigorous extensor hypertonus. The brainstem rostral to the basilar artery ligation in the anemic preparations showed marked variability in the pattern of 2-DG uptake. However, where there was uptake it was mottled and not confined to specific structures as compared to the more caudal structures or to control cats. This suggests that this pattern of uptake in the rostral brainstem was due to ischemia whereas the specific patterns seen in structures caudal to the rostral pons were not.

Hyperglycemia following decerebration compromised quantitative analysis. Changes in functional metabolism were compared as a ratio of tissue 2-DG concentration of various areas to the tissue 2-DG concentration of the central gray area of the spinal cord in each cat. Preliminary results of changes in functional metabolism as compared to control cats showed: 1) increase in the medial and inferior vestibular and lateral reticular nuclei in both AD and TD cats; 2) increase in dentate, interpositus and fastigial nuclei in AD cats; and 3) decrease in principle inferior olivary nuclei (IOP), whereas there was no change in medial (IOM) and dorsal (IOD) accessory olivary nuclei in both AD and TD cats. The increase in functional metabolism of the deep cerebellar nuclei in AD cats is consistent with the loss of inhibitory input from ischemic cerebellar cortex. The decrease in functional metabolism in IOP without change in IOM or IOD is consistent with the dependence of IOP on descending inputs from rostral structures whereas IOM and IOD are more dependent on ascending spinal inputs.

156.20 QUANTITATIVE ANALYSIS of NORMAL and REGENERATING BEHAVIORS in the SEA LAMPREY. Joseph Ayers, Gail A. Carpenter, Scott Currie and James C. Kinch. Marine Science Institute and Dept. of Mathematics, Northeastern University, Boston, MA 02115

Lamprey behaviors have been analyzed by stop-frame analysis of motion pictures. These films provide numerical data for physiological models of motor pattern generation and spinal cord regeneration. The experiments have been performed on normal ammocoete larvae, recently transformed adults, and ammocoetes recovering from complete transection of the spinal cord. The images from each frame are digitized on a magnetic tablet and analyzed by computer algorithms which determine, for example, curvature as a function of distance along the body. Further analysis determines the repetition frequency, amplitude, direction, and rate of propagation of flexion waves; the phase lag between flexions on opposite sides; and the speed and direction of motion. With this method it is possible to specify behaviors by a small number of parameters, computed automatically from the digitized data, and to compare the behaviors with cellular correlates in reduced preparations. Several behaviors have been studied, including: swimming, turning, burrowing, aversive withdrawal, forward escape, and forward and backward crawling.

A similar analysis has been performed on ammocoetes regenerating from spinal cord transection and the chronology of recovery has been traced. Spinalized animals eventually display most of the above behaviors, with some deficits. Abnormal behaviors such as coiling and shaking occur during recovery. The contribution of passive mechanical propagation is computed by analysis of body movements produced by mechanical head oscillations of dead and acutely transected ammocoetes.

The lamprey has recently become an important model system (Rovainen, C. M., Physiol. Rev. 59:1007, 1979) and the present research provides standardized criteria for systematic studies of behavior patterns and their underlying cellular mechanisms.

157.1 ABNORMALITIES IN THE EMG PATTERN OF ELBOW FLEXIONS DURING CEREBELLAR DYSMETRIA. J. Hore and T. Vilis. Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

To identify the basic features of cerebellar dysmetria we compared EMG patterns of the same monkeys during normal elbow flexion movements and during dysmetric movements. Reversible cerebellar lesions were produced by cooling through sheaths placed lateral to dentate and through interpositus. This technique allowed us to compare normal and abnormal EMG activity of biceps and triceps recorded through the same intramuscular electrodes. Cebus monkeys were trained to make prompt and accurate movements between visual targets. Movements of 40 degrees of arc were made in about 300 msec. A small load was placed on the handle to accentuate antagonist triceps activity.

Under normal conditions well-trained monkeys initiated movements by a decrease in triceps and a phasic burst in biceps. This phasic burst had two components: the first was of constant duration (30-40 msec) and, on average, was of constant amplitude for different sized movements. The amplitude and duration of the second component was related to the size of the movement. During these control movements the antagonist triceps commenced discharging tonically at a level appropriate for the new flexed position. The time of onset of triceps was fixed to the start of the movement, but variable in relation to the end of the movement. Thus the antagonist EMG activity did not play a major role in stopping the movement. These monkey movements would appear to be equivalent to the slow category of human arm movements (Lestienne, 1979) in that braking forces were predominantly generated by visco-elastic muscle properties.

During cerebellar cooling monkeys displayed both hypometria and hypermetria in consecutive movements followed in both cases by a tremor at 3-4 Hz. In these dysmetric movements there was a delay in onset of the phasic biceps EMG by about 50 msec and there was no clear cut first component. A major change was observed in antagonist activity during dysmetria. In normal movements onset of the tonic triceps activity occurred at a variable time to the end of the movement. During dysmetria there was a phasic burst in triceps which was fixed in relation to the end of the movement. When this burst occurred early in the movement it caused hypometria, while when it occurred late in the movement it allowed hypermetria. This burst in triceps initiated the terminal tremor.

Thus one major difference between these normal well-trained arm movements and dysmetric movements is that in the former case they appear to be terminated primarily by visco-elastic forces, while in the latter case they are terminated by a burst of activity in the antagonist muscle.

Lestienne, F. (1979). Exp. Brain Res. 35, 407-418.

157.2 PURKINJE CELL INHIBITION DURING THE CO-ACTIVATION OF ANTAGONIST MUSCLES IN ISOMETRIC PREHENSION. Allan M. Smith and Daniel Bourbonnais. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada.

Recordings of cerebellar Purkinje cell discharge in the awake animal has been shown to be related to various parameters of agonist muscle activity such as the duration, the direction and the velocity of limb displacement. Nevertheless, it is still unexplained how the excitation of these inhibitory neurons is related to motor performance. One possibility is that the Purkinje cells are related to the inhibition of antagonist muscles. It was decided to test this hypothesis in a situation requiring the co-contraction of mechanically opposing muscles. Monkeys were trained to exert and maintain a precisely controlled force between the thumb and forefinger for a fruit juice reward. Extensive recordings from the 24 muscles of the wrist and fingers active during the maintained precision grip demonstrated that all muscles show a similar pattern of co-activation. Purkinje cells were identified by the presence of climbing fiber discharge in extracellular recordings. All other units were considered unidentified neurons. To date, about 85% of the unidentified neurons increased discharge frequency during grasping. In contrast, 71% of the Purkinje cells were inhibited during the application of prehensile force. Purkinje cell discharge frequency for 3 neurons was inversely related to the rate at which finger pressure increased. One of these neurons also had a significant negative correlation between discharge and prehensile force. The inhibition of Purkinje cell discharge appeared to coincide with the co-contraction in the flexor and extensor muscles of the wrist and fingers. In one Purkinje cell a clear excitation was observed when extensor digitorum contracted to produce isotonic extension of the fingers, but when this same muscle contracted simultaneously with its antagonist, the Purkinje cell discharge was inhibited. These results are interpreted as suggesting that Purkinje cells are excited by stretch of antagonist muscles or the central command to stretch these muscles. The inhibition generated in the deep nuclear cells is presumed to further relax the antagonists. However, in movements requiring the co-contraction of antagonists, the Purkinje cells themselves are inhibited, probably as a result of convergent excitation from both agonists and antagonists onto basket or stellate cells.

157.3 REDUCTION OF POSTSYNAPTIC ACTIVITY ENHANCES PARALLEL FIBER FREQUENCY FOLLOWING. R. C. Malenka, J. D. Kocsis* and S. G. Waxman*. Dept. of Neurology, Stanford Sch. of Med. and Veterans Administration Med. Ctr., Palo Alto, CA 94304

It has been reported that axon excitability can be affected by (1) previous impulse conduction along the same axon (2) ephaptic interactions between axons or (3) electrical or extracellular ionic changes associated with postsynaptic activity. In this study we examine the frequency following capabilities of the parallel fibers (Pfs) in the presence and absence of postsynaptic activity.

Rat cerebella were continuously superfused with normal Ringer solution (NS). Local microstimulation of the Pfs was employed and the on-beam Pf field potential was recorded within 50 µm of the cerebellar surface. In addition the extracellular DC slow potential (SP) was recorded. The latency and amplitude changes of consecutive Pf responses to stimulus trains (10-80 Hz) were analyzed. Postsynaptic activity was manipulated either by superfusion with Mn^{2+}, Mg^{2+}, or 4-aminopyridine (4-AP); or by giving a conditioning stimulus train.

In NS consecutive Pf responses to stimulus trains revealed an initial supernormal period followed by a gradual transition into subnormality as determined by latency and amplitude variation. A pronounced negative SP was present during these trains. Both the Pf amplitude reduction and the SP amplitude were frequency dependent. In the absence of postsynaptic activity, the Pfs showed enhanced frequency following as evidenced by a much reduced amplitude cut-off during stimulus trains. In the presence of 4-AP the postsynaptic potential was increased as was the SP amplitude and conduction block occurred after the first or second volley of the stimulus train. Addition of Mg^{2+} to the 4-AP superfusate abolished the postsynaptic potential, reduced the SP amplitude and restored the frequency following properties of the Pfs.

These results suggest that changes associated with postsynaptic activity in the cerebellar cortex may dampen the frequency following capabilities of the afferent Pfs. Other investigators (Nicholson et al, J. Neurophysiol. 41, 1978) have shown significant changes in extracellular ionic concentrations due to postsynaptic activity during tetanic stimulation. Our results suggest that these changes may influence Pf excitability. A morphological channel may be available for ionic movement through the extracellular space since the Pfs are extremely fine, non-myelinated axons with few intervening glial elements. (Supported in part by the NIH (RR-5353 and NS-15320), the Veterans Administration, and the National Multiple Sclerosis Society (RG-1231).)

157.4 IMPULSE ENTRAINMENT: A TIMING MECHANISM FOR PARALLEL-FIBER ACTIVATION OF PURKINJE CELLS? K.L. Cummins*and J.D. Kocsis*. (SPON: L. Masukawa). Dept. of Neurology, Stanford Univ. Med. Ctr., and V.A. Med. Ctr., Palo Alto, CA. 94305.

The fine-caliber parallel fibers (Pfs) of the cerebellar cortex propagate action potentials over a wide range of conduction velocities (CVs), depending on the time since the previous impulse. This dependence of CV on spike interval may have physiologic significance by controlling the precise spacing of these neural signals. In the simple case of two propagating action potentials, the recovery of CV of the second impulse in the pair is characterized by three distinct periods; CV is increased during the supernormal period (SNP) and decreased during the relative refractory (RRP) and subnormal periods. A result of this recovery process is "entrainment" whereby impulses initiated over a wide range of initial intervals converge to the same interspike interval after propagation (Kocsis et al, Exper. Neurol., 65:230, 1979).

We have studied the phenomenon of entrainment using both computer simulation and experimental methods. The simulations used a simple parametric model to generate the spatial and temporal properties of impulse propagation from the relationship between instantaneous CV of the second impulse and the interval between the impulses. Using this model the three phases of recovery were studied and impulses were shown to converge to one of three intervals at infinite propagation distance. For finite propagation the simulations demonstrated that manifestation of entrainment was dependent upon the particular recovery curve, conduction distance, and the initial interval between impulses.

When recovery data from rat Pfs were used, the model accurately predicted the spatial and temporal properties of Pf interspike interval during conduction, and demonstrated that convergence toward entrainment occurred at physiological distances for propagation during the RRP and early SNP. This result is discussed in terms of the timing of Pf activation of Purkinje cells.

157.5 LIDOCAINE DIFFERENTIALLY BLOCKS FAST AND SLOWLY INACTIVATING SODIUM CONDUCTANCE IN PURKINJE CELLS: AN IN VITRO STUDY IN GUINEA PIG CEREBELLUM USING IONTOPHORETIC GLUTAMIC ACID. M. Sugimori* and R. Llinás (SPON: C. Nicholson). Dept. Physiology & Biophys., New York Univ. Med. Ctr., 500 First Ave., New York 10016.

Cerebellar slices obtained from guinea pig cerebellum were utilized following the experimental techniques of Llinas and Sugimori (J. Physiol. 305: 1980 in press). Intrasomatic and intradendritic recordings were obtained while a second electrode filled with glutamic acid was kept in the vicinity of the impaled neuron. Extracellular iontophoretic injection of glutamic acid produced a fast depolarization capable of activating both sodium and calcium-dependent action potentials. This depolarization could be reversed by direct modification of the membrane potential level to 0 mV, suggesting that in these cells glutamic acid produces simultaneous conductance to both sodium and potassium. Following application of cadmium, cobalt, manganese or D-600, voltage-dependent calcium spikes could be blocked and the non-inactivating sodium action potential (Sugimori and Llinas, Soc. Neurosci. Abst. 5: 107, 1979) was evoked by either direct or glutamic acid depolarization. This voltage-dependent plateau conductance generated trains of action potentials which often reached inactivation level. Further studies have indicated that lidocaine at low concentrations (10^{-5} to 10^{-4} M) can produce a blockage of the fast sodium action potentials but does not block the slowly rising sodium-dependent plateau depolarizations. Addition of tetrodotoxin to the bath, however, blocked both the fast and the non-inactivating sodium conductances. The differential effect of lidocaine on the inactivation and non-inactivation of sodium conductance is in agreement with recent experiments, suggesting that local anesthetics block sodium conductances in their inactivated states by increasing drug binding when the h gate is closed (Cahalan, Biophys. J. 23: 285, 1978). While the present study does not address this question directly, it is at least consistent with the fact that sodium channels which do not show inactivation are less susceptible to certain local anesthetics. (Supported by USPHS grant NS-13742 from NINCDS)

157.6 DISCHARGE PATTERNS OF DENTATE NEURONS DURING BALLISTIC ARM MOVEMENTS IN THE MONKEY. G. Spidalieri* and Y. Lamarre. Centre de recherche en sciences neurologiques, Fac. de méd., Univ. de Montréal, Montréal, Québec, Canada H3C 3J7.

The cerebellum is presumably involved in the initiation of some fast ballistic movements. Previous observations showed that dentate lesion can delay the initiation of arm movements that are triggered by light and sound but not of those triggered by somesthetic stimuli. This led us to examine the activity of dentate neurons in monkeys trained to execute the same arm movements (flexion or extension) in response to randomly presented light signals, pure tones, or small elbow displacements. The majority of neurons recorded in the dentate increased or decreased their rate of firing at least 100 msec before the onset of elbow displacement (mean 121 ms) while in the interpose nucleus, change of neuronal activity occurred later (mean 75 ms). Clear reciprocal pattern of activity with flexion and extension was seen only in the interpose nucleus. The pattern of discharge of many neurons varied according to the modality of the triggering stimulus. This was seen mainly in the posterior half of the dentate (40% of the neurons) where several units changed their activity only when the movement was triggered by light and/or sound. These data provide further evidence in favor of the hypothesis that the lateral cerebellum is particularly involved in the initiation of arm movements triggered by teleceptive input signals. (Supported by the MRC of Canada)

157.7 CHANGES IN SACCADE DURATION DURING CEREBELLAR DYSMETRIA. T. Vilis and J. Hore. Departments of Ophthalmology and Physiology, University of Western Ontario, London, Canada N6A 5C1.

The accuracy of saccadic eye movements made by four trained Cebus monkeys was studied during reversible lesions produced by cryoprobes implanted between the fastigial and interpositus nuclei (medial probe) or lateral to the dentate nucleus (lateral probe). Cooling through the lateral probe did not impair the accuracy of vertical or horizontal saccades. However cooling through the medial probe produced a dysmetria whose magnitude was dependent on the position of the eye and on the direction of the saccade (c.f. Ritchie, 1976). While hypermetric saccades primarily occurred for centripetal saccades and hypometric saccades predominated in the centrifugal direction, examples of both hypometric centripetal and hypermetric centrifugal saccades were noted. The duration of dysmetric saccades was related to their amplitude; hypermetric saccades had longer durations while hypometric saccades had shorter durations compared to controls between the same target displacements.

The dysmetria seen for a horizontal or a vertical target displacement corresponded to the dysmetria observed in the equivalent horizontal or vertical components of saccades resulting from an oblique target displacement. For example if a purely horizontal saccade was hypometric, the equivalent horizontal component of an oblique saccade directed to the same final position was also hypometric. Moreover the trajectories of these oblique saccades remained essentially straight during medial probe cooling even when the dysmetria in the two components was unequal. Thus, for example, when the magnitude of one component became hypermetric while the other remained normal during cooling, the duration of both components increased. This implies that the mechanism which produces dysmetria in one component must interact with the gaze center that determines the duration of the other component.

Cooling the cerebellar nuclei through either the lateral or medial probes did not alter the time of onset (reaction time) of saccades to a randomly timed step change in target position. This result differs from that found for limb movements where cerebellar dysmetria was associated with increased reaction times (Holmes, 1939).

These results provide evidence that the cerebellum through the medial nuclei normally plays a role in terminating but not in initiating saccades.

Holmes, G. Brain 62: 1-30 (1939)

157.8 TONIC RESPONSES TO GALVANIC VESTIBULAR STIMULI ARE FOUND IN 'NON-VESTIBULAR' PARTS OF THE CEREBELLUM. David W. Jensen. Dept. of Otorhinolaryngology and Program in Neuroscience, Baylor College of Medicine, Houston, Texas 77030.

Experiments have begun with the goal of measuring the changes induced in the spontaneous neural activity in response to direct currents applied to the labyrinth. Guinea pigs were semichronically prepared, including implantation of an Ag-AgCl ball electrode on one round window membrane for d.c. stimulation. The next day the animals were checked for the presence of spontaneous nystagmus and/or body postural asymmetries. No asymmetries were found in 4/4 animals, and the thresholds for producing body postural asymmetry and eye nystagmus were from 0.1 to 0.2 mA. Anodal and cathodal polarizations of one ear induced postural reactions similar to those that would occur if instead the ipsi- or contralateral ears respectively were ablated.

Three of the implanted animals were prepared for single unit recording from the posterior vermal cerebellar cortex during light ketamine anesthesia (30 mg/Kg/hr) and local anesthesia of would edges with 1% Lidocaine with 1:100,000 epinephrine. The ongoing activity of Purkinje cell-type unitary potentials was measured during unilateral anodal and cathodal d.c. stimulations of 0.3 mA or less in amplitude and 5-10 seconds in duration. The stimulating reference electrode was in the ipsilateral pinna, in the proximal portion and removed from the facial nerve. Preliminary recordings have thus far revealed several new observations regarding vestibular input to the cerebellum: 1) Tonic vestibular influences are demonstrable in "non-vestibular" cerebellar cortex, and 2) For most cells, unilateral anodal and cathodal vestibular polarizations of equal absolute magnitude produced responses that are: a) not opposite in the direction or time course of ongoing modulations, and b) not equal in the absolute values of modulations.

157.9 COORDINATE AXES OF THE VISUAL CLIMBING FIBER INPUT TO THE FLOCCULUS. C. Leonard*, W. Graf* & J.I. Simpson, Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016

Cells of the dorsal cap (DC) of the inferior olive project as climbing fibers to the contralateral flocculus and transmit direction and speed information about movement of large portions of the visual world. The spatial organization of the receptive fields (RFs) of DC cells was investigated in anesthetized, paralyzed rabbits by extracellularly recording unit responses to large-field, rotational visual stimuli. For all cells the majority of the RF is above the horizontal plane. Some cells are driven exclusively from one eye; others are driven from both eyes, but more effectively from one eye than the other. The RF organization for the dominant or exclusive eye can be used to assign cells to one of three categories according to the orientation in space of the axis about which rotation of the visual world produces best modulation. The categories are termed Vertical Axis, Anterior (45°) Axis and Posterior (135°) Axis. The cells of each category occupy distinct zones within the DC. Vertical Axis cells are driven only from the contralateral eye (re: recording site) and are best excited by horizontal movement in the temporo-nasal direction. The RF extends along the horizon from the nose (0°) up to 160° posteriorly. Anterior (45°) Axis cells are divided into two sub-classes: one driven only from the ipsilateral eye and the other driven from both eyes, but with ipsilateral dominance. The ipsilateral RF has two parts, each with a different preferred direction. In the anterior part (from 0° to approx. 45° along the horizon) the preferred direction is up and somewhat backward; in the posterior part (from approx. 45° to at least 160°) the preferred direction is down and somewhat backward. Thus, the optimal stimulus is rotation of the visual world about an axis at approx. 45° to the midline. For binocular Anterior (45°) Axis cells, the RFs are axially symmetric about the midline. The Posterior (135°) Axis cells are driven from both eyes, but with contralateral dominance. The contralateral RF extends from 0° to approx. 135° posteriorly; the preferred direction is up and somewhat backward. The ipsilateral RF is centrally symmetric to the contralateral RF with respect to the intersection of the RFs with the horizontal plane. The ipsilateral preferred direction is down and somewhat backward and is thus in concert with the contralateral preferred direction for rotation about the common principal axis running from 45° ipsilateral to 135° contralateral These findings indicate that the principal axes of the floccular visual climbing fiber inputs are oriented similarly to the semicircular canal principal axes. Supported by USPHS Grant NS-13742 and DFG Grant GR-688/1.

157.10 VISUAL PROPERTIES OF NEURONS IN THE PARAFLOCCULUS OF THE RAT CEREBELLUM. Richard A. Burne and Donald J. Woodward. Department of Cell Biology, The University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

The parafloccular lobule was recently identified as a cerebellar visual area in the rat by the anatomical and electrophysiological demonstration of inputs from the visual cortex and superior colliculus via the basilar pontine and reticular nuclei (Burne and Woodward, 1978, Neurosci. Abst. 4:64). As part of the general aim of determining the functional significance of the parafloccular visual input, the current study was undertaken to characterize the response properties of visually sensitive cells in the paraflocculus.

Single unit recordings of neuronal cell activity in unanesthetized, immobilized rats were obtained, and peri-event raster and histogram analyses were employed to determine the response properties following the presentation of computer-controlled visual stimuli. Of 32 identified parafloccular Purkinje (P) cells, 23 cells showed evidence of pure excitatory, inhibitory or mixed excitatory-inhibitory mossy fiber (MF) and/or climbing fiber (CF) inputs. MF mediated excitatory responses were also elicited in 13 additional cells which did not exhibit the typical climbing fiber bursts that are characteristic of Purkinje cells. MF mediated and CF burst responses were evoked in Purkinje cells by flashed on-off stationary bars or spots of light or by visual stimuli moving at 50-800°/sec at specific orientations. CF burst responses preceded or occurred coincident with simple spike responses. Parafloccular neurons excited by stimuli in the nasal field were often inhibited by visual presentations in the temporal field, suggesting the presence of a visuotopic map in the paraflocculus. Overall, the spatial-temporal properties of visual units in the paraflocculus are grossly similar to the highly specialized units identified in parallel studies of rat visual cortex (Parnavelas et al., Neurosci. Abstr. 1980).

In summary, responses of visually sensitive parafloccular cells were elicited by stationary and moving stimuli, and showed evidence for dirtectional, velocity and positional sensitivities. Our hypothesis is that the paraflocculus may integrate information received by the visual cortex concerning ongoing events in visual space into the control of motor patterns.

157.11 PARAFLOCCULUS AND POSTERIOR VERMIS: AUDITORY AREAS OF THE CEREBELLUM. A. Azizi, R.A. Burne and D.J. Woodward. Dept. of Physiol., Univ of Tx Hlth Sci Ctr at Dallas, Dallas, Tx 75235.

Previously we presented evidence suggesting the existence of an auditory cortical input to the paraflocculus of the cerebellum. The present study was undertaken with the aim of determining the electrophysiological response properties of the sound sensitive neurons within the paraflocculus and midvermis of the rat cerebellum as determined by: (1) electrical stimulation of the auditory cortex and inferior colliculus and (2) presentation of controlled, time locked tones to the animal.

Single unit recordings were obtained from 105 identified parafloccular and 98 midvermal (lobules VIa-VIIb) Purkinje cells in halothane anesthetized rats. Post-stimulus time histogram (PSTH) analysis of 23 parafloccular Purkinje cells showed evidence of excitatory and/or inhibitory mossy fiber inputs following electrical stimulation of the auditory cortex (double pulses, 0.2 msec duration, -.05 to -.8 mA, 1-20 HZ), with latencies ranging from 6-13 msecs. No climbing fiber activation or response to tectal stimulation was observed. Fourteen midvermal units (13.9%) elicited inhibitory and/or excitatory responses with latencies ranging from 4-25 msec upon stimulation of the inferior colliculus. No responses were observed following the auditory cortical stimulation. These observations suggest that the auditory input to the midvermis and the paraflocculus may be from different sources.

Single unit recordings of an additional 11 units in the paraflocculus in unanesthetized immobilized rats showed evidence through PSTH analysis, for excitatory or inhibitory mossy fiber and climbing fiber inputs following presentation of tones in the auditory field. Simple and complex spike responses were elicited following presentation of tone bursts composed of white noise 500-1000 pulses/sec and intensities of 65-80 db. (background noise intensity was 58 db.). Two types of responses were evident, units with either long (70-85 msec) latencies or units with short (20-25 msec) latencies. The data suggest the existence of two different sources of auditory input to the paraflocculus. In addition, some units showed evidence of facilitation or occlusion when a combined auditory and moving visual stimuli were presented to the animal.

In summary, these observations argue for the presence of an auditory input to the paraflocculus. Our hypothesis is that the paraflocculus operates in parallel with the classical auditory-visual midvermal area in mediating visual-auditory sensorimotor integration by the cerebellum. Supported by NSF 77-01174 to DJW and an award from the Biological Humanics Foundation.

157.12 FRACTURED AND ORGANIZED SOMATOTOPY OF TACTILE AREAS OF CAT CEREBELLAR HEMISPHERES. Jeffrey Kassel, Georgia Shambes, and Wally Welker, Dept. of Neurophysiology, Univ. Wisconsin, Madison, WI 53706.

Snider's pioneering studies of tactile responses in the cerebella of cats and monkeys suggested that posterior regions of the cerebellar hemispheres receive somatotopically organized projections. However, recent studies in rats, using high-density microelectrode mapping techniques, have shown that tactile projections to the granule cell (GC) layer of the cerebellar hemispheres are somatotopically fractured (Shambes et al., BBE 15, 94-140, 1978). We decided, therefore, to reexamine the organization of tactile projections to the cerebellar hemispheres of cats using microelectrode micromapping methods.

Mechanical stimulation of cutaneous surfaces evokes multiple-unit responses in the cerebellar GC layer in ketamine or barbiturate anesthetized cats. Facial structures project to the more medial folia of posterior crus II and to several folia of the anterior paramedian lobule (PML), while the forelimb projects to anterior and posterior folia of PML. All projections are from tactile receptive fields (RF's) on the ipsilateral head and forelimb. We have not yet observed cerebellar responses to light tactile stimulation of the trunk or hindlimbs.

Cerebellar folia (in crus II & PML) receiving facial inputs display an array of patch-like projections similar to the somatotopically fractured tactile representation previously described in rats. Within single patches, tactile projections are somatotopically organized, but adjacent patches receive projections from noncontiguous body regions. Within a single folium, a particular facial region may project to two or three spatially separated patches. Patches with facial RF's are small, usually less than 1 mm^2. Forelimb patches in PML are larger, typically extending the entire length and breadth of a folial crown.

These data confirm Snider's original report of the locations of tactile projections to the cat cerebellar hemispheres, but reveal a more complex pattern of organization than previously believed. Together with our previously reported data for rats and unpublished observations in gray squirrels, these studies suggest that a mosaic pattern of patchy projections is a common feature of the organization of tactile inputs to the GC layer of the mammalian cerebellum. (Supported by NSF grant BNS-16230 and NIH grant 5 F32 NS06047.)

157.13 THE CEREBELLO-TECTAL PROJECTION IN THE HOODED RAT. A. Frankfurter and R. M. Beckstead. Depts. of Neurosurgery & Anatomy, Univ. of Virginia Sch. of Med., Charlottesville, VA 22908.

Projections from the deep cerebellar nuclei to the superior colliculi have been documented. However, neither the location nor morphology of the cells of origin of these projections, nor their laminar termination in the superior colliculi have been studied in detail. The present study was designed to address these issues.

Unilateral deposits of horseradish peroxidase were electrophoretically delivered into the superior colliculi of hooded rats. The present results indicate that almost all of the labeled neurons are located within a ventral and lateral, crescent-shaped sector of the deep cerebellar nuclei contralateral to the injection site, which extends across cytoarchitectonic boundaries, and includes the large and small cell divisions of the lateral nucleus and nucleus interpositus. All of the labeled cells seem to be of uniform size and morphology. This projection is clearly topographic. Injections into the anterior half of the superior colliculus result in labeling of neurons which are located in a more anterior sector than those observed following injections into the posterior half of the superior colliculus. Labeled neurons were never observed within either medial segments of the lateral nucleus or medial segments of nucleus interpositus. Infrequently, one or two labeled neurons were observed in the medial nucleus contralateral to the injection site. No evidence for an ipsilateral projection has been observed. The available data also suggest that the laminar termination of these neurons within the contralateral superior colliculus is in the stratum griseum intermediale, since the largest number of labeled neurons were always observed when the pipette tip was centered within this lamina. A detailed analysis of this basic organization is currently in progress.

157.14 A CORRELATED AUTORADIOGRAPHIC AND EM DEGENERATION STUDY OF THE PROJECTION OF THE SUPERIOR COLLICULUS TO THE BASILAR PONTINE NUCLEI IN THE RAT. C.B. Watt*, R.A. Burne and G.A. Mihailoff. (SPON: R. Galosy). Dept. Cell Biology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, Tx 75235.

As part of ongoing studies concerning the synaptic organization of the rat basilar pontine nuclei (BPN), an attempt was made to 1) investigate the pattern of organization in the tectopontine projection system using light microscopic autoradiography and 2) to utilize the electron microscopic degeneration technique to establish the identity of tectopontine axonal boutons and characterize their synaptic relationships within the BPN. Initially, ^{3}H-Leucine was stereotaxically delivered to the superior colliculus of Long-Evans rats utilizing either pressure or electrophoretic injection systems. After a 24 hour survival period, frozen sections were processed routinely for autoradiography and allowed to expose for five weeks. Upon examination of autoradiograms, the majority of tectopontine axons were found to terminate ipsilaterally within the lateral pontine region throughout much of the middle 3/5 of the basilar pons. The heaviest labeling was concentrated in the dorsolateral pontine region, while a less dense termination zone was observed in the ventrolateral portion of the BPN. The superior colliculus also gave rise to a sparse, contralateral pontine projection. The latter terminal zone was situated within a restricted portion of the contralateral, dorsomedial pontine region. Following bilateral electrolytic superior collicular lesions, degenerating axon terminals were identified within those pontine regions which received a tectal input as determined in previous autoradiography studies. Tectopontine axonal boutons (.8-2.2 µm) exhibited early dark degenerative changes following survival periods from 2 to 4 days. With longer survival times (4-7days) degenerating boutons became more electron dense and shrunken while being engulfed by glial elements. Tectopontine axon terminals contained small, round synaptic vesicles and formed asymmetric synaptic contacts with small diameter dendritic profiles. These observations when correlated with previous autoradiography studies provide anatomical evidence suggesting a functional connection between the superior colliculus and the basilar pontine nuclei in the rat.

157.15 AUTORADIOGRAPHIC AND EM DEGENERATION EVIDENCE FOR AXONAL SPROUTING IN THE CORTICOPONTINE SYSTEM OF THE RAT. G.A. Mihailoff and A.J. Castro. Dept. Cell Biology, The Univ. Texas Hlth. Sci. Ctr., Dallas, Tx. 75235 and Anatomy Dept., Loyola Univ. Stritch Sch. of Medicine, Maywood, Il1. 60153.

Several previous accounts in the literature employing silver degeneration techniques have reported the existence of sprouting in the corticopontine and cerebellopontine systems when either system is interrupted in the neonatal rat brain (1-4 days postnatal). We have sought to confirm these findings in regard to the corticopontine system, utilizing the orthograde transport method (autoradiography) and to investigate the possible synaptic remodeling which might occur in the pontine gray in this situation using electron microscopy. Newborn (1-4 days of age) Long-Evans rats received large frontal cortex ablations by aspiration under hypothermic anesthesia. Several weeks (10-13) later, when the animals had attained a weight of 250-350 gm, one group received a ^{3}H-Leucine injection in sensorimotor cortex contralateral to the neonatal lesion while another group was subjected to a large sensorimotor (SM) lesion in that (contralateral) hemisphere. The autoradiographic studies demonstrated the normal corticopontine projection zones within the pontine gray ipsilateral to the leucine injection and also revealed axonal and terminal labeling in the contralateral pontine gray where the normal corticopontine input had been removed by the neonatal lesion. The implication here is that the contralateral labeling is demonstrating the sprouted corticopontine axons. Recently, similar findings have been obtained in animals which received an adult SM lesion followed 3-79 days later by a ^{3}H-Leucine injection in the opposite hemisphere suggesting that the capacity for sprouting might be retained by mature corticopontine axons. In the group of animals subjected to an SM lesion long after degenerating elements resulting from the neonatal ablations should have been cleared, the presence of numerous fragmented axons and degenerating synaptic boutons was evident in the pontine gray neuropil contralateral to the second (adult) SM lesion. Interestingly, the degenerating boutons included both the electron dense and filamentous varieties and frequently it was noted that what appeared to be a postsynaptic locus (membrane specialization) was apposed to a glial process as if the postsynaptic profile had been abandoned by its presynaptic cortical bouton. The combination of autoradiographic and EM studies thus support the notion that sprouting of cortical axons has occurred across the midline into the pontine gray which had been cortically deafferented shortly after birth.

157.16 LIGHT AND ELECTRON MICROSCOPIC ANALYSES OF PURKINJE CELL AXON COLLATERALS: AN INTRACELLULAR HRP STUDY IN THE CAT. G.A. Bishop, J.S. King, and R.A. McCrea. Dept. of Anatomy, The Ohio State University, Columbus, Ohio 43210; and Dept. of Physiology and Biophysics, New York University, New York, New York.

Purkinje (Pk) cells of the intermediate anterior lobe and paramedian lobule in the cat cerebellum were intracellularly injected with horseradish peroxidase (HRP). The axon collaterals of 24 injected Pk cells were reconstructed from serial sections using a light microscope and drawing tube. In one animal, data were obtained on the ultrastructural characteristics of the collaterals. One to three collaterals arose from Pk cell axons either as they traversed the granule cell layer or as they entered the white matter immediately subjacent to this layer. In most cases, these collaterals remained unbranched as they coursed through the granule cell layer toward the Pk cell somata. On reaching the Pk cell layer, each branch arborized to form a plexus which extended 200-1000 µm in the sagittal plane and 200-400 µm in the frontal plane surrounding the somata of adjacent unlabeled Pk cells. This ganglionic plexus was characterized by a series of round or irregularly shaped enlargements (0.5 - 1.5 µm in diameter) connected by thin axonal strands. Two distribution patterns were formed by the collateral plexuses. In most cases, collaterals extended bidirectionally in the sagittal plane relative to the soma of origin. However, in some cases, collaterals extended only unidirectionally in the same plane. Some beaded branches from the ganglionic plexus extended into the molecular layer and coursed among the dendrites of the parent cell. Electron microscopic analysis of collaterals in the ganglionic plexus demonstrated that they lost their myelin sheath just prior to forming a series of boutons en passant, in some cases with a single post synaptic element. The boutons were filled with pleomorphic vesicles and formed symmetric junctions of variable lengths. Evidence for an autaptic contact between a labeled Pk cell dendrite and its own collateral was also obtained. In the granule cell layer finely myelinated and unmyelinated collaterals immediately surrounded the glomeruli. These data confirm and extend earlier descriptions of these collaterals derived from correlative Golgi-electron microscopic observations. (Chan-Palay, 1971: Z. Anat. Entwickl. - Gesch. 134:200). (Supported by USPHS NS-08798).

157.17 THE ORGANIZATION OF OLIVO AND PONTOCEREBELLAR PROJECTIONS TO THE PYRAMIS AND COPULA PYRAMIDIS: SAGITTAL ORGANIZATION IN THE RAT. L.M. Eisenman. Department of Anatomy, Thomas Jefferson University, Philadelphia, PA. 19107.

Retrograde transport of horseradish peroxidase was used to study the organization of the projections from the inferior olivary complex and pontine nuclei to the pyramis (Lobule VIII) and copula pyramidis in the rat. Small injections of horseradish peroxidase (20-30 nl of a 10 % solution) were made in different sagittal regions of this cerebellar lobule. Retrogradely labelled cells were seen in numerous brainstem nuclei including the inferior olivary complex, pontine nuclei, lateral reticular nucleus, perihypoglossal nuclei, extermal cuneate nucleus and others. Detailed study of the labelled cells seen in the inferior olivary complex indicates that sagittal zones in the pyramis and copula pyramis receive afferents from different regions of the caudal inferior olive. Labelled cells in the pontine nuclei in these same cases appear to indicate the existance of a sagittal organization in this projection system too. It does appear somewhat different from that coming from the inferior olivary complex in that wider regions of the pyramis and copula pyramidis receive projections from similar pontine locations. Three sagittal zones in this cerebellar lobule could be distinguished as receiving a projection from different regions of the pons where as six zones of varying width receive input from different regions of the inferior olivary complex. Chan-Palay et al, Exp. Brain Res., 30: 561, 1977) have shown that the sagittal zones of olivary terminations in the rat are narrow. The present data suggests that some of these adjacent sagittal zones receive input from similar regions of the inferior olivary complex. Whether a similar relationship exists in the ponto-cerebellar projection remains to be determined.

157.18 LENGTH OF PARALLEL FIBERS IN VARIOUS LOBULES OF THE CEREBELLAR CORTEX OF THE CAT. AN AUTORADIOGRAPHIC STUDY. J. Courville, H. Kitahara. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, H3C 3J7.

A recent study (Brand, Dahl and Mugnaini, Exp. Br. Res. 26: 39-58, 1976) using an anterograde degeneration method demonstrated that the total length of parallel fibers approximates 6 mm. The authors also indicated that parallel fibers cover the whole extent of those folia which are shorter than that length. For the present study, 0.02-0.5 µl injections of concentrated radioactive L-leucine (250 µCi/µl) were placed subcortically in the following regions of the cat cerebellar cortex: lobules VI and VIII, Crus I and II and paramedian lobule. Survival time was 24 hours in all animals except for one cat held for 48 hours; the observed length of the fibers remained the same. Optimal labeling was obtained with injections centered in the white matter and extending into the granular layer. Sections were cut in a plane approximately tangent to the surface and the complete series, extending from the surface through the whole thickness of the folia, were studied. Trigonometric reconstructions of the actual length of parallel fibers could thus be achieved even when their long axis did not coincide with the plane of section. The present observations confirmed that the parallel fibers extending through the superficial part of the molecular layer, originate from cells in the upper part of the granular layer. These are a little longer than those fibers which run in the deeper portion of the molecular layer. The latter stem from more deeply situated granule cells. The maximum length of one branch of the bifurcating fibers is approximately 1.8 mm in lobule VI, 2.0 mm in Crus I and II, 1.2 mm in the paramedian lobule and 1.3 mm in lobule VIII. Granular cells positioned centrally along the long axis of the folia have two branches of equal length while those located near the ends have one short and one long branch. Provided that synaptic contacts are distributed regularly along the length of these fibers, it can be suggested that centrally situated granular elements contribute relatively more connections with the arborizations of Purkinje cells, than those which are located distally. Evidence was also obtained that the orientation of the fibers is at times not strictly parallel to the long axis of the folia in regions where the cerebellar cortex presents sharp curvatures such as at the bottom of a sulcus.

157.20 THE ORGANIZATION OF CEREBELLAR CORTICONUCLEAR FIBERS IN OPOSSUM: EVIDENCE OF ZONES IN ANTERIOR LOBE. P. Satrulee*, J.L. Culberson and D.E. Haines. Department of Anatomy, West Virginia Univ. Sch. of Med., Morgantown, WV 26506.

Although more than three longitudinal zones have been described in the cerebellar cortex of cat and primate, no effort has been made to elucidate the presence and/or arrangement of zones in a more generalized mammal, such as the North American opossum, Didelphis virginiana. In a series of adult opossums, small lesions were made in the cerebellum by applying the heated tip of a teasing needle to the cortex of a single folium or lobule. Following 4-9 days survival animals were killed by transcardiac perfusion with 0.9% heparinized saline followed by 10% formalin. Brainstem and cerebelli were sectioned at 40 µm in parasagittal and coronal planes, and impregnated using the Fink-Heimer method. In opossum, there appear to be 6 ipsilateral zones: two comprising the vermis (A,B) three in the intermediate area (C_1, C_2, C_3) and at least one in the lateral cortex (D). Following damage to zone B of lobule V, degenerated fibers are found primarily in rostrodorsal portions of the lateral vestibular nucleus (LVN). In contrast, only fibers of passage and sparse preterminal debris are present in the medial cerebellar nucleus (NM). Damage restricted to zone A of lobule V produced greater amounts of debris in NM and relatively fewer numbers of degenerated axons in LVN. Similar medio-lateral patterns were seen following injury of lobule IV. Lesions involving the lateral aspect of lobule III produce preterminal debris in the vestibular complex and the anterior and posterior interposed nuclei. This suggests that there are zones B (lateral vermis) and C_{1-3} (paravermal area) in lobule III. The midline portion of this lobule projects primarily to NM. The results of this study provide data concerning the arrangement of zones in the anterior lobe cortex of a generalized mammal. Zones A and B are proportionately larger than those seen in other mammals such as ferret, rabbit and bushbaby and zones C_{1-3} appear to overlap extensively. From indirect evidence, zone D is probably very narrow. The individual cortical zones become progressively narrower in more rostral lobules and, collectively, converge towards the midline. Although zones in the anterior lobe of opossum are not sharply demarcated there is an obvious medio-lateral organization.

Supported in part by a Royal Thai Government Scholarship (P.S), NSF Grant 794172 (J.L.C.) and USPHS Grant NS 11327-4,5 (D.E.H.).

157.21 MORPHOGENESIS OF THE PURKINJE CELL IN THE OPOSSUM: L.C. Laxson and J.S. King, Departments of Anatomy and Surgery, The Ohio State University, College of Medicine, Columbus, Ohio 43210.

Cerebellar cortical development was studied in pouch young opossums from birth (12 days after conception) to weaning (postnatal day 90) using Golgi and Nissl preparations. Purkinje (Pk) cells were analyzed throughout the vermis in parasagittal sections. At birth the cerebellum is present as an undifferentiated plate of cells with numerous mitotic figures in the ventricular zone. Pk cells cannot be distinguished nor has the external germinal layer (EGL) appeared. At day 10 the cerebellum has enlarged and the EGL is evident as a thin covering of cells over the entire cortical surface. Pk cells have not formed a distinct band at this age.

By 21 days the Pk cells are in a zone 4-5 cells deep beneath a thin molecular layer. The EGL has increased in thickness and rudimentary folia are developing. In Golgi impregnations Pk cells have a long apical process extending toward the pial surface and a thickened varicose axon coursing toward the deep cerebellar nuclei. The soma and proximal portions of the apical process exhibit lateral processes with irregular bulbous expansions.

During the next two weeks (21-35 days) the folia resemble those of the adult, the EGL increases in depth, and the Pk cell zone is reduced to a thickness of 1-2 cells. Golgi impregnated Pk cells at postnatal day 35 have a stellate appearance with numerous long fine perisomatic processes radiating from an elongated soma. These neurons typically lack the long apical process seen at day 21. Recurrent collaterals were observed arising from Pk cell axons within the granule cell layer.

The Pk cells are in a monolayer by day 49 and the EGL has now decreased in depth. In Golgi preparations a range of Pk cell morphology is seen. The least mature forms have some perisomatic processes and 1-3 thick apical dendrites with club-like appendages. In the more mature Pk cells perisomatic processes are reduced in number and length. A single apical dendrite gives rise to numerous branches which are covered by filopodia and sessile spines. Between day 49 and day 90 the Purkinje cell attains its adult appearance.

Data obtained from Golgi impregnations suggest that the spatial orientation of Pk cells occurs during or prior to the fusiform stage of development (day 21). Later developmental changes (days 35-90) correspond to previous descriptions of Pk ontogeny. (Supported by USPHS NS-08798; we are indebted to Dr. K. Morest for the use of his Golgi collection).

158.1 MODIFICATION OF OPTOKINETIC TRACKING (OKN) BY MAINTAINED VISION REVERSAL IN NORMAL AND STROBE REARED CATS. G. Melvill Jones, G. Mandl & M. Cynader*. Dept. of Physiol. McGill Univ., Montreal; Dept. of Psychol.* Dalhousie Univ., Halifax; Canada.

The present experiments were undertaken to determine whether OKN would be modified in subjects whose vestibulo-ocular reflex (VOR) gain had been attenuated by maintained vision reversal. Since it has been suggested that VOR adaptation and OKN tracking are activated by the vector of retinal image slip, both normal animals and animals whose complement of direction selective visual cells in cortex and superior colliculus (SC) had been reduced by strobe rearing, were employed.

METHODS. One normal and 2 strobe reared (8 Hz) cats were chronically prepared with a head fixation implant and a scleral eye coil for measurement of eye movements. OKN stimulation was achieved by first gradually accelerating (subthreshold for VOR) the animal in the dark up to a steady angular velocity of 20°/sec. This steady state was continued in the dark for a further 2 min. The lights were then suddenly switched on providing the rotating animal with a view of the laboratory environment in the absence of vestibular stimulation. Monocular OKN (temporal or nasal) was recorded for 50 secs with the visual field (no prism) restricted to that available during optical vision reversal. VOR gain attenuation of 60-90% was established by means of left-right reversing dove prisms having a binocular visual field of 50° solid angle.

RESULTS. Mean slow phase eye angular velocity was measured over consecutive 5 sec periods, from which was derived the cumulative slow phase eye position (CEP) over the whole 50 sec period of OKN stimulation. In all conditions and all animals, nasal stimuli produced larger CEP values than temporal stimuli. The 2 strobe reared animals performed better in strobe light than the normal control animal. However, normal light was always more effective than strobe light, independently of rearing conditions. After adaptive attenuation of VOR gain, CEP values for both nasal and temporal OKN were significantly reduced in all animals, in both normal and stroboscopic (8 Hz) light. The fact that strobe reared cats produced both nasal and temporal OKN implies that direction sensitive visual detectors in cortex and SC are not necessarily involved in generating these responses. Since the strobe reared cats produced adaptive attenuation in VOR and OKN, such detectors also seem unnecessary for these adaptive processes. The concurrent adaptation of VOR and OKN suggests a sharing of adaptive mechanisms in common neural circuits.

Supported by the Canadian Medical Research Council.

158.2 ELEVATED GAIN OF OPTOKINETIC NYSTAGMUS WITH PROLONGED EXPOSURE. Terry Fauvel*, L. R. Harris* and M. Cynader (SPON: K. Reverley). Dept. of Psychol., Dalhousie Univ., Halifax, N. S. B3H 4J1.

Compensation for motion of the retinal image during head and eye movement is achieved by optokinetic and vestibulo-ocular reflexes. When the optokinetic response (OKN) is studied in isolation by rotating a striped drum around the animal, many investigators have found that the velocity of the slow phase of OKN matches the velocity of the drum, thus compensating for its motion. We have found, however, that prolonged exposure to a rotating drum results in eye velocities which may exceed drum velocities by 30-50%.

We recorded eye movements in cats whose heads were held fixed with implanted tubes, using the magnetic search coil technique of Fuchs and Robinson (J. Appl. Physiol., 21: 1068, 1966). A striped drum (stripe period 20°) was rotated around the animal for 30 minutes at a velocity of 6°/sec. Slow phase OKN velocity rose rapidly over the first 5-10 seconds to match that of the drum, but with further exposure (varying from 2-20 minutes), eye velocity rose beyond that required for image stabilization so that the gain of OKN (defined as eye velocity/drum velocity) rose to 1.3 or more. This elevation of gain persisted throughout the 30 minute recording session.

To determine whether the increased gain represented addition of a constant bias velocity to the OKN or whether eye velocity maintained a constant ratio with drum velocity, we increased drum velocity to 9°/sec, 13.5°/sec and then 26°/sec in steps after an initial viewing period of 30 minutes. In this situation, eye velocity exceeded drum velocity by a constant percentage (i.e., gain stayed constant at 1.3-1.5) regardless of the speed of the drum. Reduction of drum velocity from 26°/sec to 0 in several decremental steps also resulted in a constant OKN gain of 1.3-1.5 regardless of drum speed. When the drum stopped rotating, OKN ceased as well.

This phenomenon was observed with binocular viewing and also when one eye viewed the drum moving medially (i.e., leftward with the right eye open). With lateral motion, results were much less consistant. The mechanisms underlying this anomalous enhanced OKN gain followed prolonged exposure remain unknown. (This research supported by USPHS Grant EY02248 and grants from MRC and NSERC of Canada.)

158.3 EFFECT OF LONG-TERM CHANGES IN THE VESTIBULO-OCULAR REFLEX (VOR) ON OPTOKINETIC RESPONSES (OKR) IN MONKEY. S.G. Lisberger, F.A. Miles, L.M. Optican*, and B.B. Eighmy*. Lab. of Neurophysiology, NIMH, Bethesda, MD 20205

Recordings from the primate medial vestibular nucleus (MVN) reveal that secondary vestibular neurons discharge in relation to optokinetic stimulation (Waespe & Henn, Exp.Brain Res. 1977), but show no manifestation of adaptive changes in VOR gain (Lisberger & Miles, J.Neurophysiol. 1980). This suggests that the modifiable elements subserving VOR gain control lie downstream from the MVN and may be shared by signals driving OKR. If the above is true, changes in the gain of the VOR should cause, as a secondary consequence, parallel changes in at least some aspect of the OKR. Adaptive changes in VOR gain were achieved by having animals wear either x2-telescopic spectacles or goggles providing a visual field that always moves with the head (equivalent to x0-telescopic spectacles). VOR and OKR tests were applied at 1-3 day intervals. VOR gain was measured as peak-to-peak eye velocity divided by peak-to-peak head velocity during sinusoidal, whole-body oscillation in total darkness. Horizontal OKR were elicited by seating the animal inside a full-field striped cylinder that rotated at constant velocity; the resulting nystagmus consists of smooth tracking eye movements in the direction of stripe movement (interrupted by resetting saccades). After sudden illumination of the moving stripes, the velocity of the tracking eye movements shows an initial rapid rise (lasting a few hundred msec) followed by a more gradual increase (lasting 10 to 15 sec); these rapid and gradual events are believed to represent two separate components of the OKR. After the illumination goes out, there is an initial rapid decrease in smooth eye velocity followed by a long-lasting afterresponse (OKAN), the initial velocity of which is assumed to be an index of the level achieved by the gradual component of the prior OKR. Six-fold changes in VOR gain (0.29 to 1.80) were associated with parallel, 4.5-fold changes in the initial eye velocity of OKAN, but little or no change in two measures of the rapid component of OKR (eye acceleration in the first 100 msec and peak eye velocity achieved in the first sec). That the rapid and gradual events of OKR are differentially affected by changes in VOR gain supports the idea that they represent separate components mediated by separate neural pathways. Furthermore, these findings imply that the modifiable elements subserving VOR gain changes lie after the point at which the pathways mediating the gradual component of the OKR (OKAN) and the VOR converge, but before the point at which the pathways mediating the rapid changes in eye velocity and the VOR converge. A computer simulation of such a model predicted even the quantitative details of the experimental observations.

158.4 THE "ERROR SIGNAL" SUBSERVING LONG-TERM ADAPTIVE GAIN CONTROL IN THE VESTIBULO-OCULAR REFLEX (VOR) IN MONKEY. F.A. Miles and S.G. Lisberger, Lab. Neurophysiology, NIMH, Bethesda, MD 20205

While the process underlying adaptive VOR gain changes depends ultimately on the association of visual and vestibular inputs, in theory any reliable central correlates of the same would suffice. In fish and rabbit, for example, others have shown that VOR gain changes depend on the association of retinal slip and eye velocity. In both these species, prolonged sinusoidal optokinetic stimulation without head oscillation induces increases in VOR gain; in rabbit, passive oscillation with reversed vision causes increases or decreases in VOR gain depending upon whether the eye movements during adaptation were or were not reversed. We now report that, in monkey, these same experiments yield quite different answers: VOR gain was unaffected by sinusoidal optokinetic stimulation alone, even though the retinal slip and eye velocity were similar to those effective during passive oscillation with telescopic spectacles; passive oscillation with reversed vision always produced decreases in VOR gain. These results imply that, in monkey, eye velocity per se is irrelevant and the adaptive process must use some direct measure of head velocity. In monkey, as in other species, passive oscillation with telescopic spectacles produces changes in VOR gain specific to the adapting frequency. That the mechanisms involved are similar to those at work during active head turns can be seen by adapting monkeys to telescopic spectacles with passive oscillation alternating between 0.2 and 2.0 Hz. This produces equal VOR gain changes at all frequencies (0.1 to 4.0 Hz) and parallel changes in optokinetic responses; both are also true of adaptation with active head turns.

We have also found that VOR gain changes can be induced in the absence of peripheral retinal slip. Eye movement was recorded in a monkey rewarded for fixating a small light in totally dark surroundings. During fixation the light and monkey were oscillated in the horizontal plane either in-phase or 180° out-of-phase, simulating the eye-head movement relationship normally associated with low- or high-gain spectacles. Eight hours of coordinated tracking caused adaptive VOR gain changes as large as 50% of those seen after equivalent passive oscillation in spectacles. That foveal pursuit during head movement is sufficient to elicit VOR gain changes implies that central correlates of pursuit might furnish part of the error signal guiding the adaptive process. Since 1) Purkinje cells in the flocculus discharge in relation to pursuit, 2) floccular lesions severely disrupt the adaptive process (Optican et al, Soc. Neurosci. 1980), and 3) the changes in Purkinje cell vestibular responsiveness accompanying VOR adaptation imply that the flocculus is not the site of the modifications, we suggest that the flocculus exerts an inductive effect on modifiable elements located elsewhere.

158.5 OCULOMOTOR DEFICITS IN MONKEYS WITH FLOCCULAR LESIONS.
L. M. Optican*, D. S. Zee, F. A. Miles and S. G. Lisberger. Laboratory of Sensorimotor Research, NEI, Laboratory of Neurophysiology, NIMH, Bethesda, MD 20205 and Dept. of Neurology, Johns Hopkins Univ., Baltimore, MD 21205.

We studied the effects of bilateral flocculectomy in two monkeys. The optokinetic response (OKR) and adaptive gain control of the vestibulo-ocular reflex (VOR) were studied with the methods of Lisberger et al. (Neurosci. Abstr., 1980), and adaptive control of the pulse-step ratio of saccades was studied as in Optican & Miles (Neurosci. Abstr., 1979). 1) The tracking moiety of the normal OKR has rapid and gradual components. After flocculectomy, the rapid component was considerably attenuated (open-loop gain, measured as eye acceleration divided by retinal slip, was only 25% of normal), while the gradual component achieved nearly normal amplitude but over a much longer time course. Thus, saturation of the gradual component (as indicated by the maximum initial velocity of the after-nystagmus, OKAN) was almost normal, while the "charging" time constant of OKAN (determined by the methods of Cohen et al., J. Physiol., 1977) was two to four times normal. 2) Before flocculectomy, one day of passive oscillation at 0.2 Hz. with x0 spectacles caused the VOR gain (eye velocity divided by head velocity) to drop from 1.00 to 0.49 in one animal, and 0.98 to 0.55 in the other. After flocculectomy, the VOR of both monkeys had low gain (0.92 and 0.76, which persisted for four months) and showed reduced adaptability: e.g., even after 2 days of passive oscillation at 0.2 Hz. with x0 spectacles, the gains only fell to 0.78 and 0.64, respectively. 3) The animals' ability to adapt to optically-imposed post-saccadic retinal slip was estimated from changes in the pulse-step mismatch (PSM), defined as amplitude of the post-saccadic ocular drift divided by magnitude of the antecedent saccade. Exponential slip imposed in the direction of the antecedent saccade (with a 50 msec time constant and 50% of the saccade's amplitude) resulted in large, adaptive changes in the PSM before the lesion (from -3% to -70% in one animal and -1% to -50% in the other), while afterwards these changes were considerably reduced (from -2% to -7% , and +1% to -5%, respectively).

The reduction in the rapid component of OKR after flocculectomy supports the hypothesis that the flocculus acts to boost the gain of visual following mechanisms (cf., Zee et al., Neurosci. Abstr., 1978). The reduced adaptability of the VOR gain and the saccadic pulse-step ratio is consistent with the hypothesis that the flocculus provides the visually-based "error signal" guiding the underlying adaptive processes (Miles & Lisberger, Neurosci. Abstr., 1980).

158.6 INFLUENCE OF OPTICAL REVERSAL ON EYE-HEAD ORIENTING MECHANISMS.
R.M. Douglas* and D.E. Guitton, Dept. Physiology, Aviation Medical Research Unit and Montreal Neurological Institute, McGill University, Montreal, Canada, H3A 2B4.

When the head is passively and suddenly moved, a reflexive rapid eye movement (here called the initial quick phase) occurs with a short latency. The purpose of this movement is to point the gaze axis in the direction of head motion (Melvill Jones, Aerospace Med. 35:316-332, 1974). The initial quick phase is of particular interest because Barnes (J. Physiol. 287:127-147, 1979) has shown that it is part of one of the major motor strategies used in carrying out a normal eye-head orienting response towards a visual target. The aim of the present experiments was to examine whether, and how, the initial quick phase is modified during the period of adaptation to reversing prisms. The results were obtained from a cat subjected to continuous vision reversal for a two week period, at the end of which the gain in the dark of the vestibulo-ocular reflex had decreased to a value of 0.25. Throughout the adaptive period the cat was placed on a horizontally rotating table and subjected to velocity steps ranging from 15 to 100°/sec.

Results: In the normal unadapted cat the amplitude of the initial quick phase increased with head velocity. This observation agrees with that of Chun and Robinson (Biol. Cybernetics, 28:209-221, 1978). As the time of adaptation increased, the amplitude of the initial quick phase decreased for each head velocity tested. The fact that slow phase velocity also simultaneously decreased suggested that the initial quick phase amplitude might be proportional to slow phase velocity. However, analysis revealed that the decrease in amplitude of the initial quick phase was, over a large range of head velocities (30 - 100°/sec), larger than that predicted by the decrease in slow phase velocity. The major cause underlying the amplitude decrease appears to be an adaptive change in the quick phase mechanism itself.

158.7 DEFICITS IN SPATIAL LOCALIZATION FOLLOWING MONOCULAR PARALYSIS IN ADULT CATS.
J. M. S. Winterkorn. Dept. of Anatomy, Cornell Univ. Med. Coll., New York, N.Y. 10021.

The effect of immobilizing an eye on performance of a simple visual task by adult cats was studied. Visual perimetry was conducted in an apparatus consisting of a semicircular table with a radius of 50 cm surrounded by an opaque black screen. The cat was positioned facing the screen and trained to fixate on a light located at an aperture in the screen at 0°. Other lights, located in apertures in the screen at 15° intervals from Left 90° to Right 90°, could be illuminated at variable intensities and for variable intervals.

Experimentally naive, intact adult cats were trained to respond to the onset of a light at any position on the perimeter by orienting to it and retrieving a piece of dry cat food from a small black cup located beneath the light. Fixation and eye movements were observed through a peep hole near the central fixation point. Accuracy of orientation responses was evaluated separately by two observers. The cats' visual fields were determined binocularly and monocularly using an opaque scleral lens.

After stable preoperative performances were achieved, cats were subjected to monocular paralysis by transection of the third, fourth and sixth cranial nerves. From the first postoperative day on, visual perimetry was carried out at least twice weekly for up to twelve weeks.

Postoperatively, the extent of the visual field was not observed to change significantly. Observations were made of the cats' orientation to either a steady or briefly flashed light presented through each eye from 90° ipsilateral to 30°-45° contralateral. However, when the stimuli presented were brief flashes, the accuracy of orientation responses mediated by the immobilized eye deteriorated significantly-- especially to ipsilateral stimuli presented at 60°-90°. When a light was flashed in these locations, the cat turned its head in the general direction of the light, indicating an intact visual field, but the cat then frequently approached a food cup beneath a neighboring stimulus, most often 15°-45° medial to the flashed stimulus. Thus, when using the immobilized eye, the cat had a diminished ability to maintain the localization of a short flash of light in the monocular field.

Similar difficulty in accurately localizing visual stimuli has been reported in human patients with paralytic strabismus.

158.8 BINOCULAR COUNTERROLLING IN HUMANS DURING SUSTAINED BODY TILT.
Shirley G. Diamond and Charles H. Markham. Reed Neurological Research Center, UCLA School of Medicine, Los Angeles, CA 90024.

To examine the belief that ocular counterrolling (CR), a utricular reflex, is maintained at a steady, conjugate level during sustained body tilt, normal subjects were securely strapped into a rotating chair, the head position stabilized by a bite bar. Subjects were then rolled about their naso-occipital axes in separate trials to 30°, 60° and 90°, at a velocity of 3°/sec, with acceleration below the threshold of the semicircular canals. A camera mounted on the rotating chair photographed both eyes at each 10° during roll, and at each 10 sec while the subject was held for 10 min in the tilted position. A control trial of 10 min in upright position was also studied.

CR in both eyes was measured independently using a dual projector system (Diamond et al., Acta Otolaryngologica 87:490-498, 1979) in which mechanical accuracy is 1 minute of arc and practical accuracy is 15 minutes of arc.

Results showed the eyes moved in a smooth, conjugate manner during the roll from and back to the upright position. During the sustained tilt, however, the eyes were unstable with respect to both amount of CR and conjugate movement. Variations in CR during the 10 min of each tilt position ranged up to 4° in a single subject. At 30° tilt, CR ranged from 3.5° to 7.5°; and at both 60° and 90° tilt, CR ranged from 6° to 9.5°. Fluctuations in CR did not appear to be related to time.

The downward eye consistently rolled more than did the upward eye, with this effect more pronounced the greater the degree of tilt. Disconjugate movements similarly were more evident with increasing tilt. At 30°, 23% of the observations were disconjugate compared to the previous observation of the two eyes. At 60°, 35% were disconjugate, and at 90°, 47% were. This is consistent with our previous findings in dynamic CR that sensitivity increases the closer the position is to upright.

The observations in the upright position showed that small torsional movements are present in the eyes in the absence of tilt stimulation. Variations during 10 min ranged up to 1.5° Disconjugate movements were seen in 23% of the observations, the same amount as in the 30° tilt.

These studies suggest that each eye receives input from each utricle, and that in a given tilted position the planes of sensitivity may be slightly different in the two utricles, resulting in differing behavior in the two eyes.

158.9 VARIATIONS IN SACCADIC EYE MOVEMENT STEREOTYPES IN THE LITERATURE - A HYPOTHESIS. P.E. Hallett, Department of Physiology, University of Toronto, Toronto, Ontario M5S 1A8, Canada.

The saccadic system is regarded as being slavishly servomechanistic only at the lowest motor level. Each saccade is assumed to arise from a new 'decision' as to the next spatial goal, which reflects not just the immediate spatial scene but also memories and diverse factors. The 'decision' delay is very variable in duration and is usually triggered by a change in the scene or by the prior saccade. A new decision may 'cancel' an on-going decision in an all-or-none fashion at an early stage, or modify the amplitude of an inevitable response at a late stage ('compromise'). The very variable latency data in the literature can be reduced to a few temporal stereotypes. The observed stereotype in a given individual and task is hypothetically selected by variations in the source of the trigger for the decision delay, the value of the mean decision delay relative to the fixed delays, and the respective advantages of cancellation or compromise.

158.10 BEHAVIOR OF EYE MOVEMENT NEURONS IN POSTERIOR PARIETAL CORTEX DURING CONTROL OF EYE POSITION IN TOTAL DARKNESS. Stephen Whittaker*, Gregory Moulton*, and Alex Skavenski. Dept. of Psychology, Northeastern University, Boston, MA 02115.

Substantial behavioral evidence from people indicates that information about eye position combines with retinal image position information of a target to determine the target location relative to the head. Thus, responses, such as a hammerblow, may be accurately directed at the target. Existing evidence from lesion experiments as well as single neuron recordings suggests that portions of posterior parietal cortex (PPC) are involved in selecting and localizing visible targets in space. Cells in this area have been found to have firing rates related to the retinal locus of stimulation. Although others have found the activity of cells related to eye and arm movement directed at visible targets, such relations have not been quantitatively studied in the absence of retinal stimulation.

In the present experiment, we identified two classes of cells related to eye position in total darkness. Single neurons were isolated in PPC near the intraparietal sulcus of intact, alert macaca nemistrina. Monkeys were trained to fixate a target lamp and maintain that eye position for periods when the target had been removed from view (in complete darkness) by giving reinforcing squirts of juice when the eye position was within $2\frac{1}{2}^{o}$ of the target position. The target position was systematically varied. Eye position, stimulus position and retinal image position of the target could be defined (within 15 min arc) over a 30^{o} X 40^{o} area. For one class of neurons the relation between eye position and concurrent discharge rate of each cell increased monotonically with eye position in a particular direction during steady fixation of a visible target and maintainance of the eye position in complete darkness. During control of eye position in the dark, another class of eye position related cells, "error cells", systematically increased discharge rate as actual eye position deviated from the eye position that matched the locus of the intermittently lit target. This activity is likely to be derived from a comparison of absolute eye position information with some stored analogue of the target position or "correct" eye position. The existence of this comparator mechanism and neural analogues quantitatively related to retinal error, eye position, and eye position error further suggests that PPC is involved in visual localization.

158.11 VERTICAL OPTOKINETIC NYSTAGMUS DEFICIT FOLLOWING LESION OF PARIETO-OCCIPITAL ASSOCIATION CORTEX IN RHESUS MONKEY. Jay W. McLaren and James C. Lynch, Department of Physiology, Mayo Clinic and Foundation, Rochester, Minnesota 55901.

Unilateral damage of parieto-occipital cortex in humans and monkeys usually causes asymmetric horizontal optokinetic nystagmus (OKN) with slow phase velocity diminished toward the side of the lesion. The effects of cortical lesion on vertical OKN has not been studied extensively, although some clinical reports have suggested that deficits follow bilateral hemispheric lesions.

In the present study, vertical OKN was measured in 5 rhesus monkeys before and after unilateral and bilateral lesions of parieto-occipital cortex. OKN was induced by projecting a pattern of alternating black and white 5° wide stripes onto a 52° square tangent screen in front of the monkey. The pattern could be moved upward or downward at velocities ranging from 30°/sec to 160°/sec. Eye position was measured with chronic electrooculographic (EOG) electrodes. EOG signals were digitized and stored by a small computer for later analysis. Five monkeys had unilateral cortical ablations. After at least 2 weeks of testing, 3 of these monkeys received a similar lesion in the other hemisphere. Two monkeys had lesions limited to the inferior parietal lobule; 3 had lesions which included the inferior parietal lobule and immediately adjacent prestriate cortex and superior parietal lobule. Eye velocity during each OKN slow phase was measured by the computer, and the mean slow phase velocity during 27 seconds of stimulation was calculated for each stimulus velocity. Mean eye velocity during a 5-day period immediately preceding cortical lesion was compared with mean eye velocity during the 5 days immediately following unilateral or bilateral lesion.

Before lesion, no monkey showed consistent slow phase velocity asymmetry between upward and downward stimulus conditions. OKN efficiency (mean eye velocity/stimulus velocity) was lower than that of horizontal OKN induced by a full-field drum, but was comparable to that of horizontal OKN induced by projected stimuli. All 3 monkeys which had bilateral lesions showed significant ($p < .005$) reductions in mean slow phase velocity in both directions. Four monkeys were tested before and after unilateral lesions; only one showed any reduction of slow phase velocity following lesion, and then only in some stimulus conditions.

These results suggest that parieto-occipital cortex is important to normal vertical OKN, and that the parieto-occipital cortex of a single hemisphere can support both upward and downward slow phase eye movement.

(Supported by a grant from the Mayo Foundation and NIH grants EY 2640 and 5 S01 RR 5530-14.)

158.12 FRONTAL EYE FIELD AFFERENTS FROM THE BRAINSTEM IN THE CAT. Gary J. Pascuzzo* and Leslie C. Skeen (SPON: J. Maxwell). Institute for Neuroscience and Department of Psychology, University of Delaware, Newark, DE. 19711

Microelectrode recordings have shown that some neurons in the cat frontal eye fields (FEF) discharge before, during, or after certain types of eye movements (Guitton & Mandl, '78). The specificity and timing of these neuronal discharges indicate that the cat FEF may receive inputs from structures that are directly involved in the control of eye movements. With the goal of discovering the anatomical bases of these eye-movement related discharges, we have been examining the connections of physiologically defined areas in the cat FEF.

The boundaries of FEF areas were defined in cats under light chloral hydrate anesthesia (60-80 mg/kg) while monitoring their eye movements during intracortical microelectrode stimulation. In FEF areas where minimal stimulation (25-50 μA) consistently elicited constant-amplitude eye movements, small amounts of horseradish peroxidase (HRP; Sigma VI, 10-60%) were injected either by pressure (0.05-0.2 μl) or by iontophoresis (1-5 μA square wave pulses, 4-16 min.). After surviving for two days, the animals were perfused and sections (30-48 μm) from their brains were processed using a modified tetramethyl benzidine procedure (Mesulam, '78).

All injections restricted to physiologically defined FEF areas reveal retrogradely labeled cells in regions of the infratentorial brainstem that have been implicated in the modulation of oculomotor functions. Cases with very small injections have labeled neurons in the raphe nuclei and locus coeruleus. Both structures exhibit bilateral labeling although the cells ipsilateral to the injection site are much more prominent. These structures have been implicated in several broadly defined oculomotor functions including visual attention and rapid eye movements during sleep (Jouvet, '67; Goldberg & Wurtz, '72; Chu & Bloom, '74). Clusters of labeled cells are also present in the central grey of the midbrain and in the reticular formation immediately lateral to the medial longitudinal fasciculus. These areas have been implicated in vergence movements (Carpenter, '71). In cases with somewhat larger injections, but still restricted to the FEF, the above pattern of labeling is more pronounced and additional labeled cells appear more caudally in the paramedial pontine reticular formation. Several studies have demonstrated the importance of this region in the control of horizontal eye movements (Highstein et al., '75, '76; Graybiel, '77).

158.13 THALAMIC NEURONS RELATED TO HEAD AND EYE MOVEMENTS. H. Maldonado and J. Schlag. Dept. of Anatomy and BRI, UCLA, Los Angeles, CA 90024.

Neurons of the thalamic internal medullary lamina (IML) in cat are known to discharge in relation with eye movements. Since electrical stimulation of the IML elicits head as well as eye movements, unit recordings were made in alert cats able to turn their heads in an horizontal plane. The animals were implanted with silver-silver chloride electrodes for recording the horizontal and vertical electrooculogram (EOG). Horizontal head rotations were measured with a low torque potentiometer mounted on a head holder. Tungsten microelectrodes were stereotaxically driven through the dura. EOG, head position and unit activity were simultaneously recorded on magnetic tape and polygraph paper.

130 units in the IML region were found active with either head movements (31%), eye movements (34%) or both (35%). These figures include phasic discharges related to movements and tonic firings related to positions. Most head-movement units had a direction preference, usually for the contralateral side. They paused during movements in the off- direction. Some cells discharged with passive as well as active head movements and they had the same directional preference in both cases. Cells active with both head and eye movements showed phasic discharges with ocular saccades which occurred without head turning. Their directional preference was the same for both eye movements alone or head-eye combined rotations. Increases of firing related to active head movements started from 0 to 100 msec before the movements.

Some of these units also responded to visual stimuli. The finding of cells related to head, eye movements and visual stimulation gives further support to the role of IML in targeting. (Supported by USPHS Grant NS 04955). Dr. Maldonado is a fellow from CONACYT #16005.

158.14 PREOCULOMOTOR BRAINSTEM NEURONS RECORDED DURING EYE-HEAD COORDINATION. D. A. Whittington*, F. Lestienne* and E. Rizzi. Dept. of Psychology, M.I.T., Cambridge, MA 02139.

Single unit recordings from the brainstem of four monkeys have provided information on the behavior of preoculomotor neurons during coordinated eye-head movements. Of the generally recognized classes of preoculomotor cells, some acted in a manner entirely consistent with previous studies. For instance, tonic cells always fired in tight correlation with eye position, independent of head movements. On the other hand, some burst and pause cells showed behavior not demonstrated in previous head-fixed experiments.

Within the category of medium lead burst cells having a fairly constant burst rate, we found two quite distinct subgroups. When the head was restrained, these two groups were indistinguishable, both having a strong correlation between the number of spikes in a burst and the size of the associated saccadic gaze shift. However, when the head was free to move, this population of bursters could be subdivided into two classes. This subdivision was related to the fact that saccades during coordinated eye-head movements contribute only part of the total gaze shift; the rest being supplied by the head. The first class included cells whose firing activity was closely related to the size of the saccadic eye movements, while in the second class of bursters, the firing was correlated with the total gaze shifts, including the head-movement contribution. We have tentatively characterized these latter cells as being upstream in preoculomotor processing at a level where the total shift in gaze is specified. Following this schema, the first class of bursters is conceived to be further downstream toward the oculomotor plant at a point where the contribution of the head has been subtracted out of the total gaze shift, presumably via the vestibulo-ocular reflex.

With respect to pause cells, we have recorded from a number of subgroups. The subgroups which were not vestibularly modulated did not display any head-related activity. In contrast, some pausing cells, whose tonic component was vestibularly modulated displayed head-related pauses that were a function of the magnitude and direction of head velocity. Although it has been proposed that pausing cells may be an important link in saccade generation, our results indicate that this property cannot be attributed to all pausing cells. (Research supported by NS09343, NGR 22-009-798 and EY02621.)

158.15 CONTROL OF EYE MOVEMENTS IN RAT SUPERIOR COLLICULUS. J. McHaffie* and B.E. Stein (SPON: A.J. Szumski). Dept. of Physiology, Medical College of Virginia, Richmond, VA 23298.

The superior colliculus plays an important role in sensorimotor integration, and it is generally assumed that this structure is integral in visual scanning. The activity of many cells in the superior colliculus of monkeys and cats has been closely related to the generation and control of eye movements. Electrical stimulation of the colliculus in these animals has been shown to evoke contralateral saccadic eye movements whose directions and amplitudes are predictable on the basis of the visuotopic map in this structure. However, it is often assumed that rodents, unlike monkeys and cats, make few saccades, and visual orientation occurs by head rather than by eye movement. The possibility that a fundamental species difference in the organization of the colliculus could underlie these differences prompted the present experiments.

Seven urethane anesthetized Sprague-Dawley rats were used. Immobilization of the head was accomplished by attaching a chronically implanted bolt to a modified stereotaxic head holder. Mirrors were glued to the anesthetized corneas and light beams were reflected from these mirrors onto a translucent hemisphere. Eye movements were indicated by displacements of the reflected spots of light. The visual cortex was aspirated exposing the dorsal surface of the colliculus. Electrical stimulation (70 msec trains, 0.1 msec pulses, 200 pps, 10-700 μA) of the colliculus evoked conjugate, contraversive saccadic eye movements. Closely spaced electrode penetrations were made over the collicular surface, and a map of evoked eye movements was constructed. Stimulation of medial sites yielded movements with upward components (as great as 30° above the horizontal axis), and lateral sites evoked movements with downward components (as great as 80° below the horizontal axis). Most of the eye movement map of the colliculus was devoted to saccadic movements which were nearly horizontal. The amplitude of any saccade varied directly with stimulus intensity and with stimulus location. Medial and caudal sites in the colliculus generally produced the largest saccades and movements of up to 15° of excursion were noted. The lowest thresholds for eye movements were in the intermediate and deeper laminae. Stimulation here also evoked vibrissae, ear, neck, and body movements. Although no systematic study of these other movements was made, they too appeared to be topographically organized. While a preference for orientation by head or eye movement may vary among primate, carnivore and rodent, the fundamental aspects of eye movement organization in the colliculus appear to be substantially the same for these different species. (Supported by grant NS 15912.)

158.16 CONNECTIONS OF A PREMOTOR REGION IN THE LATERAL MIDBRAIN RELATED TO CONTROL OF THE PINNAE. Craig K. Henkel, Dept. Anatomy, Bowman Gray Sch. Med., Winston-Salem, NC 27103.

That pinna movements in the cat are elicited by electrical stimulation of the superior colliculus may indicate that auditory modulation of motor activity occurs in a structure typically identified as a visual reflex center. However, in a recent study we showed that colliculuar control of the pinnae can be mediated through connections with a paralemniscal zone in the lateral midbrain tegmentum (Henkel and Edwards, '78), and it is not known what other brainstem and possibly auditory inputs may modulate activity at this premotor level. The present study is an attempt to identify the afferent connections of the midbrain paralemniscal zone in the cat, using the retrograde horseradish peroxidase tracing method. Preliminary results after HRP was deposited in the lateral midbrain indicate that the paralemniscal zone receives connections from numerous brainstem sources. In the ipsilateral subthalamus, a few cells were labeled in the zona incerta and fields of Forel. In the midbrain, small cells (16-25 μ) were labeled on the side of the deposit in the periaqueductal gray matter that in many cases were similar to those in the stratum griseum profundum. In the posterior and anterior pretectal nuclei, a smaller number of cells was also labeled. Starting in its rostral part, labeled cells in the cuneiform nucleus were sparse but became more numerous in caudal areas adjacent to the inferior colliculus. A commissural connection from the contralateral paralemniscal zone was also present. In the pons, labeled cells were present bilaterally in the ventral part of nucleus pontis oralis, but especially overlying the ipsilateral superior olivary complex. Finally, in the medulla an aggregation of cells (24-37 μ) was labeled in the contralateral nucleus prepositus hypoglossi. It remains to be shown whether labeled neurons found in the dorsal cochlear nucleus resulted from labeling the lateral lemniscus at the HRP deposit. In evaluating these afferent connections, it is noteworthy that the paralemniscal region does not receive a predominance of sensory inputs, but rather appears to be modulated by activity in other motor areas. It is particularly of interest that several of these regions contain units that appear to code information related to head and eye movements. Supported in part by BRS grant RR 05404.

158.17 NEURONAL ACTIVITY IN THE NUCLEUS RETICULARIS TEGMENTI PONTIS IN ALERT MONKEY. E.L. Keller and W. Crandall. The Smith-Kettlewell Institute of Visual Sciences, San Francisco, CA 94115.

The nucleus reticularis tegmenti pontis (NRTP) is a relatively large pontine reticular nucleus appearing as a dorsal extension of the pontine nuclei proper. It has been differentiated from these latter nuclei on an anatomical basis, however, its functional role is almost completely unknown. It has been most widely described as a precerebellar reticular nucleus, but on the basis of its known sources of afferent connections, a role for NRTP in the control of eye movements or gaze seems likely. It has also been suggested that NRTP forms a relay site for the visual pathways mediating the optokinetic (OK) modulations of vestibular nucleus cells. Therefore we studied the activity of neurons located in NRTP in alert monkeys trained to fixate a small visual target. Within the medial extent of NRTP two major classes of cell responses were found. A small fraction (less than 10%) of the cells showed a spontaneous discharge that could be modulated by the motion of a large-field, OK drum. Since the animal would fixate during drum rotation, we could relate the neural responses to actual retinal slip velocity of the OK stimuli. All cells saturated at stimulus velocities of 1 to 2 deg/sec which is well below the effective velocities reported to modulate vestibular neuron discharge in monkey. A majority of NRTP neurons were related to saccadic eye movements. Most of these latter cells (33 of 62) were silent except for intense bursts associated with (and preceding in most cases) certain saccadic eye movements. Some cells showed movement fields similar to those reported in the deeper layers of the superior colliculus. There was no spatial organization of the movement fields within the structure. Other neurons located in this nucleus showed a spontaneous discharge during fixation which either burst (7 cells) or paused (5 cells) during saccades. A small number of neurons (7 cells) showed a burst-tonic discharge similar to oculomotor neurons.

158.18 RESPONSES OF VESTIBULAR NUCLEI CELLS DURING VERTICAL VESTIBULAR AND PURSUIT EYE MOVEMENTS. R. D. Tomlinson* and D. A. Robinson. The Wilmer Institute, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Recent recordings made in the MLF (medial longitudinal fasciculus) of awake primates have demonstrated a class of cells carrying head velocity, smooth pursuit eye velocity, and eye position signals from the vestibular nucleus to the oculomotor nucleus (J.Neurophysiol. 39: 1135, 1976; J.Neurophysiol. 41: 245, 1978). These cells have been reported to not change their vestibular modulation depth when the animal cancels its VOR (vestibulo-ocular reflex) by fixating a target moving with the head. This observation is at odds with the generally accepted notion that VOR cancellation is accomplished by adding on an equal and opposite smooth pursuit signal in order to eliminate the unwanted vestibular drive.

One of the above studies observed only the VOR while the other studied only pursuit. The present study reinvestigated those observations by using both stimuli in the same animal. Recordings were made from the vestibular nuclei of rhesus monkeys. The animals were trained to follow a dot which was rear projected onto a tangent screen located 1 m away. Horizontal and vertical target position was controlled by mirror galvanometers. Eye movements were measured by the search coil-magnetic field method. Single cells in the vestibular nuclei were tested in four different conditions: 1) various positions of fixation; 2) smooth pursuit tracking; 3) vertical VOR in darkness; 4) vertical VOR cancellation. Eye, head, and target position and neuron firing were digitized and stored on magnetic tape for further analysis.

Discharge rate-position and rate-velocity curves were plotted for each unit and vestibular sensitivity was calculated both during VOR in darkness and VOR cancellation. Typically, pursuit and vestibular sensitivities were about 0.6 and 1.0 (spike/sec)/(degree/sec) respectively. Firing rate modulation during vertical sinusoidal head rotation (0.8 Hz, 60 deg/sec peak velocity) in darkness was compared with that obtained during VOR cancellation for cells with pursuit velocity signals. No significant differences in modulation depth were noted between the two test conditions. If, for example, a cell was modulated just as strongly during pursuit as during the VOR in the dark, then, during cancellation, the pursuit and vestibular commands should cancel and the modulation should decrease to zero. However, the modulation did not decrease at all. Thus, the hypothesis that VOR cancellation is accomplished by a simple addition of pursuit and vestibular commands on central neurons is incorrect. If pursuit and cancellation are related it must be in a rather complicated manner.

158.19 ARE FAST LATERAL HEAD MOVEMENTS MEDIATED BY PONTINE RETICULOSPINAL FIBERS? David W. Sirkin, Barbara Ann Rogowski*, Barbara E. Schlumpf*, and Albert S. Feng. Program in Neural and Behavioral Biology, Dept. of Physiology and Biophysics, and Dept. of Psychology, Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801.

Lesions of the pontine reticular formation (PRF) cause a loss of ipsilaterally directed horizontal fast eye movements (voluntary saccades as well as quick phases of nystagmus). A previous study in the rat (Sirkin et al., Soc. Neurosci. Abstr. 4:615, 1978; Exp. Neurol., in press, 1980) and preliminary results in the cat (Siegel, J.M. and Sirkin, in progress), showed that PRF lesions have effects on head movements that are analogous to the effects on eye movements: fast head movements to the ipsilateral side, notably quick phases of head nystagmus, are abolished. Since the PRF's control over eye movements is believed to be mediated by a direct projection to the motor nuclei (especially the homolateral abducens), we thought the same might be true of its control over head movements. The PRF is known to be a source of supraspinal fibers innervating the ventral horn. In this study we assess the role of these fibers.

We first verified with the autoradiographic method that the site of effective PRF lesions gives rise to reticulospinal fibers. [^{3}H]-leucine, injected using the same stereotaxic coordinates used for lesions in the earlier study, labeled strongly a projection to the cord, largely homolaterally. In another series of animals we made lesions to interrupt this projection in the medulla, where it runs in the medial longitudinal bundle, and begins to sweep ventrolaterally over the dorsal surface of the medial part of the inferior olive. These lesions caused deficits in fast ipsilaterally directed head movements similar to those caused by PRF lesions. Histological analysis with the Fink and Heimer method revealed degenerating reticulospinal axons descending from the sites of behaviorally effective lesions. A control lesion placed more laterally did not cause degeneration of reticulospinal axons, and had no observable effects on lateral head movements. These results suggest that pontine reticulospinal fibers play an essential role in mediating fast lateral head movements, thus providing a specific function for one supraspinal system.

158.20 AFFERENT PROJECTIONS TO THE MONKEY FLOCCULUS. T.P.Langer*,A.F. Fuchs, M.C.Chubb*, and C.Scudder*. Dept. of Physiology and Biophysics and Regional Primate Research Center, Univ. of Washington, Seattle, WA 98195.

The flocculus has been shown to participate in vestibular and oculomotor behaviors. In interpreting these studies and initiating others the anatomical projections to the flocculus are of considerable importance.

We have examined these afferents in 3 rhesus monkeys following injections of horseradish peroxidase into their flocculi. After three days,the monkeys were perfused with 1% paraformaldehyde:2% glutaraldehyde in 0.1M phosphate buffer and the labelled neurons were demonstrated with the TMB or BDH methods.

The projections to the flocculus were largely from six sources: 1.The contralateral dorsal cap of Kooy in the inferior olive, 2. parts of the vestibular complex, bilaterally, largely medial vestibular nucleus,but also regions of most of the other nuclei,3. the perihypoglossal complex,bilaterally,and the raphe nuclei at the same level,4.parts of the abducens nucleus and adjacent perigenu regions,bilaterally,5.midline and lateral parts of the nucleus reticularis tegmenti pontis,bilaterally,6.the pontine nuclei particularly the contralateral dorsolateral and ventrolateral rostral nuclei. Virtually every neuron in the dorsal cap of Kooy was labelled. Also a large number of the neurons in the nucleus intercalatus,nucleus Roller,nucleus praepositus hypoglossi and nucleus raphe compacta were labelled. The medial vestibular nucleus projection was patchy and involved a small fraction of the neurons mostly dorsomedial and caudal in the nucleus. There were small projections from the superior,inferior,supravestibular,interstitial vestibular and infracerebellar(y-group)nuclei. Several groups of labelled neurons were located about the genu of the facial nerve. Dorsal to the genu,the supragenu nucleus was heavily labelled. Medial to abducens nucleus and in its dorsal and rostral borders there were large numbers of labelled neurons comparable to the motor neurons. The pontine nuclei represented by far the largest projection. Small numbers of labelled cells were scattered through the medial and ventrolateral reticular formation,particularly the lateral reticular nucleus,and in the lateral cuneate and facial nuclei.

The sources of input to the flocculus are largely nuclei associated with vestibular and oculomotor activity,but their diversity and broad distribution suggest a complex interaction of a multiplicity of vestibular and oculomotor signals. One input that has been largely ignored is the massive projection from the pontine nuclei which may be a dominating influence on flocculus function.

158.21 SOME AFFERENT CONNECTIONS TO THE OCULOMOTOR COMPLEX IN THE MACAQUE MONKEY. D.J. Magnuson, M. Rezak and L.A. Benevento. Dept. of Anat., Univ. Ill. Med. Ctr., Chicago, IL 60612

Although the oculomotor complex is known to control the musculature of the eye, relatively little is known about the monosynaptic inputs to the various subdivisions of this complex. It was the aim of this study to identify these inputs and thereby assess the relative contributions that these structures make in the control of oculomotor functions.

Discrete injections of horseradish peroxidase (HRP) were made in specific portions of the oculomotor complex through a stereotaxically implanted cannula which was used in order to avoid any uptake by structures other than our desired target. Control injections of HRP were made at points lateral, anterior, posterior, dorsal and ventral to the oculomotor complex.

We found that the oculomotor complex receives input from a large number of structures including the ipsilateral nucleus of the posterior commissure, the trochlear and perihypoglossal nucleus as well as the contralateral pretectal olivary and abducens nucleus. Bilateral projections from the intermediate layers of the superior colliculus and both the superior and medial vestibular nuclei as well as from the midbrain reticular formation were observed.

More specifically, it was found that the non-retinorecipient pretectal nucleus of the posterior commissure has a relatively sparse ipsilateral input to the nucleus of Darkschweitz and the interstitial nucleus of Cajal, while the retinorecipient pretectal olivary nucleus had a strong contralateral projection to the Edinger-Westphal nucleus (EW). Since EW receives a heavy direct foveal input via the pretectal olivary nucleus (Soc. Neurosci. Abs., 5:794, 1979) the present findings provide for a quick route whereby information from the fovea may effect the intrinsic musculature of the eye.

It is also important to note that the intermediate layers of the superior colliculus receive convergent input from visual cortices and have bilateral projections to the rostral portions of EW as well as the anterior median nucleus which function in bulging of the lens and pupil constriction during the accomodative reflex.

158.22 THE ARBORIZATION AND SYNAPTIC PATTERNS OF PREMOTOR AXONS RELATED TO HORIZONTAL EYE MOVEMENT IN OCULOMOTOR NUCLEUS IDENTIFIED BY HORSERADISH PEROXIDASE. N. Furuya* and C. H. Markham. UCLA School of Medicine, Department of Neurology, Los Angeles, CA 90024.

Two different cell groups are known to send ascending excitatory influences from the horizontal canals to the medial rectus (MR) motoneurons. One group consists of internuclear interneurons in abducens nucleus (AB interneurons). The other is composed of secondary vestibular neurons which pass in the ascending tract of Deiters (ATD) (Baker and Highstein, 1978). It is not clear if this pathway carries canal or otolith information or both. Further, there is disagreement whether the ATD terminates ipsilaterally or possibly contralaterally also.

In the present experiment, cats were anesthetized with 1% procaine and Ketamine, and the stimulating electrodes were implanted in both labyrinths, both abducens nuclei and the individual extraocular nerves in one orbit. A few days prior to the acute experiment, horseradish peroxidase (HRP) was applied to the MR muscle and nerve in one orbit. Premotor axons were recorded intracellularly and were characterized by their responses to horizontal rotation and stimulation of the labyrinths, abducens nuclei and extraocular nerves. HRP was then injected into the axons through the recording electrode. After sacrifice, the midbrain was cut in 100 μm coronal serial sections and treated with diaminobenzidine. Each single axon was traced using camera lucida technique. The terminal arborizations and synaptic connections of HRP-injected premotor axons were observed.

At the time of writing, there are several findings: 1) AB interneurons showed arborization and termination only in the contralateral oculomotor nucleus. 2) Two types of secondary vestibular axons responding to horizontal rotation were identified. One type showed crossing fibers and terminated in both oculomotor nuclei. Another type revealed arborization only in the ipsilateral oculomotor nucleus. 3) Some of the secondary vestibular axons ran clearly lateral to the medial longitudinal fasciculus, presumably in the ATD. 4) Horizontal canal information is carried in the ATD to both oculomotor nuclei. 5) Those fibers which terminated ipsilaterally could be seen to have terminal boutons very close to MR motoneurons.

158.23 ACCESSORY ABDUCENS NUCLEUS INNERVATION OF RABBIT RETRACTOR BULBI MOTORNEURONS LOCALIZED WITH HRP RETROGRADE TRANSPORT. J.F. Disterhoft and M.T. Shipley, Dept. of Anatomy, Northwestern Univ. Med. Sch., Chicago, IL., 60611.

Analysis of the conditioned reflex arc established during tone-signalled nictitating membrane (NM) conditioning in rabbit requires an understanding of the neuroanatomical circuitry involved. NM extension in rabbit is a passive result of retractor bulbi (RB) contraction (Cegavske et al., J. Comp. Physiol. Psychol., 1976, 90, 411). As a first step in delineating this circuitry with neuroanatomical methods, we have localized the brainstem motorneurons innervating RB using HRP pathway tracing.

Thirteen male Dutch rabbits were used. The extraocular mm. were visualized by retracting the eyelids and incising the conjunctiva in the field of an operating microscope. RB injections were made after the scleral insertions of the other extraocular mm. were cut and the eyeball collapsed. 20 mg of HRP dissolved in 40 μl of 2% DMSO in H_2O was injected into all 4 RB slips. The animals were sacrificed after 48 hours. Perfusions and TMB reactions were as described by Mesulam (Neurosci. Short Course, '78).

Acc. VIth motorneurons were heavily labeled after all RB injections. This nucleus is ventral and slightly caudal to the VIth nucleus and just dorsal to lateral superior olive. Axons from Acc. VI coursed dorsal and rostral through the main VIth nuc., to join its axons and form the VIth nerve root. Additional labeled neurons were seen: (1) between Acc. VI and VI nuc. along the trajectory of the Acc. VI axons; (2) in VI nuc.; (3) in the dorsal, intermediate region of the VIIth nuc. shown to innervate orbicularis oculi in rabbit (Van Gehuchten, 1906); (4) in the oculomotor complex; and (5) in the Vth motor nuc. All labeled cells were ipsilateral to the injection except in the oculomotor complex where there was heavy, bilateral labeling.

Our data indicate that the tracing technique used is exquisitely sensitive to HRP that leaks from the injection site. It is possible that labeling in the main VIth nuc. after RB injections may be attributed to this effect. To minimize this possibility we cauterized the lat. rectus prior to injecting RB in 3 experiments. Uptake in VI was drastically reduced with heavy, apparently complete, Acc. VI labeling. These experiments are being continued.

Knowledge of the inputs to and the neurophysiology of the neurons controlling RB should advance our understanding of the cellular basis of NM classical conditioning. Since our data show that most (if not all) of these motorneurons are located in Acc. VI nucleus in rabbit, the analysis of this final common path should be feasible.

158.24 SINGLE MUSCLE UNITS OF THE CAT MEDIAL RECTUS MUSCLE. M.A. Meredith* and S.J. Goldberg. Dept. of Anatomy, Med. Coll. of Va.-VCU, Richmond, VA 23298

Conjugate eye movements in the horizontal plane require the synchronous activation of the lateral rectus (LR) muscle of one eye and the medial rectus (MR) muscle of the other eye. While the characteristics of LR muscle units have been reported, the present experiments were conducted to examine the mechanical properties of MR muscle units.

Cats were anesthetized and the oculomotor (OC) nerve was stimulated in the brainstem. In the orbit, the MR muscle and the 4 slips of the retractor bulbi (RB) muscle were freed from their insertions and attached to individual sensitive strain gauges. The cortex above the superior colliculus was aspirated. Cells in the OC nucleus were identified by their antidromic response to OC nerve stimulation. Single OC cells were penetrated with a micropipette and those which elicited mechanical responses in the MR muscle when intracellularly activated were identified as MR motoneurons. A variety of stimulus patterns were presented to the MR motoneurons and the subsequent muscle unit responses were recorded.

Although every mechanical parameter of each muscle unit could not always be examined, MR muscle units appear to be faster and somewhat stronger than reported for those of the LR. MR motor units present a wide range of twitch tensions (9-130mg) and maximum tetanic tensions (18-590mg). The average twitch contraction time was 5.7 msec., and the average fusion frequency was 212 pulses/sec with a range of 75-250 pulses/sec. Further investigation is needed to examine the possible presence of functionally different muscle units within the MR muscle as well as to understand the significance of the differences in the responses of LR and MR muscle units.

Although no individual motoneurons were encountered which caused contractions of the RB muscle, stimulation of the whole OC nerve always caused contraction of the RB muscle. Experimental controls including extirpation of all extraocular muscles other than the 4 RB slips, lesions of the brainstem isolating the abducens nucleus and the mechanical response characteristics to single pulse stimulation of the OC nerve all indicate that RB axons present in the OC nerve were responsible for the contraction of the RB muscle. However, the recorded twitch tension of the RB muscle to OC nerve stimulation indicates that the number of RB motoneuron axons in the OC nerve is probably quite small and their functional significance is a matter for future investigations.

This research was supported by NIH Grant EY01442.

158.25 THE AVIAN ACCESSORY OCULOMTOR NUCLEUS. D. Lyman* and E. Mugnaini. Dept. of Biobehav. Sci., Univ. of Connecticut, Storrs. CT 06268.

Studies were undertaken on adult chickens to define the accessory oculomotor nucleus (AOMN), the avian homologue of the Edinger-Westphal nucleus. Reconstruction of serial sections demonstrate each AOMN is a discrete bean-shaped nucleus with a medioventral hilus of efferent fibers. Located dorsal and lateral to the main oculomotor nucleus, AOMN (1070x770x410μm; average volume 1.48×10^{-1} mm^3; 2370 neurons; 1.6×10^4 neurons/mm^3) is surrounded by a thin shell (~50μm) of fine myelinated fibers in which a few small neurons lie. In our material AOMN is not divisible into distinct medial and lateral compartments as claimed by others. AOMN neurons have round, fusiform or polygonal perikarya measuring 10-23μm in diameter; the nuclei are 6.9-10.6μm. A plot of cell perimeter vs. area suggests at least two populations: large, and medium to small size cells. Nearly all cells exhibit a varyingly prominent ring of Nissl substance adjacent to the nuclear envelope. Most of the large and medium sized cells contain, in addition, uniformly distributed Nissl bodies similar to those of the larger oculomotoneurons. The small and some medium size cells have few large, irregular chromatophilic masses. A small percentage of the large and medium sized cells have only a sparse, granular array of chromatophilic bodies. Throughout the rostrocaudal extent of AOMN the larger cells tend to be located laterally. Retrograde transport of HRP injected into the ciliary ganglion demonstrates AOMN is the sole origin of preganglionic fibers in the III nerve. Large and medium diameter HRP-labeled axons fasciculate in the rostral portion of the III nerve root while large and medium size cells throughout the ipsilateral AOMN demonstrate reaction product. Even after multiple injection of peroxidase, some AOMN neurons, predominantly of small diameter, remain unlabeled. In Golgi sections of adult chickens the shell contains fine varicose axons, apparently continuous with fibers in the adjacent lateral central gray, which arch dorsally and ventrally around AOMN, becomming progessively scarce medially. Many of these fibers enter the nucleus to come into close apposition with dendritic shafts and cell bodies in AOMN. AOMN neurons are multipolar with 4-8 primary dendrites that branch scarcely beyond third order and taper only moderately. Infrequent pleiomorphic spinous evaginations occur on the dendrites; a few somatic spines are present. Most dendritic branches remain in the nuclear domain; however, dendrites are often seen extending across the shell up to 150μm into adjacent regions. Dendrites of neurons in adjacent nuclei do not enter AOMN. Electron microscopic investigations are in progress. Preliminary observations show simple axo-somatic and axo-dendritic contacts without complex synaptic fields such as glomeruli and serial synapses. Supported by NIH grant 09904.

158.26 THE DISTRIBUTION OF HORSERADISH PEROXIDASE-LABELED PROPRIOCEPTIVE NEURONS FROM INDIVIDUAL EXTRAOCULAR MUSCLES IN THE ADULT PIGEON. Avrim R. Eden, Manning J. Correia, and Paul G. Steinkuller*. Departments of Otolaryng., Physiol. & Biophys., and Ophthalmol., University of Texas Medical Branch, Galveston, TX 77550.

Horseradish peroxidase (HRP) was injected in one of the six extraocular muscles in each of six adult pigeons. The experiment was repeated three times for each muscle for a total of 18 animals. The HRP injection (0.3-0.5 microliter; 50% solution) was divided into smaller aliquots deposited along the length of the muscle belly. Although infrequently experienced, any excess HRP was immediately suctioned. Following a 16-20 hour post-injection survival, the brain was fixed by bilateral transcardiac intracarotid catheterization and perfusion. The brains were serially sectioned (40 micron intervals) in either the coronal or sagittal planes, and the HRP reacted by the tetramethylbenzidine (TMB) blue reaction process.

Heavily labeled proprioceptive neurons were consistently clustered in a small segment (0.8 mm x 0.3 mm x 0.2 mm) of the ipsilateral nucleus descendens nervi trigemini (TTD) caudal to the superior olive for all the extraocular muscle injections except the lateral rectus. The confinement of labeled proprioceptive neurons to precisely the same small segment of the TTD for all the five extraocular muscles was such that tissue sections from different muscle injections in different animals could be superimposed without overlap. In the lateral rectus injections approximately one-third of the labeled proprioceptive neurons were located more rostrally in the ipsilateral nucleus motorius nervi trigemini (Mv), the remaining two-thirds located in the same portion of the ipsilateral TTD as the other extraocular muscle proprioceptive neurons. There were no contralateral labeled proprioceptive neurons.

The labeled proprioceptive neurons in the TTD were remarkedly uniform in shape and size. These multipolar neurons had a mean axial measurement of 23 microns (S.D. ± 3, n = 44). Those of the lateral rectus in Mv were somewhat smaller and more varied in shape.

While the absolute number of labeled proprioceptive neurons varied from animal to animal, in each experiment the number of labeled proprioceptive cells relative to the number of labeled motoneurons ranged between 5-13%, e.g. Inferior oblique injection: 35 labeled proprioceptive neurons, 711 labeled motoneurons; medial rectus injection: 273 labeled proprioceptive neurons, 2149 labeled motoneurons.

(Supported in part by NIH Grant NS 16082 and NASA Contract NAS9-14641.)

159.1 CONNECTIONS OF THE C LAMINAE OF THE DORSAL LATERAL GENICULATE NUCLEUS WITH THE VISUAL CORTEX IN THE CAT. Alan C. Rosenquist and Denis Raczkowski. Dept. Anat., Sch. of Med., Univ. Pennsylvania, Phila., Pa. 19104.

In the course of investigating the thalamocortical connections of the several retinotopically defined visual cortical areas in the cat, we have made the discovery that the ventral C laminae (C1-3) of the dorsal lateral geniculate nucleus (LGNd) project to nearly the entire visual cortex. Our method was to inject a solution of horseradish peroxidase (HRP) and tritiated leucine into cortical areas at retinotopically defined sites, identified by recording through the pipette containing the injection mixture. Two days later, the animal was sacrificed and the tissue processed for HRP histochemistry using o-dianisidine, or prepared for autoradiography. We have injected ten visual cortical areas: 17, 18, 19, 20a, 20b, 21a, ALLS, AMLS, PLLS and PMLS. Except for those injections involving areas ALLS and AMLS, HRP labeled neurons were always present in the parvocellular C laminae. It is likely that layers C1-3 all contribute to the projection since labeled neurons were seen distributed throughout the width of the region intercalated between the magnocellular C lamina and the optic tract. This projection is retinotopically organized. An injection made into area PLLS on the horizontal meridian (HM), 5^{o} removed from the vertical meridian (VM), led to labeling of cells in the medial aspect of the LGNd, the region containing a representation of central vision. In another experiment, an injection was placed in area 20a, at a retinotopic locus adjacent to the HM some 70^{o} removed from the VM. Reflecting the shift in retinotopic locus of the injection, all of the labeled cells were confined to the lateral portion of the parvocellular C laminae, where the representation of the visual periphery is located. Finally, a cortical descending projection which reciprocated the geniculocortical projection was demonstrated autoradiographically.

The fact that the dorsal layers of the LGNd (A, A1 and C) project to cortical visual areas beyond the striate cortex has prompted the suggestion that the geniculocortical system in the cat is unique. Our finding that the ventral layers (C1-3) project to nearly the entire visual cortex also serves to underscore this conclusion. Funded by EY-05342 & 02654

159.2 GOLGI LIKE STAINING OF THALAMIC RELAY NEURONS FOLLOWING INJECTION OF HORSERADISH PEROXIDASE (HRP) INTO CATS VISUAL CORTICAL AREAS. K.Albus and G.Meyer*, MPI Biophys.Chem., 34Göttingen, Fed.Rep.Germ.

In the course of an experimental series of HRP injections into visual cortexwe have found neurons in the thalamus whose somata, dendrites and sometimes also axons were completely filled with diffuse HRP reaction product. This Golgi like staining has provided new informations on the typology of geniculate and extrageniculate relay neurons; it allows also to relate directly morphologically identified neurons in the thalamus with their respective cortical projection areas. The following neuronal types have been found when HRP was injected at the 17/18 border (classification of neurons is according to Guillery, R.W., J.comp.Neur. 128:21-50, 1966). Dorsal lateral geniculate nucleus (LGNd): 1) Large radiate neurons (classI). 2) Medium size neurons with dendritic appendages (classII). 3) A few small cells. The soma size is like that of small classII neurons, or smaller. Mostly at the terminal parts of the dendrites short, spine like appendages or clusters of spines are found. Some cells included in this group have dendritic appendages, but their dendrites are fine, with only few ramifications not following the tufted branching pattern typical for classII cells. The latter type may represent an intermediate form between classII and III, the former probably classIV. LGNd, C-laminae: 1) Large radiate cells (classI), located mainly in C but also more ventrally. 2) Few medium size neurons with dendritic appendages (classII). 3) Small to medium size neurons (classIV). One type of this group has a spindle shaped or triangular soma; 4-6 dendrites of wavy appearance are covered with a variable number of spine like protrusions; cells of this type with extremely flattened fusiform soma are seen more ventrally. Another type has a round or polygonal soma like the small cells in the A-laminae. Medial interlaminar nucleus (MIN): 1) Large to medium size neurons (classI). 2) Few medium size neurons with dendritic appendages (classII). 3) Small neurons with fusiform soma (classIV ?); located mainly in ventral and medial parts of the nucleus. The dendrites of all cell types in MIN typically branch in a bipolar direction following the principal axis of the nucleus. Posterior, and lateroposterior nucleus: 1) Medium size neuronswith a few spine like or club shaped specialisations on beaded dendrites, tufted branching pattern; in comparison with classI andII neurons of LGNd the axons of these cells are finer. 2) Medium size neuron with dendritic appendages (similar to classII neurons in LGNd).

HRP has been injected in a number of cases into either area18 or into area 17. A preliminary analysis of the data shows that with the exception of classII neurons all cells described above project to area 18. ClassII cells become stained when HRP is injected into the callosal zone at the 17/18 border, or into area 17. Further analysis will possibly allow to estimate the proportion between the various neuronal types projecting to the cats visual cortex.

159.3 AN EM-AUTORADIOGRAPHIC ANALYSIS OF THE CORTICOCOLLICULAR PROJECTION IN THE CAT. Mary Behan, Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706.

The projections of visual cortical areas 17, 18 and 19 to the superior colliculus have been studied using the EM-autoradiographic method. Following injection of ^{3}H-proline into the region of area 17 which contains the representation of the central visual field, labeled terminals were found throughout the stratum zonale and all three sublaminae of the stratum griseum superficiale, but were most numerous in SGS2. This laminar distribution of area 17 terminals in the superior colliculus is similar to that established by light microscopic autoradiography and degeneration studies, i.e., in regions of the colliculus which contain the central representation of the visual field, SGS1 contains a moderate number of area 17 terminals (Updyke, JCN, 173:81, '75).

Our EM-autoradiographic data show that terminals of area 17 neurons are remarkably uniform in size, measuring approximately 1.3μm mean diameter. Like retinal terminals, area 17 terminals contain round vesicles, mitochondria and synapse asymmetrically upon dendrites and dendritic spines. Occasionally dense-core vesicles, coated vesicles or multivesicular bodies are found in either pre- or postsynaptic profiles. Most terminals synapse upon a single profile, but two or more contacts may occur. However, these multiple contacts are formed less frequently by terminals of area 17 neurons than by retinal terminals. In the stratum zonale and SGS1, SGS2 and SGS3 the number of labeled terminals synapsing upon two or more postsynaptic profiles is 9%, 16%, 9% and 8% respectively.

Some of the postsynaptic processes of area 17 terminals contain scattered round vesicles and form the intermediate elements of serial synapses. The percentage of these vesicle-containing postsynaptic profiles varies considerably: 28% in the stratum zonale and 15%, 10% and 21% in SGS1, SGS2 and SGS3 respectively.

Preliminary EM-autoradiographic data indicate that terminals of cortical neurons within areas 18 and 19 are very similar to those of area 17, i.e., they contain round vesicles, mitochondria and synapse asymmetrically upon one or more postsynaptic profiles, some of which contain scattered round vesicles.

159.4 FUNCTIONAL PROPERTIES OF THE CORTICOTECTAL PROJECTION IN THE RABBIT. L.H. Ostrach, J.W. Crabtree*, and K.L. Chow, Dept. Neurol., Stanford Univ. Sch. Med., Stanford, CA 94305.

Extracellular single unit activity in rabbit superior colliculus (SC) was recorded during electrical stimulation of the visual cortex (VC). Two types of electrodes were used to deliver 0.1 msec square wave pulses of 10-10,000 μA to the VC. Three silver ball electrodes in a triangular array were placed on the dura over the VC. The pair that elicited the largest evoked response in each SC penetration was used to drive single units. Low impedance tungsten-in-glass microelectrodes were driven through the dura 1 mm into the VC after matching cortical and collicular receptive field (RF) locations. Receptive fields for each SC neuron were defined (Masland et al., J. Neurophysiol. 34: 148, 1971) and their locations mapped on a tangent screen. Upon identification of a cortically activated unit, the response threshold was determined and 10 successive responses were photographed to calculate the average response latency. The location of units within laminae of the SC was determined using micrometer readings and histological reconstruction of each penetration.

In the silver ball electrode preparation twelve penetrations yielded recordings from 116 SC units. Thirty three units (28%) were driven by stimulation of the ipsilateral VC. In 11 penetrations in the microelectrode preparation 104 SC units were recorded; 32 (31%) were driven by the ipsilateral VC. Stimulation of the contralateral VC failed to activate SC units. The frequency distribution of RF types that were driven was not significantly different ($\chi^2 = 5.06$; $df = 6$; $p > .50$) between the two kinds of stimulation.

Units of all RF types were driven by VC stimulation. Only the motion (MOT) type of RF cells showed a significant difference between the proportion of normally encountered MOT cells and the proportion of this type that were driven by VC stimulation ($Z = -2.11$; $p < .05$). There was a greater proportion of MOT cells driven than that proportion found in the normal population.

The laminar distribution of VC activated SC cells was: 70.8% in stratum griseum superficiale, 24.6% in stratum opticum, 4.6% in stratum griseum intermediate. Both response thresholds and latencies were extremely variable and were unrelated to depth in SC.

Supported by NIH grants NS 07012 and EY 00691.

159.5 REACHING TO THE PERIPHERY ABOLISHES DEFICITS IN PERIPHERAL VISION OF MONKEYS WITH SUPERIOR COLLICULUS LESIONS. D. Kurtz, C. Leiby* and C.M. Butter. New England College of Optometry, Boston, MA and Neuroscience Lab., Univ. of Mich., Ann Arbor, MI 48109.

Kurtz and Butter reported that monkeys with selective lesions of the superior colliculus (SC) are impaired in discriminating between stimuli when they are presented in the periphery of the visual field but not when they are presented centrally. They attributed this impairment to the lesioned monkeys' deficiency in orienting their eyes to the periphery. We evaluated this interpretation by testing monkeys with SC lesions in a discrimination task in which stimuli too brief to fixate were presented peripherally or centrally. We also evaluated the effects on discrimination performance of reaching to the periphery vs. the center to make the choice response.

In this task, a pair of stimuli differing in color was presented for 2 sec. or 100 msec. on a screen facing the monkey immediately after it fixated a panel centrally located on the screen ('fixation panel'). The stimuli were presented at varying degrees of eccentricity (8^{o}, 20^{o}, 32^{o}) from the fixation panel. On half the sessions, the monkey's choice response was made by pressing one of two panels located centrally, 8^{o} from the fixation panel; on alternate sessions the choice response panels were located peripherally, 32^{o} from the fixation panel. Preoperatively, the monkeys' performance was worse the greater the spatial separation between the response sites and the stimuli: their performance with stimuli presented at 32^{o} eccentricity was worse when the response panels were central than when the response panels were peripheral. The reverse was true when the stimuli were presented at 8^{o} eccentricity. After SC lesions, the monkeys were not impaired in discriminating between centrally-presented stimuli. They were impaired in discriminating between peripherally-presented stimuli when they reached to response panels located centrally but not when they reached to response panels located peripherally. The impairment was independent of stimulus duration.

Since the impairment was abolished when the monkeys reached to the periphery to make the choice response, it cannot be due to reduced sensory capacities in peripheral vision. Neither can the impairment be due to a deficiency in fixating the peripheral stimuli, since the impairment was present when the stimuli were too brief to fixate. The impairment may be due to a deficiency in shifting attention from central to peripheral vision, a process that may normally accompany eye movements. This attentional loss may be compensated by an attentional mechanism linked to arm movements; this mechanism presumably involves extra-collicular structures, perhaps posterior parietal cortex.

159.6 VISUAL INPUT TO NUCLEUS RETICULARIS THALAMI AND ITS MODULATION BY MESENCEPHALIC RETICULAR AND CORTICOFUGAL INFLUENCES. F.Schmielau* (SPON:E.Pöppel). Institute for Medical Psychology, Ludwig-Maximilians University of Munich, D-8000 Munich 2 , Federal Republic of Germany.

Extracellular recordings were obtained from neurons of the feline nucleus reticularis thalami (NRT)dorsal of the lateral geniculate nucleus (LGN). The responses of these cells to light stimuli and to electrical stimuli,applied to the optic chiasm (OX),visual cortex (VC), superior colliculus (SC), and to the mesencephalic reticular formation (MRF),were investigated.Reversible inactivation of VC by cooling was used to demonstrate corticofugal influences upon NRT neurons. 45% of the cells responded to light stimulation. Binocular driven cells were preferentially found in a lamina close to LGN, in the perigeniculate nucleus (PGN) of the NRT. Those neurons responded to OX-stimulation mainly with short latencies (0.9-1.5 msec) indicating a monosynaptic retinal innervation.In contrast, more dorsal cells of the NRT responded with much longer latencies (up to 6.0 msec). 92% of the NRT cells were driven by VC-stimulation with a latency between 0.8 and 4.0 msec. As no NRT neuron could be driven antidromically, their axons apparantly do not project to VC. 43% of the cells were activated by stimulation of SC. The typical response pattern to all electrical stimuli was a grouped discharge (Primary excitation), which was followed by a peroid of inhibition (Postexcitatory i.) Stimulation of the MRF caused a pronounced inhibition in 63% of the neurons, throughout the nucleus.However two laminae were found where MRF stimulation evoked activation. Cortical cooling reduced the spontaneous activity in NRT cells, and caused a prolongation of the primary excitation as well as an enhancement of the responses to light stimulation. On the basis of these findings, and derived from recent anatomical data, a model is proposed, showing the NRT as an interface between retina,visual cortex and the mesencephalic reticular formation on one side, and the lateral geniculate nucleus on the other side. Via the NRT,inhibitory influences are mediated to LGN. Thus, various structures may exert a powerful control of the geniculocortical transmission of visual information.

159.7 RELATIONSHIP OF THE SUBDIVISIONS OF THE PULVINAR COMPLEX TO THE VARIOUS VISUAL AREAS WITHIN THE OCCIPITAL LOBE OF MACAQUE MONKEYS. G. P. Standage and L. A. Benevento. Dept. of Anatomy, Univ. of Illinois, Col. of Medicine, Chicago, IL 60612.

Our past neuroanatomical studies have described the projections of the inferior pulvinar (PI) and lateral pulvinar (PL) to the occipital cortex (areas 17, 18 and 19 of Brodmann) in the macaque monkey (e.g., Brain Res. 108, 1976; 167, 1979). Recent physiological and anatomical studies of visual topography in old world monkeys have demonstrated that cortical areas 18 and 19 contain a number of visual representations (e.g., Zeki, Nature 274, 1978). It was of interest then to refine our understanding of pulvino-cortical projections by relating their organization to these multiple visual areas within occipital cortex. Combined electrophysiological, histological, horseradish peroxidase (HRP) and autoradiographic techniques were used. Injections of HRP and tritiated amino acids were effectively restricted to 1 mm^3 or less of the cellular layers of cortical tissue. Standard extracellular recording techniques were employed as an aid for identification of the regions (as defined by Zeki) to be injected with the tracers.

It was found that PI projects preferentially to primary visual cortex (V1) and the cortex of the lunate and superior temporal sulci. Areas receiving preferential input from PI were also found to be the primary projection targets of V1, i.e., V2 and the area within the superior temporal sulcus (STS of Zeki, analogus to MT in new world monkeys, Ungerleider, 1979). Projections from the portion of PL which is adjacent to PI (PLα) parallel those of PI, thus providing in addition to the tectal input via PI, cortico-thalamocortical interconnections for these cortical regions. The remainder of PL projects to V4 and inferotemporal cortex, while the immediately adjacent portions of the medial and lateral pulvinar nuclei project to area PGa of Seltzer and Pandya (1978). With the exception of MT, prestriate areas injected with HRP show that their strongest inputs are from adjacent cortical areas. Although pulvinar projections overlap, it may be that specialized visual cortical subregions receive unique patterns of input from specific subnuclei of the pulvinar complex each of which has its own particular input from the tectum, pretectum and various cortical regions. (Supported by NIH Grant EY 2940)

159.8 VISUOTOPIC ORGANIZATION OF STRIATE PROJECTIONS TO INFERIOR AND LATERAL PULVINAR IN RHESUS MONKEY. Leslie G. Ungerleider, Thelma W. Galkin* and Mortimer Mishkin. Lab. Sensorimotor Research, NEI and Lab. Neuropsychology, NIMH, Bethesda, MD 20205.

Anatomical material from two series of monkeys (Macaca mulatta) was used to determine the full extent and visuotopic organization of striate projections to the pulvinar. One series had been processed for degeneration by the Fink-Heimer procedure following unilateral lesions of lateral, posterior, or medial striate cortex, areas representing the central, peripheral, and far peripheral hemifield, respectively; collectively, the lesions included all of area 17. The second series had been processed for autoradiography following tritiated amino-acid injections into striate sites representing the center of gaze and eccentricities ranging from 0.5^{o} to 45^{o} in either the upper or lower hemifield.

The results were as follows. (1) Within the rostral third of the inferior pulvinar (PI), striate projections representing a progression from central to far peripheral vision terminate in a progression from dorsolateral to ventromedial PI, with central vision represented at the dorsolateral margin of the nucleus, adjacent to the caudal tip of the dorsal lateral geniculate nucleus. The vertical meridian is represented at the lateral and dorsal borders of PI, while the horizontal meridian runs obliquely across the nucleus in a dorsolateral to ventromedial direction, with the lower hemifield represented dorsomedially and the upper hemifield, ventrolaterally. Missing from the rostral third of PI, however, are striate projections representing the fovea itself. (2) These latter projections add a rostral-caudal dimension to the topography. Thus, whereas eccentricities greater than 5^{o} are represented entirely within the rostral third of PI, those of 5^{o} to about 2^{o} extend into the middle third as well, and those of less than 2^{o} occupy the middle and caudal third, with the center of gaze located at the caudal pole of the nucleus. (3) At the level of the caudal two-thirds of PI, where striate projections representing eccentricities of 5^{o} or less terminate, the lateral pulvinar (PL) also receives a striate projection. This second projection originates only in the parts of striate cortex representing central vision, and appears to be a mirror image of the projection to adjacent PI, with the representation of the vertical meridian forming the common border. (4) Whereas the striate projection zone occupies the entire rostral half of PI, it occupies only a dorsal segment in the caudal half of this nucleus, and only a limited, adjacent segment in PL.

These results, coupled with the known visuotopic arrangement of striate and pulvinar projections to the prestriate cortical area OB, indicate the existence of two sources of striate input to area OB that are in perfect register: one, direct, i.e., corticocortical; and the other, indirect, via PI and PL.

159.9 CROSSED CORTICOFUGAL PROJECTIONS IN THE CAT. N. Berman and B. R. Payne. Depts. Anatomy and Physiology, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Multiple injections of a mixture of tritiated leucine and proline were made into the lateral, postlateral, suprasylvian and ectosylvian gyri of 3 adult cats and the brains were processed for autoradiography. Survival times were 2 to 7 days; exposure times were 10 to 14 weeks. Transported label was found in many ipsilateral and in several contralateral subcortical regions. These contralateral regions included the claustrum, caudate-putamen, thalamic intralaminar nuclei, pretectum, superior and inferior colliculi.

In the claustrum, label was found in the dorsal part of the caudal claustrum but did not extend to its most dorsal margin. Label in the putamen was found in its most dorsolateral part just medial to the external capsule. In the head of the caudate, the label formed several dorsomedially to ventrolaterally oriented strips. Label in the dorsal part of the body of the caudate was found as far caudal as the level of the rostral pole of the lateral geniculate nucleus. These labeled axons from the cortex to the contralateral claustrum, caudate and putamen cross in the corpus callosum. In the thalamus light label was present throughout the contralateral central medial nucleus, the most medial nucleus of the intralaminar group. The axons cross the midline within the nucleus. The pretectal region contralateral to the injected side contained three labeled zones: a dorsoventrally oriented strip in the medial part of the anterior pretectal nucleus, a patch within the posterior pretectal nucleus and a band just beneath the pia within the nucleus of the optic tract. The axons from the cortex to the contralateral pretectal region cross in the posterior commissure. In the contralateral superior colliculus label was present at the lateral margin of the stratum griseum superficiale and in the lateral brachium throughout its rostrocaudal extent. Label was also present just beneath the pia along the entire mediolateral extent of the superior colliculus at its rostral and caudal borders. The projection from the cortex to the contralateral superior colliculus crosses in the tectal commissure. This finding confirms a similar report by Powell (1976). Label was present in the inferior colliculus contralateral to the injected side in the dorsomedial division of the central nucleus, in the pericentral nucleus and in the dorsal part of the external nucleus. The labeled axons cross in the commissure of the inferior colliculus. A similar projection has been described by Rockel and Jones (1973).

Thus, the crossed corticofugal projections in the cat are more extensive than has been previously reported.

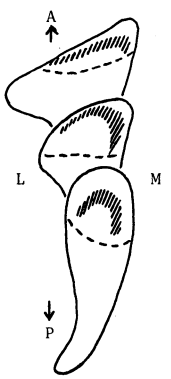
159.11 VISUAL AREA IN CAT CLAUSTRUM. 1: INPUTS AND TOPOGRAPHY. H. Sherk* and S. LeVay (SPON: U. Dräger). Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115.

The visual regions of the cat's cortex, including areas 17,18, 19, and the Clare-Bishop areas, send inputs to the posterior part of the ipsilateral claustrum. Do they form a map of the visual field there? To answer this question, we made small injections of ^{3}H-proline at physiologically defined sites in these areas and studied the claustral projection zones autoradiographically. In addition we did extensive physiological mapping of receptive fields in 3 cats, and made more limited observations in another 9 animals.

Both anatomical and physiological methods demonstrated a single, orderly map of the contralateral visual hemifield, occupying the posterior 3 mm of the claustrum. The lower visual field lies rostrally, the upper field caudally. The far periphery is represented at the dorsal surface and the vertical meridian (VM) more ventrally. Rostrally the visual map forms a thin slab occupying only the dorsal claustrum. The cells below it are visually unresponsive: their input is from the splenial gyrus. A series of vertical electrode penetrations made across the mediolateral extent of the claustrum gives a series of very similar receptive field progressions, moving rapidly from the far periphery to the VM at the same elevation. Thus one visual field point maps onto a line that traverses the width of the claustrum. This is clearest rostrally where the claustrum is broad and flat-topped. Caudally the lines representing visual field points wrap around a central core representing the VM. The 3 coronal sections at left, taken at different rostrocaudal levels, show labeling from ^{3}H-proline injections in area 17 at 3 different visual field elevations, all about 15° from the VM. The dashed lines show the approximate boundaries of the visual region.



Claustral injections of HRP retrogradely labeled a tier of pyramidal cells in the middle of layer VI of the visual cortical areas, and smaller numbers of cells at the III/IV laminar border. In addition, labeled cells were found in the n. centralis thalami, the medial geniculate n., and the lateral posterior n. The latter two nuclei, however, were shown by ^{3}H-proline autoradiography to project not to the claustrum but to adjacent cortex. The visual input to the claustrum appears therefore to derive solely from the cortex.

159.12 VISUAL AREA IN CAT CLAUSTRUM. 2: STRUCTURE, RECEPTIVE FIELDS AND OUTPUTS. S. LeVay and H. Sherk* Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

The internal structure of the claustral visual area was studied by the Golgi method and electron microscopy. The principal cell type is a large spiny-dendrite cell whose axon leaves the claustrum after issuing collaterals. A second type is smaller, and has beaded spinefree dendrites and a local axon. After lesions of visual cortex, degenerating terminals in the claustrum were all of Gray's type 1; 80% of them synapsed on spines, 20% on beaded dendrites. Thus both cell types receive a direct cortical input. No complex or dendrodendritic synapses were seen. In general the structure of the visual claustrum resembles that of cortex, aside from the absence of layers.

The receptive field properties of 231 single units were examined using tungsten electrodes in 12 paralyzed, anesthetized cats. 30 cells were studied quantitatively, the rest with hand-projected stimuli. Most cells responded vigorously to a long slit or dark bar, appropriately oriented and moved slowly across their receptive fields. 209 of 231 cells were orientation-selective, with tuning curve half-widths at half height as narrow as 17°. Sequences of similar or systematically shifting preferred orientations were often encountered on vertical penetrations. Very few cells showed strong directional preferences. All cells except those with fields in the far periphery were binocular, the majority being equally influenced by the two eyes. Velocity tuning was broad. The most striking property of claustral units was their summation with increasing slit length: most cells responded poorly to 2.5° or 5° slits and increasingly well as the slit was increased to 40°, yet stimulation of the central few degrees was required for a response. Stationary slits elicited poor or no responses. Spontaneous activity was very low (0-2 spikes/sec). No auditory or somatosensory responses were obtained within the visual claustral region. The response properties of claustral cells might be explained by a convergence of inputs from a number of layer VI cortical cells (Gilbert, '77) with a common orientation preference but varying ocular dominance and directionality.

Claustral efferents were studied using ^{3}H-proline and HRP transport. There is a retinotopic projection to all ipsilateral visual cortical areas, and to at least one cortical representation of the vertical meridian (the 17-18 border) on the contralateral side. The projection to area 17 ends diffusely in all layers, but most lightly in layer V. No subcortical projections were seen. Since the majority of cells in area 17 have smaller receptive fields and tend to be more monocular and direction-selective than claustral cells, it is unlikely that the claustrum provides a major excitatory input, at least to this area.

159.13 CORTICO-CORTICAL AND THALAMIC CONNECTIONS OF STRIATE AND EXTRASTRIATE VISUAL REGIONS IN THE CORTEX OF THE MOUSE. Vance Lemmon and Alan L. Pearlman. Dept. of Physiology and Biophysics, and Dept. of Neurology, Washington University School of Medicine, St. Louis, MO 63110.

The neocortex of the occipital region of the mouse, like that of other mammals, contains several anatomically and physiologically distinct visual regions. We have analyzed the thalamic and cortico-cortical connections of the striate (Area 17) and extrastriate (Areas 18a and 18b) visual regions in the mouse to provide a framework for our studies of the reeler mutant mouse. Horseradish peroxidase (0.01µl) was pressure-injected through a micro-pipette into the superficial aspect of these areas; after 20-24 hours the animals were fixed and the brains sectioned and processed with the DAB-cobalt chloride procedure.

Area 17 receives thalamic afferents from the dorsal lateral geniculate nucleus (LGd). Areas 18a and 18b do not receive afferents from the LGd; the thalamic input to 18a is provided by n. lateralis posterior and to 18b by n. lateralis. Areas 17 and 18a are reciprocally connected, as are areas 18a and 18b. Area 18b projects to area 17, but we have not found definite evidence for a projection from 17 to 18b. In each area the cells of layers II, III and V provide these association connections. In addition, area 29 in the posterior-medial aspect of the hemisphere projects to both 17 and 18a.

(Supported by NIH Grants R01-EY00621 and T01-EY00092).

159.14 SUBCORTICAL PROJECTIONS OF THE INFERIOR PARIETAL LOBULE (AREA 7) OF THE STUMPTAIL MACAQUE MONKEY. Joseph T. Weber and Tom C.T. Yin. Dept. of Neurophysiology, Univ. of Wisconsin, Madison, Wis. 53706.

The anterograde transport of ^{3}H-proline and ^{3}H-leucine was used to investigate the subcortical projections of the inferior parietal lobule in the stumptail monkey. Following placement of large multiple injections (.4 µl total, at 50 µCi/µl) of a combination of the two amino acids within area 7, transported label was observed over a number of nuclei within the basal ganglia, thalamus and brainstem.

With regards to the basal ganglia, transported label lies ipsilaterally over the putamen, claustrum and caudate nuclei. The label over the putamen and the claustrum is found over their mediolateral extent, but tends to stay within the more ventral aspects of these nuclei. Label over the caudate nucleus is observed within the head and body regions.

Within the ipsilateral thalamus, dense aggregates of silver grains are seen to overlie the oral, lateral and medial divisions of the pulvinar nucleus and over the lateral posterior nucleus. The transported label over these above nuclei is usually "patchy" in appearance. These regions have been shown by others to be the recipient zones of ascending projections from the superior colliculus and pretectal nuclei. Less dense patches of label are evident over the supragenicular nucleus and single loci of silver grains are seen at the ventral border of the ventral posterior medial nucleus and over the ventral lateral nucleus (pars postrema). Sparse label also overlies the region at the border of the central lateral and medial dorsal nuclei and over the centromedian and reticular nuclei of the thalamus.

The densest concentration of transported label within the brainstem is located ipsilaterally over the dorso-lateral and dorso-medial pontine grey. This label is segregated into small dense islands and overlies the regions between the fascicles of the corticospinal tract. Sparse label is also found over the superior colliculus at the border of the pretectal nuclei and is restricted to lamina IV.

159.15 BINOCULAR DISTANCE ESTIMATION IN THE FLY, CALLIPHORA. Hendrik E. Eckert and Kurt Hamdorf. Dept. Animal Physiol., University of Bochum, P.O. Box 102148, D-463 Bochum, FRG.

Stereoscopic distance estimation in flies was investigated by employing the landing response (LR) which can be elicited by approaching objects. The LR consists of a series of leg movements of which the most conspicuous is the sudden upward throw of both foreleg tibiae. The foreleg response to 20 stimulus presentations was measured and a standard response was defined in which 50% of the stimuli elicited a response (P_{50}).

Two vertical stripes, 1 cm to 6 cm apart were moved from a starting position of 20 cm away in 1 cm steps towards the animal; a P_{50}-response was elicited at a distance depending on the angular separation of the stripes: if they were 3 cm or more apart, a P_{50}-response was elicited at a distance corresponding to 30 deg angular stripe separation. However, for stripe separations 2 cm or less apart, this angle changes to 14 deg. In these experiments, the starting position of stripes, e.g., 2 cm and 4 cm apart, was the same and thus, the change in angular separation between starting and P_{50}-position is different. Therefore, the starting position of the stripes was changed so as to keep the increase in angular separation of the stripes constant for a 2 cm and a 4 cm pattern. Under these experimental conditions in which only 30% of stimulus presentations with the stripes 4 cm apart elicit a reaction, a 100% response is elicited with a pattern of stripes 2 cm apart. This indicates that flies are capable of distance estimation for distances of up to 65 mm away from the animal. This distance agrees well with theoretical calculations (Eckert and Hamdorf, J. Comp. Physiol., in press).

159.16 FREQUENCY DOMAIN ANALYSIS OF HUMAN STEREOPSIS. A. Norcia, Stanford University, Stanford, CA 94305 and C.W. Tyler*, Smith-Kettlewell Institute of Visual Sciences, San Francisco, CA 94115.

The activity of cortical neurons selectively tuned for retinal disparity was studied under binocularly correlated noise modulation. The amplitude and phase of the steady-state evoked response was measured as a function of the amplitude and frequency of the input disparity modulation. The display consisted of a 14x20 deg noise plane that was square-wave modulated between a range of small crossed and uncrossed disparities.

The display was generated using feed-back shift register noise passed through push-pull digital delay lines input to the red and blue color guns of a modified broadcast TV.

Responses were recorded on the mid-line using a bipolar derivation of 3 and 6 cm nasalward from the inion referenced to the earlobe. The 2nd harmonic (2f) response was synchronously demodulated using a digital sin/cos-phase switch. The resulting filter characteristic is a sinc-function with a nominal band width of .08 hz at 3 db down. Filter output was integrated over 10 sec periods with and without temporal modulation. Sessions were run at either a constant disparity or a constant temporal frequency.

At $\pm$15 arcmin disparity, the amplitude spectrum obtained from 2 subjects consists of a multiple peaked function with an upper limit of 12-13 hz. This range can be extended by decreasing the disparity, suggesting that stereopsis is velocity limited.

The highest amplitude peak occurs near 3 hz in a region where the subject sees a plane moving in depth. The other peaks occur in a region where the subject sees depth but no coherent movement in depth. This suggests that neurons responsible for local disparity detection may be represented in the response to high frequencies, whereas neurons responsible for global stereopsis may be represented in the response to frequencies below 5 Hz.

In the low frequency region, the response amplitude is linearly proportional to log disparity amplitude for values less than $\pm$30 arcmin. Psychophysical threshold can be predicted from an extrapolation to zero volts.

159.17 PATTERN PROCESSING AND SLOW WAVES IN VISUAL CORTEX. J.D. Glass and R.W. Hall*, Department of Pharmacology, Sch. of Med., University of Pittsburgh, Pgh., PA 15261.

Within the past two decades, vision research has seen enormous strides in our understanding of the cortical mechanisms for encoding the physical features of a visual stimulus. Work on the adult visual system has led to further studies providing new insights into the postnatal development of the encoding process. These studies are of great potential value to our understanding of developmental visual disorders in humans. Since the animal work has been performed with single-unit recording while investigations of the human visual system have been performed with slow-wave recordings, extrapolation from animals to humans must be approached with caution. We have therefore initiated a series of experiments to determine how pattern processing mechanisms of the visual cortex in animals are reflected in the slow-wave response. With such knowledge one would be able to make more direct comparisons between electrophysiological studies in animals and humans.

In four cats, bipolar nichrome wire electrodes were implanted into areas 17, 18 and 19 (visual cortices) and 4 (motor cortex). Recordings were taken with the cat alert and restrained, with its head in a fixed position. Stimuli were presented at approximately 0.3 Hz. Three stimuli, equated for luminance, were used, diffuse and two checkerboard patterns with the checks subtending 1.2° and 3.5° of visual angle. The stimulus panel subtended 42° of visual angle. Three intensities, 17.6, 11.7, and 7.8 ft. lamberts were studied. The contrast ratio between the white and black checks was 124:1. Twenty-five trials were summed with a CAT averager. The responses were separately analyzed for amplitude and variance with a general purpose computer.

Repeated recordings over several months showed the response to be extremely reliable. The response to the diffuse stimulus was most different from the response evoked by the 1.2° checks. Differences between the diffuse stimulus and the 3.5° checks were present, but were not as large as for the 1.2° checks. The differences in these waveforms occurred primarily between 55 to 200 msec following the stimulus. The evoked potential components occurring prior to 55 msec were identical, regardless of the stimulus. Minor differences could be seen in the "late waves"; but these were not as substantial as those occurring prior to 200 msec. Changing the intensity of the stimulus altered the amplitude of the response. However, intensity changes altered the pattern-dependent differences in the waveform only for the highest intensity evaluated. The responses recorded from motor cortex were similar across stimuli.

159.18 HOMOLOGY OF MONKEY AND HUMAN VEP. K. Nakayama, M. Mackeben and E. Sutter. The Smith-Kettlewell Institute of Visual Sciences, San Francisco, CA 94115.

The primary visual cortex in the human is a multifolded surface, comprising the calcarine fissure and the mesial walls of the occipital lobes. This is bordered by multiple secondary projection fields extending outward to the surface of the occipital lobe. Because of this complexity and the lack of anatomic detail on specific VEP subjects, a consensus as to the origins of human VEP components is lacking. In the monkey striate cortex, the central 10-15° of the visual field are represented on the unconvoluted outer surface of the occipital lobe. Secondary projection fields extend forward and are in part buried in the lunate and superior temporal sulci.

As an alternative approach in the investigation of human VEP origins, we are examining the pattern VEP of the alert monkey (Macaca fascicularis), using sinusoidal gratings. Despite the complete lack of correspondence regarding the anatomical lay-out of monkey and human projections, the steady-state VEP in both species shows striking similarities in the following aspects: (1) extremely narrow spatial and temporal frequency tuning, especially at higher contrasts (shown in humans by Tyler, C.W., Apkarian, P., and Nakayama, K., Exp. Brain Res. 33:535, 1978), (2) a match between VEP thresholds and psychophysics as in humans (Campbell, F.W. and Maffei, L., J. Physiol. 207:635, 1970), (3) a predominance of 1st harmonic over second harmonic responses for appearance/disappearance sequences and its dependence on spatial frequency (Bodis-Wollner, J. and Hendley, C.D., Soc. for Neurosci. Abstract Vol. 4, #1971, St. Louis, 1978).

Because of the large differences in gross cortical anatomy, we suggest that these VEP similarities represent functional properties of homologous cortical areas. Thus, further physiological investigation of the origins of the monkey VEP could greatly aid in determining the origin of human VEP components.

159.19 TRIETHYLTIN: VISUAL SYSTEM TOXICITY IS AMBIENT-TEMPERATURE DEPENDENT R.S. Dyer and W.E. Howell. Neurotoxicology Division, U.S. Environmental Protection Agency, Research Triangle Park, N.C. 27711

Carbon monoxide (CO) hypoxia produces toxicity which is ambient-temperature dependent, and is probably related to the influence of ambient temperature on core temperature in hypoxic rats (Annau & Dyer, Fed Proc., 36: 1624, 1977). CO at an ambient temperature of 20°C produces a dose-related decrease in core temperature. At an ambient temperature of 30°C the same exposure level of CO is more toxic but does not reduce core temperature. Acute exposure to triethyltin (TET) is known to produce edema and vacuolization of myelin. In addition, TET is a metabolic poison, inhibiting oxidative phosphorylation and coupled respiration in mitochondria, thereby producing a cytotoxic anoxia. In the present investigation, TET also produced a dose-related decrease in core temperature which, following a single injection of 9 mg/ kg TET bromide in saline, reached a level of 33.3°C (ambient temp 20°C). Animals given 9 mg/kg TET and maintained at ambient temperatures of 30°C only decreased their core temperatures by 1.5°C compared to control. To investigate whether these toxicant by temperature interactions have consequences for CNS function, 40 male Long-Evans hooded rats were surgically implanted with screw electrodes for recording flash evoked cortical potentials and were divided into 4 groups of 10. Each group was exposed to either 0 or 6 mg/kg TET and maintained for 7 hrs at either 20° or 30°C. After 7 hrs all animals were maintained at 20°C for the next 5 days. Flash evoked potentials were recorded immediately before exposure, and at 1.5, 4, 7, 24, 120 and 324 hrs post exposure. There was a significant increase in N1 latency of the cortically recorded response at all points up to 7 hrs for both warm (maximum increase mean ± SEM, = 12.5% ± 3%) and cold (maximum increase = 15 ± 3%) exposure conditions. At 24 hr the animals exposed at 20°C had returned to baseline, but the animals exposed at 30°C retained elevated N1 latencies at 24, 120 and 324 hrs post exposure. P3 latencies showed a similar pattern, but the warm exposure group returned to baseline at 324 hrs. It is hypothesized that metabolic demand placed upon the CNS by maintaining normal core temperature is responsible for the apparently permanent increase in N1 latency in the animals exposed to TET and maintained in a warm environment for 7 hrs.

160.1 THE SURVIVAL AND DEGENERATION OF MONKEY RETINA AND ITS PATHWAYS AFTER STRIATE CORTEX REMOVAL. J. Dineen*, A. Hendrickson, and E.G. Keating. Dept. Ophthalmology, Univ. Washington, Seattle WA 98195 and Dept. Anatomy, SUNY Upstate Med.Ctr., Syracuse NY 13210.

The morphology of the retina and its projections was studied in two adult Macaca fascicularis monkeys that had received a complete bilateral removal of striate cortex at 5+ years of age. These animals had subsequently undergone extensive behavioral testing (Dineen and Keating 1979) for 2 years. One day before sacrifice, the retinal projections of the right eye were labeled by an intravitreal injection of 500uci tritiated proline, and then the brain was processed for autoradiography. The retina of the left eye was flat mounted and the right eye was serially sectioned in the horizontal plane.

Light microscopy of the retina and dorsal lateral geniculate nucleus (dLGN) revealed that the dLGN had undergone complete retrograde neuronal degeneration, indicating that the striate cortex lesions were complete. There was no evidence of lamination remaining in the dLGN. Although sections of the retina looked quite normal, counts of retinal ganglion cells in the whole mounts showed a loss of 30% of the ganglion cells near the fovea and 10% of the peripheral ganglion cells. Dark field microscopy of the autoradiographs from degenerated dLGN demonstrated a surprisingly normal distribution of retinal input which was sharply laminated into S, magnocellular and parvocellular laminae; however, the parvocellular layers did have fewer grains than the magnocellular and S layers, and showed marked disruption at some levels.

Dark-field examination of extra-geniculate pathways labeled by autoradiography revealed other alterations in these retinal pathways: 1. the ventral geniculate nucleus showed exaggerated and enlarged terminal fields; 2. the olivary, pretectal and posterior pretectal nuclei all showed a marked reduction in retinal input; and 3. the contralateral superior colliculus projection was thinner and had lost its normally patchy configuration. The accessory optic and suprachiasmatic nuclei appeared normal.

These results suggest that: 1. the major period of retrograde transneuronal retinal ganglion cell degeneration occurs later than 2 years after striate cortex removal in adulthood; 2. the marked loss of parvocellular retinal input which occurs after long survival in monkeys lesioned as infants (Weller, Kaas and Wetzel 1978) was not found in our animals, but some changes which could be interpreted as the onset of this process were observed; and 3. retinal ganglion cell terminations in nuclei other than dLGN are also affected by striate cortex removal. This occurs in nuclei which receive direct striate input like superior colliculus as well as in those like pretectum which do not. (Supported by EY-01208, EY-01730, EY-07013 and EY-02941)

160.2 QUANTITATIVE ANALYSIS OF RETROGRADE TRANS-SYNAPTIC DEGENERATION IN THE CAT'S RETINA. D. Labar[1], H. Pearson[1], B. Payne[2], P. Cornwell[3]* and N. Aggarwal.[3]* Depts. of Anat.[1] and Physiol./Biochem.[2], The Medical College of Penna., Philadelphia, PA 19129, and Dept. of Psych.[3], Penna. State Univ., University Park, PA 16802.

The retrograde transneuronal effects on the ganglion cells of the cat's retina caused by neonatal visual cortex ablation were studied with Nissl-stained whole-mounted retinae. From retinae of three cats with bilateral lesions of areas 17, 18 and 19 and three normal cats, 4,380 cells were drawn and their mean diameters measured in samples from the central retina and from 2mm dorsal to area centralis. In the peripheral retina of normal cats, ganglion cell size was distributed tri-modally (α (Y) mode, centered at 34-36 μm diam.; β (X) mode, 18-20 μm diam.; γ (W) mode, 10-12 μm diam.). In cats with neonatal cortical lesions, ganglion cell size in the periphery was distributed bi-modally, with a "large" cell mode, similar to α (Y) mode in normals, and a "small" cell mode, similar γ (W) mode. The small cell peak in lesioned cats, however, was broader and centered on a larger diameter (12-14 μm) than the γ mode in normal cats. In central retina, the unimodal ganglion cell size distributions had slightly smaller cells in the lesioned cats ($\bar{x}$ diam. ± S.D.: normals: 10.87 ± .66 μm; lesioned: 10.05 ± .65 μm). Ganglion cell density was calculated to see if absence of the β (X) mode in lesioned cats was reflected in a decreased overall density of ganglion cells. In peripheral retina, density was 32% lower in lesioned than in normal cats ($\bar{x}$ density ± S.D.: normals: 1129 ± 225/mm^2; lesioned: 758 ± 134/mm^2), and in central retina was 16% lower in lesioned cats ($\bar{x}$ density ± S.D.: normals: 7448 ± 115/mm; lesioned: 6261 ± 621/mm^2).

Severe retrograde transneuronal degeneration, reported to produce loss of up to 75% of ganglion cells and a complete loss of "X" cells, occurs in the monkey retina after neonatal visual cortex lesions (Cowey, Percep. 3:257; Weller et al., Brain Res. 160:134). We conclude that although the cat is like the monkey in that medium sized ganglion cells are most susceptible to retrograde transneuronal degeneration, cell loss is far from complete in the cat, and a sizable population of ganglion cells remains after neonatal visual cortex ablation. Our results also indicate that retrograde transneuronal degeneration is more severe in peripheral retina than in central retina.

160.3 PRENATAL DEVELOPMENT OF THE RETINOGENICULATE PATHWAY IN THE CAT. C.J. Shatz and A.C. DiBerardino. Dept. Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

The prenatal development of connections between retina and lateral geniculate nucleus (LGN) was studied by means of orthograde axonal transport of ^{3}H-proline or HRP injected intraocularly in 23 fetuses of known gestational age (Gestation is 65 days.) By embryonic day 32 (E32), the youngest age at which unilateral eye injections have been successful, a clear bilateral projection to the thalamus is present: the optic tracts are densely labeled and label is seen within the anlage of the LGN. By E39 the LGN has increased in size and substantial label is found throughout both ipsilateral and contralateral LGNs. Little difference is seen in the pattern of labeling on the two sides and there is no indication that input is segregated into right- and left-eye territories. Segregation is found, however, by E46, and is more evident on the ipsilateral side. Inspection of cresyl violet (CV) stained sections indicates a complete absence of cellular lamination at this age. The segregation of eye input was verified in another E46 fetus by injecting one eye with ^{3}H-proline and the other with HRP. Within each LGN regions containing exclusively HRP or silver grains were found, indicating the onset of segregation. Nevertheless, overlap of eye input as indicated by dually labeled regions is still extensive.

Segregation, as determined by double-label experiments, is much further advanced by E54 and the first suggestion of cellular lamination can be seen in CV stained frontal sections cut through the LGN. However, the pattern seen in this plane of section is far from adult-like and the characteristic A- and C-laminae could not be identified. To aid in identification embryos were injected with ^{3}H-thymidine on E30, when it is known that neurons primarily comprising the C-laminae are generated (Hickey,1979). In autoradiographs of an embryo killed at E54, thymidine labeled cells were found largely within posterior and lateral LGN regions, suggesting that at this age the C-layers lie posterolateral to the A-layers, and that the nucleus might appear more familiar if viewed in horizontal section. This was confirmed in another double-label experiment at E54 in which the LGN was cut horizontally. The pattern of segregation is remarkably adult-like with C-layer input clearly positioned posterolateral to that to the A-layers. Even viewed horizontally however, almost no cellular lamination could be seen in CV stained sections (see also Kalil, 1978). Thus, the onset of segregation precedes that of cellular lamination by at least 10 days. Further, as in the monkey (Rakic, 1977), in the cat the characteristic laminar segregation of eye input present in the adult is only achieved secondarily, due to the refinement of an initially diffuse set of connections.

160.4 POSTNATAL DEVELOPMENT OF CORTICOGENICULATE AND CORTICOTECTAL CONNECTIONS IN PIGMENTED RABBITS. A. S. Kelly* and D. A. Schwartz (SPON: A. Gordon). Dept. Physiol., Univ. Calif. Sch. Med., San Francisco, CA 94143.

We have studied the normal postnatal development of connections from striate cortex to two subcortical centers, the lateral geniculate nucleus (LGN) and the superior colliculus (SC), in dutch belted rabbit pups. In order to visualize the rather sparse initial innervation of these nuclei we have used two anterograde transport methods. Horseradish peroxidase (HRP) (Sigma Type VI, 20-40% in saline) or a mixture of HRP and tritiated amino acids ((L 3,4(n)) proline, 20-40 uCi and (L 4,5) leucine, 10-20 uCi) was injected into the striate cortex at 4 - 8 separate sites. Total injected volume was 0.16-0.3 ul. Following survival times of 22-28 hrs, pups were sacrificed and alternate frozen sections were reacted by the Mesulam method using tetramethyl benzidine for demonstration of the HRP (J. Histochem. Cytochem. 26, 106, 1978), and/or were processed for autoradiography. The results indicate that by 36 postnatal hrs corticofugal fibers have penetrated parts of both the LGN and SC. Relatively dense label was found in the anterolateral portion of the LGN. Label was much sparser or absent in more medial and posterior portions however. Label was rather diffusely spread throughout the anterior part of the SC. More caudally it was restricted to the middle of the SC, being sparse or absent medially and laterally. Some indication of segregation of the label to stratum opticum was seen at this time in the middle of the SC. This became more pronounced in the next few days, and innervation also spread to the caudal borders of the LGN and SC. By the time of eye opening (postnatal day 9-10) both nuclei were completely innervated and label in the SC was primarily concentrated in stratum opticum.

Mustari and Lund (Brain Res. 112, 37, 1976) demonstrated that in the rat, unilateral visual cortical lesions up to postnatal day 15 resulted in expansion of the remaining contralateral corticotectal pathway to innervate the entire stratum opticum of both superior colliculi. We have attempted to demonstrate this sort of plasticity in the rabbit. Pups underwent unilateral ablation of visual cortex 12-36 hrs after birth. Six weeks or three months later the remaining visual cortex was injected as above with a cocktail of 40% HRP, 40 uCi proline and 20 uCi leucine in 0.3 ul saline. Animals survived 24-28 hrs, and again alternate sections were processed for autoradiography or reacted for HRP. In 6 animals studied to date, no evidence of a crossed corticotectal pathway has been found. Although it is possible that earlier or prenatal lesions might result in the formation of such a crossed pathway, we feel it is noteworthy that no crossed connections are seen with ablations done at a time when the corticotectal pathway is known not to be complete.

160.5 MATURATION OF CORTICOTECTAL INFLUENCE IN CAT SUPERIOR COLLICULUS. B.E. Stein and H. Gallagher* Dept. of Physiology, Medical College of Virginia, Richmond, VA 23298.

The maturation of visual cells in cat superior colliculus (SC) requires approximately two months. Toward the end of the 2nd week of post-natal life, the specialized properties of directional selectivity and binocularity begin to appear. While the appearance of these properties is believed to reflect the development of corticotectal influences, corticotectal projections already exist in 2-day old kittens. In the present investigation, we sought to assess the functional state of corticotectal projections at different developmental stages.

Single units (n=188) were recorded in 63 kittens 7-54 days of age. Corticotectal activity was blocked by placing crushed saline ice onto the brain and later reinstated by rewarming the tissue with warm saline. In adults, cortical cooling depresses the activity of visual cells receiving projections from cortex. In the present study, a marked correlation between the maturation of specific receptive field properties and cooling-induced depression was observed.

Prior to 13 days of age, SC cells were predominantly monocular, best activated by stationary pulsed light, and cortical cooling had no significant effect upon their activity. The increased effectiveness of movement and the development of directional selectivity and binocularity coincided with the appearance of cooling-induced depression. Regardless of age, directional selectivity and binocularity in a given cell was a powerful predictor of that cell being affected by cortical cooling. Thus, 67% of the cells exhibiting either one or both of these characteristics was depressed, while only 16% of the cells which had neither property was affected by the same procedure. Since there is an increase in the proportion of directionally selective and binocular cells with age, there is a coincident increase in the incidence of cooling-induced depression in older animals. Typically, response depression consisted of a decrement in the number of evoked impulses apparent within 3 minutes of cooling and nearly complete elimination occurred after 4-5 minutes. Responsiveness was reestablished to the precooling level after 5 minutes of cortical rewarming.

These data indicate that, despite the presence of corticotectal projections in 2-day old neonates, these inputs are functionally immature. Their maturation, as indicated by the development of cooling-induced depression and the appearance of specific receptive field characteristics, is a prolonged process requiring approximately 8 weeks of post-natal life.

160.6 INTRACORTICAL CONNECTIVITY IN THE VISUAL SYSTEM OF NORMAL AND BINOCULARLY DEPRIVED RATS. H. Jackson, A. Frankfurter, and A.B. Butler. Dept. of Neurosurgery, Univ. of Virginia Medical Center, Charlottesville, VA 22908.

We have recently devised a method for depositing horseradish peroxidase into the supragranular layers of the cerebral cortex. Variations on this procedure allow either visualization of isolated cellular morphology or gross patterns of intracortical connectivity. Injections of supragranular layers in area 17 of the rat result in labelling of layer II and III neurons as well as layer V pyramidal neurons. Although the axons of layer II-III neurons and apical dendrites of layer V cells can be seen traversing layer IV, layer IV itself is largely devoid of labelled cells and terminals. Layer III neurons of area 17 possess descending axons from which emanate a series of oblique collaterals. These collaterals apparently terminate within discrete columns in the lateral peristriate cortex (area 18). Layer V neurons also innervate these columns through horizontal axon collaterals. Within lateral peristriate columns labelled by injection of area 17, both terminal and cellular label are seen. The majority of cellular label is found in layer V with the balance scattered over more superficial layers. Terminal label is seen across layers V-II. These results indicate reciprocal connections between discrete columns in area 17 and the lateral peristriate region. These connections are formed by layer V pyramidal cells which innervate at least the supragranular layers of the associated column and by supragranular neurons which likely project to layers V-II.

We are now investigating the effects of bilateral enucleation on this cortical organization. Preliminary observations on subjects enucleated 1-3 days after birth suggest several possible effects of this treatment. At six weeks after enucleation, injections of area 17 result in diminished labelling of lateral peristriate columns (terminals and cells) which suggests a decrease in reciprocal connections between these regions. On the other hand, there seems to be an increase in the callosal projection from area 17. Finally, there is an apparent increase in terminal label within layer IV of area 17. At present it is unclear whether this reflects a true projection from layers II and III to layer IV or simply a shrinkage of layer IV following enucleation. A detailed examination of these and other possible effects is currently underway.

161.1 GROWTH CONES IN THE LONGITUDINAL CHANNEL SYSTEM OF THE DEVELOPING AMPHIBIAN SPINAL CORD. R.H. Nordlander* and M. Singer (SPON: J. Brodkey). Dept. of Anatomy, Case Western Reserve Univ. Sch. of Med., Cleveland, Ohio 44106.

Electron microscopy of the developing spinal cord of the amphibian tail has shown that earliest fiber tract development occurs by the ingrowth of axons into small but discrete longitudinally oriented spaces between neighboring cells of the neural tube (Nordlander and Singer, J. Comp. Neurol., 180:349, 1978). These spaces, which are located at the periphery of the cord, are empty at the most primitive levels but with further development are infiltrated by increasing numbers of neurites.

Growth cones were observed in both transverse and longitudinal sections of the channels and were distinguished from other channel components by their generally larger size, irregular outlines, and cytoplasmic contents. Overall cytoplasmic density of the growth cones was usually less than that of either other axons or the neuroepithelial cell processes which also occupied the channels. Most growth cones were seen as bulbous endings containing a light granular matrix and few organelles, among them assorted vesicles, mitochondria, occassional autophagic vacuoles, and agranular reticulum. Microtubules were usually lacking. A few growth cones differed from this general description by displaying focal dense accumulations of the organelles mentioned above. "Synaptoid" profiles (Nordlander and Singer, Cell Tissue Res., 166:445, 1976) were seen facing other axons and presumptive glial processes. Fine cytoplasmic processes, presumably microspikes, extended from the bulbous portions of the growth cones into spaces between adjacent cells and axons.

Growth cones always appeared in the most peripheral position within each channel. This was especially obvious in longitudinal sections of channels containing more than one growth cone. In these instances the more rostral cones were directly peripheral to trailing axons of fibers whose cones appeared more caudally. This observation suggests that new fibers are added to these fasicles at progressively more peripheral positions.

161.2 MECHANISMS OF AXONAL GUIDANCE DURING THE FORMATION OF CENTRAL NERVOUS SYSTEM COMMISSURES. Jerry Silver. Dept. of Anatomy, Case Western Reserve Univ., School of Medicine, Cleve., OH. 44106.

What are the structures within the embryonic central nervous system that guide axons across the midline during development of the commissural pathways (corpus callosum, anterior commissure)? I have investigated this question histologically with the use of serially sectioned, timed mouse embryos. During day 15 of gestation the previously separated, medial walls of the cerebral hemispheres (septal regions) begin to fuse ventrally. On day 16, fusion proceeds rostro-dorsally. For about 100μm forward of the lamina terminalis and subjacent to the interhemispheric fissure, the fusion process is augmented by an influx of presumptive glial cells which appear to migrate medially from the ventricular germinal zones of each hemisphere. This local accretion of glial precursors results in the formation of a structure which resembles a "sling" coursing beneath the interhemispheric fissure and suspended from the medial walls of each lateral ventricle. Within the hemispheres, axons of the corpus callosum grow in a nucleisparse zone between the germinal region and cortical plate. The pioneer axons approach the "sling" on day 17 and apparently are directed across the midline by this glial scaffolding. Later developing axons of the corpus callosum cross rostrally but are not supported by a glial bridge. Instead, they traverse the cerebral midline (which at this stage is unfused far rostrally) by fasciculating on the pioneering and caudally formed callosal axons.

The fibers of the anterior commissure appear to be guided across the midline by a different mechanism. Movement of these axons occurs through a preformed pathway of intercellular glial channels. The channels form within the lamina terminalis on day 14 in advance of the outgrowth of the first commissural axons(E16).

I have also examined the developmental stages of a primitive, acallosal marsupial, Didelphis virginiana (opossum). In this species, fusion of the medial walls of the cerebral hemispheres and glial sling formation do not occur. Instead of traveling dorso-medially the "callosal" axons turn ventrally and pass contralaterally by way of the anterior commissure.

These observations have demonstrated that oriented glial tissues, by forming channels or "slings" and, presumably, by assuming a variety of other configurations, may play crucial roles in the guidance of axons. However, orderly fasciculation of axons is also an important guidance mechanism during CNS development. The developmental sequence in the opossum suggests that genetic alterations may change fundamental morphogenetic events (such as midline cerebral fusion) which, in turn, can alter glial patterns and, thereby, contribute to the evolution (or malformation) of axonal pathways. To further explore this theory we are studying an acallosal mouse mutant. (Supported by NIH grant NS-15731-01)

161.3 AN ELECTRON MICROSCOPIC STUDY OF THE DEVELOPING CORPUS CALLOSUM IN FETAL AND NEONATAL RATS. Karen L. Valentino and E.G. Jones. Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

The development of callosal axons has been studied in rats by means of light and electron microscopy. Axons were identified by anterograde tracing techniques, and then followed as they cross the midline and grow to their targets in the cerebral cortex. The relationships between the growing axons and other cell types in the developing corpus callosum were also examined.

Material from rats aged 15 days gestational to 7 days postnatal was processed for routine electron microscopy. In other animals, prepared for both light and electron microscopy, horseradish peroxidase (HRP) was injected unilaterally into the cortex and white matter to anterogradely label the growing axons. This method also labels other cell classes via ventricular, subarachnoid, and perhaps vascular diffusion.

Some preliminary observations include the organization of the axons into bundles separated by elongated interstitial cells and associated spaces. Axonal growth cones filled with HRP can be identified and occasionally, transient synapse-like structures on as yet unidentified elements in the callosum have been observed. There is some evidence for degeneration of a proportion of the young axons.

Astrocyte and oligodendrocyte precursors, as well as earlier glial precursors can be recognized. In addition to these cells, many macrophages are found in the corpus callosum and in the associated vascular, perivascular, and meningeal tissues. When labeled by injected HRP, these cells can be seen with the light microscope to surround the callosum and extend for long distances along its fibers as they penetrate into the hemispheres. With the electron microscope in normal and HRP material, the phagocytic cells are often oriented along the callosal axons, with processes around them. The origin of the macrophages is uncertain, although they are tentatively believed to arise from non-neuroepithelial sources. Their function and fate are likewise unclear: it is uncertain to what extent they serve to guide callosal axons across the midline and towards their targets and whether they are ultimately transformed into microglial cells.

Supported by Grant Numbers NS 15070 and NS 07057 from the National Institutes of Health, United States Public Health Service.

161.4 A MECHANISM FOR THE GUIDANCE OF PERIPHERAL SPIRAL GANGLION CELL AXONS IN THE DEVELOPING MOUSE AUDITORY SYSTEM.
Paul R. Carney* and Jerry Silver (SPON: Scott Brand). Dept. of Anatomy, Case Western Reserve Univ., School of Medicine, Cleve, OH. 44106.

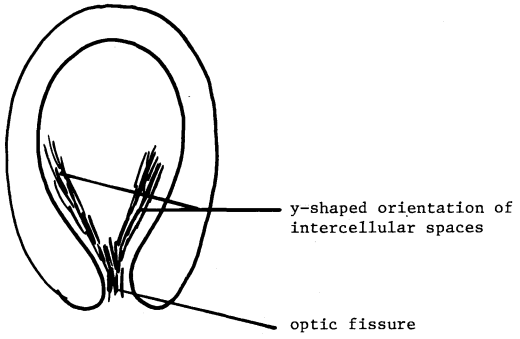
Cajal (1890) and others have described the earliest peripheral spiral ganglion cell axons as a wandering bundle that perforates its way into the otocyst. Upon their arrival at, but before entering, the otocyst, it was also believed that the pioneer fibers became stationary for awhile, awaiting differentiation of the cochlear canal.

Examination of timed mouse embryos at days 9.0 - 10.5 by the use of light and electron microscopy as well as quantitative histological techniques, has revealed mechanisms of axonal guidance and entrance of fibers into the otocyst that differ from previous beliefs. During embryonic days 9.0 - 10.0, a discrete region of cell death occurs in the caudo-medial portion of the basal otocyst (basal otocyst is the presumptive cochlea). This necrotic process is accompanied by a local breakdown of marginal gap junctions and basement lamina, with obvious widening of the extracellular spaces between the neuroepithelial cells. This sequence of events progresses as a wave to the lateral and rostral portions of the presumptive cochlea. During embryonic day 10.5, pioneering, peripheral fibers take a circuitous route and ascend from the spiral ganglion to innervate the neuroepithelia of the presumptive cochlea, directly behind the zone of cell death. En route to the cochlear rudiment, the fibers seem to follow a condensation of cells that appears prior to the outgrowth of the first spiral ganglion cell axons. This cell aggregation, shaped like a funnel, begins broadly at the caudal portion of the spiral ganglion, and narrows at its ending in the zone of cell separation at the caudo-medial margin of the basal otocyst. It is at this particular site of cell disunion that the fibers are first directed into the presumptive cochlea. The enviroment surrounding the remainder of the otocyst and spiral ganglion (i.e., that region devoid of auditory axons) is a loosely arranged cellular meshwork.

These observations suggest that the itinerant peripheral axons of the spiral ganglion may not wander, perforate, or ever be stationary but, instead, grow along a series of extrinsic stuctures that may guide them directly towards and allow them immediate passage into their target destination.
(Supported by NIH Grants AG-00785-03, NS-15731-01 and RR-05410-18).

161.5 PRENEURAL PATHWAYS IN THE EMBRYONIC CHICK RETINA. Susan R. Krayanek* and Stephen Goldberg (SPON: R. Clark). Dept. of Anat., Univ. of Miami Sch. Med., Miami, Fla. 33101

Optic axons of the early chick retina grow in a directed fashion toward the optic fissure (Goldberg, S. and A.J. Coulombre, J. Comp. Neurol, 146:507, 1972). Embryonic chick retinas were examined for factors that may guide the earliest optic fibers. At stage 16, prior to the morphological appearance of optic axons, intercellular spaces were oriented in the direction of the fissure. Serial section reconstruction of lu parasagittal sections, revealed that the oriented spaces were arranged in a y-shaped pattern around the fissure (Figure). Oriented spaces were present at the entrance to the optic stalk but spaces within the stalk itself were not oriented in the direction of optic fiber outgrowth. Electron microscopy of stage 16 retinas, showed the spaces to be bounded by aligned processes of neuroepithelial cells. At stage 18, optic axons could be seen growing adjacent to and forming close contacts with the oriented neuroepithelial cells. Thus, alignment of neuroepithelial cells in the chick embryonic retina may aid in the guidance of optic axons.



Stage 16 retina (flat mount view).

161.6 ABSENCE OF DEGENERATIVE DEBRI GUIDANCE IN THE SPECIFIC GROWTH OF SEPTAL TISSUE GRAFTS IMPLANTED INTO NEONATAL HOSTS. E. Lewis, P. Kelly and C. Cotman Dept. of Psychobiology, U.C. Irvine, Irvine, CA 92717.

Pieces of embryonic septal tissue placed in the entorhinal cortex of neonatal rat hosts (P2-P3) will innervate the host hippocampal formation and send processes into appropriate laminar zones within the molecular layer of the dentate gyrus. What mechanisms guide the axons of implanted neurons to their target cells in the host brain? Results from studies of tissue grafts in adult recipients indicate that processes emanating from the graft may follow the path of degenerating axons in the host neuropil. We have assessed this role of degenerative debri in the implant paradigm by 1) characterizing the distribution and time course of removal of degeneration following implant surgery in neonatal rats, and 2) examining the growth of septal implants in a host brain devoid of observable degenerative debri.

A distinct pattern of degeneration argyrophilia (De Olmos stain) is present in rats sacrificed 24 and 48 hours following implant surgery on day 3. By 72 hours following surgery, virtually all argyrophilic material has been removed. Some areas in the hippocampal formation destined to receive innervation from the implanted septal tissue never show degeneration products at any time after surgery.

The rapid removal of degenerative debri in the immature brain makes it possible to test for the presence of debri guidance by introducing a delay between the time at which the implant cavity is made and the time of implantation. A cavity created in the entorhinal cortex of 3 day old rats was used to accommodate an embryonic septal graft (E18) implanted on day 9. Also on day 3, a transection of the septohippocampal fibers in the neonatal host was performed to eliminate native septal efferents. One month later the growth of the septal implant was examined with a stain for acetylcholinesterase (AChE). Implanted cells sent numerous AChE positive processes toward the host dentate gyrus. In the dentate molecular layer, AChE reaction product occupied the same two laminar zones that stain positively in normal rats.

Thus, axons from implanted septal neurons are guided to the hippocampal formation through a host neuropil from which degeneration argyrophilia has been removed. Furthermore, the laminar distribution of these axons in the dentate molecular layer is independent of the pattern of degenerating afferent terminals in the host immediately following the implant surgery. This suggests that axons of implanted septal neurons maneuvering through an immature host neuropil are guided by mechanisms similar to those which are active during the development of laminar specificity in vivo. 170.1 BRANCHING OF AFFERENT AXONS IN THE SPINAL NERVE. Richard E. Coggeshall and Lauren A. Langford. Depts. of Anatomy and of Physiology and Biophysics and the Marine Biomedical Institute. The University of Texas Medical Branch, Galveston, Texas 77550.

An important concept in the understanding of the organization of the peripheral nervous system is that each dorsal root ganglion cell gives rise to a single central process and a single peripheral process. If this is true, and there are no extraneous axons in the roots or nerves and no extraneous neurons in the ganglion, then there should be an equal number of axons in dorsal roots, nerves and ganglion cells in the dorsal root ganglion. In a previous study, however, we demonstrated that there were no extraneous axons or neurons but the numbers of dorsal root axons and dorsal root ganglion cells were not equal. Thus we concluded that dorsal root axons branch in the dorsal root.

In the present study we are determining the number of dorsal root ganglion cells and axons in the spinal nerve for segments L6-S3 in the rat. The axons in the spinal nerve and dorsal root are counted with the electron microscope. The rats have had unilateral ventral rhizotomies of segments L6-S3 and sympathectomies to remove the motor fibers and postganglionic fibers from the spinal nerve. Our results are presented in the following table.

RAT	SEG	GANGLION CELLS TOTAL	SPINAL NERVE MY + UN = TOTAL	DORSAL ROOT MY + UN =TOTAL
1	S3	1249	1156 + 3340 = 4496	1035 + 2607 = 3642
2	S3	907	802 + 2705 = 3507	929 + 1225 = 2154

Note that there are many more axons than ganglion cells for these nerves. If these preliminary results are confirmed, then there is a great deal of branching of peripheral processes of dorsal root ganglia in the ganglion or proximal peripheral nerve. Possible consequences of this arrangement will be discussed.

170.2 PATTERNS OF CUTANEOUS INNERVATION IN NORMAL AND REINNERVATED HAIRY SKIN. J.K. Terzis, P.A. Ballard* and B.G. Turnbull*. Depts. of Surgery & Physiology, McGill University, Montreal, P.Q., Canada.

Restoration of sensation following nerve transection and repair is seldom normal. Whether factors affecting reinnervation are restricted to the repair site, or whether additional factors operate distal to the lesion is not known.

Innervation patterns of normal and reinnervated skin subsequent to section and repair of the great auricular nerve in rabbits were studied. Proximal to the repair, single fascicles were placed onto a recording electrode, and the cutaneous area innervated was determined by brushing the dorsal surface of the ear. The fascicular map and areas of highest activity were transcribed onto photographs of the ear, and the location of the fascicle in the nerve noted. This procedure was then repeated distal to the nerve lesion. Single fiber recordings were obtained using microdissection techniques. Patterns of reinnervation were assessed at 3, 6, and 9 months post-injury. Normal fascicular maps had smooth contours and exhibited moderate overlap; the area of highest activity was centrally located and the transition from low to high activity areas was uniform. A topographical relationship existed between the location of the fascicle within the nerve and the location of the cutaneous territory on the dorsal surface of the ear. Distal fascicular recordings revealed the same patterns, but the areas innervated were smaller. The normal pattern of innervation was greatly distorted in the repair groups. Proximal fascicular maps in test animals were huge with excessive overlap. The areas of highest activity were ectopic, and the transition among areas of different activity was abrupt. The topographical correspondence between fascicle and skin area innervated was lost in the early groups. Fascicular recordings distal to the repair showed minimal distortion, although some parameters remained abnormal.

All single fiber receptive fields (RF's) lay within mapped fascicular territories, and the density and overlap among RF's corresponded well to the relative activities as determined by the fascicular maps. Normal RF's had smooth contours, and showed uniform activity. Reinnervated RF's showed two basic patterns: most were smaller than normal RF's, but some fibers innervated large skin regions, with diffuse or multiple areas of activity. Such multiple RF's were found both with proximal and distal recordings, indicating that such fields probably arose from peripheral sprouting.

Despite the fact that various parameters improved with time, distortions in cutaneous innervation patterns persisted throughout the study. These findings are useful in understanding clinical observations of altered sensibility and false localization subsequent to nerve injury and repair.

170.3 DORSAL HORN OF NEONATE RATS "IN VITRO": NEURONAL RESPONSE TO AFFERENT VOLLEYS AND AFFERENT TERMINALS' RESPONSE TO SUSPECTED TRANSMITTERS. Ian Hentall and Howard Fields, Dept. of Neurology, UCSF, San Francisco, CA 94143.

The hemisected spinal cord from neonate rats has been used for "in vitro" pharmacological studies of compound dorsal and ventral root potentials. We describe here its use for study of single elements in dorsal horn. Approximately 8 thoraco-lumbar segments are dissected from 1-10 day old rats and perfused with oxygenated, artificial, cerebrospinal fluid at 28°C.

Second Order Neurons: A medial-to-lateral approach through the dorsal horn of the hemisected cord using 30MΩ KCl-filled microelectrodes revealed 11 extracellular units with properties stable for at least 3-4 hours. These properties were: (1) spontaneous activity of 5-10Hz., (2) a response to electrical stimulation of dorsal rootlets consisting of 1-3 spikes after an inhibitory period (seen in multiple sweeps) of about 50msec., (3) abolition of both spontaneous and evoked activity by 10^{-6}M tetrodotoxin and 10mM Mg^{++}. Of adult mammalian dorsal horn units, these most strongly resemble a type found in the substantia gelatinosa. We find the neonatal dorsal horn in Nissl-stained sections to be undifferentiated,with few dendrites. However, the existence of this activity in 2nd order neurons makes the preparation useful for assessing connectivity and transmitter actions in the dorsal horn.

Primary Afferent Terminals: Single units were recorded from attached dorsal root ganglia with ventral roots cut, and their threshold for antidromic activation from the dorsal root entry zone was measured by computer-controlled search (0.3Hz. pulses). The following drugs were applied; 10^{-6}M (D-ala^2) met-enkephalinamide (ENK), 10^{-6}M morphine sulfate (MS), 10^{-7}M naloxone (NAL), 10^{-5}-10^{-6}M substance P (SP), and 10^{-6}M serotonin (5HT). Eighty units were looked at, all in the slowest range of conduction velocities of 0.12-0.75 m/sec (at 28°C); their velocities increased by about 70% at 37°C, into the range typical for mammalian C-fibers. ENK increased thresholds in 5 of 16 units and MS in 7 of 11. This strengthens similar findings on mammalian C-fibers "in vivo", since blood pressure effects and other artefacts can be ruled out. NAL reversed the opiate-induced increase in threshold. SP decreased thresholds in 4 of 7 units, including one opiate-responsive one. Thus the primary effect of SP is probably not to release enkephalin from interneurons. 5HT raised thresholds in 5 of 15 neurons, and in 2 other cases increased the effect of MS without itself having any influence. Separation of direct and indirect actions upon terminals by use of high Mg^{++} conc. has not yet been achieved, since the antidromic response often disappears in this circumstance (5 of 9 units); this could be due to blocking of Ca^{++} spikes or a direct effect on Na^{+}-spike threshold.

170.4 ANATOMICAL CHARACTERIZATION OF ULTRAFINE PRIMARY AXONS IN LAYER I OF THE DORSAL HORN OF ADULT CATS. Stephen Gobel, William Falls and Emma Humphrey*. Neurocytology and Experimental Anatomy Section, Neurobiology & Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20205.

Virtually all of the primary axonal endings that have been described in layers I and II, as well as those in the deeper layers of the dorsal horn are relatively large elliptical endings, measuring 0.5 x 1.0 μm or larger. This study identifies a morphologically distinct group of ultrafine primary axons in layer I whose endings and parent branches are much finer than those of primary axons which terminate throughout the dorsal and ventral horns. The terminal arborizations of primary axons in adult cats were visualized either by filling them with horseradish peroxidase (HRP) in experiments in which HRP was applied to the cut central ends of cervical and lumbar dorsal roots or in Golgi analyses of layer I in medullary, cervical and lumbar dorsal horns. Ultrafine primary axons consist of long, unmyelinated strands (0.3 μm or less in diameter) which extend for several hundred μm in the rostrocaudal axis of layer I. Each strand gives rise to enormous numbers of very closely spaced fine endings, most of which are less than 0.5 μm in diameter. For example, as many as 14 endings have been found along a 10 μm length of strand whereas primary axonal strands in layer II rarely have even three endings in a 10 μm length of strand. At least two different kinds of ultrafine primary axons exist; one has only fine rounded endings, while the other has highly elongated, fusiform endings.

Electron microscopical analysis of the axonal endings of HRP-filled ultrafine primary axons shows that they contain a few dense core vesicles and form synapses in layer I on dendritic spine heads, and on dendritic shafts. The postsynaptic densities of these axodendritic synapses vary. Some contain appreciable postsynaptic densities and resemble Gray type I synapses. Some contain subsynaptic Taxi bodies while many others contain only scant amounts of postsynaptic dense material. Ultrafine primary axons also receive synapses on their endings and on their strands from processes which contain a mixture of small oval and highly flattened synaptic vesicles.

Ultrafine primary strands in layer I, unlike some primary axonal strands in layers IIa and IIb (Gobel and Falls, Brain Res. 175: 335-340, 1979), have not been found originating from thicker parent branches. A few have been traced from layer I directly to 0.3 μm parent branches in Lissauer's tract in the spinal cord. Such observations suggest that ultrafine primary axonal strands in layer I originate from primary neurons with either unmyelinated or extremely fine myelinated central axonal branches.

170.5 SPINAL TERMINATIONS OF LOW THRESHOLD MECHANORECEPTIVE AFFERENT FIBERS. M. David Egger, Natalie C. G. Freeman*, Patricia Masarachia*, Sasha Malamed* and Eric Proshansky*. Dept. of Anatomy, CMDNJ-Rutgers Med. Sch., Piscataway, N.J. 08854.

Using the method of intra-axonal injection of horseradish peroxidase, we stained functionally identified afferent fibers from slowly adapting (Type I), rapidly adapting and Pacinian corpuscle receptors in the glabrous skin of the hind paw of the cat. At the light microscopic level, we were able to observe the distribution of terminal collaterals of single afferents over a rostrocaudal extent greater than 3.5 mm. Swellings in the terminal collaterals, presumably corresponding to synaptic contacts, occurred predominantly in Rexed's laminae IV and V for both the slowly adapting and rapidly adapting terminal fibers. The Pacinian corpuscle afferents, on the other hand, sent a major projection more dorsally, concentrated in lamina III and dorsal lamina IV. The swellings in the terminal collaterals of the slowly adapting afferent fibers approached about 2.0 μm in longest dimension; those of the rapidly adapting and Pacinian corpuscle afferent fibers approached 4.0 μm or more in longest dimension. Many collaterals of the Pacinian corpuscle afferents formed characteristic grape-like arbors of terminal swellings. In addition to light microscopy, electron microscopic observations, similar to those of Ralston and co-workers (Neuroscience Abstracts, 1978, 4: 570; Anatomical Record, 1980, 196: 152A), were made of terminals of three of the slowly adapting afferent fibers and of one Pacinian corpuscle afferent. The predominant mode of termination in these labelled synaptic contacts was axodendritic, including what appeared to be series of boutons en passant strung along single dendrites. In some cases, it appeared that more than one dendrite was related postsynaptically to a single terminal swelling. The vesicles in the labelled terminals were round, clear and about 30-50 nm in maximum diameter. Consistent with the light microscopic appearance, the vesicle-containing terminal regions of the Pacinian corpuscle afferent appeared to be larger than those of the slowly adapting afferent fibers.

170.6 THE INTERMEDIOMEDIAL ZONE OF THE LUMBOSACRAL SPINAL CORD IN THE CAT: AFFERENTS AND PEPTIDERGIC ELEMENTS. J.C. Bresnahan, M.S. Beattie, G.M. Mawe and R.H. Ho. Dept. Anat., Coll. Med., The Ohio State University, Columbus, Ohio, 43210.

The intermediomedial zone (IMZ) of the spinal gray has been implicated in autonomic processing, and more recently has been shown to be a major source of spinothalamic tract (STT) axons in the cat at lumbosacral levels (Carstens and Trevino, '78). We have examined this region to determine the nature of primary afferent input and its overlap with axons traveling in the dorsal portion of the lateral funiculus (DLF), and the relationship of these afferents to substance-P (SP) and methionine-enkephalin (ENK) immunoreactive elements.

Primary afferent input to the IMZ was assessed by light and electron microscopic observations of terminations in this region after anterograde, diffuse, injury-filling of lumbar and sacral dorsal roots with horseradish peroxidase (HRP), and after transganglionic HRP labelling of sciatic nerve. The projection to the IMZ from axons in the DLF was similarly analyzed by applying HRP to cut axons in the DLF. SP and ENK elements were labelled by either Sternberger's PAP method or the indirect immunofluorescence technique of Coons.

Dorsal root labelling reveals a dense, discrete projection of axons emanating from the dorsal columns. The terminal distribution of these axons forms a continuous column in the lumbosacral cord roughly corresponding to the position of the intermediomedial nucleus described by Petras and Cummings ('72). The synaptic contacts of these axons occasionally form relatively complex glomerular-like structures similar to those seen in the substantia gelatinosa (SG). Unlike in the SG, synapses were often seen on proximal dendrites or cell bodies, sometimes associated with sessile spines. These synapses contained small, clear, oval vesicles with an occasional small dense core vesicle (DCV).

The major projection zone of the dorsal roots overlaps, but does not coincide with the dense labelling of SP and ENK elements seen in lamina X. Axons of DLF origin contribute a medial projection to this region.

The correspondence between the primary afferent termination pattern and the location of spinothalamic tract cells seen in previous studies is striking. In conjunction with our observations of descending input of possible brainstem origin, and the proximity of this region to SP and ENK immunoreactive elements this pattern suggests that the IMZ may be an important processing center for nociceptive, cutaneous, and perhaps visceral information. (Supported by N.I.H. Grants NS-10165 and NS-14457.)

170.7 SUBSTANCE P ANALOGUE REDUCES TAIL FLICK LATENCY WHEN GIVEN INTRATHECALLY TO THE RAT. K. Yashpal*, D.M. Wright* and J.L. Henry. (SPON: G.E. Lucier). Dept. Research in Anaesthesia and Dept. Psychiatry, McGill University, Montreal, PQ.

Substance P has been found in small diameter afferents and has an excitatory effect specifically on nociceptive neurons in both dorsal horn and trigeminal nucleus caudalis. To test the hypothesis that substance P has an excitatory role in transmission in spinal pain pathways the present study was done. Its point of genesis was the assumption that any such agent should produce hyperalgesia, manifested at least as a reduction in pain threshold. Male Sprague-Dawley rats were implanted chronically with intrathecal polyethylene catheters by a method similar to that of Yaksh (Physiol. Behav. 17: 1031, 1976). After recovery times of 5 or more days each animal was tested for nociceptive threshold by measuring the reaction time to tail flick from a noxious radiant heat stimulus. Trials consisted of a number of such stimuli delivered at 5 min intervals. The substance P analogue, eledoisin related peptide (ERP), was dissolved in artificial CSF and administered in doses of 1.25 to 10 μg in a volume of 10 μℓ. When given one min prior to a test for tail flick latency ERP caused a dose-dependent reduction from pre-administration control times: the first tail flick response after ERP administration was reduced to a mean of 22% of the control latency at the highest dose, and to a mean of 90% of the control latency at the lowest dose. The second response after ERP administration had almost returned to control levels. A similar volume of vehicle administered to the same rats under identical conditions failed to alter tail flick latency. Thus, the results of the present study, showing that the substance P analogue ERP produces a transient hyperalgesia in the tail flick test, support the earlier suggestion that substance P has an excitatory role in transmission in spinal pain pathways.

170.8 RESPONSES OF THORACIC DORSAL HORN UNITS TO VISCERAL INPUTS AND TO AMINO ACIDS IN THE CAT. S.B. Backman* and J.L. Henry (SPON: P. Anninos). Dept. Physiology, McGill Univ., Montreal, PQ.

Responses of dorsal horn neurones to visceral inputs were studied because some of these neurones may be involved in spinal cardiovascular reflex pathways. In chloralosed cats single unit extracellular spikes were recorded from the dorsal horn in segments T1-T4 using multibarrelled micropipettes. The centre recording barrel was filled with 2.7 M NaCl. Barrels for iontophoresis were filled with Na-L-glutamate (1 M, pH 7.4), γ-aminobutyric acid (GABA, 1 M, pH 4.3), glycine (1 M, pH 3.5) and NaCl (165 mM acidified to pH 5.5) used as a control against artifacts due to changes in current or in pH. The ipsilateral inferior cardiac nerve and upper thoracic sympathetic chain were stimulated electrically to activate visceral afferents. Units responding to these visceral inputs were also tested for somatic inputs by electrical stimuli to the skin of the forelimb or by natural stimuli. Units responding to visceral inputs were recorded between 1.47 and 3.37 mm from the surface. Only 4 of 17 such units had ongoing activity. Latencies of responses to visceral afferent stimulation ranged from 1.58-19.26 msec. Responses of 2 of the 17 units occurred at about 1.5 msec; the remaining were greater than 3.2 msec, with two modes at 5 and 18 msec. Evoked responses had burst sizes of 1-6 spikes with a mean of 2.2. About half of the viscerosensitive units tested for somatic input could also be excited by skin stimuli. All units were excited by glutamate (10-25 nA). Evoked responses could be inhibited by GABA and glycine (5-40 nA); these had about equipotent effects on longer latency responses but shorter latency responses tended to be less inhibited by glycine. These results confirm earlier reports of visceral inputs to thoracic dorsal horn neurones but in addition demonstrate that not all of these neurones also receive somatic input. In addition, viscerosensitive dorsal horn units are excited by glutamate and inhibited by GABA and glycine. The differential effects of GABA and glycine suggest the possible existence of different functional groups within the population of viscerosensitive neurones.

170.9 HYPOPHYSECTOMY PREVENTS EXCITATORY ACTIONS OF NALOXONE ON NOCICEPTIVE UNITS IN THE DORSAL HORN OF THE SPINAL CAT.
J.L. Henry, Dept. Research in Anaesthesia, McGill University, Montreal, PQ.

The finding that naloxone excitation of dorsal horn units in the spinal cat (Neuroscience 4: 1485-1491, 1979) shows a diurnal variability (The Physiologist, 22: 71, 1979) suggested the possibility that the pituitary might participate in this excitation, for example by secreting on a diurnal rhythm an agent which inhibits spinal nociceptive neurones. Six cats were hypophysectomized under nembutal anaesthesia by suction via a trans-buccal approach. After recovery times of 5 to 26 days they were anaesthetized with chloralose. Spinal cords were transected at L_1, and segments L_5-L_7 were exposed for recording. Extracellular unit spikes were recorded with glass micropipettes filled with 2.7 M NaCl. Single units responding in a reproducible way to periodic applications of noxious radiant heat were tested. Naloxone, in doses of 0.1-0.5 mg/kg, failed to alter either the on-going discharge rate or the response to noxious radiant heat. On the other hand, in two sham operated cats and four intact cats, the same doses of naloxone induced elevations in both on-going activity and the nociceptive response. These results support the earlier suggestion that a circulating factor is exerting an inhibitory effect on transmission in spinal nociceptive pathways and furthermore implicates the pituitary in the regulation of circulating levels of this factor.

The author is a Chercheur-Boursier of the Quebec MRC; this work was supported by a grant from the Canadian MRC.

170.10 INHIBITORY EFFECTS OF MEDIAL AND LATERAL MIDBRAIN STIMULATION ON ENCODING BY SPINAL DORSAL HORN NEURONS OF NON-NOXIOUS AND NOXIOUS SKIN STIMULI.
E. Carstens, H. Bihl*, D.R.F. Irvine, M. Zimmermann* II. Physiol. Inst., Univ. Heidelberg, Heidelberg (W. Germany).

Electrical stimulation in the midbrain periaqueductal gray (PAG) and lateral reticular formation (LRF) strongly inhibits spinal dorsal horn neuronal responses to noxious skin heating. To determine if non-noxious input is also under descending control, we examined the effects of midbrain stimulation on dorsal horn neuronal responses to controlled brushing of hairs in the cutaneous receptive field. Single lumbar dorsal horn neurons with hair follicle input were recorded in cats anesthetized with Nembutal and N_2O. Controlled brush stimuli were applied with a motor-driven toothbrush. The averaged response to 10 identical brush stimuli (excursion 8 mm, 1 per 6 sec, velocity 3.2- >27 mm/sec) was established without and again during midbrain stimulation (mean 30 Hz, 450-600 μA).

Two classes of units were studied: those receiving only A-fiber input from hindlimb nerves and responding only to brush and light touch (class 1), and those receiving A- and C-fiber input and responding in a graded fashion to brush, pressure and noxious heating (class 2). Brush-evoked responses were reduced during PAG stimulation in 18/26 class 2 (range: to 32-103% of control) and 11/19 class 1 units (range: 42-113%). LRF stimulation reduced the brush-evoked responses of 25/27 class 2 (range:6-103%) and 11/15 class 1 units (range:37-103%). More powerful inhibitory effects were induced from LRF than PAG in units in which both were tested (mean inhibition by LRF: 72%; by PAG: 81%, for 15 class 1 and 21 class 2 units).

Unit responses increased monotonically with velocity of hair movement up to a certain level. When the velocity series was repeated during PAG or LRF stimulation, various changes were observed in the linear portion of the velocity response curve including reduction in slope and/or increase in intercept with velocity axis ("threshold" velocity). The averaged effects of PAG and LRF stimulation on velocity coding by class 1 and 2 units were identical (slope reduction to 77% of control; threshold increase of 1.5 mm/sec; N= 18 units). This contrasts with findings on graded noxious heat intensity coding, whereby PAG stimulation reduces the slope, while LRF stimulation increases the threshold, of the temperature-response curve (Carstens et al., J. Neurophysiol. 43:332-442, 1980).

Class 2 units also responded to noxious radiant skin heating (50°C, 10 sec). On the average, heat-evoked responses were more powerfully inhibited (PAG: 55%; LRF: 54%) than brush-evoked responses (PAG: 81%; LRF: 72%) by midbrain stimulation in 15 units tested.

The results indicate that complex mechanisms are involved in the descending control of input to spinal dorsal horn neurons from different cutaneous receptor classes.

170.11 PROPERTIES OF NEURONS IN THE CAUDAL RAPHE NUCLEI OF THE CAT WITH AXONS THAT PROJECT TO THE SPINAL CORD.
Chen-Tung Yen* and Paul S. Blum, Dept. of Physiol., Thomas Jefferson Univ., Philadelphia, PA 19107.

The physiologic properties were investigated of neurons in the caudal raphe nuclei (CRN) of the medulla with axons that project to the spinal cord (raphe spinal neurons). Adult cats were anesthetized with alpha-chloralose (60 mg/kg) and paralyzed with gallamine. The activity of single neurons was recorded using standard extracellular techniques, and raphe spinal neurons were identified by the presence of an antidromic response after stimulation of the spinal cord at C2. In 35 raphe spinal neurons, the location of the axon of the unit within the white matter of the spinal cord at C5 was determined by microstimulation techniques. Thirteen units had axons located in the dorsolateral funiculus (DL units), 12 units had axons in the ventrolateral funiculus (VL units), and 10 units had axons located in the ventromedial funiculus (VM units). Although there was considerable overlap, the perikaryon of DL units were found primarily in the most ventral portion of the CRN, VM units were found in the most dorsal portion of the CRN, and VL units were found in an intermediate position. The conduction velocity and percentage of neurons that responded to different modalities of sensory stimuli of these units are summarized in Table I. Conduction velocities of the VM fibers were significantly faster than the DL fibers. Almost all the units responded to gentle tapping at sites throughout the body surface. Compared to VM units, the DL units appeared to have less sensory convergence from hair, visual, or auditory stimuli. The VL units had an intermediate profile. This is in agreement with the properties of a separate population of 241 CRN units in which a higher percentage of units in the dorsal region responded to cutaneous, visual, and auditory stimuli compared to units in the ventral region. These data indicate that there are functional differences between neurons located in the dorsal portion and ventral portion of the CRN in terms of position and diameter of spinal-projecting axon, and response to sensory stimuli.

170.12 LOCUS COERULEUS PROJECTIONS TO THE SPINAL CORD: ANATOMY & PHYSIOLOGY.
C. J. Hodge, A. V. Apkarian†, R. T. Stevens†, G. D. Vogelsang* and H. J. Wisnicki† Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

The locations of cells in the brain stem of the cat containing catecholamines (CA) were determined using glyoxylic acid induced histofluorescence. Retrograde transport of HRP, conjugated with wheat germ agglutinin, injected into the lumbar spinal cord was used to determine which of the CA containing areas in the pons projected to the lumbar cord. The areas which were labeled by both these techniques included the caudal locus coeruleus (LC), the subcoeruleus (SC) and the parabrachial nuclei.

The effects of LC and SC stimulation on dorsal horn cell responses to cutaneous stimulation were then determined. Extracellular recordings were made from lumbar DHC in cats anesthetized with chloralose. Bipolar stimulating electrodes were placed in LC bilaterally. The effects of repetitive stimulation of LC, either ipsilaterally or contralaterally, on DHC responses to innocuous hair displacement and noxious thermal stimuli were determined. All LC stimulation sites were evaluated histologically. DHCs were divided into four groups on the basis of their response characteristics to cutaneous stimuli. Group I cells responded only to innocuous stimuli. Group II cells responded only to noxious stimuli. Group III cells responded to both innocuous and noxious stimuli. Group IV cells had characteristics of "novelty detection cells."

Of thirty-two group I cells encountered, twenty-four had responses that were inhibited and three had responses that were facilitated by LC stimulation. Sixteen group II cells were studied. Thirteen of these cells were strongly inhibited and one was facilitated by LC stimulation. Eighty-two percent (9/11) of group III cells had their responses to noxious cutaneous stimuli inhibited by LC stimulation. When the effects of LC stimulation on responses of cells of this group to innocuous skin stimulation was tested (4 cells), two showed inhibition and two facilitation. Both group IV cells were strongly facilitated following LC stimulation. The effects of stimulating the ipsilateral or the contralateral LC were always the same. The inhibitory effects were not abolished by pretreatment with the serotonin depletor parachlorophenylalanine, but were abolished by pretreatment with reserpine. The anatomic and physiologic results indicate that the projections from LC to the spinal cord are functionally bilateral and primarily inhibitory. The coeruleo-spinal system is one of the mechanisms by which alterations in noradrenergic activity might affect behavioral responses to pain.

171.1 PROJECTIONS OF RETINAL GANGLION CELLS IN THE FETAL CAT. Robert W. Williams and Leo M. Chalupa. Department of Psychology and Physiology Graduate Group, University of California, Davis, CA 95616.

The prenatal organization of retinofugal projections was studied in fetal cats with anterograde transport methods. Laparotomies were performed on timed-pregnant cats, and following the exposure of a fetal head horseradish peroxidase (HRP) was injected into the right eye, while the left eye was injected with tritiated leucine. After a twenty-four hour survival period the fetuses were removed by Caesarian section and perfused through the heart with saline followed by a glutaraldehyde and paraformaldehyde mixture. Alternate sections through the thalamus and midbrain were processed for HRP or autoradiographically using conventional procedures. Retinal whole mounts were examined to check for possible damage which could have resulted from the injections. To date our results indicate that by ten days before birth all subcortical structures which are known to receive direct retinal projections showed some sign of label. In general, on embryonic day 57 the ipsilateral projection is less developed than the contralateral input. This is especially clear in the dorsal lateral geniculate nucelus (dLGN). In the dLGN there is no indication of laminar organization in neutral red counterstained sections. However, the contralateral and ipsilateral inputs were clearly segregated. In frontal sections the bands of crossed and uncrossed label were oriented approximately vertically rather than in the horizontal plane as is found in the adult cat. In the thalamus label was also seen at the medial border of dLGN and most likely, this represents the retino-pulvinar projection. In the fetuses 10 days before birth the densest label was in the ventral lateral geniculate nucleus (VLGN) and in the contralateral superior colliculus. The collicular label was most dense just ventral to the stratum zonale, that is, in the dorsal portion of the superficial grey layer. Since this region of the superior colliculus (e.g., McIlwain, J. Neurophysiol., 1978) and the VLGN (Spear et al., J. Neurophysiol., 1977) receive predominantly W-type ganglion cell projections, our findings imply that the projections of W-cells may develop earlier than those of other retinal ganglion cells. On going studies of earlier fetal material should provide more information regarding the validity of this suggestion.

171.2 DISRUPTION OF CORTICAL BINOCULARITY DUE TO EARLY EXPERIENCE WITH 32° OF ROTATIONAL DISPARITY BETWEEN THE LEFT AND RIGHT EYES' VISUAL FIELDS. Michael R. Isley*, Diane C. Rogers*, Michael Podell*, and Paul G. Shinkman. Univ. North Carolina, Chapel Hill, NC 27514.

Binocular visual cortical cells in normally reared kittens have a mean interocular disparity (IOD) of 0° between preferred stimulus orientations in the left and right eyes. In previously reported experiments, we showed that when kittens' early visual experience consisted of left- and right-eye visual fields optically rotated in opposite directions about the visual axes (16° of disparity between the two eyes), the IOD distribution was found subsequently to be centered about the rotation experienced during early development. Except for the IOD distribution, the organization of visual cortex resembled that found in normally reared kittens, in terms of ocular dominance, orderly arrangements of orientation columns, and topographic representation of the visual field.

The present experiment was part of a series designed to assess the parametric limits of this plasticity in the development of visual cortex. Kittens were reared as before, wearing goggles fitted with small prisms that introduced equal and opposite rotations of the visual fields about the visual axes. For these kittens, however, the prisms were arranged so as to introduce 32° of rotational disparity between the two eyes' visual fields (16° counterclockwise in the left eye and 16° clockwise in the right eye for some animals, and the opposite for others). Kittens experienced 75-100 hr of visual experience starting at 4 weeks of age and continuing for 1-2 months, and remained otherwise in the dark. Control kittens wore goggles with prisms that introduced 0° disparity. The results differed in three principal ways from the earlier (16°) experiments. First, the ocular dominance distribution was U-shaped rather than normal, with some increase in the number of visually unresponsive cells. Second, the distribution of preferred interocular orientation disparities was not centered at 32°; it was nearly rectangular, with significantly greater variance than that of normally reared kittens or control kittens. Third, there was a significant overrepresentation of cells with preferred stimulus orientations in the dominant eye near horizontal or vertical (± 22.5°). We conclude that under these rearing conditions a rotational disparity of 32° (with concomitant interocular positional disparity) disrupts the development of cortical binocular connections in terms of both ocular dominance and interocular matching of preferred stimulus orientations.

171.3 REORGANIZATION IN THE CORTICOTECTAL PROJECTION OF THE CAT FOLLOWING NEONATAL DAMAGE OF VISUAL CORTEX. Leo M. Chalupa, Robert W. Williams, Robert W. Rhoades and Stephen E. Fish. Department of Psychology and Physiology Graduate Group, University of California, Davis, CA 95616.

Unilateral damage of visual cortex in infant rats (Mustari and Lund, Brain Res., 112, 37-44, 1976) and hamsters (Rhoades and Chalupa, J. Neurophysiol., 41, 1466-1494, 1978) results in an aberrant crossed corticotectal projection from the intact visual cortex. Therefore we sought to determine whether or not a similar reorganization occurs in the cortico-collicular projection of the cat. For this purpose unilateral ablations of visual cortex were made in three cats on the second day after birth. When these animals reached adulthood a series of injections of tritiated amino acids were made into the visual cortex contralateral to the damaged side. Similar cortical injections were also made into the visual cortex of two adult normal animals. The brains were sectioned and processed autoradiographically using standard procedures. It was found that in the control animals collicular label was seen only on the side ipsilateral to the injected cortex. In contrast, in the neonatally brain damaged cats label was found in both the contralateral and ipsilateral superior colliculus. On both sides it was confined to the superficial grey layer and homotopic portions of the tectum were labeled. However, the contralateral label was much less dense and also more restricted than that on the ipsilateral side. The main focus was in the rostral portion of the contralateral tectum. Furthermore, unlike in rodents the crossed projection was not limited to the medial portion of the contralateral colliculus. These autoradiographic data indicate that reorganization in the cortico-collicular projection of the cat does occur as a consequence of neonatal, unilateral ablation of visual cortex. Thus, our findings suggest that reorganization in the corticotectal projection may be a general response of the developing mammalian visual system to early damage of the visual cortex.

171.4 SYNAPTIC CHANGES IN THE VISUAL CORTEX OF MONOCULARLY DEPRIVED HOODED RATS. S. Boyce* and Eva Fifkova, Dept. of Psych., Univ. of Colorado, Boulder, CO 80309.

Monocular lid-suture of 2 months (P75) causes a significant decrease in the synaptic density of the deprived visual cortex and an increase in density of the visual cortex connected with the functional eye. In these experiments the lid-suture was performed at the time of the physiological eye opening (P15) when synaptogenesis of the visual cortex is not yet completed. In the present experiments, therefore, the postdeprivation changes were studied at P15 under conditions of unobstructed vision (4 pups) and at P21 under conditions of unobstructed vision (4) and monocular deprivation (5). The first period of axodendritic synaptogenesis appears to be completed by P15, since there is no increase in synaptic density of axodendritic contacts between P15 and P21. Monocular lid-suture of 7 days duration (from P15 to P21) had no impact on the density of these synapses. Between P21 and P75 a second period of axodendritic synaptogenesis occurs, which seems to be affected by deprivation: by P75 a loss of axodendritic synapses has been noted. The density of axospinal synapses increases dramatically from P15 to P21. Deprivation of 7 days results in a significant increase in the density of axospinal synapses in the functional cortex, leaving the density of the deprived cortex unchanged as compared to controls. Between P21 and P75 in controls the axospinal synaptogenesis continues at a lower pace in layers I-II, while in layers III-IV a loss of these contacts occurs. In the functional cortex in layers I-II of deprived rats, the axospinal synaptogenesis continues; it, however, ceases in these layers in the deprived cortex. This results in the, by P75 observed, higher axospinal density in functional layers I-II and lower density in the deprived ones, indicating a halt of synaptogenesis in the latter. In layers III-IV of the functional cortex, a loss of synapses similar to that of controls occurs leaving, however, the density here still significantly higher than in controls. Contrary to that in the deprived layers III-IV, the loss of synapses was twice as large as that of controls between P21-P75 indicating disuse as a likely cause of this change. From the comparison of our previous results on the synaptic development in the visual cortex (Juraska and Fifkova: J.Comp.Neur.183:257,1979) and the present data, it is obvious that the density of axodendritic synapses between P10 and P15 does not change, whereas, the density of axospinal synapses is considerably increased in this interval and even more so between P15 and P21. Also, qualitative changes occur in spines between P10 and P21. At P10 the spine apparatus is not yet developed; at P15 it has a very immature configuration and in some spines it appears to gain its adult form by P21. (Supported by NIH Grant EY 01500-06.)

171.5 BRIEF PERIODS OF VISUAL EXPERIENCE CAN MODIFY OCULAR DOMINANCE OF CORTICAL NEURONS IN KITTENS. V. S. Ramachandran*, Marylouise Ary* (SPON: M. Konishi). Div. of Biology, Calif. Inst. of Technology, Pasadena, CA 91125.

Kittens 5-6 weeks of age were used to study the effects of brief visual experience on the ocular dominance of cortical neurons. Kittens were deprived monocularly for 2-3 days, and as in earlier studies, the ocular dominance shifted almost completely towards the experienced eye. Four of these kittens had their deprived eye stimulated by rotating high contrast gratings for 3-4 hr while still anesthetized and paralyzed. Recordings soon after stimulation showed a small but significant increase in the extent to which neurons could be driven by the deprived eye. Essentially identical results were obtained in a 5th animal which was not anesthetized or paralyzed during stimulation but was fixed in a head holder. Two control kittens had their deprived eyes exposed to a white screen for 4 hr instead of rotating gratings and no change in ocular dominance was observed. However, if 4 days of darkness was allowed to elapse after grating stimulation, the degree of recovery seen was greater than if the recording was done immediately after stimulation.

Another two kittens were revived from anesthesia and their deprived eye was stimulated on 4 successive days for 1 hr each day. They were kept in total darkness whenever thay were not being stimulated so that the deprived eye received only a total of 4 hr of experience as in the previous animals. In these animals, recovery of functional connections through the deprived eye was even more striking and in fact the two eyes became almost equally dominant. Thus, distributed stimulation may be more effective than massed stimulation. A third control kitten was kept in total darkness for 4 days (i.e., without grating stimulation) and no significant recovery was seen.

We conclude that: a) very brief periods of visual experience (3-4 hr) can modify the eye preference or ocular dominance of visual cortical neurons, and b) even after active synaptic stimulation has ceased, some time dependent process akin to "consolidation" may continue to occur in the dark.

171.6 INTERHEMISPHERIC COMPETITION DURING POSTNATAL DEVELOPMENT. M. Cynader, F. Lepore and J. P. Guillemot. Dept. of Psychol., Dalhousie Univ., Halifax, N. S. and Dept. of Psychol., Université de Montréal, P. Q., Canada.

The corpus callosum is a bidirectional pathway interconnecting the visual cortices on the two sides of the brain. This report shows that it is possible to induce a functional asymmetry in the connections of the corpus callosum by arranging for one hemisphere to receive visual input during postnatal development only via a projection from the other hemisphere.

Four kittens were reared normally from birth until 21 days of age. Then the optic chiasm was surgically sectioned, abolishing retinal input to the opposite side of the brain, and the left eyelid was sutured shut. The kittens subsequently received normal visual exposure until 4 months of age. This procedure ensures that visual input reaches the left visual cortex only via the following pathway: right eye-right lateral geniculate nucleus (LGN)-right visual cortex-left visual cortex (via corpus callosum).

In normal cats, optic chiasm section greatly reduces, but does not abolish the influence of the contralateral eye in the visual cortex. While only 10% of the neurons are driven more strongly through the contralateral eye than the ipsilateral eye (versus 55% in normal cats), over 80% of the units encountered near the area 17/18 border receive some input via the contralateral eye. All contralateral eye input is abolished by removal or inactivation of the opposite hemisphere.

In the kittens described above, recording at the area 17/18 border on the side of the brain ipsilateral to the exposed eye (the "exposed" hemisphere) reveals no input at all from the contralateral (deprived) eye. This finding indicates a loss of functional input from the other side of the brain to the exposed hemisphere. Recordings on the side of the brain ipsilateral to the deprived eye (deprived hemisphere) in the same kittens showed that most neurons (over 60%) receive their dominant input from the contralateral (exposed) eye despite the chiasm section. This indicates a substantial increase in the effectiveness of callosal input from the "exposed" hemisphere to the "deprived" hemisphere.

The results show that the functional effectiveness of callosal connections can be markedly enhanced or diminished on different sides of the same brain. In effect, our manipulation has transformed the corpus callosum from a bidirectional pathway to a one-way route. Information originating in the exposed hemisphere flows to the deprived hemisphere but not in the reverse direction. 171.7 ORIENTATION COLUMNS IN CATS REARED IN STRIPED CYLINDERS SHOWN WITH ^{14}C 2-DEOXYGLUCOSE. Dorothy G. Flood*, Paul D. Coleman, Robert C. Emerson, and Mary E. Bahn* (SPON: V. Laties). Dept. of Anatomy and Center for Visual Science, Univ. of Rochester, Rochester, NY 14642.

We have demonstrated variable degrees of modification in the preferred orientation of visual cortical cells with single unit recording and also with ^{14}C 2-deoxyglucose (2-DG) following rearing in striped cylinders. Cats were exposed to either horizontal or vertical stripes for 2 or 6 hrs/day for 10 wk. Orientation selectivity was determined physiologically for single cells from the medial bank of the postlateral gyrus. The cells of one cat showed a strong bias for the rearing orientation while those of all others showed no clear bias. Cats reared in striped cylinders and control cats then received 100-150 μCi/kg of 2-DG (NEC-495) while the right visual field (left hemisphere) was stimulated with horizontal stripes and the left visual field (right hemisphere) with vertical stripes (0.3 cycles/deg, moving at 6°/sec, and covering 35° x 45° in each hemifield). After 45 min the hemispheres were removed, frozen at -40°C, sectioned at 20 μm, and exposed to x-ray film. In the control cats, both hemispheres showed a similar amount of labeling. In the stripe-reared cat with a strong physiological bias, the hemisphere seeing the orientation of stripes viewed during rearing was more heavily labeled (Brain Res., 173 (1979) 538-542). In the stripe-reared cats that showed no physiological bias, the hemisphere seeing the orientation of stripes viewed during rearing was either similar to labeling in the controls or slightly more heavily labeled than in the controls. The 2-DG method is a more sensitive indicator of small alterations due to rearing in striped environments. Supported by NSF grant BNS-7912273 and PHS grants AG-1121 and EY-01440.

171.8 VISUAL FIELD DEFICITS OF CATS REARED WITH ROTATION OF ONE OR BOTH EYES. Carol K. Peck, Grayson Barber*, Cindy Pilsecker* and Robert Wark*. Department of Psychology, Pomona College, Claremont, CA 91711.

Following surgical rotation of one or both eyes, cats show substantial evidence of visual function in the rotated eye(s). On most observations of visuomotor behavior, they are difficult to distinguish from normal. The present experiments measured the visual fields of cats which had undergone surgical rotation of one or both eyes at 3 d, 16 d, 3 mos, or 6 mos of age. The horizontal visual field was tested using the procedures previously described by Sprague and by Sherman. Procedures for hemispheric perimetry were also developed to test both vertical and horizontal fields.

All animals showed excellent localization of visual stimuli and responded to the actual location of targets in space rather than to the retinal locus normally associated with that location. This is additional evidence in support of proposals that the cat's nervous system remains plastic to at least 6 mos.

In cats with rotation of only one eye, the visual fields of the unoperated eye were normal, extending from 90° ipsilateral to 30° contralateral. Cats with surgery at 3 or 6 mos had essentially normal fields in the rotated eye as well, while cats with surgery at 3 or 16 d had restricted horizontal fields. Specifically, they responded only to stimuli in the ipsilateral hemifield; they were blind in the contralateral visual field. Their superior and inferior visual fields were normal. The field deficits related consistently to visual field coordinates, could not be explained by simple physical displacement of the retina or other peripheral factors, and were independent of other visual abilities (e.g., acuity). Cats with bilateral rotations could see across the midline with at least one eye. Thus, the extent of the field depends on the sensorimotor experiences of the cat both before and after surgery, but the smaller fields of cats with rotations of one eye cannot be attributed to a competitive disadvantage, as usually understood, because non-corresponding retinal loci are involved.

When tested with both eyes open, half of the experimental cats did not respond throughout the visual field seen by each eye alone. The binocular field was less than the sum of the two monocular fields; greatest losses were found at the temporal margin of the field ipsilateral to the rotated eye. Changes in eye position (e.g., convergence during binocular viewing) were not involved. We suggest that they indicate a suppression of the deviated eye which must have a central origin.

171.9 PERMANENT DEFICIT IN VISUAL ACUITY FOLLOWING NEONATAL SURGICAL SECTION OF THE POSTERIOR CORPUS CALLOSUM IN CATS. Andrea J. Elberger. Dept. of Anatomy, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA 19104, and Dept. of Neurobiology and Anatomy, Univ. of Texas Med. Sch. at Houston, Houston TX 77025.

Visual acuity in cats was measured by testing the threshold for discrimination of square wave gratings. Using a modified Lashley jumping stand (Mitchell et al, Vision Res. 16:363, 1976), kittens were trained to jump to the projected image of a square wave grating when compared with the projected image of uniform grey of the same mean luminance. Jumping distance was 10, 12, 15 or 18 inches, depending on the age and motor ability of each animal. If 7 out of 10 trials were correct the spatial frequency of the grating was increased by changing the projected image, not by increasing the jumping distance. Images were back projected onto hair-trigger trap doors; an incorrect response caused the trap door to open. No food or water deprivation was used; the cat's desire to avoid a trap door opening was sufficient to induce adequate performance on the behavioral task.

Three groups of kittens were tested: Normal, unoperated cats (3 cats); Anterior Corpus Callosum sectioned cats, with less than 50% of the C.C. length sectioned (4 cats); Posterior Corpus Callosum sectioned cats, with a minimum of the Posteriormost 30% of the C.C. sectioned (7 cats). Surgeries were performed from the day of birth to 22 days. Testing was begun as early as the cat's 40th day of age and continued once or twice per week until at least 175 days of age. Results for Normal and Anterior C.C. cats did not differ significantly, and their data were combined to form a Control group of 7 cats.

Compared with the Control group, the Posterior C.C. cats showed a deficit in visual acuity. From the beginning of testing the Control group improved in spatial acuity gradually until 125-155 days of age, when the stable adult level was achieved (5-7.5 cycles per degree), after which the visual acuity apparently remained unchanged. The Posterior C.C. cats also improved in acuity gradually over time, but they improved at a slower rate than the Controls, and the stable adult level of spatial acuity (2.5-3.5 c.p.d.) remained statistically significantly lower than that of the Control cats. The lowered visual acuity following neonatal Posterior Corpus Callosum section may be related to the disruption in depth perception in kittens tested on the visual cliff (Elberger, Vision Research 20:177-187, 1980), and may be affected by the alteration in binocular vision seen both behaviorally (Elberger, Experimental Brain Res. 36:71-85, 1979) and electrophysiologically (Elberger, Neuroscience Abstract #2630, 1979) in this same type of cat.

Supported by Training Grant No. T32 EY07035 - 02 awarded to the University of Pennsylvania.

171.10 A POSSIBLE ROLE FOR CYCLIC NUCLEOTIDES IN PLASTICITY OF VISUAL CORTEX. Takuji Kasamatsu. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

We have proposed that catecholamine (CA)-containing terminals in the cerebral cortex may play an important role in the changes in neural connectivity that can take place in the postnatal critical period in response to alterations of sensory experience. The local availability of norepinephrine correlates well with the level of modifiability as determined in experimental paradigms which lead to either an increase or a decrease in the number of normal binocularly driven cells in kitten visual cortex (J. Comp. Neurol., 1979; ARVO Abst., 1978). A later study showed that if the visual cortex was perfused with a β-adrenergic blocker, propranolol, at the same time as monocular lid suture, the usual ocular dominance shift was prevented (ARVO Abst., 1979). These previous results suggested that the level of cyclic nucleotides in the postsynaptic visual cells may be involved in changes in ocular dominance.

Six- to seven-week-old kittens were bilaterally implanted at the postlateral gyrus with a cannula-minipump system which contained 4 mM 6-hydroxydopamine (6-OHDA). After one week the minipump on the left side was replaced with one which was filled with 1-10 mM dibutyryl cyclic AMP (dbcAMP) in 0.4% ascorbate saline (pH 3). The implanted cannulae were left in place at this time, and the right eyelid was sutured. Single unit recordings were made following a week of monocular deprivation. Tungsten-in-glass microelectrodes were placed 2 mm anterior to the site of perfusion.

Three observations have been made. First, the overwhelming majority of sampled cells had normal receptive field properties. Second, the usual shift of ocular dominance was observed in the hemisphere perfused with dbcAMP, although the other hemisphere contained many binocular cells, as expected from our previous results. Since exogenous dbcAMP was perfused into cortex whose CA-terminals had been destroyed by prior 6-OHDA treatment, the present results strongly suggest that the cyclic nucleotide worked directly on the postsynaptic visual cells. Third, under the current paradigm the proportion of binocular cells was lower than normal in the control, nonperfused hemisphere which had been pretreated with only 6-OHDA. This may indicate that at the concentration of cyclic nucleotide employed, some spread of dbcAMP took place from the perfusion site to the other hemisphere. By varying the concentration of cyclic nucleotides stored in the minipump, the concentration-effect relationship is currently being studied.

172.1 CELL LINEAGE ANALYSIS IN LEECH NEUROGENESIS BY TRACER INJECTION AND ABLATION OF IDENTIFIED EMBRYONIC CELLS. D. A. Weisblat, S. S. Blair* and G. S. Stent. Dept. Mol. Biol. UCB, Berkeley, CA 94720.

Glossiphoniid leeches are well-suited for neurodevelopmental studies because both the early embryo and the segmental ganglia of the adult nerve cord contain large identifiable cells, accessible to observation and experimental manipulation. Five bilateral pairs of teloblasts, consisting of one pair of mesodermal progenitors (M) and four pairs of ectodermal progenitors (N,O,P and Q), produce columns of stem cells that ultimately give rise to the segmental tissues of the animal, including the ventral nerve cord.

By injecting horseradish peroxidase (HRP) into identified blastomeres, we have previously shown that a spatially stereotyped fraction of the neurons of the hemilateral segmental ganglia derives from the ipsilateral N teloblast and that the remainder derive from the ipsilateral OPQ teloblast precursor. Similar HRP injection experiments to be described here have revealed that some descendants of the OP teloblast precursor also appear to occupy stereotyped sites within the developing ganglion, whereas others give rise to non-neural ectoderm. Moreover, some descendants of the Q teloblast migrate medially to the ventral midline from their original position at the extreme lateral edge of the embryo.

Labeling the progeny of one teloblast with HRP in an embryo in which a second teloblast, or teloblast precursor, has been ablated by injection of pronase or deoxyribonuclease reveals an altered spatial distribution of the progeny of surviving teloblasts. If an N teloblast is ablated, some progeny of the surviving N teloblast are found on the ablated, contralateral side. By contrast, the distribution of the progeny of the OPQ teloblast precursor appears unaffected. However, if the OPQ teloblast precursor is ablated, the surviving OPQ teloblast precursor does contribute progeny to the ablated side.

172.2 DEVELOPMENT OF AN IDENTIFIED NEURON AFTER REMOVAL OF ITS PERIPHERAL TARGETS IN GRASSHOPPER EMBRYOS CULTURED IN VITRO. Corey S. Goodman and Kimberly A. Ridge*. Dept. of Biol. Sci., Stanford University, Stanford, CA 94305

We previously reported on the differentiation and cell lineage of the first three progeny of the median neuroblast (MNB) in the metathoracic segment during grasshopper embryogenesis (Goodman and Spitzer, Nature, 1979). The third cell division of the MNB gives rise to a cell which develops into the identified neuron DUM 5 (DUMETi) whose peripheral axons innervate the extensor tibiae (ETi) muscles in each of the two metathoracic legs.

Here we report on the embryonic development of DUM 5 after removal of one or both of its peripheral targets prior to its arrival. This type of experimental manipulation requires that the embryo continue its normal development outside of the egg case and thus in vitro. We have modified the methods of Mueller (Dev. Biol., 1963) such that grasshopper embryos develop in culture from day 7 (35%) to the day of hatching (day 20); this includes having the embryos proceed through katatrepsis in culture.

Our first experimental use of this culture system has been to remove DUM 5's targets. Normally, the axons of DUM 5 arrive at the ETi muscles on day 12 and extend over the muscle by day 13. DUM 5 becomes electrically uncoupled and electrically excitable shortly before this time (days 11-12). Although it initially has many extra peripheral branches, it loses these incorrect branches by day 15. The cell body rapidly enlarges in diameter after day 12 and becomes the largest amongst the MNB progeny.

We removed one or both of the metathoracic legs on days 10-11, and examined the morphology and physiology of DUM 5 on days 13-15. DUM 5 becomes electrically uncoupled and electrically excitable, even when deprived of both targets. However, its cell body does not gain its distinctive size, and it retains some of its multiple peripheral branches. When only one leg is removed, it retains multiple branches on the operated side but loses them on the normal side. In such cases, the cell body develops its distinctive size.

Thus, for the identified neuron DUM 5, we conclude that (i) the development of uncoupling and excitability are independent of direct contact with its normal targets, and (ii) the development of its normal cell body size and peripheral morphology are dependent on interactions with its targets. We are currently using other experimental manipulations in an attempt to understand the interactions of lineage and environment in the survival and differentiation of this identified neuron.

(Supported by NSF Grant BNS 79-04670.)

172.3 EMBRYONIC MORPHOGENESIS OF AN IDENTIFIED SENSORY NEURON. R. David Heathcote* (SPON: David Bentley). Zoology Department, University of California, Berkeley, CA. 94720.

In insect appendages, a class of cells termed peripheral pioneer neurons have been shown to establish the first connection between the peripheral and the central nervous systems (Bate, C.M. Nature 260: 54-56, 1976). Whether pioneer neurons establish such connections for all sensory organs is unknown. To investigate this, I have examined the embryogenesis of the wing Stretch Receptor (SR) sensory complex in the locust, Schistocerca nitens.

SR is a sensory neuron that provides feedback from wing position to flight motor neurons in adult locusts. The morphology of SR, its synaptic connections to identified motor neurons, and its firing pattern in adult flight have been described. The monosynaptic excitation of the First Basalar flight motor neuron by SR throughout postembryonic development shows that this synapse, although mediating an adult behavior, is already present early in development (Heathcote, R.D., J. Comp. Neurol. 191: in press). This suggested that SR has an embryonic origin.

SR was located in living embryonic locusts using Nomarski optics and intracellular injection of Lucifer yellow dye. At approximately 40% of embryonic development, a group of cells located at the junction of the pleuro-tergal border is associated with a folding of the epithelium. Following this, a cell appears which can be distinguished from other cells by its large size, multipolar shape and its association with the epithelium. Dye fills of this cell show; 1) many somal branches interdigitating among the epithelial cells, 2) a single long axon extending toward the CNS and making a Y-shaped branch to two different ganglia and 3) many fine branches from this main axon growing into the epithelium. Dye fills of many other cells in the vicinity of SR show that no other cells have axons at this stage. The tips of the two axonal branches end in expanded and filamentous growth cones. The progress of the growth cones into the CNS was followed by injecting dye into SR at different embryonic stages. Most of the identified central branches of SR were found to be present by 60%. The fine processes branching off of the axon of SR disappear by 55% and are not visible in the oldest animals injected (90%).

The cell studied is unequivocally identified as SR by 1) its unique peripheral branching pattern (it is the only cell to make a Y-shaped branch to two different ganglia), 2) its size, multipolar shape and the location of its soma, and 3) the configuration of its central branching. Therefore, SR is present and reaches the CNS by 45% of embryogenesis (this is much earlier than any bipolar sensory neuron has been shown to reach the CNS). Moreover, since SR is the first neuron from its region to send a process to the CNS, it appears to establish nerve 1D2.

172.4 EMBRYONIC DEVELOPMENT OF GRASSHOPPER GIANT INTERNEURONS AND THE CERCAL SENSORY AXONS WHICH INNERVATE THEM. S. Martin Shankland Neurobiology Group, Univ. Calif., Berkeley, Ca. 94720

The grasshopper has large interneurons (the so-called Giant Interneurons or GIs) in its terminal abdominal ganglion which receive sensory input from the cercus. I have characterized these neurons by axonal diffusion cobalt fills. The four largest axons in the abdominal connective derive from cells whose dendrites associate with the cercal sensory afferents, and will be defined as GIs. Three of these cells appear to be segmental homologues, and send their grouped axons into the lateral region of the connective. The other GI has a quite distinct branching pattern and an axon in the medial connective, and is believed to be homologous to the Medial Giant Interneuron (MGI) of crickets.

In adult grasshoppers, MGI has a contralateral cell body located at the ganglion equator, and a neurite which crosses the neuropil in the horizontal plane. A small dendrite arises at the ganglion midplane, but the major dendrite extends from the junction of neurite and axon. This dendrite forms an egg-shaped cluster of branches. Heavily ramified and interwoven cercal sensory axons terminate over the surface of this dendrite, thus forming a hollow shell of sensory arbor which contacts the tips of the dendritic branches. These two structures coordinately form the cercal sensory glomerulus. The major dendrite has two fine, unbranched processes which continue from the glomerulus ipsilateral to the axon into the contralateral glomerulus.

I have examined the embryonic development of both the sensory axons (Shankland; Neurosci. Abstr. 5:178) and the GIs. Cobalt fills show that the sensory axons first enter the CNS at 65% of embryogenesis. The formation of branching patterns was followed for several different types of sensory afferent. Silver stains of the embryonic neuropil demonstrate that the GIs appear at the same stage. No GI branching patterns were discernable from 35% to 60%, but at 65% a large neuron was identified as MGI on the basis of its branching structure and association of its dendrite with the future site of the glomerulus. The sensory axon terminals and MGI dendrite then mature morphologically during subsequent embryonic stages. Therefore, presynaptic and postsynaptic processes appear simultaneously within the neuropil, and undertake a concurrent arborization during embryonic life which leads to their adult form.

172.5 TOPOLOGY OF AN ADULT INSECT SENSORY NERVE IS ESTABLISHED BY THE PIONEER AXON PATHWAY. Haig Keshishian. Neurobiology Group, Univ. Calif., Berkeley, Calif. 94720.

The development of nerve branch 5b1 of the metathoracic leg of the grasshopper Schistocerca nitens was examined in cultured embryonic preparations, using both time-lapse microphotography and intracellular Lucifer Yellow dye-fills. In adults, 5b1 arises from the subgenual organ on the anterior-proximal region of the tibia, runs along the anterior-ventral side of the femur, and ultimately crosses over to the posterior-ventral side of the femur to fuse with branch 5b2 at the femoral-coxal border (Heitler & Burrows, '77, J.E.B.,66: 221). This branch anatomy is conserved throughout post-embryonic development, and is evident in the embryonic metathoracic leg.

The earliest event in the organization of the nerve branch is the genesis of a pair of pioneer neurons (Bate, '76, Nature, 260: 54), hereafter termed the PN1 neurons. This cell-pair is the sole progeny of a mother cell that appears at the tip of the limb-bud ectodermal epithelium at the 29% stage of embryonic development (Keshishian, Dev. Biol., in press). The mother cell divides within the epithelium, and its progeny migrate out of it to occupy a characteristic locus near the tip, between the ectoderm and the inner squamous mesoderm of the limb-bud. From there the cell-pair initiate axonogenesis, projecting their axons proximally between the two epithelia. Initially running along the anterior side of the limb-bud, the axon pair cross to the posterior side of the limb at the mid-femoral region, growing along the ventral face. The axons continue proximally on the posterior side, and reach the CNS by the 35% stage.

The path traced out by the PN1 axons establishes the topology of the adult sensory nerve branch. This was determined by serially dye-filling the PN1 cell-pair after their initial differentiation, and examining their relationship to the genesis of the nerve branch, using Nomarski optics and timed embryos. As the limb-bud elongates the somata of the PN1 cells become displaced from the tip. Ultimately they come to lie on the anterior-proximal region of the tibia. By the 40% stage the previously naked PN1 axons become ensheathed by glia. As a result, the axons and associated glia become a distinct chain of cells retaining the original topology of the PN1 axons. Dye-fills up to the 55% stage reveal that the most distal elements of this primitive branch are the PN1 somata. By the 45% stage the somata lie immediately proximal to the subgenual organ. Tracing the nerve branch to the coxal border, it fuses with another posterior branch, possibly 5b2. Thus a nerve branch possessing the adult topology is generated around the PN1 cells, providing a substrate for the subsequent fasciculation by metathoracic leg afferents.

172.6 EXPERIMENTAL INFLUENCES ON THE DEVELOPMENT OF CLAW LATERALITY IN LOBSTER. K. S. Kent* and C. K. Govind (SPON: J. G. Hildebrand). Boston University Marine Program, MBL, Woods Hole, MA 02543

The claws of the adult lobster, Homarus americanus, are dimorphic. The cutter claw is long and slender while the crusher claw is large and stout. Initially, both claws resemble the adult cutter. Differentiation of the claws and claw closer muscles occurs over a series of juvenile molt stages. In the fourth stage, the closer muscles are composed of both fast and slow muscle fibers. The proportion of fast muscle increases in the presumptive cutter claw until the closer muscle is predominantly composed of fast muscle fibers. In the presumptive crusher claw, the proportion of fast muscle decreases until the closer muscle is entirely composed of slow muscle fibers. There is an equal chance that the crusher will develop on the right side as on the left side. However, claw laterality can be influenced if one claw is removed prior to the fourth and fifth stages. The remaining claw will become a crusher while the regenerating claw will become the cutter. Earlier results by Lang and co-workers (Science, 201:1037-1038, 1978) suggested that claw use might influence crusher claw determination. Lobsters reared in smooth plastic chambers which lacked added substrate often did not develop a crusher at all.

We have repeated these experiments and further tested the hypothesis that claw use is a factor in crusher claw determination. Lobsters raised from the fourth stage in the presence of mud, gravel, crushed plastic or crushed oyster shells developed dimorphic claws. However, virtually 100% of the lobsters raised in substrate-free chambers did not develop a crusher claw at all. These results suggested that claw use, stimulated by an appropriate substrate, might indeed be a requirement for crusher claw determination. This hypothesis was further tested by manipulating the right claw during the fourth and fifth stages. Banding the right claw closed and cutting off the dactyl of the right claw did not affect claw laterality. As in control conditions, the number of lobsters developing right crushers equalled the number developing left crushers. However, tenotomy of the right claw closer muscle greatly reduced the number of lobsters developing right crusher claws. This treatment prevented isometric tension development in the closer muscle whereas banding or dactylotomy did not. These results indicate that there is some minimum requirement for tension development in the closer muscle at early critical stages in order for crusher claw determination and transformation to occur. The development of a certain level of tension may, in turn, depend upon the presence of an appropriate substrate. The role played by the innervating axons in mediating this tension requirement remains to be resolved. (Supported by NIH and NSF grants awarded to Fred Lang.)

172.7 COLLATERAL SPROUTING OF IDENTIFIED MOTONEURON FOLLOWING MICROLESION IN THE LARVAL PRAWN *MACROBRACHIUM ROSENBERGII*. D.R. Friedlander and C. Levinthal. Department of Biological Sciences, Columbia University, New York, N.Y. 10027.

Our experiments in the CNS of the larval prawn showed that the removal of a motoneuron (the giant motoneuron, or GMN) frequently results in anomalous connections involving interneurons that were deprived of a target cell which has been deleted (Friedlander and Levinthal, Soc. Neurosci. Abstr. 5:245,1979; Friedlander, Ph.D. Thesis, 1980). This paper deals with the effect of the removal of a GMN on the anatomy of the neuromuscular connections in the larval prawn. The GMN contributes the largest axon innervating the deep flexor muscles responsible for the tail flip response. These muscles are homologous to those described in the adult crayfish. Microlesions were produced by focusing a beam of light which has a significant percentage of its energy in the ultraviolet, on a region of the ganglion containing the GMN. We followed the innervation in film strips of aligned light micrographs of 1 μm thick cross sections, stained with toluidine blue. Finer details of the arborizations were analyzed by observation of 20 μm thick horizontal sections of larvae that had been stained in block with silver.

The normal innervation of the flexor muscles is provided by axons of the ipsilateral 4th root (3rd in crayfish). By removing a GMN, the target deep flexor muscles on one side of the abdomen are partially deprived of afferents. The deletion invariably elicited vigorous sprouting of the remaining GMN, which sent collaterals over the midplane invading the partially denervated muscles. Two muscles (Ai and P) normally innervated by the GMN are in contact with their contralateral homologues. The sprouting collaterals innervating the partially deprived Ai and P muscles originate from branches of the axon supplying in a normal way their contralateral homologous muscles.

In agreement with the results of our experiments in the CNS, these observations in the periphery indicate that the normal ipsilateral connections are not due to strict developmental rules that preclude contralateral connections. The results which demonstrate collateral sprouting in the periphery in the larval prawn are in contrast with those of lesions denervating muscles of adult Crustacea Decapoda, in which no collateral sprouting was observed (Bittner and Johnson, J. Comp. Physiol. 89:1-21,1974).

These studies were supported by NIH grant 5 RO1 NS 09821 and Computer Graphics Facility NIH grant 5 P 41 RR-00442.

172.8 NORMAL AND REGENERATED CNS SYNAPSES IN THE CRAYFISH DO NOT DIFFER. R.J. Strandburg and F.B. Krasne, Dept. Psychology, UCLA, Los Angeles, CA. 90024.

In contrast to the situation in mammals, a number of examples of regeneration of central connections can be found in invertebrates. The availability of identified central interneurons to which regeneration can occur in these preparations presents an opportunity for detailed analysis of such synapses which has, heretofore, been only partially exploited. Hence, in this study, the ability of regenerating sensory axons to establish normal connections with an identified CNS target cell in the crayfish was assessed intracellularly. Comparisons were made between normal crayfish (N) and regenerate preparations (R) in which root 4 (R4) had been cut and directed back to an extensively denervated (roots 2-5 severed) sixth abdominal ganglion. Eight to fifteen weeks postoperatively, an identified interneuron (A) in this ganglion was impaled, and its response to water currents, electrical stimulation of R4, and stimulation of individual sensory hairs supplying axons to R4 was studied along with several other properties of the pre- and post-synaptic neurons.

Overall, few differences were observed between N and R. In particular, unitary EPSP amplitude distributions were comparable across groups, and axons from each of three subregions of R4's receptive field that were examined had similar probabilities of reconnection with A in both groups. While the resting membrane potential and the critical firing level did not vary between N and R, input impedance was significantly lower in R. Coupled with the unitary EPSP amplitude data, this suggests that individual axons in R may provide greater synaptic input to A than their N counterparts, consistent with the possibility that regenerating afferents (which are growing to an extensively denervated target) are sprouting collaterally.

Compound electrically elicited EPSPs were similar in amplitude, rise time and half amplitude width, but differed slightly in latency to onset (R>N). This was accounted for by differences in the conduction time to the ganglion for regenerated axons. Central delay estimates further suggest that connections in both groups were monosynaptic.

The response to giant interneuron activation demonstrated that recurrent presynaptic inhibitory inputs as well as postsynaptic excitatory and inhibitory inputs were normal in R. Synaptic depression, which is normally responsible for behavioral habituation in this system, was comparable across groups, and protection from habituation was observed in both N and R if stimulation was preceded by giant interneuron activation.

172.9 EFFECT OF A LIMITED TARGET AREA ON THE REGENERATION OF SPECIFIC NEUROMUSCULAR CONNECTIONS IN THE CRAYFISH. Samuel J. Velez and William P. Hunt*. Department of Biological Sciences, Dartmouth College, Hanover, New Hampshire 03755.

The superficial flexor muscle of the crayfish is innervated by six axons that distribute their innervation in a very specific pattern over the muscle surface (Velez & Wyman; J. of Neurophys. 41: 75-96). Axon 6, the largest excitor, grows first through medial muscle fibers making some synaptic connections with them (the probability of these connections increases as the nerve gets closer to the lateral muscle fibers). Axon 6 innervates all the lateral fibers of the muscle, the lateral population being its main target area. The distribution of connections made by this axon was studied after the nerve was cut, and in previous work it was shown that full innervation of the entire muscle was achieved between 5 and 10 weeks when the nerve was cut between medial fibers (Ely & Velez; Soc. Neurosci. Abstr., Vol. 5, p. 677, 1979). Experiments are being performed to study the effects of a reduced target area on the regeneration of the different neurons in this system. In one group of animals the nerve is cut as it begins to cross the medial muscle fiber population, and the lateral population of fibers is removed. In a second group of animals the medial population of muscle fibers is removed and the nerve is transplanted to the lateral muscle fibers. The animals were examined after several weeks by stimulating the nerve and recording junction potentials from the muscle fibers. Preliminary results indicate that in the group where axon 6 was growing into the lateral population only, this axon regenerated all its connections in 4 weeks; when axon 6 was growing into the medial population only, the first connections were being formed by 4 weeks and full innervation was achieved several weeks later. The time course for regeneration appears to be influenced by the nature of the target area: axon 6 regenerates at a faster rate when it is growing into its main target area when compared to regeneration rate when growth occurs outside its main target area. The type of synapses formed under these experimental conditions is currently under investigation.

172.10 MOTOR NEURON ASYMMETRY AND ITS ALTERATION IN SNAPPING SHRIMP. DeF. Mellon and J. A. Wilson, Dept. of Biology, Univ. of Virginia, Charlottesville, VA 22901

In alpheid shrimps the major claws exhibit a basic asymmetry which includes not only external morphology and overall size, but also the fine structure and junctional physiology of fibers in the major closer muscles, Cl_1 (Wilson, E.B., Biol. Bull., 4:197, 1903; Stephens, P.J., Mellon, DeF., J. Comp. Physiol.,132:97, 1979; Mellon, DeF., Stephens, P.J., J. Exp. Zool. In Press). We now report that these differences reflect predictable asymmetries in the structure of the motor neurons which supply Cl_1. The closer muscles of pincer and snapper claws of Alpheus are each innervated by two excitor and two inhibitor axon (Mellon, DeF.,Stephens, P.J., J. Comp. Physiol., 132:109, 1979). We have used cobalt backfilling of limb nerves and intracellular injection of cobalt into physiologically identified motor neurons to determine the location of the somata and the extent of dendritic arborization of these four cells. The cell body of one of the inhibitor motor neurons (DoPI) is paired with its contralateral functional homologue at the dorsal midline of the first thoracic ganglion. In pristine individuals (those in which claw asymmetry is completely expressed) the DoPI cell body of the snapper claw is twice the diameter (80-100 μM) of the pincer claw DoPI. The size difference in this neuron pair characterizes a general but less dramatic asymmetry in cell volume of the other motor neuron pairs. Differences in electrical properties are also expected and are now being sought. Pincer claws of Alpheus can be transformed into snapper claws following loss of the original snapper or damage to its nerve supply (Wilson, E.B., op. cit.;Mellon, DeF., Stephens, P.J., Nature, 272:246, 1978). Dramatic changes in neuron size and placement occur during transformation. DoPI cell body drops down to a mid-ventral position within the ganglion and its volume increases to equal that of the original snapper DoPI. It is known that an intact nerve supply to the pincer claw is necessary for claw transformation to occur, but the nature of this determinative relationship is not understood. Our observations of neuronal asymmetries and alterations lend support to the possibility that fundamental change in claw motor neuron properties initiates and provides the primary control in the transformation process.

172.11 ELECTRICAL PROPERTIES AND INNERVATION OF IDENTIFIED MUSCLE FIBERS IN THE CRAYFISH DURING GROWTH. Gregory Lnenicka* and DeForest Mellon, Jr. (SPON: T.R. Johns). Dept. of Biol., Univ. of Virginia, Charlottesville, VA 22903.

The electrical properties, and innervation of identified muscle fibers in the crayfish superficial flexors were studied at various stages of growth. Each of the paired, sheet-like, superficial flexors of the third abdominal segment receives innervation from six identified motor neurons in a predictable pattern (Velez and Wyman, J. Neurophysiol. 41 75 1978). By limiting our studies to the two most lateral muscle fibers in the sheet, we have examined elements with predictable electrical properties, which are reliably innervated by two identified excitatory motor neurons. This allows the detection of changes in muscle fiber electrical properties, and innervation during growth.

Experiments were conducted to determine the muscle fiber length constant, input resistance (R_o), time constant, and diameter (d). The electrical constants were then calculated on the basis of cable theory. Measurements were made on crayfish ranging in size from 1 cm. carapace length (wt. 0.2g) to 5 cm. carapace length (wt. 24g). The lateral muscle fiber diameter increased from 20μ in the small animals to 320μ in the large animals.

If muscle fiber resistivity (Rm) and internal resistivity (Ri) are constant, R_o is predicted by cable theory to be proportional to $d^{-3/2}$. Although Rm decreased slightly during growth, the decrease in R_o was accurately predicted throughout the range of diameters by $d^{-3/2}$ ($p<.001$). For the range of muscle fiber diameters studied, approximately a 60-fold change in R_o was observed. Specific membrane capacitance (Cm) increased linearly with d ($p<.001$). Cm of the largest muscle fibers was nearly 7 times greater than the smallest muscle fibers. A linear increase in Cm with d has been reported for vertebrate muscle fibers (Hodgkin and Nakajima. J. Physiol. 221 105 1972), and appears to be due to a contribution of the T-tubules to Cm.

Preliminary measurements of EJP amplitudes for one of the excitatory axons indicate that no significant change occurs as the muscle fibers grow from a 20-60μ diameter to a 160-200μ diameter. Therefore, we expect to find an increase in quantal output which compensates for the decrease in R_o, and increase in Cm, during growth. Previous experiments with lobster muscle fibers have demonstrated a compensatory increase in quantal output during a 2-2.5-fold decrease in R_o (DeRosa and Govind, Science 273 676 1978).

Experiments are currently in progress to determine the effect of retarded muscle fiber growth upon the increase in quantal output, and conversely, the effects of reduced innervation upon muscle fiber growth. (Supported by a grant from the Muscular Dystrophy Association).

172.12 SYNAPTIC DIVERSITY IN THE DIMORPHIC CLAWS OF THE SNAPPING SHRIMP. Christine E. Phillips and DeForest Mellon, Jr. Department of Biology, Gilmer Hall, University of Virginia, Charlottesville, VA 22901.

The first pair of chelipeds in alpheid shrimp are asymmetric, one a large snapper claw and the other a smaller, more slender pincer claw. Removal of the snapper claw results in the transformation of the pincer into a snapper over the next several moult cycles (Wilson, E.B., Biol. Bull. 4 (1903) 197-210). The main closer muscles in both claws are innervated in a similar pattern by 2 excitatory and 2 inhibitory motorneurons, but their synaptic physiology is different. EJPs in the snapper range up to 30mV with few failures and they show facilitation at 10 Hz. Pincer EJPs fluctuate in size (≤12mV) with frequent failures and poor facilitation (Stephens, P.J., Mellon, D., J. Comp. Physiol. 132 (1979) 97-109).

The closer muscles in the two claws are innervated by contralaterally homologous neurons. As noted above, during transformation of the pincer into a snapper, the synaptic physiology of the existing pincer innervation undergoes transformation also. Therefore we were interested to see if the differences in the synaptic physiology of the two claws were reflected in their synaptic untrastructure. Nerve terminals on muscle fibers from the two claws were serially sectioned and compared. Measurements were made of terminal size, area of the terminal devoted to synaptic density and numbers of synaptic vesicles. Nerve terminals were found on the periphery, as well as deep within the fibers, and both types were measured. In snapper fibers the size of the terminal area, as well as the area devoted to synaptic densities, exceeded those in the pincer fibers by as much as a factor of 2. The numbers of synaptic vesicles per terminal was greater in snapper fibers also. By these criteria and in good agreement with its synaptic physiology, innervation of the pincer claw appeared to be in an immature state as compared with that of the snapper.

Supported by grant NS 15006 USPHS to D. Mellon, C.E. Phillips is a University of Virginia, Department of Biology, postdoctoral fellow.

173.1 PROTEIN PHOSPHORYLATION: A POTENTIAL "ACTION-SITE" OF MEMBRANE-LOCALIZED RECEPTORS. Yigal H. Ehrlich. Depts. of Psychiatry and Biochem., Univ. of Vermont College of Med., Burlington, VT 05405

The discovery of high affinity binding-sites for various neurotransmitters and neurohormones was accompanied by the admonition that site-occupancy alone cannot account for receptor function. Thus, it has been postulated that the binding of agonists induces a conformational change, which triggers a chain of events leading to neuronal responses. Such a transducing mechanism is referred to here as an "action site" of the receptor. The cyclic phosphorylation and dephosphorylation of proteins produces rapid and reversible conformational changes which have been implicated in the regulation of numerous neuronal functions. This study was initiated to determine whether endogenous phosphorylation systems in synaptic membranes constitute a target for various neurohormones and neurotransmitters, and thus have the potential for serving as an "action-site" of their respective receptors.

Preparations containing synaptic membranes were obtained from the cerebra, cerebral cortices or neostriata of adult albino rats. Endogenous phosphorylation assays were carried out by incubating the membranes in the presence of γ-^{32}P-ATP, with addition of various agonists and antagonists to the preincubation and/or reaction medium. For analyzing calcium/calmodulin-dependent phosphorylation, membranes were prepared from synaptosomes osmotically shocked in the presence of 50μM $CaCl_2$.

Addition of the potent opiate agonist etorphine or the opioid peptide β-endorphin (1-10 nanomolar) to the reaction mixture resulted in over 200% increase of endogenous phosphorylative activity in the membranes (Ehrlich,Davis,Keen and Brunngraber, Life Sci., In Press). SDS-polyacrylamide gel electrophoresis and autoradiography revealed that the protein bands whose phosphorylation was stimulated by this addition co-migrated with proteins the phosphorylation of which is dependent on calcium ions and calmodulin (Schulman and Greengard, Nature 271:478, 1978). The specific antagonist of opiate receptors, naloxone (1μM), completely blocked the stimulatory effects of β-endorphin and etorphine on protein phosphorylation. Further studies revealed that this endogenous phosphorylation system is affected also by agonists of dopamine, norepinephrine, acetylcholine and benzodiazepine receptors, tested in the presence and absence of the appropriate antagonists. These results are compatible with the hypothesis (Ehrlich, Adv. Exptl. Med. Biol., 116:75, 1979) that conformational changes induced by altered protein phosphorylation may constitute a transducing-mechanism triggered by the interaction of ligands with membrane-localized receptors.

173.3 OPIOID RECEPTORS UNDERGO AXONAL FLOW. W.S. Young III, J.K. Wamsley, M.A. Zarbin* and M.J. Kuhar. Depts. of Pharmacology and Psychiatry, The Johns Hopkins University School of Medicine, Balto., Md. 21205.

Previous studies in our laboratory indicate the presence of opiate receptors on axons of the rat vagus nerve and on other small diameter fibers. These observations led to the suggestion that all or some of these receptors might be undergoing axoplasmic flow and/or axonal or dendritic transport (Atweh et al., Neuropharmacol. 17:65, 1978). We have further examined the distribution of opioid receptors in the rat vagus and elsewhere by in vitro-labeling autoradiography, a very sensitive measure of receptors (Young and Kuhar, Brain Res. 179:255, 1979). For autoradiographic studies, 8-10u sections were preincubated with 100mM sodium and 50uM GTP to rapidly dissociate endogenous ligands. The sections were then incubated with tritiated or iodinated opioid peptides for 40 min at room temperature and given two 5-min washes. Adjacent sections were co-incubated with 1uM naloxone to produce blanks. Autoradiograms were generated by the apposition of emulsion-coated coverslips.

High densities of opiate receptors were found in association with cell bodies in the nodose ganglion and in the vagus nerve trunk in the neck. Thus, opioid receptors appear in all parts of the vagus system; perhaps, particularly, in the sensory part. Ligation of the vagus nerve in the neck led to a striking buildup of receptor binding at the proximal side of the ligation which was distal to the cell bodies in the nodose ganglion. This part of the sensory cell is analagous to the dendrite of the central neuron. The accumulation of binding sites was greater at 24 hrs than at 8 hrs. The roughly estimated flow rate was about 4mm/day although this may be an underestimate. The site appears to be a valid receptor site rather than just a peptide binding site because it binds a variety of radiolabeled agonists and antagonists which are displaced by various opiate antagonists and shows stereospecificity. Agonist binding also shows a GTP shift in the vagus.

Since, after synthesis in the cell body, receptor protein must be moved to distant parts of the cell, it would not be surprising if receptors underwent axonal or dendritic movement. Thus, such movement would be a common property of most or all receptors.

173.4 BIOCHEMICAL AND PHARMACOLOGICAL SIMILARITIES BETWEEN HIGH AFFINITY MU, KAPPA, DELTA AND SIGMA OPIATE RECEPTOR BINDING Gavril W. Pasternak, George C. Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, N.Y., N.Y. 10021

Three irreversible opiates active both in vitro and in vivo have been synthesized: the agonist oxymorphazone and the antagonists naltrexazone and naloxazone. ^{3}H-D-ala-met-enkephalinamide binding in extensively washed brain membranes was reduced following in vitro incubations with 10 μM oxymorphazone (-63%), naltrexazone (-73%), and naloxazone (-69%; all $p<0.001$) while binding in oxymorphone, naltrexone and naloxone treated controls was unaffected. In vivo administration of these newly synthesized compounds significantly lowered receptor binding in washed membranes for over 24h with the decrease slowly disappearing over 3 days. Nonopioid hydrazines were without effect. Oxymorphone was analgesic in only 17% of mice (n=12) after 24h while oxymorphazone remained analgesic in 82% (n=11) for 24h and in up to 50% for 48h. Detailed experiments demonstrated that naloxazone's prolonged inhibition of binding resulted from a relatively selective blockade of high affinity mu, kappa, sigma and delta receptor binding, as demonstrated by Scatchard analysis of the following ^{3}H-ligands: naloxone, naltrexone, diprenorphine, morphine, dihydromorphine, ethylketocyclazocine, met-enkephalin, D-ala-met-enkephalinamide and SKF 10,047. α and β adrenergic, muscarinic acetylcholine, and benzodiazepin receptor binding were not affected by naloxazone pretreatment. Naloxazone administration in vivo markedly attenuated the analgesic potency 24h later of both morphine (ED_{50} increased 12-fold) and ketocyclazocine (ED_{50} increased 7-fold) as compared to naloxone treatment. The analgesic potency of β-endorphin (1μg,icv; $p<0.001$), D-ala-met-enkephalin (50μg, icv; $p<0.01$) and D-ala-met-enkephalinamide (30μg, icv; $p<0.005$) was also markedly reduced in naloxazone, but not naloxone, animals. Despite dramatic effects on analgesia, naloxazone had little effect on morphine lethality compared to naloxone controls (LD_{50} 436$\pm$25 mg/kg and 444$\pm$40 mg/kg respectively). These results raise the possibility that the analgesic properties of the various classes of opiates, enkephalins and endorphins are all mediated through a single population of high affinity binding sites while other pharmacological actions might be produced through different receptor mechanisms.

173.5 INTERACTION OF [^{3}H] CYCLAZOCINE WITH MULTIPLE OPIATE RECEPTOR SITES. Stephen R. Zukin* and R. Suzanne Zukin* (SPON: W. Norton) Dept. of Psychiatry, Mt. Sinai Sch. of Med., New York, N.Y. 10029

Cyclazocine is a psychotomimetic opiate of the benzomorphan group that has been postulated to interact with μ, K, and σ opiate receptors (Martin et al., J. Pharmacol. Exp. Ther. 197, 517 (1976)). In an effort to understand the molecular mechanisms involved in the neuropharmacological actions of this and closely related opiates, we have studied the binding of [^{3}H] cyclazocine to rat brain homogenates. Specific binding, defined as total binding minus binding in the presence of 1 μM nonradioactive cyclazocine, constituted approximately 92% of total binding (at 1.0 nM [^{3}H] ligand) and 67% of total binding (at 100 nM [^{3}H] ligand). Scatchard analyses reveal the interaction of this drug with three distinct binding sites characterized by affinities of 1.2 nM, 9.1 nM and 65 nM (50 mM Tris-HCl buffer, pH 7.4 at 4° C). In contrast, many radiolabelled classical opiates and opioid peptides exhibit biphasic binding, but do not exhibit binding to such a low affinity site. The high and low affinity [^{3}H] cyclazocine sites exhibit differential sensitivities to sodium and also to the selective sulfhydryl reagent N-ethyl maleimide. In addition, all three sites exhibit greater than 50% loss of specific binding following incubation with trypsin (5 μg/ml) for 15 min at room temperature, and greater than 80% loss of specific binding following incubation at 60° C for 15 min in the absence of added reagents. Together, these findings indicate that all three sites have a protein-like component. Competition analyses involving rank order determinations for a series of opiates and other drugs indicate that the cyclazocine binding sites represent, in order of decreasing affinity, the classical opiate receptor (the putative "μ" receptor), a second as yet uncharacterized opiate binding site, and the specific [^{3}H] phencyclidine binding site. Specific [^{3}H] phencyclidine binding can be displaced by cyclazocine (IC_{50} = 200 nM) and by related benzomorphans, but not by morphine or naloxone. We thus propose a common binding site in rat nervous tissue for phencyclidine and some of the benzomorphan opiates. Supported by NIH grant DA-01843.

173.6 EFFECT OF NALTREXONE ON REGIONAL OXYGEN SUPPLY AND CONSUMPTION IN CATS. E. Buchweitz, L. Grandison, and H. R. Weiss*. Dept. of Physiol. & Biophysics, Coll. Med. & Dent. NJ, Rutgers Medical School, Piscataway, NJ, 08854.

In the present study, quantitative regional O_2 consumption and supply were measured in brain during competitive opiate receptor blockade by naltrexone. Fourteen adult mongrel cats, tranquilized with ketamine and anesthetized with α-chloralose, were artificially respired. A left thoracotomy was performed. Left atrial and femoral artery catheters were inserted. ^{141}Ce microspheres (15 ± 3μ in diameter) were injected and cerebral blood flow determined. In seven cats, 1 mg/kg of naltrexone was administered and twenty minutes later ^{85}Sr labelled microspheres were injected. The cats' heads were quickly guillotined in two places and frozen in liquid N_2. Nine different regions were examined. Arterial and venous O_2 saturations were measured in each region with a Zeiss microspectrophotometer. O_2 consumption was determined as the product of flow and O_2 extraction. Blood pressure, heart rate and blood gases were within the normal range, and were not altered by treatment. Cerebral blood flow was significantly decreased to 63% of the control value. Flow to the pons, medulla and hypothalamus were decreased most by treatment. Cerebral oxygen consumption was significantly decreased to 51% of control. O_2 consumption in the pons, medulla and hypothalamus were decreased most by treatment. The effects of naltrexone on oxygen consumption and blood flow were not restricted to brain regions high in opiate receptor binding sites. The effects of naltrexone were more wide spread than the anatomical distribution of receptors would indicate. The O_2 supply/consumption ratio was not altered by treatment. Oxygen supply was adequate to meet metabolic demand throughout the brain during naltrexone treatment. (Supported by NIH grant HL21172 and DA2395).

173.7 PHENOXYBENZAMINE IRREVERSIBLY ALKYLATES OPIATE RECEPTORS IN VITRO BUT NOT IN VIVO. Vina R. Spiehler, Department of Psychobiology, University of California at Irvine, Irvine, CA 92717.

Phenoxybenzamine (PBz) irreversibly displaces ^{3}H-naloxone (Spiehler, V.R., et al., Mol. Pharmac. 14:587, 1978), ^{3}H-dihydromorphine and ^{3}H-D-Ala-enkephalin binding (Robson and Kosterlitz, in Endogenous and Exogenous Opiate Agonists and Antagonists, Pergamon 1980, 107.) from brain homogenates in vitro. This alkylation is prevented by preincubation of the homogenates with levallorphan, dihydromorphine or D-Ala-enkephalin respectively. However, the antinociceptive effect of PBz is antagonized by naloxone given two hours after PBz administration (15 min before the peak antinociceptive effect) rather than before PBz administration. Therefore, the assumption that PBz exerts its opiate-like effects by acting as an irreversible ligand of opioid receptors (Jacob, J., et al. ibid, 99) in vivo, was tested by examining the brains of animals which had received PBz for the ability to bind ^{3}H-naloxone or ^{3}H-morphine at different times after s.c. administration of the drug.

Male Swiss-Webster mice (20-30g) were given 100 mg/kg PBz or saline dilution of solvent s.c. and killed 1/2 and 2 1/2 hrs after treatment. There was no significant difference in ^{3}H-naloxone binding between control and PBz-treated animals after a single wash of the brain homogenate. Therefore, PBz did not alkylate the naloxone binding sites in vivo at the time of the peak antinociceptive effect (2-3 hrs). However, there was an increase in ^{3}H-naloxone binding in the PBz-treated animals as compared to controls ($p < 0.02$) after three washes of the homogenate at 2 1/2 but not at 1/2 hrs after PBz treatment. Similarly, ^{3}H-morphine binding was increased in PBz-treated animals ($p < 0.02$) after three washes at 2 1/2 but not 1/2 hrs after treatment.

The apparent receptor expansion or increased ligand lability after subcutaneous PBz suggests that PBz is not an irreversible alkylating agonist of the opiate receptor in vivo. The long-term effect observed by Jacob et al. (ibid. 99), may be due to PBz enhancement of learning or memory consolidation in their paradigm (Gold, P. and Sternberg, D., Sci. 201: 367, 1978).

173.8 BINDING OF ^{3}H-2-CHLOROADENOSINE (CADO) TO RAT BRAIN SYNAPTIC MEMBRANES. M. Williams and E. A. Risley*. Merck Institute for Therapeutic Research, West Point, PA 19486.

Adenosine (ADO) has a pronounced depressant effect on cell firing and is a potent modulator of tissue cyclic AMP levels in the mammalian central nervous system, actions thought to be mediated via extracellular receptors sensitive to blockade by methylxanthines such as theophylline. The binding of ^{3}H-CADO (specific activity, 12 Ci/mmol), a slowly metabolized analog of ADO, was examined in synaptic membranes prepared from rat brain. Specific binding was only 20% of total unless membranes were pretreated with adenosine deaminase (ADA) to remove endogenous ADO (Bruns, R.F., Fed. Proc., 39: 1010, 1980); following such treatment, specific binding was 90-95% of total and was found to be saturable, reversible, temperature-dependent and sensitive to theophylline (IC_{50} = 9 μM). Two binding sites were observed of Kd's 1.5 and 16 nM with corresponding Bmax's of 224 and 384 fmoles/mg protein. Highest specific binding was found in enriched synaptosomal subfractions (P_2B) of rat brain, a finding consistent with a role for ADO as a neurally active substance. While ADO itself was weakly active (IC_{50} = 20 μM) presumably due to residual ADA activity, CADO was a potent inhibitor of binding (IC_{50} = 2.6 nM). Adenine, inosine, hypoxanthine and d-ribose were without significant effect on binding at 100 μM as were diazepam, α- and β-adrenergic, dopaminergic and cholinergic blocking agents. These findings provide additional evidence for there being a specific extracellular receptor through which ADO modulates nervous tissue function.

173.9 BENZODIAZEPINE (BZ) RECEPTORS ARE INDIRECTLY COUPLED TO GABA RECEPTORS THROUGH ANION RECOGNITION SITES. R.F. Squires, Rockland Research Institute, Orangeburg, NY 10962

Specific binding of ^{3}H-flunitrazepam (^{3}H-FLU) to rat brain membranes has an absolute requirement for an anion. Using both unwashed, and extensively dialysed P2 fractions ^{3}H-FLU binding is greatly enhanced by a variety of anions, but not by GABA alone. Using dialysed membranes, GABA increases ^{3}H-FLU binding 50-60% in the presence of anions, and increases their affinities for anion recognition sites. Conversely, a group of GABA mimetics including THIP, isoguvacine (IGV) and piperidine-4-sulfonic acid (P4S) decrease the affinities for anions without greatly affecting maximum ^{3}H-FLU binding. These effects of THIP, isoguvacine and P4S are fully reversed by GABA in a competitive way. THIP, P4S and IGV are pure GABA antagonists in this system but are pure GABA agonists electrophysiologically. The affinity constants for chloride, bromide and iodide are increased from about 4 mM to near 40 mM in the presence of THIP (a maximal effect). Citrate, maleate, phosphate and bicarbonate are more potent promoters of ^{3}H-FLU binding with Kd values near 1 mM, which are increased 4 to 10-fold maximally by THIP or P4S. In calf brain chloride ion promotes ^{3}H-FLU binding with higher affinity in hippocampus and cerebellum (Kd= 2mM) than in cortex (Kd=4mM). Thip increases the Kd for chloride about 12-fold in cortex and cerebellum but only 6 fold in hippocampus. Hill coefficients for chloride are less than unity in all three calf brain regions. The potent activating effect of bicarbonate is of special interest in view of the anticonvulsant effects of carbonic anhydrase inhibitors and CO_2, and the ability of bicarbonate to substitute for chloride in the generation of inhibitory post-synaptic potentials (IPSPs). At least 25 anions can promote ^{3}H-FLU binding. However, several of these do not substitute for chloride ion in IPSP generation probably because they are too large, diffuse too slowly, or act as chloride antagonists. Several anions, including chloride, bromide and bicarbonate, exhibit "flat" concentration-response curves with Hill coefficients less than unity providing further evidence for two or more anion recognition sites giving rise to multiple BZ/ion/GABA receptor complexes. Although many GABA receptors are apparently not coupled to BZ receptors, the pervasive effects of GABA receptor active substances on ^{3}H-FLU binding, suggest that virtually all BZ receptors are coupled to GABA receptors which serve to regulate a common ionophore. Anion recognition sites seem to be "sandwiched" between GABA receptors on one side and a BZ receptor on the other, with little direct interaction between GABA and BZ receptors. I speculate that the "endogenous ligand" for the BZ receptor is an excitatory neurotransmitter mediating anxiety, some convulsive disorders, wakefulness and fine motor coordination, and is specifically counterbalanced by GABA.

173.10 [^{3}H]DIAZEPAM BINDING IN DISSOCIATED PRIMARY CORTICAL CELL CULTURE: A PHARMACOLOGICAL CHARACTERIZATION. P. Mallorga,* J. F. Tallman, R. C. Henneberry* and D. W. Gallager. Biological Psychiatry Branch, NIMH, Bethesda, MD 20205 and Molecular Biology Lab., NINCDS, Rockville, MD 20852

Binding of [^{3}H]diazepam was measured in membranes prepared from fetal rat cortical tissue grown in dissociated cell culture. [^{3}H]Diazepam binding was pharmacologically characterized by its ability to be displaced by the centrally active benzodiazepine, clonazepam, and by the centrally inactive benzodiazepine, RO5-4864. In these cultures total [^{3}H]diazepam binding increased with age in culture from 214 fmol/mg protein on Day 5 to 447 fmol/mg protein on Day 11 (measured at 5 nM [^{3}H]-diazepam). When cultures were treated with an antimitotic agent, cytosine arabinoside, a "neuronal-enriched" culture was obtained. 5 nM [^{3}H]diazepam binding on membranes from these "neuronal-enriched" cultures was maximally displaced by 10^{-7} M clonazepam (K_i = 5 x 10^{-9}), while RO5-4864 had little potency at this concentration (K_i >10^{-5} M). This is similar to pharmacology observed in adult rat cerebral cortex. In contrast, membranes obtained from peripheral tissue and non-neuronal cultures of rat C_6 glioma and NB_2A neuroblastoma cell lines also exhibit [^{3}H]diazepam binding, but this binding is displaced maximally by 10^{-7} M RO5-4864 (apparent K_i = 5 x 10^{-9} M) and only slightly displaced by 10^{-7} M clonazepam (apparent K_i = 2 x 10^{-6} M). Thus, the ratio of 10^{-7} M clonazepam displaceable binding to 10^{-7} M RO5-4864 displaceable binding was chosen to characterize the type of [^{3}H]diazepam binding. Neuronal enriched cultures had a ratio of clonazepam (10^{-7} M)/RO5-4864 (10^{-7} M) displaceable binding of 2.2 which remained constant at increasing age in culture. If primary cell cultures were not treated with antimitotic agents resulting in the apparent overgrowth of non-neuronal elements, total [^{3}H]diazepam binding at 11 days in culture was 294 fmol/mg protein (measured at 5 nM [^{3}H]diazepam) and a ratio of clonazepam (10^{-7} M) displaceable to RO5-4864 (10^{-7} M) displaceable binding of 0.88. These data suggest that clonazepam displaces primary neuronal [^{3}H]diazepam binding while RO5-4864 displaces primary non-neuronal binding.

173.11 RAPID REDUCTION OF ^{3}H-DIAZEPAM BINDING IN CULTURED HIPPOCAMPAL CELLS. C.R. Walker and J.H. Peacock. Dept. of Neurology, Stanford University Medical School, Stanford, CA 94305.

Metrazol or electrically induced epilepsy in rats increases ^{3}H-diazepam (Dz) binding in brain tissue within minutes. These changes return to normal within 1 hr. and are due to an increase in receptors. These data suggest that the Dz receptor in brain can react rapidly to physiological changes.

We have found a rapid and reversible decrease in ^{3}H-Dz binding in embryonic mouse hippocampal cells in culture after incubation in serum free media. A loss of 75-80% of initial ^{3}H-Dz binding occurs within 1 hr. Recovery of 50% is found within 1 hr. and complete recovery after 24 hr. in media containing serum. The initial 50% recovery can occur in the presence of 10 µM cycloheximide, but the requirement for protein synthesis for complete recovery has not been determined because of cycloheximide toxicity.

Metrazol, 20 mM, antagonizes the loss by 30% but does not affect ^{3}H-Dz binding in serum incubated cells. Dz, 20 mM, has no effect on the loss of binding during serum free incubation. Interestingly, sodium bicarbonate, a component of the serum containing media also antagonizes the loss of binding by approximately 10-20%.

A kinetic analysis of ^{3}H-Dz binding to serum free incubated cells suggests that both the binding affinity and number of binding sites are decreased. This may account for the two component recovery of binding. Serum free media may cause a conformational change in the binding site that results in a decrease in binding affinity and also increases the degradation of the binding site. Serum replacement may allow the binding site to change conformation and restore part of the loss. New binding sites would be required to replace those lost due to degradation.

Experiments with the glial cell line, C6, demonstrate an association between dynamic cell shape changes and ^{3}H-Dz binding. Within 30 minutes after serum removal, cells change from a flattened cuboidal shape to an ellipsoid shape with bipolar processes. This dramatic change in cell shape is accompanied by a rapid and reversible loss in ^{3}H-Dz binding within 1 hr.

In summary, the binding site for diazepam on cultured hippocampal cells and C6 can be rapidly changed by incubation in serum free media. The binding kinetics suggest both a decrease in binding affinity and number of binding sites. This phenomenon may represent membrane alterations that affect both the affinity of the binding site and its stability.

173.12 SOLUBILIZATION OF THE NEUROLEPTIC BINDING SITE OF HUMAN BRAIN. A. Davis, B.K. Madras and P. Seeman, Psychopharmacology Section, Clarke Institute of Psychiatry, Toronto, Ontario, M5T 1R8.

Dopamine (D-2) receptors were successfully solubilized from human putamen using the non-ionic detergent, digitonin. The ligand used was ^{3}H-spiperone with 1 µM (+)-butaclamol to define specific binding. A 1% (w/v) solution was added to a membrane preparation of combined mitochondrial (P_2) and microsomal (P_3) pellets, incubated at 0°C for 30 min and then centrifuged at 105,000 x g for 60 min (according to the method of Madras et al., 1980). Electron microscopy indicated the supernatant was free of membrane fragments. Membrane-bound receptors were assayed by glass-fibre filtration and soluble receptors by Sephadex G-50 column chromatography. Total recovery of receptor protein was 10-15% with a specific activity (fmol ^{3}H-spiperone bound/mg protein) approximately 30% that of the membranes. The drug specificity of the soluble binding closely resembled that of the membrane site (see Table). The stereoselectivity of the receptor was maintained upon solubilization with (+)-butaclamol being at least 350-fold more potent than (-)-butaclamol. A close correlation was also observed between these IC_{50} values and those previously obtained on the dog striatum neuroleptic binding site.

	IC_{50} (nM)

174.1 POLYPEPTIDE COMPOSITION AND KINETICS OF SCa AND SCb IN SCIATIC NERVE MOTOR AXONS AND OPTIC AXONS OF THE RAT. I. G. McQuarrie, S. T. Brady* and R. J. Lasek. Department of Anatomy, Case Western Reserve University, Cleveland, Ohio 44106.

Previous work from this laboratory has defined the composition and kinetics of the 2 slowest waves of axonal transport in guinea pig optic axons, using SDS polyacrylamide gel electrophoresis (PAGE). Each wave contained a unique constellation of proteins. For example, the slowest wave (SCa) was characterized by the neurofilament triplet composed of polypeptides with molecular weights of 200K, 145K and 68K, whereas the faster wave (SCb) was characterized by actin (43K) and clathrin (170K). The 2 waves were sufficiently coherent and had sufficiently different rates that they could be completely separated by using long injection-sacrifice intervals.

In rat optic axons, the composition and kinetics of SCa and SCb are similar to those found in guinea pig optic axons. However, detailed study of rat sciatic nerve motoneurons has revealed a number of differences. For example, the rates of SCa and SCb are faster than in optic axons. More importantly, the 2 waves overlap and cannot be separated at long injection-sacrifice intervals. Quantitative analysis of the movements of each SCb band seen on SDS-PAGE fluorographs demonstrates that they form a trailing wave which moves with SCa and is separated from the primary SCb wave by a valley. Three polypeptides of SCb are exceptional in that they remain confined to the primary SCb wave.

When the SCb rate component of motoneurons is further analyzed by separating the individual polypeptides on 2-dimensional PAGE, the composition is very similar to that seen in optic axons: there is no evidence of the neurofilament triplet and all of the traditional SCb polypeptides are seen (except for 60K). There is a single additional major labeled spot which co-migrates with cold cycled beta tubulin from guinea pig brain and also co-migrates with the beta tubulin stained spot in rat peripheral nerve. This suggests that beta tubulin, which is confined to SCa in optic axons, has a leading edge extending into the SCb wave in motoneurons. Quantitative analysis of the movement of the 53K band supports this conclusion.

Several lines of evidence now suggest that the SCb wave represents movement of the axoplasmic matrix, characterized in particular by actin microfilaments. The present study demonstrates that a component of SCb can move distally in the axon in association with SCa over long distances. This suggests that in motoneurons there may be a particularly intimate association between the axoplasmic matrix and the microtubule-neurofilament network which is the structural correlate of SCa.

174.2 AXONAL TRANSPORT OF MICROTUBULE-ASSOCIATED PROTEINS KNOWN AS tau FACTOR. M. Tytell, S. T. Brady*, and R. J. Lasek. Dept. of Anatomy, Case Western Reserve Univ., Cleveland, OH 44106.

The ability of a neuron to extend and maintain an axon is dependent on the structural framework provided by the cytoskeletal elements, microtubules and neurofilaments. The proteins which constitute those elements, tubulin and the neurofilament triplet, are continuously synthesized in the soma and delivered to the axon exclusively as constituents of the rate component of axonal transport called Slow Component a (SCa) (Hoffman and Lasek, J. Cell Biol. 66:351, 1975; Tytell and Lasek, Soc. Neurosci. Abs. 4:37, 1978), which has a rate of 0.3-1.0 mm/day and is the slowest of the rate components. When tubulin and the neurofilament proteins are pulse-labeled, one can observe that they move within the axon as a well-defined peak of radioactivity that changes little in shape as it travels. This suggests that tubulin and the neurofilament proteins are transported as intact structures which together form the microtubule-neurofilament network of the axon (ibid.). If tubulin is transported as microtubules, then microtubule-associated proteins (MAPs) should be included in SCa. We analyzed the proteins of ^{35}S-methionine-labeled SCa in the guinea pig optic nerve using phosphocellulose column chromatography and one- and two-dimensional polyacrylamide gel electrophoresis. Proteins corresponding to the MAPs known as tau factor were identified in SCa. However, we have been unable to detect any proteins in SCa which correspond to the high molecular weight MAPs.

These observations suggest that the tau proteins are the primary MAPs transported as an integral part of axonal microtubules. If the high molecular weight MAPs are also transported as part of axonal microtubules, they must be present in exceedingly small amounts; they are clearly not present in the quantities commonly observed in preparations of whole brain microtubules. If this observation is supported by subsequent analyses, then we must question the current assumption that brain microtubules are homogeneous. Axonally transported microtubules may represent a distinct subset of the total population of microtubules prepared from whole brain. This could be explained in either of two ways: (1) neuronal microtubules may be different from glial microtubules or (2) the composition of microtubules may vary in different regions of the neuron. The first alternative has some support from the observation that only tau factor and not high molecular weight MAPs have been found in preparations of microtubules from homogeneous cell lines derived from hamster nervous system (Nagle et al., Cell 12:573, 1977; Solomon et al., Cell 18:431, 1979). It is possible that this heterogeneity of microtubules with respect to their associated proteins may represent an adaption to the specific functions of microtubules in different cell types or in different regions of the same cell.

174.3 CALMODULIN AND CALCIUM ACTIVATION OF TUBULIN ASSOCIATED CA-ATPASE. S. Ochs and Z. Iqbal. Dept. of Physiology and Medical Biophysics, Indiana University School of Medicine, Indianapolis, IN 46223 USA

In the transport filament model of axoplasmic transport in nerve, the transport filaments and the materials they carry are moved down along the microtubules by their side-arms with the required energy supplied by ATP. A sizeable amount of Ca-Mg ATPase is found in nerve (Khan and Ochs, Brain Res. 81:413, 1974) which we recently showed to be activated by calmodulin (Iqbal, Garg and Ochs, Soc. Neurosci. Abs. 5:60, 1979) at micromolar concentration levels of Ca^{2+}. Calmodulin activates a wide variety of enzymes under the control of Ca^{2+} in micromolar concentrations, a level of Ca^{2+} believed to be present in the axoplasm. We report that the Ca-ATPase associated with tubulin, which could be a part of the side-arms, is activated by calmodulin and Ca^{2+} at micromolar concentrations. Use was made of 2 or 3 cycles of cooling and warming to purify tubulin from cat brain by the method of Shelanski or Borisy, the latter giving a higher yield of Ca-ATPase associated with the tubulin. The Ca-ATPase associated with the purified tubulin, assessed by colorimetric measurement of P_i, showed a broad bell-shaped increase on addition of Ca^{2+} over the range of 10^{-9} to 10^{-4}M with the highest activity found with 10^{-6}-10^{-7}M Ca^{2+}. The addition of 10-100 ng of purified mammalian nerve calmodulin (Iqbal and Ochs, These Proceedings) augmented the activity of the Ca-ATPase a little but irregularly. There was also an inhibiting effect of the added calmodulin at the higher concentration of 10^{-4}M Ca^{2+}, a phenomenon seen for calmodulin activation of other enzymes. It is likely that variation in the activation of Ca-ATPase by added calmodulin is due to the presence of different amounts of calmodulin in different preparations. A small but significant amount of a protein band comigrating with calmodulin was observed when 2-cycle purified tubulin preparation was analyzed on 12.5% acrylamide gels containing SDS. Further evidence for the presence of calmodulin attached to the tubulin associated Ca-ATPase is that the addition of trifluorperazine (TFP) caused a marked decrease in Ca-ATPase activity, the TFP binding to calmodulin and thus preventing it from activating the enzyme. The calmodulin may be bound to the tubulin associated Ca-ATPase in the course of its isolation or it may actually be a part of the Ca-ATPase enzyme. We can consider that the transport filament with Ca^{2+} present can activate the calmodulin-Ca-ATPase complex of the side-arm in the latter case, or that calmodulin is part of the transport filament serving to locally activate the Ca-ATPase of the side-arms in the process of its movement. 174.4 DEOXYRIBONUCLEASE I AND A γ-GLOBULIN BLOCK FAST AXONAL TRANSPORT WHEN INJECTED INTO THE CELL BODY OF AN IDENTIFIED SEROTONERGIC NEURON OF APLYSIA. David A. Harris,* Daniel J. Goldberg, Beverly W. Lubit, Ariel A. Sherbany* and James H. Schwartz. Div. Neurobiol. & Behavior, Depts. Physiol. and Pharmacol., Columbia Univ., Coll. Physicians & Surgeons, New York, N. Y. 10032.

Actin is presumed to function in a variety of processes involving intracellular motility, but evidence is lacking that it plays a role in fast axonal transport. Several proteins have been described that block the polymerization of actin, and these can be administered by pressure injection directly into the giant cerebral neuron (GCN). Since we have previously established that 5-HT is packaged into vesicles which move rapidly down the axons of this identified serotonergic cell, we have used movement of the transmitter to test for inhibition of fast transport.

When we injected DNase I intrasomatically into GCN and two hours later injected ^{3}H-5-HT, the subsequent movement of neurotransmitter into axons was inhibited. Maximum inhibition occurred with an amount of DNase equivalent to the molar amount of actin estimated to be present in the neuron. We presume that DNase interferes with transport by disrupting microfilaments within the injected neuron, since the enzyme has been shown to depolymerize F-actin by combining specifically and stoichiometrically with actin monomers (Hitchcock & Lindberg, Cell, 7, 531, 1976). We found DNase to be a much less effective inhibitor when it had been incubated before injection with G-actin purified from rabbit skeletal muscle.

Norberg, Thorstensson, Utter & Fagraeus (Eur. J. Biochem., 100, 575, 1979) have reported that normal serum from rabbits and other species contains an actin-depolymerizing factor (ADF). We have confirmed the presence of this heat-labile activity in γ-globulin fractionated by ion-exchange chromatography or gel filtration, and have found by viscometry that these preparations profoundly reduced the extent to which actin polymerizes in the presence of salt. When injected into GCN, these preparations of γ-globulin also blocked transport of 5-HT. Because the protein fractions used are still impure, we cannot be certain that the inhibition of transport obtained is caused by ADF, rather than by some other as yet unrecognized activity.

Although intracellular injection of macromolecules as specific pharmacological agents represents a novel probe of the biochemistry of fast axonal transport, these experiments do not yet permit the conclusion that actin functions directly in translocation of organelles along the axon. Just as studies with colchicine indicate that microtubules are necessary for transport, but do not specify a molecular role, experiments with agents that depolymerize microfilaments do not specify whether actin's role is dynamic or only cytoskeletal.

174.5 SPECIFIC AXONAL TRANSPORT OF ^{3}H-HISTAMINE AFTER INTRASOMATIC INJECTION OF C2, AN IDENTIFIED APLYSIA NEURON. Hideki Gotoh* and James H. Schwartz. SPON. Klaudiusz Weiss. Div. Neurobiol. & Behavior, Depts. of Physiol. and Neurol., Columbia Univ. Coll. Physicians & Surg., New York, N. Y. 10032.

Previous work with identified cholinergic and serotonergic neurons has indicated that one determinant of neurotransmitter specificity is a characteristic vesicle that serves to package the transmitter and to mediate its rapid axonal transport. We have now begun to examine this idea with C2, a putative histaminergic neuron in the cerebral ganglion of Aplysia californica (see Weinreich in Osborne, Biochemistry of Characterised Neurons, 1978).

We first injected the fluorescent dye, Lucifer yellow, to confirm that C2 has three axon branches. Next we injected ^{3}H-histamine into C2's cell body. Primarily using the axon in the posterior lip nerve for analysis, we found that the distribution of radioactivity in sequential one millimeter segments of the nerve at 1, 2, 3, 4 and 6 hours after injection showed the characteristics of fast transport, not of diffusion. ^{3}H-histamine was also found to accumulate rapidly behind a ligature tied in the lip nerve. The movement of ^{3}H-histamine, estimated at about 50 mm/day at 22^{0} C, was inhibited by colchicine and was slower at lower temperatures. We also injected ^{3}H-choline and ^{3}H-serotonin in order to test the specificity of transport: both substances appeared to move along the axon only by diffusion. A further indication for the specificity of transport was provided by a comparison of the amounts of ^{3}H-histamine and its degradation product (which Weinreich, 1979, has identified as γ-glutamylhistamine) in axons and cell body 6 hours after injection. Essentially all of the radioactivity in axons was shown to be in the form of histamine, whereas equal amounts of the labeled amine and its metabolite remained in the cell body, an indication that ^{3}H-histamine but not γ-glutamylhistamine is selectively exported.

We propose that in C2, as in other identified giant neurons, the transmitter is transported selectively because it is packaged in specific vesicles. Electron microscopy has revealed that C2 has characteristic large dense-cored vesicles. We are now studying the distribution of silver grains over electron microscopic radioautographs of C2's axons and cell body after intrasomatic injection in order to identify the organelles that transport ^{3}H-histamine.

174.6 REGULATION OF FAST AXONAL TRANSPORT OF SEROTONERGIC VESICLES IN AN IDENTIFIED INVERTEBRATE NEURON. Daniel J. Goldberg and John M. Aletta*, Dept. Pharm. and Div. Neurobiol. & Behav., Columbia U. Coll. P.& S., New York, N.Y. 10032 U.S.A.

Little is known of how the amount and composition of material delivered to the synapse by fast axonal transport is regulated. Modulation of fast transport in mature neurons has been demonstrated, other than in pathological conditions, mainly during axonal regeneration. The transection is usually close enough to the soma to disconnect most, or all, of the synapses, and there is typically a decrease in the transport of the transmitter or its synthetic enzymes.

We are studying the regulation of fast transport in GCN, a giant identified serotonergic neuron in the sea hare, Aplysia californica. Transport of the serotonergic storage vesicle is measured by labeling it with ^{3}H-serotonin that is micro-injected by pressure into the soma. GCN has only 1 axon which, just before exiting the ganglion, bifurcates into branches of similar diameter which run in different nerves and terminate on different targets. Normally, one of the nerves (connective) transports about twice as much ^{3}H-serotonin as the other (lip nerve). We had found that in vitro (synapses detached from nerves), when the connective was was transected close to the ganglion, within a few hours the ^{3}H-serotonin that would normally be transported in the connective was diverted into the lip nerve. Thus, the lip nerve was shown to be capable of transporting 2-3 times its normal amount of ^{3}H-serotonin (Goldberg, et al., J. Physiol. 259:473, 1976). As a first step in studying the regulation of transport, we have now been transecting the connective in vivo, so that the lip nerve synapses remain intact and receive much more than their normal complement of transported material. We find that, within a few days, the cell reduces the export of ^{3}H-serotonin so that the lip nerve is transporting close to its normal amount of transmitter.

One day after transection of the connective, total export of ^{3}H-serotonin from the soma was slightly decreased from normal but the lip nerve was still transporting twice its normal amount. By 3 days post-operation, ^{3}H-serotonin export was reduced to the point that transport in the lip nerve was only 19% greater than normal. No further change was seen at 7 days. The reduction in ^{3}H-serotonin transport was not the result of a general decrease in synthetic activity of the cell, since protein synthesis at 3 days post-operation, measured by incorporation of ^{3}H-leucine, was not different from normal. These data indicate that the cell may regulate its output of transmitter storage vesicles so as to maintain the amount received by synapses within narrow limits. Since the axon is capable of transporting an amount of material far in excess of these limits, the modulation of vesicle output may be elicited by events at the synapse.

174.7 DIFFERENTIAL TRANSPORT OF PEPTIDES IN PEPTIDERGIC NEURONS. S. Arch and T. Smock.* Biology, Reed College, Portland, OR 97202, and Physiology, Univ. of Calif. School of Medicine, San Francisco, CA 94143.

The bag cell organs of the central nervous system of Aplysia californica devote a considerable proportion of their protein synthetic activity to the production of two peptide species. After short-term incubation in radiolabeled leucine, extraction in acetic acid, and separation by isoelectric focusing PAGE, the two peptides together comprise about 40% of the labeled protein. One of these peptides is the alkaline egg-laying hormone (ELH), the other is an acid molecule (AP) with no presently known function. Both peptides are associated with particulate structures (presumably vesicles), transported by a colchicine-sensitive process, and are secreted (Stuart et al., J. Neurophysiol. 43:488, 1980) upon bag cell depolarization. The bag cells would appear, therefore, to be useful for determining if there are regulatory processes that differentially affect the disposition of two secretory peptides. To begin examining this question, the stoichiometries between the peptides in the cell somata and in transport were compared. In the absence of differential affects, the stoichiometry in the neurites should be the same as the stoichiometry in the cell somata. This is not the case. While the ELH/AP ratio is approximately 1.1 in the cell somata following a 6 hr pulse of labeling, the ratio in the neurites, reflecting the earliest evidence of labeled peptide transport, is approximately 0.6. At subsequent times (6, 12, 18, and 24 hr) the ELH/AP ratio in the neurites approaches the initial soma value. These observations indicate that AP enters transport earlier than does ELH. As a consequence, it should be that the labeled ELH/AP ratio will vary along the length of neurites. When this is examined by analyzing sequential segments of neurites, the most distal segment shows a low ELH/AP ratio while increasingly proximal segments show values increasing toward unity. The implication from these studies is that the two peptides are not disposed coordinately following their synthesis. Further study of this phenomenon will require evaluation of at least 3 possible explanations: 1) Molecular queuing at the time of vesicle filling favors insertion of newly synthesized AP over that of ELH, 2) the peptides are enclosed in different vesicle types and the type containing AP enters transport earlier than that containing ELH, or 3) the peptides are characteristic products of different subpopulations of bag cells.

174.8 INTRAOCULAR INJECTION OF KAINIC ACID INDUCES MODIFICATIONS OF FAST AXOPLASMIC TRANSPORT IN RAT OPTIC NERVE. P. Gomez-Ramos, J.A. Donoso and F.E. Samson. Ralph L. Smith Research Center, Univ. of Kansas Med. Ctr., Kansas City, Ks. 66103.

Kainic acid (KA), an analogue of glutamate, is an extremely potent excitant of mammalian CNS and produces a selective destruction of neurons receiving glutaminergic innervation due to excessive depolarization. Intraocular injections of KA affect amacrine and bipolar cells of the retina and produce blindness in a few minutes. Since KA induces dramatic changes in the activity of the cells that innervate retinal ganglion cells, we decided to examine if under these conditions, fast axoplasmic transport (FAXT) in the optic nerve was affected.

The rate of FAXT in the optic nerve of young adult rats is 8.86 + 1.66 mm/hr determined by means of ^{3}H-proline (10 μCi) injections in the vitreous humor. To characterize the action of KA on FAXT we injected 250 nmols of KA in the rat eye at the same time with ^{3}H-proline and no FAXT of labeled material was observed in the optic nerve and optic tract two hours later. As little as 5 nmols of KA produces the same effect. When ^{3}H-proline was injected in the eye 1 hour prior to KA, the labeled material already present in the optic nerve at the time of the KA injection was observed to move at a normal rate along the optic nerve and optic tract, but no more labeled material moved out of the retinal ganglion cells perikarya during at least 24 hours. One week after the injection of 5 nmols of KA, the profile of labeled material 2 hours after ^{3}H-proline injection is similar to controls, thus indicating a recovery from the effects of KA

We conclude that KA inhibits the initiation of FAXT in retinal ganglion cells for a period of time. This inhibition appears not to be caused by the actual destruction of some retinal cells since it is transitory and probably results from the excitatory action of KA on glutamate innervated retinal cells.

174.9 COMPUTER GENERATION OF TYPICAL AXOPLASMIC TRANSPORT ISOTOPE DISTRIBUTIONS USING THEORETICAL PRINCIPLES OF LIQUID CHROMATOGRAPHY. G. W. Gross,* G. H. Stewart,* B. Horwitz, (SPON. J. F. Hines), Departments of Biology, Chemistry and Physics, Texas Woman's University, Denton, TX 76204

We have used simple mass flux equations from liquid chromatography to generate the characteristic isotope distribution profiles created by rapid axoplasmic transport in C-fibers (1,2). Our purpose is to test the compatibility of the empirical data with chromatographic principles and to systematically investigate the validity of various assumptions about the molecular events underlying the transport phenomenon. We have assumed that all rapid transport takes place as free molecules and molecular complexes in a liquid phase from which material is lost by deposition into stationary, slowly moving or retrograde phases. Diffusion constants control mass transfer between these phases. The quantitative profile data obtained in the garfish olfactory nerve (1,2) have provided accurate information on peak spreading, peak assymetry, tailing and transport velocities. Longitudinal diffusion, which is reflected in the gaussian spread of the peak, is a sum of eddie diffusion, molecular diffusion and velocity profile effects. By plotting the peak variance at $h/\sqrt{e}$ against time, the overall diffusion constant can be obtained from the slope ($\Delta\sigma^2=2D\Delta t$). We find that $D_{(fast)}=3\times10^{-6}$ cm^2/sec and $D_{(slow)}=10^{-8}$ cm^2/sec indicating that they seem to occur in different environments. If we assume molecular diffusion to be the dominant spreading term, we can regenerate the empirical data with a surprisingly small set of specific variables. However, the assumption of diffusion in an aqueous phase appears to be necessary.

The agreement of computer generated profiles with the actual data is encouraging and supports our contention that the chromatographic model is a valuable tool for investigating the mechanism of axoplasmic transport.

174.10 Anterograde transport of wheat germ agglutinin: Direction of transport dependent on selective binding. T.P. Margolis*, C.M.-F. Marchand, H.B. Kistler, Jr.* and J.H. LaVail. Department of Anatomy, U.C.S.F., San Francisco, CA 94143.

Previous studies have indicated that the specific binding of wheat germ agglutinin (WGA) to neuronal surface membranes results in the retrograde axonal transport of this lectin. We have investigated the axonal transport of ^{125}I-WGA in the chick visual system and found that affinity purified ^{125}I-WGA is transported in an anterograde direction only. WGA was iodinated using a modification of the chloramine-T method of Hunter and Greenwood and applied to a Bio-Gel P-2 column to separate low molecular weight components. This sample was further purified by affinity chromatography on an N-acetylglucosamine (GlcNAc) column. The"active"fraction was eluted with 1 M GlcNAc and dialyzed extensively against 10 mM phosphate buffer (pH 7.5) to insure separation of the sugar from the lectin binding site. SDS gel electrophoresis and subsequent autoradiography of the gel served to identify the "active" fraction as a single band which co-migrates with cold WGA at 17,000 daltons.

Within 5 days of its preparation, 2-5 μCi of the "active" fraction (sp. act. 0.25 μCi/μg) were injected into the vitreal chamber of one eye in each of 5 chicks. After 21-23 hrs, the animals were fixed, and the eyes, superior cervical ganglia (SCG) and brains were prepared for autoradiography. The retinas and irises of all animals were heavily labeled. In addition, label was found over the Stratum opticum and layers a-f of the Stratum griseum et fibrosum superficiale, i.e., the retinoreceptive layers of the contralateral optic tectum. There was no labeling of the ipsilateral optic tectum. Moreover, neither the isthmo-optic nuclei nor SCGs contained labeled cells.

As a control, a fraction of the iodinated sample that failed to bind when passed over the affinity column was injected into one eye of each of 3 chicks. In all 3 animals, no labeling of the contralateral optic tectum was apparent, but a small population of labeled cells was identified in the ipsilateral SCG. The contralateral SCG contained no labeled cells. SDS gel electrophoresis and subsequent autoradiography of this fraction established multiple radioactive bands, one of which co-migrates with cold WGA.

In conclusion, in the chick visual system 1)"active"^{125}I-WGA is transported by retinal ganglion cells in an anterograde direction, 2)"active" ^{125}I-WGA does not appear to be transported in a retrograde direction by SCG or isthmo-optic neurons, and 3) there is a component of the iodinated sample, presumably "inactive" WGA, WGA fragments or a contaminant, that does not bind GlcNAc but is transported in a retrograde direction by SCG neurons. 175.1 EXTRAHIPPOCAMPAL CORTICAL PROJECTIONS FROM THE ENTORHINAL CORTEX IN THE RAT AND MONKEY. K.C. Kosel and G.W. Van Hoesen, Depts. of Anat. & Neurol., Univ. of Iowa, Iowa City, IA 52242.

In recent years it has been documented in several species that the subicular cortices are the major output structures of the hippocampal formation. In fact, these cortices account for nearly all of the diversity of hippocampal output, since the Ammonic pyramids contribute largely to only intrinsic and commissural circuitry within the hippocampi, and one major extrinsic projection to the septum. The subicular cortices project widely to several cortical areas, but have an especially strong projection to the deeper layers of the nearby entorhinal cortex. This reciprocates an entorhinal projection which terminates in the molecular layer of the subiculum. We have noted consistently in HRP experiments that when cortical injections are made lateral to the rhinal sulcus, a distinct pattern of labeled neurons within the entorhinal cortex can be observed. This suggests that the direct subicular projections to the cortex may represent only one of many potential output pathways of the hippocampal formation, and that others may relay in the entorhinal cortex. In both rats and monkeys, small injections of 20% horseradish peroxidase (Sigma type VI) were made into areas 35 and 36. After a 24-48 hour survival period, the animals were perfused with aldehyde fixatives and reacted according to Mesulam's tetramethyl benzidine procedure. The sections were examined microscopically using bright and darkfield illumination. In the rat, labeled neurons were observed in layers II and III of the lateral entorhinal cortex. Consistent with the topography of this cortex, they were more numerous ventrally and diminished in number dorsally. In the monkey, labeled neurons were also observed in the lateral entorhinal and prorhinal cortices. However, unlike the rat, these neurons were largely confined to layer III, although occasional labeling was observed in deeper layers. In both species labeling in the medial part of the entorhinal cortex was not observed. Thus, these results suggest that the lateral entorhinal cortex projects not only to the hippocampus and dentate gyrus, but to adjoining parts of the neocortex as well. These projections provide an additional indirect output pathway for the hippocampal formation for the influence of cortical areas in the temporal region. (Supported by grant NS 14944.)

175.2 LIMBIC CORTICAL FORMATIONS OF TEMPORAL LOBE IN THE BOTTLENOSE DOLPHIN. Myron S. Jacobs, Peter J. Morgane and Willard L. McFarland. Dept. Pathobiol., NYU Coll. Dent., New York, NY 10010; Worcester Found. Exp. Biol., Shrewsbury, MA 01545; NIH, Bethesda, MD 20014.

In the temporal lobe (TL) of land mammals, the entorhinal area and presubiculum are transitional neocortical formations of the limbic lobe that relay information to the hippocampus from diverse sources. As part of an overall study of the limbic cortical formations in the purely aquatic cetacean Order of mammals, we were particularly interested in TL limbic formations because of the small size, both absolutely and relatively, of the elements of the temporal archicortex (fascia dentata, hippocampus and subiculum). Overall, the periarchicortical entorhinal area (Ent) and presubicular area (Psb) in the dolphin are far better developed than the archicortical formations. The Ent begins considerably more anterior to the Psb, and the latter terminates more posterior to the Ent than usually occurs in land mammals. Considerable cytoarchitectonic differentiation of the Ent is present. Anteriorly it exhibits a medial transition with the periamygdalar area (PAm) of the paleocortex and a lateral transition with typical 6-layered neocortex. Distinct medial and lateral subareas of Ent are present, with the cortical plate being about 40% wider and the clearing zone (lamina dissecans, LmDis) between superficial and deep cell layers more distinct medially than laterally. At mid-temporal levels the Ent exhibits, medially, a partial superlamination over the subicular plate, which has replaced the PAm. The superficial cell zone is broken and comprised of medium sized cells. The deep cell zone is more regular, wider and contains larger cells. Laterally, the Ent exhibits further architectonic division into two subareas which differ chiefly in the distinctness of the LmDis, in the differentiation as well as presence or absence of breaks in the superficial cell zone, and in the degree of compactness of the deep cell zone. Further posteriorly in the TL, the Psb appears between the subiculum and the medial Ent and gradually expands mediolaterally as the Ent attenuates. It differs from the medial Ent by having a uniformly narrower cortical plate, by the presence of more densely packed, smaller cells in its superficial cell zone and by a less prominent LmDis. Superficial papillarity, a characteristic of the Psb in many terrestrial mammals, is absent. Although numerous differences in cytoarchitectonic details are present, cetacean limbic cortical formations exhibit an overall striking similarity to these formations in land mammals.

175.3 NEURONAL DEVELOPMENT OF THE VENTROMEDIAL HYPOTHALAMUS AND THE AMYGDALA IN THE GOLDEN HAMSTER: A QUANTATIVE GOLGI STUDY. Chia-Hung Hsü*, C. Sue Carter, William T. Greenough, Sharon Manne* and Lois Drake* Depts. of Psychology and Ecology, Ethology and Evolution and Program in Neural and Behavioral Biology, University of Illinois, Champaign-Urbana, 61820.

The purpose of this study was to analyze quantitatively neuronal morphology during postnatal development in the golden hamster. Brain tissue was stained using the Golgi-Cox procedure and 100 micron sections through the ventromedial hypothalamus (VMH) and cortico-medial amygdala (CMA)) were examined. Neurons were sampled from males and females at 5, 10, 20 and 30 days of age. There were 6 littermate pairs for each age. Approximately 20 well-stained neurons were sampled from each area of each brain. The neurons were traced on paper by camera lucida at 500X. All drawing and scoring was performed on coded slides which did not reveal sex.

In the VMH, soma size peaked on day 10. Total dendritic length increased until 20 days of age. The number of first order branches (branches from the soma) was highest on day 5 and decreased significantly after 10 days of age, and the number of higher order branches increased with age. The percentage of neurons with visible growth regions increased from day 5 to day 10 and returned to near zero on day 20 and day 30. Preliminary results indicated higher frequencies of growth regions for males than females. The percentage of neurons with multifurcation branching (more than 2 branches at the same point) slightly increased from day 5 to day 10 and then decreased to almost zero at day 30.

In the CMA, soma size also peaked on day 10, and then showed a greater decrease in females than in males such that males had a larger average soma size than females at day 30. Both total dendritic length and field size increased until day 20 and then leveled off. The number of first order branches did not change, while those of higher orders showed increases over the ages sampled. The percentage of neurons with growth regions and multifurcation branching was highest at day 5 and decreased greatly thereafter.

In general, the preoptic area (Hsü, Carter & Greenough, Abst. Soc. Neurosc. 4:115, 1978) and VMH share a similar developmental pattern. CMA differed from the other two areas in terms of soma size development patterns and the absence of an age-related decline in the number of first order branches. (Supported by NIH grant - NS 13421).

175.4 THE PROJECTION OF THE SUPRAMAMMILLARY REGION UPON THE DENTATE GYRUS IN NORMAL AND REELER MUTANT MICE. B.B. Stanfield, J.M. Wyss and W.M. Cowan. Dept. of Anatomy and Neurobiology, Wash. Univ. Sch. of Med., St. Louis, MO 63110.

The distribution of the hypothalamo-dentate projection in normal and reeler mice was investigated by making injections of a mixture of ^{3}H-proline and ^{3}H-leucine into the posterior hypothalamus of animals heterozygous (rl/+) or homozygous (rl/rl) for the reeler mutation, and subsequently processing the brains for autoradiography.

In the normal mouse (rl/+) the distribution of the hypothalamo-dentate projection is essentially the same as that which has been described previously in the rat and cat. Following injections which include the supramammillary region, silver grains indicative of anterograde transport in the hypothalamo-dentate fibers are restricted to a band which overlies the granule cell layer and the inner 10-15 μm of the molecular layer of the dentate gyrus of both sides. The grain density is consistently higher over the suprapyramidal than over the infrapyramidal blade, and is higher on the ipsilateral than the contralateral side.

The hypothalamo-dentate projection in the reeler mutant mouse (rl/rl) has some of these same features - it is heaviest over the dentate gyrus on the side ipsilateral to the injection site and is consistently heavier over the "suprapyramidal" part of the granule cell zone. However, in contrast to the narrow band of silver grains seen in the normal dentate gyrus, after an isotope injection into the supramammillary region of the reeler mouse, transported label is found throughout the zone containing granule cell somata, including not only the ill-defined granule cell layer, but also the "hilus" deep to it in which there are many ectopic granule cells. No label is seen over the molecular layer.

This dispersed distribution overlaps that which we have previously described for the commissural and associational inputs to the reeler dentate gyrus. However, whereas the latter are more concentrated at the interface between the granule cell and molecular layers and in the granule cell-free zones of neuropil in the hilar region, the hypothalamic afferents are more uniquely distributed throughout the zone containing granule cells but tend to be aggregated around the granule cell somata. Thus, despite the extensive overlap among these three afferent systems in the mutant, they appear to exhibit the same target site specificity which they display in the normal.

Supported by grants NS-10943 and EY-01255.

175.5 EFFECT OF ANISOMYCIN ON POST-TETANIC CHANGES IN THE DENTATE FASCIA. Eva Fifková, Carol L. Anderson* S. J. Young*and A. Van Harreveld. Dept. of Psych., Univ. of Colorado, Boulder, CO 80309, and Div. of Biol., Caltech, Pasadena, CA 91125.

Tetanic stimulation of the entorhinal area has been shown to induce in the dentate molecular layer long-lasting enlargement of dendritic spines. Increased protein synthesis was postulated to be the mechanism underlying this change. Therefore, an attempt has been made to suppress the spine enlargement by a protein synthesis blocking drug - anisomycin (Ani). Two groups of 14 and 13 mice survived the tetanic stimulus to the medial and lateral entorhinal area for 4 and 90 min, respectively; a control group (11 mice) had a sham procedure. Fifty-three mice received Ani subcutaneously (0.4 mg/kg) 15 min prior to the treatment. The Ani animals were divided into four groups: two of them were stimulated and were sacrificed 4 min and 90 min later. The other two groups were sham controls with survival periods similar to those of the stimulated groups. Spines in the dentate molecular layer of stimulated mice without Ani were enlarged in the 4 min poststimulation interval in the middle and distal third of the dentate molecular layer by 20% and 34% and in the 90 min interval by 28% and 32%, respectively. Ani suppressed the spine enlargement significantly in the 4 min but not in the 90 min poststimulation interval. Protein synthesis is maximally blocked between 10-90 min after application of a single dose of Ani and then it quickly recovers. Long-surviving stimulated mice were under Ani for 105 min, which is outside the maximal effective range of the drug. This could explain why the spine reaction was no longer suppressed in the 90 min interval. Since suppression of the spine reaction to stimulation and its recovery coincides in time with the blocking effect of Ani on protein synthesis, it can be concluded that protein synthesis might be the mechanism underlying the dendritic spine enlargement induced by tetanic stimulation. (Supported by NIMH Grant MH 27240-06.)

175.6 LIMBIC KINDLING: INHIBITORY INTERACTIONS IN THE TRANSFER EFFECT. Michael S. Duchowny, Frank H. Duffy, James L. Burchfiel. Seizure Unit & Dept. of Neurology, Children's Hospital Medical Center & Harvard Medical School, Boston, MA 02115.

To investigate limbic mechanisms involved in the transfer of kindled activity, we analyzed the growth of hippocampal seizures induced by epileptiform afterdischarges (ADs) arriving from two anatomically distinct hippocampal input pathways. Electrodes were implanted into the septal region and entorhinal cortex of adult rats to activate the fornix and perforant path hippocampal afferents respectively. Generalized motor convulsions were kindled independently from each site and complete mutual transfer was demonstrated between both hippocampal inputs. That is, prior kindling of one pathway significantly reduced the number of stimuli required to elicit a generalized convulsion from the other. In comparing these results to a paradigm in which stimulation of the two pathways was alternated on a trial-by-trial basis, we found markedly different outcomes. In contrast to the mutual transfer seen with massed stimulation, alternating stimulation resulted in generalized seizures being kindled from only one of the two sites. Stimulation of the other site elicited local AD activity but no progression to motor seizures, even after an excessive number of trials. Which pathway became dominant appeared to be random and not predictable by AD characteristics. There was a difference however in the characteristics of kindling depending upon which pathway became dominant. When the fornixpathway was dominant, there was considerable facilitation between the two inputs and the rate of kindling was faster than with stimulation of either pathway alone. When the perforant pathway input was dominant, the number of trials required for generalized convulsions was almost twice that for massed stimulation, as if fornical input had no effect at all.

Our results indicate that the propagation of AD activity believed to underly the kindling phenomenon is more complex than the simple summation of excitatory influences. Inhibition appears to play an important role in determining the route of propagation. When competing pathways are stimulated in alternation, one becomes dominant for kindling and the other is suppressed. Moreover, when competing pathways are active, the kindling process varies as a function of which pathway is dominant.

175.7 RESIDUAL ACHE STAINING IN THE HIPPOCAMPAL FORMATION FOLLOWING SEPTAL LESIONS: THE TOPOGRAPHY OF ACHE POSITIVE NEURONS AND ZONE 31. J.R. West, G.W. Van Hoesen, L.L. Chen,* and C.L. Barnes.* Depts. of Anat. & Neurol., Univ. of Iowa, Iowa City, IA 52242.

Following transection of the fimbria fornix and/or a lesion of the septum, both acetylcholinesterase (AChE) and choline acetyltransferase (ChAc) activity in the hippocampal formation drop precipitously. The results of several investigations place the depletion at 80-85%. The precise morphological elements which contain the residual 15-20% of the enzyme are unknown, but likely candidates exist. For example, some have reported the persistance of AChE positive neurons in the hippocampal formation following a lesion of the septum. And moreover, all agree that terminal staining persists in a portion of the molecular layer of the subiculum and CA 1 field. This pattern of staining conforms in part to Storm-Mathison and Blackstad's zone 31. We have examined the topography of residual AChE staining in the hippocampal formation of the rat following septal lesions. For all cases, the animals survived for 2-3 weeks and were perfused with saline and 4% formalin. The brains were sliced on a freezing microtome and serial sections were stained for AChE according to Genneser-Jensen and Blackstad's method. Ethopropazine was added to the incubation medium to suppress unspecific cholinesterase. In nearly all cases, AChE positive neurons in varying quantities were detected in many parts of the hippocampal formation. Their most frequent location was in the hilus of the dentate gyrus and in the subiculum, although stained neurons were also observed in the stratum oriens and radiatum of the CA 3 region and in the entorhinal cortex. In general, neurons containing AChE were more numerous in the septal end of the hippocampal formation, although they had a wide septo-temporal extent. In all cases with septal lesions, residual AChE staining was observed to persist in the molecular layer (stratum moleculare) of the inner one half of the subiculum and the outer one half of the CA 1 zone. This staining formed a conspicuous wedge-shaped or triangular pattern with the base located in the subiculum and the apex in the hippocampal CA 1 zone. On each end, the stained area was contiguous with the hippocampal fissure and did not extend across it into the molecular layer of the dentate gyrus. This pattern, present throughout the extent of the subiculum and CA 1 zones, seems to represent a part of Storm-Mathison and Blackstad's AChE zone 31 in the normal rat. The source of this staining pattern is unknown. However, it may represent the stained axon terminals of AChE neurons intrinsic to the entorhinal or subicular cortices. (supported by grant NS 14944).

175.8 RESIDUAL ACHE STAINING IN THE HIPPOCAMPAL FORMATION FOLLOWING COMBINED SEPTAL AND ENTORHINAL LESIONS: REINNERVATION OF THE PERFORANT PATHWAY TERMINAL ZONE. G.W. Van Hoesen, J.R. West, C.L. Barnes,* and L.L. Chen.* Depts. of Anat. & Neurol., Univ. of Iowa, Iowa City, IA 52242.

Reinnervation of the various terminal zones in the hippocampus and dentate gyrus following deafferentation is now a well-known phenomenon. The most extensively studied model concerns the proliferation of AChE containing axons in the outer part of the molecular layer of the dentate gyrus after removal of the entorhinal cortex. The source of axons that reinnervate this zone has yet to be shown, but it is likely that they reside in the septum, or in nearby areas that send axons through the septum enroute to the dentate gyrus. This is predicated on the fact that septal lesions and fornix transections diminish the AChE content of the dentate gyrus in both normal animals and experimental animals having a prior entorhinal lesion. While this cannot be disputed, discernible AChE staining persists in the hippocampal formation in spite of a septal lesion. We report evidence that these residual AChE positive elements are capable in and of themselves of reinnervating the perforant pathway zone in both the hippocampus and dentate gyrus following combined septal and entorhinal lesions. In 18 adult rats bilateral lesions were made in the septum. Entorhinal ablations were made by aspiration immediately thereafter. After 21 days, the rats were perfused with saline and 4% formalin and the brains were sliced on a freezing microtome. Serial sections were stained for AChE according to Genneser-Jensen and Blackstad's method. Ethopropazine was added to the incubation medium to suppress unspecific cholinesterase activity. Bilaterally AChE staining was reduced greatly. On the side with the intact entorhinal cortex, the normal residual compliment of AChE was observed in zone 31, and in some instances, AChE positive neurons were observed in the hilus of the dentate gyrus and subiculum. In contrast, on the side of entorhinal lesion, AChE staining spread from zone 31 along the stratum moleculare of the hippocampus and was detectable in the outer part of the molecular layer of the dentate gyrus. This pattern was observed at all levels of the hippocampal formation, but was especially impressive in the septal end of the structure. In all respects, the zone of reinnervation resembled the known distribution of the perforant pathway. These results suggest that non-septal AChE containing axons are capable of reinnervating sizable terminal fields in both the hippocampus and dentate gyrus and traverse long distances to do so. The source of the AChE appears to be derived from the subiculum, although a contribution from hilus neurons cannot be ruled out. (supported by grant NS 14944.)

175.9 MOST ENTORHINAL CORTEX (ERC) NEURONS PROJECTING TO THE RAT DENTATE GYRUS (DG) CONTAIN ACETYLCHOLINESTERASE (AChE). Konrad Talbot[1], Barry Fass[1], and Larry L. Butcher[1,2]. Department of Psychology[1] and Brain Research Institute[2], UCLA, Los Angeles, CA 90024.

Using the pharmaco-histochemic protocol for cholinesterases (Butcher et al., J. neural Trans. 37:127, 1975), we have discovered AChE-reactive stellate neurons throughout layer II of the rat ERC, especially at dorsal levels of its medial sector. Their morphology, density, and location match that reported by Steward and Scoville (J. comp. Neurol. 169:347, 1976) for ERC neurons innervating the rat DG. We summarize here an experiment confirming that entorhino-dentate nerve cells possess AChE.

In order to retrogradely label ERC neurons projecting to the DG, 0.20-0.25µl of 30% Evans Blue (EB) fluorescent dye was infused unilaterally into the dorsal half of the DG in 3 female, albino rats. To optimize results with the pharmaco-histochemic method for AChE, animals received 2.0mg/kg of diisopropylfluorophosphate (DFP) 12 hrs. prior to the end of the 2 day post-operative survival times allowed. Using 490nm primary and 530nm secondary filters, dark-field photomicrographs were taken of red fluorescing, EB-positive ERC cells. These were then counterstained on-the-slide in an incubation medium for AChE (see Butcher et al., ibid.) and photographed again under bright-field illumination.

The EB injection fields covered primarily the DG, including its outer molecular layer, resulting in retrograde labelling of numerous layer II stellate neurons throughout the ERC. A relatively small number of EB-positive nerve cells also occurred in ERC layers III and VI of Lorente de No (J. f. Psych. & Neurol. 45:381, 1933). Comparison of photomicrographs of labelled layer II neurons taken before and after enzyme counterstaining revealed that many, but not all, entorhino-dentate nerve cells contained AChE. Such cells are probably not cholinergic (e.g., see Storm-Mathisen, Br. Res. 80:181, 1974). Their AChE content may, however, reflect a cholinoceptive nature, especially since layer II of the rat ERC appears to be innervated by AChE-rich septocortical fibers (see Srebro & Mellgren, Br. Res. 52:19, 1973), the hippocampal terminations of which are known to be cholinergic (see Kuhar & Yamamura, Br. Res. 110:229, 1976). [Support: NS 10928 to L.L.B.]

175.10 NEURAL MODULATION OF THE IMMUNE RESPONSE. R. J. Cross*, W. R. Markesbery,*W. H. Brooks*and T. L. Roszman*(SPON:B.Peretz) Dept. of Pathology, Univ. of Kentucky Med. Ctr., Lexington, Ky. 40536.

Our recent studies have shown that the hypothalamus has a modulating effect on the immune response. This is manifest by a decrease in spleen and thymus cell number and reduced in vitro cell-mediated responsiveness in anterior hypothalamic (AHT) lesioned rats. The latter is due to the induction of suppressor macrophages which qualitatively differ from macrophages from control rats. It was demonstrated that these effects were not due to stress-induced corticosteroid release. In the present studies, bilateral electrolytic lesions were placed in the medial hypothalamus, mammillary body, hippocampus or amygdala of Fischer 344 rats. Four days after lesioning the spleens were removed, single cell suspensions prepared and their blastogenic reactivity to concanavalin A (Con A) determined. Spleen cells from animals with lesions in the mammillary bodies, hippocampus or amygdala exhibited significantly enhanced responsiveness to Con A as compared to the responses obtained with spleen cells from animals with frontal cortex lesions. Thus, our data indicates that lesions in the limbic system enhance immune responsiveness whereas AHT lesions suppress this responsiveness. These studies support the concept that the central nervous system plays a major role in regulating the immune response. This work was supported in part by NIH grants CA-18234, CA-17786, and NS-14221.

176.1 Control of Muscle Mass I: Changes in Glucocorticoid Receptor in Experimental Atrophy. Richard R. Almon and Debra C. DuBois*. Division of Cellular and Molecular Biology, Department of Biological Sciences, State University of New York at Buffalo, Buffalo, New York, 14214.

Glucocorticoids have been shown to have a profound catabolic effect on skeletal muscle. In the present report we examine the hypothesis that selective muscle atrophy, regardless of cause, is due to an increase in the sensitivity of a particular muscle to normal circulating levels of glucocorticoids.

The glucocorticoid receptor population of muscle cytosol in three experimental atrophy conditions was examined using [^{3}H]-Dexamethasone and a column chromatography assay.

The results show significant increases in receptor number with no change in affinity in the following three atrophy conditions: 1) the levator ani muscle after castration; 2) the gastrocnemius muscle after denervation and; 3)the gastrocnemius muscle after immobilization.

176.2 Control of Muscle Mass II: Changes in Glucocorticoid Receptor in Dystrophic Animal Models. Debra C. DuBois* and Richard R. Almon. Division of Cellular and Molecular Biology, Department of Biological Sciences, State University of New York at Buffalo, Buffalo, New York, 14214.

Glucocorticoids have been shown to have a profound catabolic effect on skeletal muscle. In the present report we examine the hypothesis that general muscle atrophy in pathological states is due to hypersensitivity of the muscle to glucocorticoids.

The glucocorticoid receptor population of muscle cytosol from two dystrophic animal models was examined using [^{3}H]-Dexamethasone and a column chromatography assay.

The results show that in both chicken and mouse models, muscles from the dystrophic animals contain significantly higher levels of receptor than do normal controls.

176.3 INCREASED GLUTAMATE FORMATION AFTER PORTOCAVAL ANASTOMOSIS. F. Moroni, C. Paparozzi, D. Pellegrini and C. Cortesini. Depts of Pharmacology and Experimental Surgery, University of Florence, Florence, Italy.

Rats with a surgically-constructed (end-to-side) portocaval anastomosis are considered a good experimental model for the study of behavioural and biochemical changes which occur during chronic liver disease. In this animal model, blood and brain GABA, glutamate (GL) and glutamine (GLN) content were measured by a mass fragmentographic method. Brain glutamate synthesis and brain GABA turnover were also measured by infusing the animal with ^{13}C-glucose 50 µmol/Kg/min (uniformly labelled Kor Isotopes, Cambridge Mass) and by measuring the incorporation of ^{13}C in the aminoacid molecules (Moroni, F. et al., J. Pharmacol. Exp. Ther., 207: 870, 1978). Four weeks after PCA blood GABA, GL and GLN concentrations were increased by 350, 30 and 290% respectively. Regional brain GABA content and the turnover rate of GABA showed no changes, while the GL content was increased in the parietal cortex, in n.caudatus, in the hypothalamus and in the hyppocampus by 20 - 35%. The incorporation of $^{13}C_2$ derived from ^{13}C glucose in the glutamate molecule was approximately doubled. Glutamine concentration was increased in several areas by 250 - 300%. Since administration of high doses of GL may cause convulsions, selective neuronal degeneration and gliosis, it is possible that the increased glutamate synthesis we observed plays a role in the pathogenesis of chronic hepatic encephalopathy.

176.4 EFFECT OF MORPHINE ON PRL RELEASE IN MIGRAINE PATIENTS. G.Bussone, A.Boiardi, A.M.Di Giulio, E.Tansini, B.Merati and A.E.Panerai. Istituto Neurologico "Besta" & Dept. of Pharmacology University of Milan, Italy.

It is well known that morphine has not an analgesic effect in migraine patients. It has been suggested that this lack of effect is due to a deficiency of the serotoninergic system in these patients. Morphine releases prolactin through a serotoninergic mechanism. We have treated ten female migraine patients with 10 mg s.c. of morphine hydrochloride. In these patients, morphine elicited a clear cut release of prolactin (basal values 6.3 ± 0.5 ng/ml; peak values 72.5 ± 15.6 ng/ml) similar to the one observed in normal subjects. Pretreatment with metergoline, a specific antiserotoninergic drug, (2.5 mg x 3/die for 3 days) completely inhibited the prolactin releasing effect of morphine. This observation indicates that the serotoninergic system is well tuned in migraine patients. Consistently with this hypothesis, the administration of L-tryptophan (70 mg/kg p.o.) induces a release of prolactin and growth hormone similar to the one observed in normal subjects. This observation indicates the lack of a deprivation supersensitivity to serotonin as suggested by some authors.

The deficiency of the serotoninergic system therefore cannot be advocated to explain the lack of the analgesic effect of morphine in migraine patients. It has been suggested that the lack of the analgesic effect of morphine in migraine patients is due to a functional deficiency of the opiate receptor. In our subjects, the specific opiate antagonist naloxone (5 mg i.v. over a 30 min period) completely abolished the prolactin releasing effect of morphine.

This observation indicates that in these patients the opiate receptor is present and can be activated or inhibited in order to modulate prolactin release.

Explanations other than a deficiency of the opiate receptor or the serotoninergic system have to be searched in order to interpret the lack of analgesic effect of morphine in migraine patients. The role of GABA and acetylcholine are being investigated.

Differently from what observed in migraine patients, the prolactin releasing effect of morphine is blunted in "cluster" headache patients. This observation indicates a specific functional difference between the two syndromes.

176.5 GLUTAMATE UPTAKE INTO HUMAN PLATELETS: CHARACTERIZATION AND OBSERVATIONS IN HUNTINGTON'S DISEASE. Richard M. Mangano* and Robert Schwarcz (SPON: N. Khazan). Maryland Psychiatric Research Center, Baltimore, Md. 21228

Blood platelets have been repeatedly used as a model of putative neurotransmitter uptake systems in brain tissue. Extending an early report on the energy-dependent uptake of amino acids into platelets (Zieve and Solomon, Am.J.Physiol., 214,58,1968) we have now studied the uptake of L-glutamate, a neurotransmitter candidate thought to be etiologically implicated in the neurodegenerative disorder Huntington's disease (HD; Coyle et al., Prog. Neuro-Psychopharmacol., 1,13,1977), in human platelets.

L-glutamate uptake into human platelets revealed two components: a high-affinity system (K_{mH} = 3.1 µM), which was sodium-dependent and a low-affinity site(K_{mL} = 88 µM) displaying temperature- rather than sodium-dependency. These kinetic properties, along with pH-dependency and pharmacological characteristics of the platelet system (see below), were similar to those found in synaptosomal preparations and brain slices. However, V_{max}-values were far higher in brain (V_{maxH} = 325 ± 96, V_{maxL} = 3759 ± 1116 pmoles/mg wet weight x min) than in platelets (V_{maxH} = 14 ± 6, V_{maxL} = 313 ± 63 pmoles/mg platelet protein x 10min), indicating a denser population in brain than in platelets of qualitatively similar sites.

Pharmacological analysis substantiated the resemblance of nerve endings and platelets: the specific uptake inhibitors threo-3-hydroxy-DL-aspartate and DL-aspartate-β-hydroxamate as well as D- and L-glutamate and L-aspartate showed similar- though not identical - IC_{50} values in both preparations; and a spectrum of compounds devoid of inhibitory effects in synaptosomes also did not interfere with glutamate uptake in platelets.

Uptake parameters were studied in a population of human volunteers to determine the variability of platelet glutamate uptake. Whole blood could be stored up to six hours after venipuncture without any appreciable change in experimental values. Coefficients of variation between 0.09 and 0.28 for three repetitive (weekly) assays in single subjects indicated that uptake measurements were sufficiently suited for clinical studies.

Finally, platelets from HD-patients were analyzed for changes in glutamate uptake in order to test a possible etiological role of (a reduction in) this parameter in HD. No significant changes occured in HD-platelets compared to control values when uptake was performed at 10^{-7}M glutamate (high-affinity uptake conditions; N = 15 per group). However, preliminary kinetic data indicated a trend towards higher affinity (lower K_m) in the patient population.

This work was supported by a grant from the Wills Foundation.

176.6 INCREASED EXCRETION OF HOMOVANILLIC ACID (HVA) IN URINE BY YOUNG CHILDREN WITH INCREASED LEAD ABSORPTION. J.J. Chisolm, Jr.* and E.K. Silbergeld, (SPON: R. Irwin) Dept. of Pediatrics, Johns Hopkins Medical School, Baltimore, MD, and NINCDS, NIH, Bethesda, MD 20205.

Studies in neonatal rodents have revealed a disturbance in central dopamine metabolism, due to lead exposure, which is associated with increased levels of HVA in brain and urine (Silbergeld and Chisolm (1976) Science 192:153). This study was undertaken to test the relevance of the animal work to increased lead absorption in children. A statistically significant positive linear relationship between blood lead (PbB) concentration and the 24-hr excretion of HVA in urine was found in 25 children with PbB in the range of 38-72 µg/100 ml whole blood ($r=.729$, $p<.001$). Eleven children were restudied 13-60 months after chelation therapy when their PbB levels were in the range of 20-42 µg/100 ml whole blood. There was a corresponding decrease in levels of urinary HVA, suggesting reversibility of the effects of lead on dopamine metabolism. These data provide the first evidence in humans for a dose-effect relationship between blood lead concentration and a biochemical indicator of an effect of lead on the nervous system. Because indicators of altered heme synthesis are widely used in the diagnosis of lead intoxication, the relationships between HVA, erythrocyte protoporphyrin and urinary δ-aminolevulinic acid (ALAU) were evaluated. There were no significant correlations between HVA, ALAU, or erythrocyte protoporphyrin, or the excretion of lead in urine after chelation. The data thus suggest that evidence of disturbance in heme synthesis due to lead may not reliably predict the effects of lead on the nervous system in children. The PbB "threshold" appears to be between 30-40 µg/100 ml for significant increases in both HVA and ALAU. This is consistent with other clinical studies suggesting that increased lead absorption associated with PbB>30 µg/100 ml is potentially neurotoxic for young children.

176.7 TRIETHYLTIN INTOXICATION ALTERS ACETYLCHOLINE RELEASE FROM RAT PHRENIC NERVE-DIAPHRAGM. G.G. Bierkamper*, A.M. Goldberg, J.J. Valdes, Division of Toxicology, The Johns Hopkins University, Baltimore, MD 21205

Organotin compounds are manufactured for use in chemical synthesis, marine anti-fouling paints, wood preservation, pesticides, plastics, fungicides and other industrial processes. Mammalian exposure to triethyltin (TET), the most toxic trialkyltin compound, may produce cerebral edema, affective disturbances, muscular weakness and damage to the myelin sheath. The purpose of this preliminary study was to determine the effect of acute and chronic TET exposure on unstimulated and stimulated release of endogenous acetylcholine (ACh) from a neuromuscular model system--the vascular perfused rat phrenic nerve-hemidiaphragm preparation (Bierkamper & Goldberg, JEPT 6:40-46, 1978).

Adult male Long-Evans hooded rats (250-350g) were exposed acutely to one injection of TET (10 mg/kg, i.p.) or chronically to TET (30 mg/L) in their drinking water. Hemidiaphragms were obtained from treated and age-matched control rats 24 hrs after acute exposure or 1, 2 and 3 weeks after initiation of the chronic exposure regimen. Twenty-four hours after the acute dose of TET, rats were completely incapacitated and usually died within 48 hrs; however, unstimulated and stimulated release of ACh were unaltered in the edematous hemidiaphragms from these animals. Chronically exposed animals progress through an increasingly compromised state beginning with mild ataxia and hindlimb weakness after one week of exposure to hindlimb paralysis, piloerection, penile erection, exopthalmos, and aggressive responsiveness by 3 weeks. Spontaneous (unstimulated) ACh release was 1.21±0.20 pm/min/hemidiaphragm (mean ± SEM; n=5) in control preparations and did not vary in TET-preparations. Stimulated release of ACh (via phrenic n.) was 6.83±0.57 and 9.89±1.02 pm/min after 45 min of 7 Hz and 20 Hz stimulation, respectively, in control preparations. Stimulated release from TET-preparations was 5.57±0.91, 4.32±0.86, 4.40±0.94 pm/min after 45 min at 7 Hz and 9.95±1.73, 6.78±1.31, 3.02±0.88 pm/min after 45 min at 20 Hz for 1, 2 and 3 weeks of exposure, respectively. These results clearly demonstrate that chronic, but not acute, TET intoxication results in a time-dependent decrease in stimulated ACh release. Interestingly, TET-preparations also had a reduced capacity for maintaining stimulated ACh release over longer periods even in the presence of 10 µM choline.

176.8 SUBNORMAL CONCENTRATIONS OF BRAIN CIRCUMVENTRICULAR ANGIOTENSIN II RECEPTORS IN HEREDITARY DIABETES INSIPIDUS. M. van Houten*, E.L. Schiffrin* and B.I. Posner*. (SPON: R. Hirsh). Dept. of Medicine, McGill University and the Clinical Research Institute of Montréal, Quebec H3A 2B2.

In a previous study (Brain Research 186:480, 1980) we localized specific binding sites for blood-borne 125I-angiotensin II (AII) to the circumventricular organs (CVO) of the rat brain, using quantitative in vivo light microscope radioautography. We observed that the greatest concentration of AII receptors occurred in the subfornical organ, a key region implicated in AII-mediated thirst. In the median eminence AII receptors were concentrated in the medial palisade zone, rich in vasopressin. In the present study we evaluated the binding capacity of the CVOs for blood-borne 125I-AII in an animal model of hereditary diabetes insipidus, exhibiting chronically elevated circulating AII, insatiable thirst, and a genetically-determined inability to synthesize vasopressin. 125I-AII was injected systemically into male Long-Evans and homozygous Brattleboro rats, some of which were infused with saralasin (10nmol/Kg/min.) during and for 30 minutes prior to 125I-AII injection to determine levels of non-specific 125I-AII binding. Three minutes after injection brains were fixed by vascular perfusion for light microscopic quantitative determination of 125I-AII-specific binding, as described in the article cited above. Briefly, 125I-AII-specific binding in all of the CVOs of the homozygous Brattleboro rat was 55-92% below control levels, although levels of non-specific binding were normal. Deficiencies in AII-specific binding capacity were most severe(80-92% subnormal) in regions of the CVOs normally containing the greatest concentration of AII receptors. AII receptors in the pars nervosa, concentrated peripherally along the interface with the pars intermedia in normal rats, were undetectable in Brattleboro rats. These observations reveal a remarkable paradox: elevated circulating AII, insatiable thirst, and profoundly subnormal concentrations of brain circumventricular AII receptors. Studies are in progress to determine whether these deficiencies in brain AII receptors represent a reversible consequence of diabetes insipidus and elevated AII levels, or an irreversible brain AII receptor lesion.

176.9 CATECHOLAMINE METABOLITES IN DEPRESSED AND NON-DEPRESSED HYPERACTIVE BOYS. W.O. Shekim, J. Javaid, H. Dekirmenjian, J. Kashani*, K. K. Hodges*, L. Cytryn*, D. McKnew*, J.M. Davis. Clinical Research Center, University of Missouri Medical Center, Columbia, MO 65201.

The diagnostic category of childhood hyperactivity is generally thought to consist of heterogeneous groups. It is considered by many to represent masked depression or a depressive equivalent. Some hyperactive children are known to present with low self-esteem, feelings of worthlessness, self-deprecatory ideations, helplessness, feelings of loss of control, and isolations from peers.

We compared the urinary catecholamine metabolites, 3-methoxy-4-hydroxyphenylglycol(MHPG) and Homovanillic acid(HVA), in two groups of hyperactive boys: one group diagnosed as depressed on the basis of the Research Diagnostic Criteria(RDC) and the other group diagnosed as non-depressed. Twenty-five hyperactive boys ages 7-12 with full scale IQ of over 80 on the WISC and who were free from any neurological abnormality were involved in the study. The children met the diagnostic criteria for hyperkinetic Reaction of Childhood in the Children Diagnostic Scale(CDS) and the Children Diagnostic Classification(CDC). The diagnosis of depression on the RDC was made from the parents' responses on the Conners Parents Questionnaire and the Deveraux Parents Symptoms Checklist and from the psychiatric evaluation, including a mental status and nurses' observation notes during the children hospitalization in the Clinical Research Center. Three 24-hour urine samples were collected from each child on ice and aliquots were frozen and then were analyzed for MHPG according to the method of Dekirmenjian and MAAS(1970) and for HVA according to the method of Dziedzic et al. (1972).

Neither hyperactive children, depressed hyperactives nor non-depressed hyperactives differed from healthy control children or from each other in age, 24-hour urinary creatinine or body surface (m^2). Hyperactive children excreted lower levels of MHPG than controls (693 $\pm$ 237 vs 922 $\pm$ 168 ug/24 hrs/m^2, $p<0.01$) while their HVA excretion did not differ (2814 $\pm$ 723 vs 2959 $\pm$ 355 ug/24 hrs/m^2, p=ns). Depressed and non-depressed hyperactives did not differ in MHPG excretion (653$\pm$206 vs 709$\pm$246 ug/24 hrs/m^2, p=ns). The non-depressed hyperactives excreted lower levels of HVA than depressed (2639$\pm$706 vs 3265$\pm$575 ug/24 hrs/m^2, $p<0.05$.

The non-depressed hyperactive children excreted lower levels of MHPG & HVA than controls while depressed hyperactive children excreted lower levels of MHPG only. The findings are discussed in terms of the heterogeneity of hyperactive children and in terms of dopamine and norepinephrine theory of hyperactivity and norepinephrine theory of depression of childhood.

176.10 ENKEPHALIN ACTIVITY IN AN ANIMAL MODEL FOR HUNTINGTON'S CHOREA. B.I. Diamond, G.S. Sudakoff*, H.S. Havdala* and R.L. Borison. Mount Sinai Hospital, Rush Medical College, and Illinois State Psychiatric Institute, Chicago, IL 60608 & 60612.

We have previously demonstrated evidence for a presynaptic facilatatory and postsynaptic inhibitory enkephalinergic input into the nigrostriatal system. Since this report, clinical studies have shown the efficacy of the opiate antagonist naloxone in Parkinson's disease and synthetic enkephalins in tardive dyskinesia. We now present experimental evidence for the role of the opiates in Huntington's Chorea (HC). Experiments were conducted using white male Sprague-Dawley rats which received intracaudate injections of kainic acid (KA). It has been shown that KA is neurotoxic to cell bodies, while sparing nerve terminals and axons in passage. Both the biochemistry and pharmacology of KA treated animals closely mimics that of HC. One week after KA injection, animals received injections of d-amphetamine (2 mg/kg) and stereotyped behavior was quantitated in the presence of drugs affecting the brain opiate system. We found that morphine (5 mg/kg, ip) produced a significant increase in stereotypy as compared to saline control. In contrast, D-phenylalanine (250 mg/kg), which is believed to block enkephalin degradation, failed to affect behavior. We also observed that methionine-enkephalin (2 mg/kg,ip) produced a significant increase in stereotypy. The administration of naloxone (20 or 40 mg/kg) produced a significant decrease in stereotypy in KA treated animals. These results differ from those found for the animal model of tardive dyskinesia, and may be reconciled by the fact that in KA treated animals there is a loss of the postsynaptic inhibitory enkephalinergic input. Our results would further suggest that opiate antagonists may have potential efficacy in the treatment of HC.

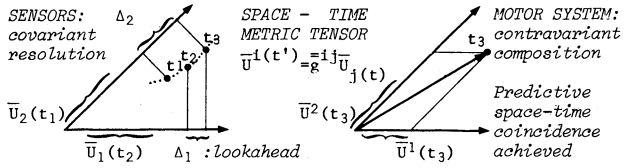
177.1 TENSORIAL REPRESENTATION OF SPACE-TIME IN CNS: SENSORY-MOTOR COORDINATION VIA DISTRIBUTED CEREBELLAR SPACE - TIME METRIC. A. Pellionisz and R. Llinás. Dept. Physiology & Biophysics, New York University Med. Ctr., 550 First Ave., New York 10016

Locating and intercepting moving objects is a coordinated sensorimotor act, aimed at achieving a coincidence of the interceptor and the target. While both sensory and motor functions relate to space-time, the conceptual basis of how such union is established by the brain is ill-understood; e.g. usually *separate time and space representations are assumed* and timing is linked to the concept of *simultaneity* (established by a centralized clock). However, the brain cannot use this timing principle, since there is no instantaneous signal capable of establishing such simultaneity.

The proposed space-time concept is based on the tensor network theory of CNS (*Neuroscience* 4:323,1979), which states that brain function is tensorial; i.e. brain activity vectors, assigned to objects of the external world, have reference-frame invariant properties. We further indicated (*Neuroscience* in press,1980) that in the oblique CNS reference-frame sensory information is resolved into *covariant* vectorial components, while motor execution is composed of *contravariant* components. Thus, coordination was defined as the geometrical transformation of the motor vector from covariant to contravariant expression; the first featuring intention, the latter allowing execution.



This scheme provides a geometrical interpretation of the unified space-time operation in CNS. Because of the different delays in the pathways sensory information relates not only to the space coordinates of the target, but also to the time of occurrence of the event, *in the past*. This information is coded in the signal itself. Given the different delays inherent in the sensory covariants a set of transformations must take place to ensure appropriate motor response: (1) Motor execution must be contravariant and (2) must refer to a *future* space-time coincidence. *The above scheme is a unification of the notion on temporal lookahead by Taylor expansion and the notion of cerebellar function as a metric tensor:* the covariant, distributed space-time components are (1)extrapolated by a "lookahead" (2)transformed by the space-time metric tensor. (Supported by USPHS grant NS13742 from NINCDS)

177.2 RESPONSES OF MOSSY FIBER UNITS IN THE MONKEY FLOCCULUS TO BACKGROUND MOVEMENTS DURING STEADY FIXATION. Hiroharu Noda. Brain Res. Inst., UCLA Sch. of Med., Los Angeles, CA 90024

The existence of visual inputs through mossy fibers to the monkey flocculus has been known. However, partially because of the fibers carrying visual information comprise only a small proportion of the afferent fibers, the properties of visual input signals to the monkey flocculus are mostly unknown. Single unit activity was recorded from the white matter of the flocculus of monkeys trained to fixate a visual target and to track the target when moved slowly. Mossy fibers were identified by eliminating fiber units of known Purkinje cell discharge patterns and climbing fiber units which discharged only once or twice per second.

A common feature of the responses of visual mossy fiber units was directional selectivity. Each unit had its own preference in the direction of stimulus movement and showed a vigorous response only when the stimulus was moved in the preferred direction. Stimulus movements in the other directions were usually not associated with discharges. The second and perhaps more important feature of the responses seen in a portion of mossy fiber units was their sensitivity to the velocity of stimulus movements. Within a range, the responses were positively related to the velocity of stimulus movements. Interestingly, their preferred velocity was within the range of that of smooth pursuit eye movements of the monkey. Responses of these fibers reflected the changes in the velocity when tested with sinusoidal background movements, showing the peak responses at approximately or slightly after the peak velocity of the movements. Most units studied in the present experiment responded optimally to sinusoidal stimulus movements whose peak velocity ranged from approximately 10 to 50 deg/sec. In response to the changes in the direction of ramp stimulus movements, mossy fiber units discharged with a mean latency of about 108 msec. In response to momentary illumination of the tangent screen with flashes of light, mossy fibers discharged with a mean latency of about 70 msec. Climbing fibers, including complex spikes which are thought to be Purkinje cell responses to climbing fiber inputs, did not show responses to visual stimulus movements in the range of slow eye movements of normal monkeys. (Supported by NIH Grant RO1 EY01051).

177.3 CEREBELLAR TARGETS OF VISUAL PONTOCEREBELLAR PROJECTIONS IN THE CAT. F. Robinson*, J. L. Cohen*, J. G. May*, and M. Glickstein (SPON: J. McIlwain). Walter S. Hunter Lab. of Psychology, Brown University, Providence, RI 02912.

The superior colliculus of the cat projects to the dorsolateral nucleus of the pons. Visual areas of the cat cortex project to a non-overlapping region of the rostral pons which is adjacent to the pyramidal tract on its medial and ventral borders.

Cells in these two pontine areas can be driven vigorously by appropriate visual targets. Previous studies (Mower, et al., J. Neurophysiol. 43:355, 1980) of antidromic invasion following electrical stimulation of the cerebellar cortex and retrograde transport of horseradish peroxidase have revealed that collicular-driven cells in the dorsolateral pons project to the vermis and the ipsilateral cerebellar hemispheres. The cortically-activated pontine visual cells project to the contralateral cerebellar hemispheres.

To study the projections of cells in these two pontine visual areas in more detail, we injected tritiated leucine for autoradiography. In one case, we injected the dorsolateral, collicular-driven area. In three cases, we injected H^3leucine amongst cells in the medial, cortically-driven area. The two visual areas in the pons were first identified by recording visually activated cells and noting their position. We then removed the microelectrode and replaced it with the needle of a microsyringe, locating the needle tip accurately in the visual pontine areas by using a microscopic zeroing stand. The animals were allowed to survive four days and their brains were processed for autoradiography.

Confirming our previous observations, the principal target of the dorsolateral visual area of the pons is the caudal vermis and ipsilateral hemisphere. The principle target of the medial, cortically-activated visual area of the pons is the contralateral cerebellar hemispheres. Within the contralateral hemisphere, the medial pontine visual area sends an especially dense projection to the dorsal and ventral paraflocculi. We also found that the medial visual area projects to the contralateral half of lobule IX of the vermis, the uvula. Though both the paraflocculus and uvula receive visual information from the medial pons, their non-visual inputs differ and they do not project to the same cerebellar nuclei. These two areas of the cerebellum may mediate visual control of two different classes of movement.

Supported by Grant # 1 RO1 EY 03114-01 from the National Eye Institute.

177.4 PONTOCEREBELLAR PROJECTIONS IN THE CAT. AN AUTORADIOGRAPHIC STUDY. K. Kawamura and T. Hashikawa*. Dept. of Anatomy, Iwate Medical Univ., Morioka 020, Japan.

After unilateral injections of a small amount (0.5µl, 10µCi) of tritiated amino acids into various parts of the pontine nuclei proper and the tegmental reticular nucleus (N.r.t.) in 34 adult cats, labeled terminals of pontocerebellar fibers were found in the granular layer of the cerebellar cortex. No evidence was obtained of labeled fibers in the molecular layer.

In general, the pontocerebellar projection is bilateral with a contralateral preponderance. Part of the dorsolateral pontine nucleus and that of the N.r.t., however, demonstrate a stronger ipsilateral projection. The projection shows complex patterns of organization, characterized by both convergence and divergence. Thus, while a small region in the cerebellum receives fibers from several pontine areas, a small pontine area sends fibers to extensive cerebellar parts with a certain degree of preferential terminations in particular lobules or folia. For example, in addition to a strong projection from the dorsolateral nucleus to lobule VII, weak projections exist as well to lobules VI, VIII and IX, crus I and II, the paraflocculus and the paramedian lobule.

Small adjoining areas within the pons have different patterns of projections. For example, fibers from the lateral, central, and medial parts of the dorsolateral nucleus have preferential terminations in lobule VII, crus IIp plus dorsal paraflocculus, and the paramedian lobule, respectively. Parasagittal terminal zones of mossy fibers appear to exist in part of the anterior lobe and the paramedian lobule.

Although principles of the projection are similar, cerebellar projections from the N.r.t. appear to be more extensive in the fields of termination than those from the pontine nuclei proper.

177.5 CONGRUENCE OF SPATIAL PATTERNS OF RECEPTIVE FIELD PROJECTIONS TO PURKINJE CELL AND GRANULE CELL LAYERS IN THE CEREBELLAR HEMISPHERES OF THE RAT. James M. Bower, Donald C. Woolston,* and John M. Gibson, Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706.

Tactile projections to the cerebellar granule cell (GC) layer of rats exhibit a precise, patchy, mosaic pattern of organization on several folia of the hemispheres (Shambes et al., BBE 15 : 94, 1978). The purpose of this study was to compare this novel spatial projectional pattern with that of the overlying (GC activated) Purkinje cells (PC's). Micromapping methods were used to sample both single-units in the PC layer and multiple-units in the underlying GC layer in the tactile hemispheres of rats anesthetized with ketamine hydrocloride. A mechanical stimulator delivered discrete tactile stimuli to a vibrissa or skin surface while spike activity of single PC's, identified by the presence of climbing fiber responses, was recorded. Dot rasters and PST histograms were used to judge the presence of initial short-latency excitatory PC responses. Two different procedures were used to determine the receptive field (RF) projectional pattern to the PC layer: 1) A single PC was isolated and the peripheral area localized which activated it; then the tactile stimulating probe was systematically placed at different points in and around that area until the exact RF of the PC was determined. 2) The probe remained in a fixed location on the skin while many single PC's in the PC layer were systematically sampled, thus determining the spatial distribution of PC's responding to stimulation of that peripheral locus. In both procedures the RF of GC's immediately underlying each PC was defined and later compared to the RF of that PC. Major results include: Tactile stimulation of the appropriate RF activates GC's at a latency of 4-6 msec and overlying PC's at a latency of 7-10 msec. With regard to excitatory peripheral RF projections, the PC layer is similar to the GC layer in the following respects: 1) The excitatory RF of each PC is very similar or identical to the RF of the subjacent GC locus; 2) the boundaries of the RF projections to the PC layer coincide with those of the RF projections to the subjacent GC patch; 3) the PC's overlying adjacent GC patches are activated by stimulation of the different RF's which project to those patches; 4) the ensemble of PC's responsive to a punctate skin stimulus is as small as the tiny GC patches lying beneath them; 5) PC's were found to be organized in a patchy, mosaic pattern which corresponds exactly with the pattern of RF's in the underlying GC layers. (Supported by NSF Grant BNS-16230 and NIH Grant NS-14748).

177.6 EFFECT OF NATURAL PERIPHERAL STIMULI ON THE PATTERNING OF SIMPLE SPIKE ACTIVITY IN PURKINJE CELLS. T. J. Ebner and J. R. Bloedel. Dept. Neurosurg. and Physiology, Univ. of MN, Minneapolis, MN 55455.

Many investigators have documented that Purkinje cells can increase or decrease their simple spike firing rate in response to natural proprioceptive and exteroceptive stimuli. However, the data processing techniques commonly employed for these analyses provide no information regarding the effects of these stimuli on the temporal dependency of the unitary activity. This study was undertaken to demonstrate that natural peripheral stimuli can evoke marked changes in the "temporal patterning" present in the simple spike activity of Purkinje cells located in the cerebellum of decerebrate, unanesthetized cats. Exteroceptive stimuli consisted of sinusoidal indentation of the skin in the animal's paw or forearm. Proprioceptive input was provided by step-like stretches of the gastrocnemius-soleus. Extracellular unitary activity of Purkinje cells was recorded in the ipsilateral vermal and paravermal region of the anterior lobe. Identification of a Purkinje cell was based on the presence of spontaneous responses to climbing fiber inputs. The autocorrelation of the simple spike activity was constructed during continuous sinusoidal cutaneous stimulation of the forearm at several frequencies as well as during spontaneous activity. Type 1 autocorrelations, characterized by a positive correlation at short lag time which decayed slowly to baseline, could be modified by exteroceptive stimuli. Both the magnitude and decay time of the positive correlation could be altered. For Purkinje cells with Type 2 autocorrelations (positive correlation at short lag time which rapidly returned to baseline), exteroceptive stimuli could alter the patterning in the spike train to produce an autocorrelation with Type 1 characteristics. These alterations in the autocorrelograms were independent of any modulation in the firing rate of the cell produced by the sinusoidal exteroceptive stimuli. Use of an additional autocorrelation technique developed for analyzing non-stationary stochastic processes allowed an examination of the effects of short duration proprioceptive or exteroceptive stimuli applied at low frequencies (0.5-1.0 Hz.) on the correlation as well as the firing rate in the simple spike activity of these cells. Some Purkinje cells were found to undergo dramatic increases in the positive correlations within their simple spike activity during the natural peripheral input, often with only minimal modulation of their firing rate. These findings demonstrate that cutaneous and proprioceptive inputs can modify the temporal patterning in the simple spike activity of Purkinje cells independent of changes evoked by the same stimuli in the firing rate of neurons. (Supported by NIH Grant No. 2RO1-NS-09447-10.

177.7 CEREBELLAR CORTEX OF THE RAT: PRESUMED INHIBITORY INTERNEURONS ARE ACTIVATED EARLIER THAN PURKINJE CELLS BY A PARALLEL FIBER VOLLEY. H. Axelrad and H. Korn, INSERM U3, CHU Pitié-Salpêtrière, Paris 13° France.

Extracellular recordings were obtained with glass microelectrodes from the cerebellar cortex of lightly nembutalized albino rats. 17 cells exhibiting diphasic spikes were discriminated as Basket cells (Bcs) since 1) they were located in the lower half of the molecular layer, 2) they responded to a parallel fiber volley (pfv) produced by a local (Loc) stimulation with 1-5 spikes, the latency of which decreased at increased stimulus intensities, 3) following a juxta fastigial (JF) stimulation spikes were only induced at long latencies and during the thereby evoked mossy fiber field potential, 4) in addition to these classical criteria (Eccles, Llinas, Sasaki, Exptl. Brain Res., 1966, 1:1-16) no collision was observed between the long latency action potentials of these neurons and those of Purkinje cells (Pcs) even when the JF stimulus was adjusted to produce a maximum amplitude antidromic field potential. Purkinje cells encountered along the same tracks were identified on the basis of their large and short latency antidromic spikes produced by JF stimulation and/or their climbing fiber responses. Two unexpected observations were made: 1) the threshold i.e. the lowest Loc stimulus strength adequate to activate Basket cells (iBc) was consistently lower than that for Purkinje cells (iPc) activation ($\bar{m}$ of iBc/iPc = 0.7; range 0.67-0.74), 2) for a given Loc stimulus, Bcs fired earlier than Pcs, with a difference which amounted to $\bar{m}$ = 1.14 msec (SD = 0.28; n= 15). However, this value does not reflect exactly the difference in latencies of activation of the two groups of cells by pf fibers which for each of them must be computed with respect to the time of arrival of the presynaptic volley. Superficially this parameter is indicated by the positive peak of the triphasic Loc evoked field described by Eccles, Llinas and Sasaki (Exptl. Brain Res., 1966, 1:17-39); in our experiments, this positive dip appeared earlier at deeper levels, with measured conduction velocity for superficial and deeper parallel fibers thus calculated being of respectively 0.33 and 0.38 m/sec. Even if morphological data showing 1) a constant gradient increase of pf diameter from the surface to deeper levels of the molecular layer 2) a different space distribution of Bc and Pc soma and dendrites (Palay and Chan Palay, The Cerebellar Cortex, Springer Verlag, 1974) were taken in consideration the deep volley→Bc firing latency was still shorter than that from the superficial volley→Pc firing with a difference reduced to only 0.49 msec (SD=0.33; n=15). These data strongly suggest that Bcs are activated by a set of pfs where deeper and faster conducting ones are statistically more numerous than those exciting the correspondingly located Pcs.

177.8 OLIVOCEREBELLAR PROJECTIONS TO THE NODULUS IN THE RAT. K.D. Phelan*, J.A. Rubertone* and W.R. Mehler (SPON: R. Snyder) NASA Ames Res. Ctr., Moffett Field, CA., 94035 and Univ. Calif. San Francisco, CA., 94143.

The topographical projection of the inferior olivary nucleus onto the nodulus in the rat was investigated using the retrograde axonal transport of horseradish peroxidase (HRP). Single iontophoretic injections (1.0-3.0 ua, 20-60 um pipette tips) of HRP (Sigma Type VI) were stereotaxically placed in the nodulus of adult rats. Following 24-48 hr survival times, each animal was perfused (1.0% Paraform-:1.5% Glutar-aldehyde), 50 um transverse serial frozen sections cut and treated with benzidine dihydrochloride (BDHC, Mesulam, '76) or tetramethylbenzidine (TMB, Mesulam, '78).

These experiments indicate that the nodulus in the rat receives afferent projections mainly from cells in the dorsal cap of Kooy (dc) and the ventrolateral outgrowth (vlo). Some cells in nucleus beta (B) and the dorsomedial cell column (dmcc) may also contribute to this projection. These findings are similar to HRP labeled cell patterns reported from this lab in an earlier investigation in the cat (Phelan and Mehler, Soc. Neurosci. Abstr., Vol. 5,p.106,'79) and other studies in the rabbit (Alley et al., Brain Res. 98: 582-589,'75; Hoddevik and Brodal, J. Comp. Neur. 176: 269-80,'77). Some minor species differences might exist in the olivocerebellar projections to the nodulus in the rat, cat and rabbit and will be discussed.

Lateral injections, with spread primarily confined to the lateral third of the nodulus only, result in HRP labeled cells limited to the contralateral vlo, while in more medially located injections labeled cells were found chiefly in the dc and vlo,and possibly B and dmcc. These preliminary results seem to indicate that a similar longitudinal distribution of olivocerebellar projections to the nodulus may also exist in the rat, as has been reported in autoradiographic studies in the cat (Groenewegen, Voogd and Freedman, J. Comp. Neur.183: 551-602,'79)

Injections involving the uvula result in labeled cells in B, dmcc, the medial accessory olive and the principal olive, a cell pattern similar to that found in the cat (Brodal, J. Comp. Neur. 166:417-26,'76;Phelan and Mehler,'79).

The distribution and size of labeled cells within the various subdivisions of the inferior olive will be discussed.

177.9 PATTERNS OF TERMINATION OF THE CEREBELLOTHALAMIC PATHWAY IN THE MONKEY. C. Asanuma, W.T. Thach and E.G. Jones. Departments of Anatomy and Neurobiology and Neurology and Neurosurgery, Washington University School of Medicine, St. Louis, MO 63110.

The cerebellar relay area in the monkey thalamus is more restricted than customarily thought. It is confined to the relay to area 4: the common VPLo-VLc nucleus, with lesser inputs to the central lateral (CL) nucleus. Single or multiple [^{3}H] amino acid injections were made into parts of dentate n., n. interpositus or n. fastigius and, for comparison, into the dorsal column nuclei. Patterns of cerebello-thalamic label are continuous across the "border" of VPLo and VLc. Label extends into anterodorsal extensions of VLc, but no terminal labelling overlies the dense cellular clusters of the VLo nucleus. Posteriorly there is no overlap into the terminal territory of the medial lemniscus in VPLc and VPM. The frequency of isolated patches of label in CL appears highest following dentate injections.

A lamellar organization is apparent within VPLo-VLc following injections of all deep cerebellar nuclei but is particularly obvious following n. interpositus injections. Parasagittal sections reveal rows of evenly spaced labelled clusters extending dorsally within VPLo and curving posteriorly within VLc. These clusters of grains are also aligned in rows in the mediolateral dimension, thus defining curving planes within which grain clusters are distributed in a checkerboard arrangement. Such arrays can be readily seen in tangential sections through these lamellar planes. Anteroposteriorly oriented rods and isolated clusters of terminal labelling result following injections of the other deep cerebellar nuclei. These rods have a tendency to intersect the lamellae. The lamellar organization corresponds to the distribution of thalamocortical relay cells: following punctate horseradish peroxidase injections into area 4, retrogradely labelled clusters of cells are aligned mediolaterally within similar lamellae extending through VPLo-VLc.

The results indicate that VPLo and VLc form a common nucleus which is distinct from the lemniscal relay nucleus, VPLc, and from the pallidal relay, VLo, and projects only to area 4. Within VPLo-VLc, there is a finer organization of topographic lamellae and subsidiary clustering of inputs and of relay cells.

177.10 CEREBELLAR CORTICAL EFFERENT FIBERS OF THE DORSAL CULMINATE LOBULE (ANTERIOR LOBE - LOBULE V) OF THE SQUIRREL MONKEY, SAIMIRI SCIUREUS. D.E. Haines and G.W. Patrick. Dept. of Anatomy, West Virginia Univ. Sch. of Med., Morgantown, WV 26506.

The efficacy of chronic cerebellar stimulation (CCS) as a viable treatment for movement disorders is debated in the literature. Although primates have been utilized as animal models in a number of investigations designed to ascertain the value of CCS little data is available concerning the spatial organization of corticonuclear fibers in primates. This study details the arrangement of cortical efferent fibers from the dorsal culminate lobule (anterior lobe) in the squirrel monkey. Lobule V was selected for this study since, in human, stimulating electrodes are frequently placed on this region of cortex.

A total of 14 lesions were made in lobule V. Additional lesions were placed in the immediately adjacent cortex of lobule VI (1 case) and lobule IV (3 cases). Following survival times of 4-12 days all animals were killed via perfusion with .9% heparinized saline followed by 10% formalin. Brainstems with cerebelli intact were cut at 40 µm is coronal, horizontal and parasagittal planes and impregnated with the Fink-Heimer method.

From lesions located in approximately the lateral one-third of the lobule, degenerated fibers enter rostrolateral and rostral portions of the lateral cerebellar nucleus (NL). This terminal field within NL may be divisible into two portions. Corticonuclear fibers arising from more medial regions of the lobule (so-called intermediate cortex) terminate primarily in portions of the anterior (NIA) and posterior (NIP) interposed nuclei. Lateral areas of intermediate cortex (IC) are related mainly to lateral and rostrolateral NIA while medial regions of IC project into medial NIA with a lesser contribution entering the caudally adjacent NIP. The pattern of degeneration in NL, NIA, NIP following lesions of lateral and intermediate cortex indicate that cortical zones D (related to NL) and C_{1-3} (related to NIA and NIP) are present in squirrel monkey. The vermis, as reflected by the trajectory of its efferent fibers, extends about 2.5 mm lateral from the midline. Lateral portions of vermal cortex project into the vestibular complex while its medial areas are related to the medial cerebellar nucleus. These represent cortical zones B and A respectively. Although specific regions of cortex project primarily into identifiable areas of their respective nuclei there is some overlap at the interface of adjacent zones. These results show that corticonuclear fibers in the primate project into the deep nuclei in a complex and highly organized manner. The sometimes capricious results of CCS may be partially related to electrode position. More precise placement of electrodes in relation to cortical zones may precipitate more consistently beneficial results. (Supported by USPHS Grant NS 11327).

177.11 VESTIBULOCEREBELLAR PROJECTIONS TO THE PARAMEDIAN LOBULE OF THE TREE SHREW (TUPAIA GLIS). G.W. Patrick and D.E. Haines, Dept. of Anatomy, West Virginia Univ. Sch. Med., Morgantown, WV 26506.

Secondary vestibular connections with the cerebellum have been described in many animal species. The vast majority of vestibulocerebellar fibers end in archicerebellar regions, that is the vermis and flocculonodular lobe. In the course of another study concerned with brainstem afferents to the paramedian lobule (PML), a moderate number of retorgradely labelled somata were found in the vestibular nuclei. This report describes the distribution of these cells. A total of ten tree shrews (Tupaia glis) were utilized in this study. Under ether anesthesia, the skull overlying the paramedian lobule was removed and a small sliver of crystalline horseradish peroxidase (HRP) was implanted. Following survival times of 22-38 hours, the animals were killed by transcardiac perfusion. The brainstems and cerebelli were cut in frozen section at 50µ in transverse plane. The tissues were subsequently processed according to both TMB or DAB techniques. HRP positive cells are present in both the medial (MVN) and spinal (SPVN) vestibular nuclei. Lateral and superior vestibular nuclei are completely devoid of HRP labelled cells. HRP-reactive somata are located primarily in the caudal two-thirds of the SPVN and MVN. The total length of these nuclei which contain labeled somata is approximately 900-1400µm. Both ipsilateral and contralateral MVN and SPVN project to paramedian lobule. HRP implants in more lateral regions of PML resulted in fewer labelled cells in the vestibular nuclei on both sides. This would suggest a diffuse medial to lateral topographic relationship fewer between the SPVN and MVN bilaterally and the PML. Since SPVN and MVN receive direct input from portions of flocculonodular lobe to which they project, it was considered prudent to check for reciprocity in the above described vestibulocerebellar pathway. In 10 animals lesions were placed in the PML and tissue was processed by the Fink-Heimer technique. The lack of terminal debris in SPVN and MVN indicates no direct reciprocity from PML to these nuclei. These results suggest that although the PML receives afferents from the MVN and SPVN, this portion of cerebellar cortex may play no direct role in motor coordination via circuits through the vestibular complex. 177.12 IMPROVEMENT OF ABNORMAL PROPRIOCEPTIVE REFLEXES IN SPASTIC MONKEYS BY CEREBELLAR STIMULATION. J. L. Vitek*, T. J. Ebner, A. Schwartz* and J. R. Bloedel. Dept. Neurosurg., Univ. of Minnesota, Minneapolis, MN 55455.

The effects of stimulating the cerebellar surface on abnormal segmental reflexes was examined in monkeys (Macaca mulatta and Cercopithecus aethiops) rendered spastic by a two stage bilateral decortication of areas 1, 2, 3, 4 and 6. The rectified, integrated EMG from the biceps and triceps as well as the torque were recorded and averaged during several successive flexion-extension movements of the arm produced by a displacement controlled torque motor. Two passive movement paradigms were employed. The first, a ramp-and-hold paradigm, consisted of a rapid 30-45 degree flexion of the forearm, a 2 sec. period during which the limb position was held constant, followed by a rapid extension returning the limb to the initial position. In the second paradigm, the forearm position was modulated sinusoidally at several different frequencies. A cerebellar stimulating electrode was placed over the pars intermedia and medial cerebellar hemispheres of the anterior lobe, although the anterior part of the posterior lobe was also contacted. Each electrode consisted of three platinum discs (each 7.6 mm.^{2}). Different frequencies (10-300 Hz.) and charge densities (1.5-10 u coul/cm.^{2}) were used to maximize the physiological effects described below. In each experimental trial short periods of cerebellar stimulation (10-30 min.) were interspersed between control periods. The findings from each experimental animal were extremely similar. As in some types of clinical spasticity, flexion or extension of the extremity was capable of evoking co-activation of flexors and extensors. Cerebellar stimulation reduced the amplitude of the phasic and tonic stretch reflexes recorded from the triceps during flexion and decreased the abnormal triceps response during its shortening. The biceps response to stretch was increased by cerebellar stimulation. However, the abnormal response during flexion was decreased. Cerebellar stimulation was also capable of improving the organization of segmental reflexes, producing a more normal reciprocal relationship in the EMG activity evoked in biceps and triceps. In the absence of cerebellar stimulation the activation of agonist and antagonist occurred at approximately the same phase during sinusoidal limb displacement. During cerebellar stimulation, the peak activity in the flexor and extensor became approximately 180° out of phase. Therefore, stimulation of the cerebellar surface can produce dramatic physiological effects in spastic monkeys, including improvement in the organization of activity evoked during the stretch reflex. This research was supported by NIH Contract No. NO1-NS-4-2332, and NIH Grant No. 2RO1-NS-09447-10.

177.13 IN VITRO STUDIES OF THE BRAIN STEM-CEREBELLAR SYSTEM PERFUSED VIA THE BASILAR ARTERIAL SYSTEM. R. Llinás, Y. Yarom* and M. Sugimori*. Dept. Physiology & Biophysics, New York Univ. Med. Ctr., 550 First Ave., New York 10016.

Last year a set of experiments on isolated brain stem in guinea pigs was reported (Yarom and Llinás, Soc. Neurosci. Abst. 5: 109, 1979). Recently we have developed the technique to include the brain stem and the cerebellum en block. This tissue may be kept alive for as long as 12 hours after Ringer solution perfusion via the arterial system while keeping the tissue under a rapidly moving Ringer solution in the external bath. The present studies indicate that both brain stem and cerebellum can survive such isolation if the perfusion fluid is kept under strict osmotic and pressure conditions (Yarom and Llinás, 1979) and oxygenated with 0.001% H_2O_2 in Ringer (Llinás and Sugimori, J. Physiol. 305: 1980 in press). Studies in the detailed electrophysiological analysis of the cerebellar cortex indicate that antidromic, climbing fiber, and mossy fiber/granule cell activation of Purkinje cells may be observed and are in every way similar to the records obtained in vivo. In addition, Golgi and stellate-basket cell inhibition have all the spatial and temporal properties found in normal circumstances. The study has allowed a definition of field potentials and intra- and extracellular unitary recordings, all of which indicate that the known properties of the normal circuitry are intact in the present condition.

The preparation is determined extremely useful for the study of pharmacology and of nerve nets under conditions of high stability. Concomitant with the electrophysiological studies, measurement of oxygen levels was obtained using platinum microelectrodes. The measurements indicate that while the oxygen levels in the extracellular medium are close to normal in the presence of H_2O_2, the firing of the neuronal components either by direct or reflex stimulation does not fall as low as in the brain perfused without such oxidating agent. In addition, in the presence of H_2O_2 the extracellular level of oxygen recuperates quickly to the normal baseline. This change in oxygen levels correlates well with the ability of the nervous system to follow stimulation at high frequencies and to show depletion following protracted stimulation. (Supported by USPHS grant NS-13742 from NINCDS)

178.1 SYNAPTOSOMAL CONVERSION OF RADIOACTIVE PYRUVATE INTO RADIOACTIVE ACETYLCHOLINE. A.M. Benjamin* and J.H. Quastel. Division of Neurological Sciences, Department of Psychiatry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5.

Whereas the presence of CoA alone (0.1 mM) in the incubation medium has little effect on the conversion of [2-^{14}C]-sodium pyruvate (5 mM) into ^{14}C-acetylcholine in the presence of choline (5 mM) by a P_2 fraction (4-6 mg protein) of rat brain, the addition of $CaCl_2$ (1 mM) causes a marked acceleration of the reaction, producing 200 nmols ACh per 100 mg P_2 protein per hour. The addition of $CaCl_2$ (1 mM) alone has no effect. With Triton X-100 (0.1%) present at a concentration that ruptures mitochondrial membranes, the addition of CoA (0.1 mM) alone to the P_2 fraction produces over a five-fold increased rate of ^{14}C-ACh conversion, the further addition of $CaCl_2$ (1 mM) having a small (20%) retarding affect. It would appear that the presence of Ca^{++} facilitates the entrance of CoA into the mitochondria where the conversion of pyruvate into acetyl-CoA occurs and/or the efflux of acetyl-CoA from the mitochondria into the synaptoplasm containing choline acetyltransferase. Whereas the addition of NAD (1 mM) to the incubation medium has little or no effect on the conversion of pyruvate to ACh in the P_2 fraction, it has a marked (30-fold) effect when Triton (0.1%) is also present. This is possibly due to restoration of the NAD concentration present originally in the mitochondria. Triton (0.1%) blocks the respiration of the P_2 fraction, but the corresponding amount of acetyl-CoA spared from respiration is only partially (about 20%) converted into ACh. Phospholipase A_2 (venom) causes release of CoA + acetyl-CoA from the P_2 fraction, presumably by affecting the permeability of the mitochondrial membrane. It would seem that the permeability effect of Triton is proportional to its concentration (0.02%-0.06%). The maximum amount of ACh derived from pyruvate in a P_2 fraction (in absence of Triton) occurs at about 1 mM pyruvate. Sodium oxaloacetate is a potent inhibitor of ACh formation from pyruvate or from acetyl-CoA, almost complete inhibition occurring at 2 mM. Sodium pyruvate (5 mM) exercises a smaller inhibitory effect from acetyl-CoA.

178.2 ACETYLCHOLINE HAS A POWERFUL DISINHIBITORY ACTION IN THE HIPPOCAMPUS. R.J. Reiffenstein*, K. Krnjević and N. Ropert* (SPON: D. Bindra). Anaesthesia Research and Physiology Depts., McGill University, Montreal, Canada H3G 1Y6.

It is known that ACh has a slow, prolonged muscarinic excitatory action on some hippocampal neurons (Biscoe & Straughan, J. Physiol. 183,341,1966). We describe here a different excitatory action of ACh seen in the superficial pyramidal layer during fimbrial stimulation. Our experiments were done on urethane-anaesthetised rats, using multibarrelled micropipettes to record field responses evoked in CA1 and CA3 areas of dorsal hippocampus by fimbrial shocks. At low frequencies of stimulation (< 2/s) the main response is a relatively large, slow positive wave (peak latency about 10 ms) in the pyramidal cell layer. This reflects the powerful IPSPs generated by recurrent collaterals of pyramidal axons (Andersen et al., J.Neurophysiol. 27,592,1964). Stimulation at higher frequencies rapidly leads to the appearance of single or multiple negative "population" spikes. Recent evidence (Ben-Ari et al., Can.J.Physiol.Pharmacol. 57, 1462,1979) suggests this "release" of firing is due to a reduced efficacy of the recurrent inhibitory pathway. We now report that a similar release of firing can be produced by iontophoretic application of ACh (≥ 10 nA) during low-frequency fimbrial stimulation. At the same time the amplitude of the positive field diminishes. That this effect is due to disinhibition, rather than direct stimulation, is strongly supported by the following: 1) ACh is effective only where the stimulus generates the largest positive field - that is, near the pyramidal cell bodies where inhibitory synapses are concentrated; 2) ACh only generates spikes at fimbrial stimulus strengths which also evoke spikes at higher stimulus frequencies; 3) the onset and offset of the ACh action is much more rapid than the time course previously described for single unit excitation; 4) L-glutamate, a powerful excitant of pyramidal cells, has no comparable effect; 5) but agents known to antagonise GABA show a similar effect (Ropert et al., 1980, this meeting). The disinhibition is muscarinic in nature since methacholine and bethanechol are also effective, while tetramethylammonium and butyrylcholine are not. However, both nicotinic and muscarinic antagonists can generate a similar excitation, possibly by blocking GABA receptors. Since eserine enhances the population spikes, as well as potentiating the effects of ACh, it appears that cholinergic inputs may play an important role in the control of hippocampal pyramidal cell firing, by reducing inhibition normally operating.

178.3 ACETYLCHOLINE: A NEUROMODULATOR OF HIPPOCAMPAL PYRAMIDAL NEURONS. L.S. Benardo and D.A. Prince. Dept. of Neurology, Stanford University Medical School, Stanford, CA 94305.

The mode of action of acetylcholine (ACh) in the mammalian central nervous system has not been studied extensively. The hippocampus is known to receive a cholinergic input from the septal nuclei, but the mechanism of excitation by ACh and the related changes in cellular behaviors have not been completely described. Intracellular recordings were obtained from a total of 105 hippocampal CA1 pyramidal cells (HPCS) utilizing the guinea pig hippocampal slice preparation. Normative data were collected from 74 HPCS. In 46 of these neurons the action of ACh was investigated, using either focal pressure application (1-200 mM) or iontophoresis (.1-1 M) onto dendrites in stratum oriens or stratum radiatum. In all HPCS, ACh induced depolarizations of membrane potential (V_m) of up to 28 mV coincident with increases in input resistance (R_N) of up to 300%. When R_N was compared at various levels of V_m before and after ACh application, increases in R_N were noted to have both voltage dependent and independent components, perhaps corresponding to actions on a delayed rectification and a resting K^+ channel, respectively. In 18 cells an initial hyperpolarization of up to 10 mV lasting 2-30 seconds, and associated with decreases in R_N, was noted to precede these events.

The increases in R_N were quite prolonged, as judged by comparisons of membrane properties in populations of neurons before and following ACh exposure, and outlasted changes in V_m. Elevations in R_N seemed to underlie the striking long-term alterations in cellular behaviors subsequently noted. Following ACh application HPCS shifted from a single spike firing mode to one of burst generation. Bursts occurred spontaneously and could be evoked by afferent or intracellular stimulation. These changes persisted for the duration of an experiment (hours).

Following perfusion of slices with solutions containing atropine (10^{-7}-1.5 x 10^{-6} M) (n = 24) or scopalamine (10^{-6} M) (n = 7) all responses noted above were blocked, indicating that these effects of ACh were mediated through muscarinic receptors. In addition, exposure to muscarinic antagonists uncovered a tonic action of endogenous ACh on membrane properties of HPCS. Mean R_N in atropine was 21.9 ± 7.7 (S.D.) MΩ, while R_N in the control group of neurons was 37.6 ± 8.7 (S.D.) MΩ, though relatively little change was noted in mean resting V_m. Thus spontaneous ACh release appears to have an important influence on resting membrane properties of HPCS. This remarkable finding considered along with the actions on voltage dependent conductance and the profound potentiation of cellular responses supports classification of ACh as a neuromodulator of HPC activities.

178.4 TWO [^{3}H] QNB BINDING SITES IN RAT HIPPOCAMPAL MEMBRANES: CORRELATION OF ONE SITE WITH CHOLINERGIC STIMULATION OF PHOSPHATIDYLINOSITOL METABOLISM IN HIPPOCAMPAL SLICES. James N. Davis, William R. Tyor*, Keith A. Crutcher and Elizabeth Hoyler*, Dept. of Medicine (Neurology) and Pharmacology, Duke University Medical Center and Veterans Administration Medical Center, Durham, N.C. 27705.

[^{3}H] Quinuclidinyl benzilate (QNB) binds to sites on brain membranes with the characteristics expected for muscarinic cholinergic membrane receptors. Recent studies have demonstrated that [^{3}H] QNB binding is more complex than originally thought, since some cholinergic agonists compete with [^{3}H] QNB as if more than one population of membrane binding sites was present. We have correlated the binding of [^{3}H] QNB to membranes from the rat hippocampal formation with the ability of cholinergic agents to elicit or block [^{3}H] myo-inositol incorporation into hippocampal slice phospholipids. Using a computer modeling approach, two [^{3}H] QNB bindings sites (Site No. 1, 0.63 pmol bound/mg protein, and Site No. 2, 0.17 pmol/mg) could be distinguished in hippocampal membranes by differences in the affinity of agonists for [^{3}H] QNB binding. At site 1, the agonists displayed a typical muscarinic potency series with oxotremorine > acetylcholine > carbachol. The potency of these agonists in competing for [^{3}H] QNB binding to site 1 was the same as their potency in eliciting [^{3}H] inositol incorporation into hippocampal slice phospholipids. By contrast the affinity of the agonists for site 2 was carbachol ≥ acetylcholine ≥ oxotremorine. [^{3}H] QNB and atropine, both active as antagonists in the incorporation of [^{3}H] I into hippocampal slice phospholipids, had the same affinity for both sites. These data demonstrate the presence of two distinct [^{3}H] QNB binding sites in hippocampal membranes, one of which (site No. 1) appears to mediate cholinergic stimulation of phosphatidylinositol metabolism in hippocampal slices. The physiological relevance of the other site remains to be determined.

Supported by VA (1680) and NIH (NS06233, AG00029, AG00006).

178.5 TEMPERATURE DEPENDENCE OF AGONIST COMPETITION AT [^{3}H] QNB BINDING SITES IN RAT HIPPOCAMPAL MEMBRANES.
William R. Tyor, Andre De Leon, and James N. Davis
(SPON: R. Nashold), Department of Medicine (Neurology) and Pharmacology, Duke University Medical Center and Veterans Administration Medical Center, Durham, N. C. 27705.

Recent radioligand binding studies have suggested that the affinity of membrane receptors for agonists, but not antagonists is temperature dependent. We studied the temperature dependence of agonists and antagonists to compete with [^{3}H] QNB for binding in rat hippocampal membranes using a computer modeling approach. Membranes were incubated with [^{3}H] QNB at either 25°C (2 hours) or 4°C (17 hours) with or without a small series of cholinergic agonists and antagonists. [^{3}H] QNB bound to 0.80 ± 0.14 pmols of sites/mg protein in these membranes. The K_D at 25° (28 ± 1 pMolar) was significantly different ($p < 0.01$) from the K_D at 4° (108 ± 10 pMolar). By contrast the other antagonist tested, atropine, showed no difference in affinity for these sites when studied at 25° and 4° (K_D, 0.27 nM). The two agonists tested at 25° and 4° also demonstrated differences in their affinity for the [^{3}H] QNB binding sites. Acetylcholine and oxotremorine competed with [^{3}H] QNB binding as if two populations of sites were present. Oxotremorine demonstrated the same affinity for both sites at 25° (0.16 ± 0.03 μM) but a significantly ($p < 0.01$) different affinity for the two sites at 4°C (0.027 ± 0.001 μM). Similarly the affinities of acetylcholine for the two populations of sites at 25°C (0.03 ± 0.03 μM, 10 ± 1 μM) was significantly different ($p < 0.01$) than the affinities of acetylcholine at 4° (0.01 ± 0.02 μM, 4.7 ± 0.6 μM). From these studies we conclude that like some other radioligand binding sites, hippocampal [^{3}H] QNB sites demonstrate a greater affinity for agonists when binding is carried out at lower temperatures.

178.6 INCREASED MUSCARINIC CHOLINERGIC RECEPTORS IN THE DEAFFERENTED HABENULA. Zehava Gottesfeld and Adriana Maggi*, Dept. of Neurobiol. & Anat., Univ. of Tex., Med. Sch., Houston; and Dept. of Cell Biol. Baylor Col. Med., Houston, Texas 77025.

It has been reported recently that the habenular nuclei (Hb) are innervated by cholinergic projections from the septal-diagonal band area via the stria medullaris (SM)(Gottesfeld & Jacobowitz, 1979). Ample evidence exists to show that drug-induced acetylcholine depletion causes supersensitivity that is associated with elevation of cholinergic receptor binding in the deprived regions. This work was undertaken to determine whether or not deafferentation of the Hb will result in an increased density of muscarinic receptors in these nuclei. Radiofrequency lesions were produced in the SM of Sprague-Dawley male rats (180-200g). Seven weeks post-lesion the animals were killed by decapitation and the Hb and the hippocampus were removed from frozen brain sections (300 μM thick). Sham-treated control rats underwent similar treatment, but lesions were not produced. The accuracy of the lesion placement was verified microscopically by observing 60 μM thionine-stained sections. Cholinergic muscarinic receptor binding was assayed using ^{3}H-Quinuclidinyl benzilate (^{3}H-QNB) as a ligand (Yamamura et al., 1974). Scatchard analysis plots carried out on the Hb of lesioned and sham-treated control rats, showed an increase of ^{3}H-QNB binding (Bmax) in the deafferented Hb by 36%, with no change in dissociation constant (Kd). In the hippocampus of control and lesioned animals, no difference was indicated in either the Bmax or Kd. Based on the present results, it appears that SM lesions induce an increase of muscarinic cholinergic receptors binding only in the Hb. Whether or not the observed elevated QNB binding is associated with acetylcholine supersensitivity in the Hb has yet to be determined.

178.7 AUTORADIOGRAPHIC LOCALIZATION OF MUSCARINIC CHOLINERGIC RECEPTORS IN RAT BRAIN STEM. M. Lewis, J.K. Wamsley, W.S. Young, III and M.J. Kuhar
(SPON: R. Dismukes). Johns Hopkins School of Medicine, Departments of Pharmacology and Psychiatry, Baltimore, Maryland 21205.

Quinuclidinyl benzilate (QNB) is a potent muscarinic cholinergic antagonist and was used previously in our laboratory to provide the first anatomical localization of muscarinic receptors in the rat forebrain by *in vivo* autoradiography. We have now extended these studies to include the localization of muscarinic cholinergic receptors in the rat brain stem and have employed a new *in vitro* autoradiographic method (Young and Kuhar, Brain Res., 179:255-270). Initially we characterized the binding of ^{3}H-QNB to our tissue sections and examined the kinetics and specificity of this binding in order to determine that we were labeling the receptors as they were originally described in pharmacological studies. Using a 2 hr incubation in 1 nM ^{3}H-QNB followed by a 10 min rinse (blanks were generated on adjacent slides by incubating under the same conditions, but in the presence of 1 micromolar atropine) we were able to generate specific to nonspecific (signal to noise) ratios as high as 70 to 1. Thus, the *in vitro* method provides an easy and economical method with which we can label muscarinic cholinergic receptors with a high specificity not possible with conventional methods of autoradiography. Our results have demonstrated high concentrations of muscarinic cholinergic receptors in the superficial layers of the superior colliculus , in the pontine nuclei, parabrachial nuclei and the nucleus of the trigeminal nerve. The locus ceruleus showed a more moderate level of grains and the superior olive demonstrated virtually no binding sites for ^{3}H-QNB at all. The medial vestibular nucleus was seen to have a high grain concentration after incubation with ^{3}H-QNB while the other nuclei of the vestibular system showed only low levels of grains. The nucleus of the facial nerve also demonstrated a high concentration of autoradiographic grains while the nucleus tractus solitarii and nucleus ambiguus were seen to have intermediate numbers of muscarinic binding sites. The dorsal column projection sites, nucleus gracilis and nucleus cuneatus were also seen to have intermediate numbers of muscarinic receptors. The spinal cord bound a high concentration of ^{3}H-QNB in the substantia gelatinosa of the dorsal horn. A slightly lower number of grains were found in lamina IX and X in the ventral horn of the spinal cord. These autoradiographic localizations of muscarinic cholinergic binding sites will help to localize the muscarinic cholinergic sites of action of the neurotransmitter acetylcholine and may help explain the effects of various anticholinergic drugs.

178.8 GLIAL STORAGE OF ACETYLCHOLINE IN THE FROG FILUM TERMINALE. T. Ritchie, S. Glusman and B. Haber. Marine Biomed. Inst., Dept. Human Biol. Chem. & Genetics & Dept. of Neurology, Univ. Tex. Med. Branch, Galveston, TX. 77550

We have been utilizing the filum terminale (FT) of the frog spinal cord, a structure composed predominately of normal glial cells with only a few peripherally located myelinated axons, to study a number of properties of normal glia. The frog FT is a structure formed during normal development as a result of the degeneration of motoneurons in terminal segments of the tadpole spinal cord during metamorphosis. We have measured the content of acetylcholine in different areas of the frog CNS using a sensitive radiometric assay and found levels in the FT to be roughly 3-10 times higher than in other CNS regions. The enzymatic activity of choline acetyltransferase, the biosynthetic enzyme for ACh, is extremely low in the FT suggesting an absence of cholinergic nerve terminals in the frog FT. These observations would strongly suggest a glial storage of ACh in the frog FT. Observations by Miledi and Slater with the denervated neuromuscular junctions of amphibia show that the reappearance of miniature end-plate potentials following denervation may be related with acquired capabilities of Schwann cells to store and also release ACh in a quantal manner. This is further consistent with the demonstrated presence of ACh in the Schwann cells of the squid giant axon (Villegas, et al.). At the present the source of the ACh in the glia of the FT is obscure, but is unlikely to represent glial synthesis. It is interesting to note that the glia in the FT also contain some serotonin (5HT), and probably also contain significant levels of γ-aminobutyric acid (GABA). The observations of the presence of ACh, GABA and 5HT are supportive evidence for the glial storage of neurotransmitters and are consistent with the presence of high affinity uptake processes for neurotransmitters in both transformed and normal glia.

178.9 DIETARY CHOLINE MODIFIES THE RESPONSIVENESS OF THE HIGH AFFINITY CHOLINE UPTAKE SYSTEM TO PHARMACOLOGICAL MANIPULATION. B.A. Trommer*, K.L. Parrish and L. Wecker. Department of Pharmacology, Louisiana State Univ. Med. Ctr., New Orleans, LA 70112.

Recent results from our laboratory have indicated that the acute administration of choline to rats prevents both atropine-induced depletion of acetylcholine (ACh) and increased sodium-dependent high affinity choline uptake (HACU) in brain (Sci. 199:86,1978). However, with chronic choline supplementation, the ACh depleting action of atropine was potentiated (Neurosci. Abst.4:436,1978). Therefore, the present study was designed to investigate the effects of dietary (chronic) choline availability on the responsiveness of the HACU system to pharmacological manipulation. Rats were randomly divided into 3 groups and maintained for 28-32 days on: a)choline deficient diet, b)basal choline diet (0.2% choline chloride) or c)choline supplemented diet (2.0% choline chloride). Rats were injected with either saline or atropine sulfate (7.0 mg/kg, i.p.) and sacrificed 30 minutes following injection. The kinetic characteristics (Vmax and Km) of the HACU system were determined in striatal and hippocampal synaptosomes (P_2 fraction) utilizing choline concentrations of 0.1-1.43 uM. In synaptosomes from rats maintained on the basal diet, atropine increased the Vmax of uptake in both striatum and hippocampus to 119% and 124% of controls, respectively. In brain tissue from choline supplemented rats, the atropine-induced increase was potentiated with a Vmax of 131% of control in striatum and 151% of control in hippocampus. In synaptosomes isolated from rats maintained on the choline deficient diet, which were characterized by a dietary-induced elevation in Vmax, atropine administration had no further effect. The affinity of the HACU system was unaltered by either dietary regimen or drug treatment. Contrary to studies with acute choline administration, in which choline blocked the atropine-induced increase in HACU, dietary choline supplementation potentiated the atropine-induced increase in uptake as reflected by an increase in Vmax. Hence, dietary choline supplementation renders the HACU system more sensitive to atropine-induced alterations, in agreement with previous studies on the effects of atropine on the steady-state concentration of ACh (Neurosci. Abst.4:436, 1978). Results support the hypothesis that dietary choline availability modifies the responsiveness of central cholinergic neurons to pharmacological manipulation. The specific mechanisms involved in this drug-diet interaction are currently being investigated in our laboratory. (Supported by NIMH # 33443).

178.10 INDUCTION OF D-SLEEP PHENOMENA WITH THE MUSCARINIC CHOLINERGIC AGONIST BETHANECHOL. MP Goldberg, D. Riew, E. Vivaldi, RW McCarley and JA Hobson. Laboratory of Neurophysiology, Harvard Medical School, 74 Fenwood Road, Boston, MA 02115

Bethanechol (B-methyl carbamyl chloride), a derivative of carbachol, is a cholinergic agonist which is not degraded by cholinesterases. Unlike carbachol, which is a mixed agonist, the action of bethanechol is specific to muscarinic receptors. We now present evidence that the striking effects obtained by microinjection of carbachol into the pontine reticular formation (FTG) of cats can be duplicated using bethanechol.

Bethanechol (2-5 ug) was dissolved in saline or distilled water. The injection volume of 0.5-1.0 µl was pumped over 30 sec through broad-tipped micropipettes (50-200 µm tip diameter) placed stereotaxically or directed by chronically implanted guide tubes. 9 trials were conducted in 4 different animals. In each case, the target was the same region of the FTG as had proven effective for injections of carbachol (AP -3.0, L 2.0, V -7.0 HC).

Polygraphic data (EMG, EEG, EOG) were analyzed for time of occurrence and duration of waking (W), synchronized sleep (S), and desynchronized sleep (D). After four of the injections (one in each animal subject), the cat entered a state indistinguishable from D by electrographic or behavioral criteria. The latency was reduced to less than 1/3 of control values (range 12-30 min vs 60-275 mins) and was not preceded by intervening S sleep in 2 of the 4 cats. The first episode was two to four times longer than is normal (range 10-40 minutes vs 4-10 mins) in the five hours following injection, the amount of D was increased 400% over baseline (range 6-58% vs. 1.5-15%). Effects endured for 3-24 hours. In the five other trials the results were negative, probably because of failure to eject drug from the pipette.

Behavioral observation demonstrated that the bethanechol induced D state was posturally indistinguishable from physiological D. Furthermore, the cats could be awakened by auditory or tactile stimuli. The pupils, which were fissurated in D, promptly dilated when the cats were aroused. During periods of spontaneous or induced waking, the cats were alert, responsive to visual and auditory stimuli and capable of a full range of motor behavior.

We conclude that the cholinergically induced D state may be mediated by muscarinic receptors.

178.11 A COMPARATIVE STUDY OF CHOLINE AND LECITHIN TREATMENT ON DOPAMINE (DA) SYNTHESIS AND TURNOVER IN THE STRIATUM AND HIPPOCAMPUS OF RATS. Ram B. Rastogi, N.P.V. Nair*, and S. Lal*. Laboratories for Research, Douglas Hospital Research Center, and Dept. of Psychiat. McGill Univ., Montreal, Canada, H4H 1R3.

Studies have shown that cholinergic drugs accelerate both DA synthesis and turnover in the striatum (H. Corrodi et al Life Sci. 6:2557, 1967; F. Javoy et al, J. Pharm. Pharmacol. 27:677, 1975). It has also been demonstrated that administration of the acetylcholine (Ach) precursors such as choline and lecithin elevate brain Ach levels (E.L. Cohen and R.J. Wurtman, Life Sci. 16:1095, 1976; M. Hirsch et al, Brain Res. 125:383, 1977). In the present study we examined the effect of these precursors on DA metabolism in six discrete rat brain areas (striatum, hippocampus, pons, midbrain, cerebral cortex, hypotholamus). Our data demonstrated that a single i.p. injection of choline chloride (120 mg/kg) significantly increased tyrosine hydroxylase (TH) activity in the soluble fractions of striatum and hippocampus by 33% and 51%, respectively. A similar magnitude of increase was seen in the striatum of rats after a single injection of lecithin (200 mg/kg, i.p.) but in hippocampus TH activity was increased by 89% as compared to control values. Administration of both precursors also significantly increased tyrosine levels (the substrate for TH) in striatum and hippocampus. Acute choline treatment produced no change in DA levels in several brain areas except cerebral cortex where it was significantly decreased by 18%. The same treatment significantly increased the concentrations of homovanillic acid both in striatum and hippocampus suggesting that the turnover of DA was increased in these regions. After 7 days treatment with choline chloride TH activity as well as levels of tyrosine and homovanillic acid were increased in striatum and hippocampus however, the magnitudes of change were virtually the same as those seen after a single injection of choline chloride. Our data raise the possibility for the existence of presynaptic inputs from cholinergic neurons on dopaminergic neurons in striatal and hippocampal areas of brain. Experiments are underway to examine if such changes in DA synthesis and turnover persist after long-term treatment with choline and lecithin. (Supported by funds from Douglas Hospital Center).

179.1 TRIGEMINAL OROSENSORY FACTORS AND DIETARY SELF-SELECTION. M. G. Miller. Food and Drug Administ., Washington, DC 20204.

Rats given the opportunity to select the components of their diet maintain a stable protein/carbohydrate (P/C) ratio in their daily intake. To investigate the underlying neural control mechanisms, the animals' oral sensory abilities were manipulated by partial trigeminal deafferentation affecting somatosensation of the lower portion of the oral cavity (anterior 2/3 of the tongue, floor of the mouth and lower teeth). Taste, proprioceptive and motor innervation of tongue and muscles of mastication were spared. The animals had access to two isocaloric diets, a protein (soy bean meal, 44% protein) and a carbohydrate (dextrinized starch) fraction, each containing fat, vitamins and minerals in adequate amounts. Before surgery, the animals selected a mixture of both diets, which amounted to 12% protein intake, and maintained the same growth rate as a non-selection control group which received an isocaloric combination of both fractions (22% protein).

After trigeminal deafferentation, self-selection and non-selection groups exhibited the characteristic deafferentation symptoms of prolonged hypophagia, body weight loss, and delayed recovery of preoperative weight. The dietary self-selection pattern was disturbed throughout the postsurgical period (6 weeks), even when total daily intake reached preoperative levels. Four sequential stages could be distinguished: (1) Protein intake essentially zero, carbohydrate intake severely depressed, body weight decreasing; (2) P/C ratio below preoperative mean, body weight stabilizing at low level; (3) P/C ratio at preoperative level with high between-day variability, body weight increasing; (4) P/C ratio above preoperative level with high between-day variability around the mean of randomly distributed intake (22% protein); body weight increasing. Not all animals entered the last stage.

To ascertain that these changes were not simply a response to body weight loss, an additional control group was reduced in body weight to comparable levels by forced food deprivation. Although on the first day of refeeding, compensatory intake was disproportionately increased for the protein fraction, the C/P ratio rapidly returned to normal levels and showed no increased variability. The disruptive effects of partial trigeminal deafferentation on P/C selection suggest that somatosensory inputs from the oral cavity are important factors for dietary adjustment to metabolic requirements.

179.2 DEHYDRATION-INDUCED ANOREXIA: OLFACTORY CONTRIBUTIONS. J. P. Bruno* and W. G. Hall, Research Section, NC Div. Mental Health, Raleigh, NC 27611 and H. J. Grill, Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA 19104.

Dehydration inhibits feeding behavior in weanling and adult rats. To determine the component of feeding inhibited by dehydration we studied its effects when food was infused into the mouth or when it was presented in shallow cups. Dehydration inhibited feeding from the external environment but did not alter the active swallowing of oral infusions (Table 1).

TABLE 1

Condition	Fluid	Cup Fed (% BW)	Infusion Fed (% infused)
Baseline	Water	.64 ± .12	27.9 ± 5.7
(2-4 hr deprived)	Milk	2.60 ± .70	65.1 ± 5.0
NaCl	Water	3.27 ± .30	72.7 ± 8.6
(1M, 2% BW)	Milk	1.04 ± .21	82.4 ± 6.2

Twenty-day-old subjects in baseline conditions consumed more milk than water in both feeding tests. Dehydrated rats consumed much less milk than water when feeding from a cup. In contrast to the cup-fed group, when infusions were made into the mouth water and milk intakes were comparable following dehydration. Dehydration also inhibited feeding from a cup but not feeding during oral infusions in adult rats. The cup-feeding test requires subjects to locate and approach, as well as to lick and swallow the fluids; as such, it recruits several acts not required by the infusion test. Exteroceptive sensory cues (i.e., olfaction) may thus be more important in the cup-fed group than in the infusion-fed group. The fact that cup-fed dehydrated rats took twice as long to initiate milk consumption (12.6 min) as water consumption (5.4 min) suggests that distal olfactory cues might contribute to the inhibition of milk intake. We tested this hypothesis by offering dehydrated rats water that contained an odor cue with little taste (2% almond extract). Table 2 shows that dehydrated, but not control, weanling rats avoid water scented with almond.

TABLE 2

Condition	Fluid	Intake (% BW)
Baseline	Water	.53 ± .16
(2-4 hr deprived)	Water + Almond	.68 ± .20
NaCl	Water	2.86 ± .36
(1M, 2% BW)	Water + Almond	1.36 ± .71

These results demonstrate that the inhibition exerted by dehydration may act, via olfaction, on only the approach component of feeding while the oral consummatory component remains unaffected.

179.3 GLUCAGON INDUCED SUPPRESSION OF FOOD INTAKE IS ASSOCIATED WITH HEPATIC GLYCOGENOLYSIS WITHOUT LIPOLYSIS OR KETOGENESIS. Nori Geary†, W. Langhans* and E. Scharrer* (SPON: W.T. Lhamon). E.W. Bourne Lab., New York Hosp., White Plains, NY 10605, and Inst. Tierphysiol., Univ. München, D8000 München, FRG.

Meal contingent changes in carbohydrate metabolism may contribute to production of satiety. We have previously shown prandial hyperglycemia to be at least partially caused by transient hepatic glycogenolysis occurring concomitant to ad lib meals in the rat. Further, glucagon injections eliciting similar degrees of hepatic glycogenolysis and hyperglycemia significantly reduce meal size. We now report the effects of similar injections on lipid metabolism. Rats were first administered 180 µg glucagon i.p. as they began to eat after a 12 hr fast. Meal size was reduced in comparison to vehicle injected controls (3.4 ± 0.5 vs. 5.2 ± 0.5 g, $\bar{x}$ ± sem). Then, after two weeks, similar injections were made, and the rats sacrificed 15 min later for liver and aortic blood samples. Metabolite levels in rats sacrificed at meal onset (O), 15 min after vehicle injection (V) or after glucagon injection (G) were:

	O	V	G
Blood glucose (mg/dL)	86	100	115ab
Liver glycogen (%)	1.8	1.7a	0.7ab
Plasma hydroxybutyrate (µM/ml)	0.94	0.18a	0.19a
Plasma free fatty acids (µM/ml)	0.91	0.54a	0.53a

a = different from O value, t-test
b = different from V value, t-test

A glucagon dose which suppressed food intake therefore also elicited rapid hepatic glycogenolysis and exaggerated hyperglycemia without affecting lipogenesis or ketogenesis. We conclude glucagon can influence food intake through its effect on carbohydrate metabolism. Such effects may be signalled to the brain via hepatic vagal afferents.

179.4 GLUCOSE INFUSION BLOCKS ALLOXAN-INDUCED IMPAIRMENT OF GLUCOPRIVIC FEEDING. Sue Ritter and Joan Murnane*. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Alloxan is a toxic drug which can be given systemically to destroy insulin-secreting pancreatic beta cells. Alloxan also reduces the capacity of taste buds to respond to glucose. Several investigators have demonstrated that the effect of alloxan on both pancreatic beta cells and on taste buds can be competitively inhibited by D-glucose, suggesting that gluco-receptors in diverse tissues may have similar properties.

Recently, Woods and McKay reported that centrally-administered alloxan abolishes or greatly attenuates the feeding response to 2-deoxy-D-glucose (2DG) (Science, 202:1209, 1978). These authors suggested that alloxan damaged brain glucoreceptors responsible for 2DG-elicited feeding. In the present experiment we replicated the results of Woods and McKay. In addition, we have demonstrated that alloxan-induced impairment of glucoprivic feeding can be prevented if glucose and alloxan are administered simultaneously.

Adult male Sprague-Dawley rats were given either alloxan (40 µg in 5 µl saline), alloxan and glucose (40 µg alloxan in 5 µl of 3 M glucose) or saline (5 µl) through lateral ventricular cannulae. Body weight and spontaneous food intake did not appear to be altered by any treatment. Feeding and blood glucose responses were measured for 6 hr following subcutaneous injection of 2DG (150 mg/kg), insulin (2 U/kg) and saline. After 2DG injections, controls ate 4.3 ± 0.6 g of pelleted lab chow in the 6 hr test, whereas alloxan-treated rats ate only 1.6 ± 0.5 g ($p < 0.01$). Likewise, after insulin injections, controls ate 5.6 ± 0.3 g of food, while alloxan-treated rats ate only 3.6 ± 0.2 g ($p < 0.001$). In rats that received glucose and alloxan simultaneously, feeding responses were indistinguishable from control in both tests (3.6 ± 0.6 g after 2DG and 5.4 ± 0.6 g after insulin). Blood glucose concentrations did not differ between groups either before or after administration of glucoprivic agents.

Our findings (1) confirm the report that alloxan impairs 2DG-elicited feeding, (2) suggest that the deleterious effects of alloxan may be produced in brain by a mechanism similar to that exerted by alloxan on the pancreatic β-cell and taste bud, and (3) supports the contention that alloxan-induced impairment of glucoprivic feeding is due to a glucose-specific effect on a cellular mechanism.

179.5 INSULIN-INDUCED FEEDING AND INCREASED NOREPINEPHRINE TURNOVER ARE PREVENTED BY INTRAVENOUS GLUCOSE INFUSIONS. Steven I. Bellin and Sue Ritter. Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Several investigators have demonstrated enhanced hypothalamic norepinephrine (NE) utilization after administration of glucoprivic agents such as insulin or 2-deoxy-D-glucose. We have shown that the activity of hypothalamic NE neurons appears to be uniquely related to the insulin-induced feeding response rather than to the stressful aspects of the glucoprivic challenge per se (Bellin, S.I. and Ritter, S., Neurosci. Abstr., #688, 1979). The goal of the present experiment was to determine the mechanism by which insulin increases the activity of NE neurons. If these neurons are activated by glucoprivation, then glucose infusions which prevent glucoprivation during hyperinsulinemia should also prevent the insulin-associated increase in NE turnover. This result would be consistent with the view that increased hypothalamic NE activity is causally related to food intake, since other investigations have demonstrated that this treatment also abolishes post-insulin hyperphagia. On the other hand, if hypothalamic NE neurons are activated by insulin itself, then turnover should be enhanced after insulin, even when glucoprivation is prevented.

Forty-eight adult male Sprague-Dawley rats (400-500 gm) were divided into four treatment groups. Continuous intra-atrial infusions of 0.15 M saline or 1.2 M glucose (8 ml/hr) were begun 15 min prior to injection of either saline or insulin (2.5 U/kg s.c.). At 30 min post-injection, infusion rates were reduced to 2.0 ml/hr for the duration of the study. One and one-half hr later, α-methyl-p-tyrosine (AMT, 350 mg/kg, s.c.) was administered to each subject, followed by decapitation sacrifice of 6 animals per group 1/2 and 1 hr post-AMT. Catecholamine concentrations in 4 brain regions were determined by fluorometric analysis. In insulin-treated subjects, glucose infusions abolished the enhanced hypothalamic NE turnover observed in the saline-infused group. NE concentrations 1 hr after AMT were 1.96 ± 0.36 ug/g for glucose-infused rats and 1.37 ± 0.24 ug/g for saline-infused rats ($p < 0.01$). Simultaneous glucose infusions also prevented the hypoglycemia and hyperphagia normally observed after insulin administration. These results suggest that glucoprivation, and not insulin per se, is responsible for enhancing hypothalamic NE neuronal activity. Thus, deficits in either glucose or other energy substrates utilizable by brain may mediate the behavioral and neurochemical consequences of large insulin doses. We are currently testing this hypothesis using infusions of fructose and β-hydroxybutyrate solutions in insulin-treated rats.

179.6 POSTABSORPTIVE GLUCORESTORATION IS ASSOCIATED WITH TERMINATION OF POSTGLUCOPRIVIC FEEDING. Nancy L. Pelzer*, Steven I. Bellin and Sue Ritter (SPON: F.A. Young). Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Recently, Ritter et al. demonstrated that insulin and 2-deoxy-D-glucose (2DG) exert delayed effects on food intake that outlast the glucoprivic episode itself (Ritter, R.C. et al., Am. J. Physiol., 234:E617-E621, 1978). They showed that glucoprivic challenges elicited a significant increase in food intake 6-8 hr after insulin or 2DG, even though blood glucose values indicated that glucoprivation had abated; i.e., postglucoprivically. The amount of food consumed in a 2 hr postglucoprivic feeding test was similar to the amount consumed when food was continuously available during the entire glucoprivic episode. In pursuing these findings, we observed that limited access to food at the nadir of hypoglycemia (1 1/2 - 2 hr after 2.5 U/kg of regular insulin) blocked postglucoprivic feeding. Subsequently, we systematically varied the amount of food that rats were allowed to ingest during that 30 min time period. We found that consumption of as little as 2.5 g of pelleted lab chow was effective in blocking postglucoprivic feeding, even though this amount of food was only 30% of the amount consumed when food was continuously available during glucoprivation. Rats with 30 min access to 2.5 g of food (n = 11) ate 0.3 ± 0.4 g in a 2 hr postglucoprivic feeding test, whereas rats which were not pre-fed (n = 12) ate 6.7 ± 2.6 g of food during the postglucoprivic test. Furthermore, ingestion of glucose (13% solution), but not saccharin (0.1% solution), 1 1/2 - 2 hr after insulin also abolished postglucoprivic feeding. Quantities of food or glucose solution associated with blockade of postglucoprivic feeding were also associated with a rapid and sustained restoration of normoglycemia.

Our results do not explain why rats continue to feed when glucorestoration is allowed to occur spontaneously in the absence of food. Nor can we account for the apparent failure of parenteral glucose administration to abolish postglucoprivic feeding. It is possible that the glucorestoration we observe after ingestion of food is an epiphenomenon and that termination of glucoprivic feeding depends primarily on orogastric stimulation. However, the fact that saccharin consumption did not abolish postglucoprivic feeding suggests that the abolition of this behavior may require the cooperation of both pre- and postabsorptive signals.

179.7 SIMILAR FEEDING PROFILES IN TUMOR-BEARING AND DEXAMETHAXONE-TREATED RATS SUGGEST ENDORPHIN DEPLETION IN CANCER CACHEXIA. M. T. Lowy* and G. K. W. Yim (SPON: S. Sangiah). Dept. of Pharmacology and Toxicology, Purdue University, W. Lafayette, IN 47906.

The feeding patterns of male Sprague-Dawley rats bearing hindlimb Walker-256 carcinosarcomas (W-256/SD) were examined. Three hr daytime rat chow consumption induced by 2-DG (2-deoxy-D-glucose, 400mg/kg) was attenuated in tumor bearing rats (TBR) as compared to control (CON) rats (2.4 ± 0.5 gm vs 7.1 ± 0.8 gm, $p < .001$). Hyperphagia induced by 24 hr food-deprivation (FD) was also decreased in TBR as compared to CON (3.3 ± 0.6 vs 9.3 ± 0.7 gm, $p < .001$). In addition, 12 hr night time food intake was selectively depressed by 25-30% ($p < .01$) in TBR. Since these hyperphagias are naloxone-sensitive, whereas insulin-induced(10U/kg) hyperphagia is intact in naloxone-treated (Lowy et al. Life Sci. 26: 2113, 1980), and in anorexic W-256/SD rats (Morrison, Cancer Res. 33: 526, 1973), it appears that feeding deficits of the W-256/SD rats involve a defective endorphin system. The administration of the glucocorticoid, dexamethasone(400 and 200 μg/kg;24 and 2 hr pretreatment), which inhibits pituitary β-endorphin synthesis (Rossier et al., Proc. Nat. Acad Sci. 77: 666, 1980), produced an identical feeding profile in normal rats (i.e. reduction of 2-DG, FD and night time, but not insulin hyperphagia).

These results suggest that the elevated corticosteroid levels of the W-256/SD rats (Morrison, Phys. Beh. 17: 705, 1976) may have inhibited endorphin synthesis sufficiently to result in endorphin depletion and anorexia in the W-256/SD rats. (Supported in part by Pharmacology-Toxicology Training Grant GM-709504 (MTL) and American Cancer Society Grant IN 172).

179.8 TUMOR ANOREXIA: A ROLE FOR LEARNED FOOD AVERSIONS AND NUTRIENT DEFICIENCES. I. Bernstein* and C. Treneer* (Spon. G. Clark) Dept. Psychol. Univ. of Washington, Seattle, WA 98195

A decline in food intake and body weight is observed in cancer patients and animals with experimental tumors. Although a number of possible central and peripheral mechanisms for this anorexia have been proposed, agreement as to the causes of tumor-produced loss of appetite and weight has not been reached. One possible factor contributing to tumor anorexia is the development of learned food aversions. Tumor-bearing animals may associate some physiological consequence of tumor growth with the available food, develop a learned aversion to that food and reduce their intake of it.

The present studies evaluated this hypothesis by examining the food intake and diet preferences of animals with transplantable tumors. Wistar-Furth (W/Fu) rats with transplantable polyoma-virus induced sarcomas were given continuous access to nutritionally adequate diets. The decline in food intake which accompanied tumor growth was associated with the development of aversions to the specific diet consumed during tumor growth. An immediate and marked elevation in food consumption occurred when a novel diet was introduced. These findings suggested that the development of learned aversions to the specific diet eaten during tumor growth may be a causal factor in the development of tumor anorexia. In this regard tumor-bearing animals are similar to animals suffering from certain nutrient deficiencies.

Since amino acid deficiencies and imbalances are known to produce dramatic depressions in food intake we evaluated whether tumor-induced nutrient deficiencies, specifically deficiencies in specific amino acids, play a role in the development of anorexia and learned food aversions. Plasma samples were obtained from anorexic, tumor-bearing animals and pair-fed controls and amino acid profiles were obtained from these samples. Significant imbalances in the plasma profiles of the tumor-bearing animals were observed, including a marked depression in plasma tryptophan. Subsequent studies have been aimed at determining whether alterations in dietary amino acid composition could correct these imbalances and reduce the anorexia and food aversions seen in tumor-bearing animals.

179.9 DIURNAL VARIATION IN THE POTENCY OF CHOLECYSTOKININ FOR INHIBITION OF EATING IN RATS IS NOT DEPENDENT UPON CHOLECYSTOKININ'S EFFECT ON GASTRIC EMPTYING. F.S. Kraly. Dept. of Psychology, Colgate University, Hamilton, NY 13346.

Cholecystokinin (octapeptide, CCK-8) is less potent ($p < .002$) for inhibition of eating in the night than in the day: Threshold and ID_{50} at night are roughly twice threshold and ID_{50}, respectively, in the day for rats eating 1 min after i.p. CCK-8 at the midpoint of the night or day phases after 24-hr food deprivation (Kraly, 1980). To assess whether this phenomenon is dependent upon the ability of CCK-8 to alter gastric emptying, gastric emptying of food into the intestine was prevented by sham feeding in the following experiments:

Rats (n=49) with gastric fistula sham fed GIBCO 116EC liquid food at the midpoints of the night or day (12:12 cycle) after 3-hr food deprivation. CCK-8 (i.p., 5-180 U/kg; 1 U $\hat{=}$ .05 mcg) affected sham feeding in a dose-related manner in the night and day, but CCK-8 inhibited sham feeding less at night than during the day ($p < .005$): Threshold for inhibition in the day was 5 U/kg, but was 30 U/kg at night. While 10 U/kg caused 35.4% inhibition in the day, it enhanced sham feeding at night by 20.8% ($p \leq .05$). ID_{50} in the day ($r^2 = .55$) was 15.1 U/kg; ID_{50} at night ($r^2 = .92$) was 64.0 U/kg. The slopes of the regression lines were not different (night vs. day: $p > .10$).

The diurnal variation in the potency of 20% pure cholecystokinin (CCK; Karolinska Institutet) was of a different character: CCK (i.p., 5-180 U/kg) inhibited sham feeding in a dose-related manner in the night and day. While impure CCK failed to systematically inhibit sham feeding less at night than during the day ($p > .20$), ID_{50} in the day ($r^2 = .79$) was 14.4 U/kg, ID_{50} at night ($r^2 = .86$) was 24.7 U/kg, and the slopes of the regression lines were different ($p < .02$). Finally, CCK and CCK-8 were equally potent for inhibiting sham feeding in the day ($p > .20$), but CCK was more potent ($p < .05$) than CCK-8 for inhibiting sham feeding at night.

These results show (1) that the diurnal variation in the potency of cholecystokinin for inhibition of eating is not dependent upon cholecystokinin's effect on gastric emptying and (2) the potency of impure CCK is not equivalent to the potency of CCK-8 for inhibition of sham feeding at night.

179.10 CHOLECYSTOKININ OCTAPEPTIDE ACTS AT AN ABDOMINAL, NOT HYPOTHALAMIC, SITE TO PRODUCE SATIETY IN RATS. K.J. Simansky, C. Jerome* and G.P. Smith. Dept. of Psychiatry, Cornell Univ. Med. College and Bourne Laboratory, New York Hospital, White Plains, NY 10605.

The peripheral administration of the octapeptide of cholecystokinin (CCK-8) produces satiety in rats and other mammals. However, the locus at which this hormone activates satiety mechanisms has been controversial. Bilateral abdominal vagotomy has been reported to either abolish (Lorenz & Goldman, 1978), greatly attenuate (Smith & Cushin, 1978), or have no effect (Anika et al., 1977) on CCK-8 satiety. Similarly, Stern et al. (1976) found that bilateral lesions of the ventromedial hypothalamus (VMH) blocked the satiety effect of a single dose of caerulein--a decapeptide related structurally and in its visceral activity to CCK-8--while Kulkosky et al. (1976) failed to block CCK-8 satiety with VMH lesions.

We investigated this problem further by testing the satiety action of CCK-8 in rats with total abdominal vagotomy (VGX; n=8) or large bilateral hypothalamic lesions placed to include either the VMH (n=8) or another putative central site for the mediation of satiety--the paraventricular nuclei (PVN; n=9) (Eng et al., 1979). VGX rats were also tested with 1.25-160 U/kg i.p. of caerulein. Thirty min intakes of liquid diet were measured in 17-hr food-deprived rats beginning 15 min after injection of peptide or saline. VGX blocked the satiety effect of 80 U/kg of CCK-8. This dose of CCK-8 reduced food intake by 54 ± 4% ($p < .01$) in surgical controls (n=8) while VGX rats ate 15 ± 13% ($p > .10$) more. VGX also greatly diminished the satiety effect of caerulein. Controls demonstrated a significant 34% suppression of food intake after 2.5 U/kg, and 90% decrease after 80 U/kg while only the 160 U/kg dose reduced intake in VGX rats (-26 ± 9%; $p < .05$).

In marked contrast to the effect of vagotomy in blocking the satiety induced by CCK-8 or caerulein, neither VMH nor PVN lesions significantly altered this behavioral action of 10-160 U/kg i.p. of CCK-8. For example, the 80 U/kg dose suppressed intake by 50 ± 15% in controls (n=3) and by 43 ± 5% in VMH-lesioned rats ($p < .01$). Similarly, PVN rats demonstrated a dose-related decrease in food intake after 20, 40, 80, and 160 U/kg, including a 50 ± 8% decrease after 80 U/kg. Thus, destruction of the putative central satiety sites in the area of the VMH and PVN did not disrupt CCK-8-induced satiety.

These results, therefore, strongly suggest that peripherally administered CCK-8 and caerulein act at an abdominal site innervated by the subdiaphragmatic vagus to produce satiety in rats.

179.11 RATS PREFER REAL FEEDING TO SHAM FEEDING. W. Van Vort* and G.P. Smith. Dept. Psychiatry, Cornell Univ. Med. College and E.W. Bourne Behavioral Research Lab., The New York Hospital, White Plains, NY 10605.

To investigate the relative preference of rats for real feeding and sham feeding, male Sprague-Dawley rats weighing about 350 g were implanted with chronic gastric cannulas (GF). After recovering from surgery, rats were maintained on pellets and water and adapted to a 17 h food deprivation schedule. At the end of the deprivation period, rats were offered sweet milk. On alternate days the rats really ate the milk (GF closed) or sham fed the milk (GF open). For each condition - open or closed - the diet was marked with a specific flavor (almond or vanilla) and offered at a specific spout location at the front of the cage (left or right) for each rat. For example, rat Z would always be offered vanilla on the left on a real feeding day and almond on the right on a sham feeding day. The assignment of flavor and location was randomized. Two groups of 9 rats each were tested separately.

On real feeding days (GF closed), rats (n = 18) ate a large meal (16.5 ± 2 ml) within 10 to 15 min and then displayed the behavioral sequence characteristic of satiety. The milk was removed after the satiety sequence occurred. On sham days (GF open), rats (n = 18) ate almost continuously (102 ± 8 ml) for 60 min and did not display the satiety sequence. Thus, rats ingested approximately six times as much milk during sham feeding as during real feeding. Pellets were given 30 min after the test period and were removed at the beginning of the deprivation period.

Preference testing was conducted under the same deprivation schedule with GF closed. Rats were given simultaneous access to both test diets in their usual location for a 4 min period. Sixteen of 18 rats preferred the diet associated with real feeding. In the first group, 8 of 9 rats ate more of the diet associated with real feeding after 10 sham and 10 real feeding trials. Mean intakes were 7.1 ± 0.5 ml (closed) and 2.4 ± 0.8 ml (open), $p < .005$, paired t test. The second group showed a significant preference after 12 sham and 12 real feeding trials. Again, 8 of 9 rats ate more of the diet associated with real feeding. Mean intakes were 5.6 ± 0.8 ml (closed) and 1.7 ± 0.9 ml (open), $p < .05$.

Thus, under these conditions, rats prefer a real meal that ends in postprandial satiety to a period of sham feeding that is 4 times as long and during which 6 times as much milk is ingested.

179.12 VAGOTOMIZED RATS ARE INSENSITIVE TO GASTRIC DISTENTION CUES OF SATIETY. M. F. Gonzalez* and J. A. Deutsch* (SPON: R. M. Boynton). Department of Psychology, University of California, San Diego, CA 92093.

Prior research has established that receptors present in the stomach of the rat are responsible for the production of short-term satiety (Deutsch, J. A., W. G. Young, and T. J. Kalogeris, Science, 201:165, 1978). It has also been demonstrated that there are two classes of receptors involved, one sensitive to gastric volume and the other to the level of nutrient present in the stomach (Deutsch, J. A., M. F. Gonzalez, and W. G. Young, Brain Res. Bull., Suppl. 4, 1980). The present work examines how this information travels from the stomach to the CNS.

Male, Sprague-Dawley rats were kept on a restricted diet of condensed milk and were either vagotomized at the subdiaphragmatic level or subjected to a control laparotomy. Upon recovery from this surgery they were implanted with gastric cannulas and inflatable pyloric cuffs. When the animals were tested after a 15 h period of deprivation with the stomach isolated from the duodenum by means of the cuffs both groups were sensitive to nutritive cues but only the control group was responsive to volume cues of satiety.

When 5 ml of milk were siphoned off the stomach control subjects drank 7.8 ml over baseline level ($t = 5.36$, d.f. = 2, $P < 0.05$), while vagotomized subjects overdrank by 6.5 ml under the same conditions ($t = 3.18$, d.f. = 4, $P < 0.05$). On the other hand, when the animals were counterinjected with normal saline with one half of the volume voluntarily ingested by mouth, control rats exhibited a 29% decrease in their intake ($t = 4.95$, d.f. = 2, $P < 0.05$) while vagotomized rats showed a 10% increase in intake ($t = 0.81$, d.f. = 5, $P > 0.05$). This phenomenon was also observed when saline was counterinjected at a higher one to one ratio.

These results show that nutrient satiety signals that arise from the stomach are not vagally conveyed, but volume satiety signals are.

180.1 IMMUNOHISTOCHEMICAL IDENTIFICATION OF PARAVENTRICULAR HYPOTHALAMIC NEURONS WHICH PROJECT TO THE MEDULLA OR SPINAL CORD IN THE RAT. P.E. Sawchenko* and L.W. Swanson, Dept. Anat. & Neurobiol., Wash. Univ. Sch. Med., St. Louis, MO 63110

We have developed a method for the simultaneous localization of a retrogradely-transported fluorescent dye (true blue) and antigen to obtain estimates of the relative number, location, and biochemical specificity of cells in the paraventricular nucleus of the hypothalamus (PVH) which project to the medulla and/or spinal cord. Nine rats received a 50 nl injection of 5% true blue in the dorsomedial medulla at the level of the obex, and 10 received two 0.5 µl injections of true blue in upper thoracic segments of the spinal cord. After 7-14 days, the rats were perfused with neutral buffered formalin; multiple series of 20 µm frozen sections were saved and were either left untreated for examination of retrogradely-labeled cells, stained with thionin, or prepared for localization of oxytocin (OXY), vasopressin (VAS), somatostatin (SS) or tyrosine hydroxylase (TH) using an indirect immunofluorescence technique. Preliminary estimates of the number of PVH cells stained with each antiserum, and the number of cells doubly-stained with both true blue and each antiserum are given below. Because some PVH cells project to both the medulla and spinal cord,[1] the percentages given reflect minimum and maximum percentages of antigen-containing somata which may project to one or both loci.

Antigen	Total No. Cells in PVH	No. Double-Labeled after: Spinal Inj.	Medullary Inj.	%
OXY	1858 ± 149	169 ± 18	73 ± 37	9-13
VAS	1530 ± 353	81 ± 36	20 ± 10	5-7
SS	778 ± 135	10 ± 4	10 ± 0	1-3
TH	533 ± 61	19 ± 4	21 ± 1	4-8

OXY- and VAS-containing cells which project to the spinal cord were concentrated in the dorsal, medial and lateral parvocellular regions of the PVH, in the caudal half of the nucleus; OXY- and VAS-containing cells which project to the medulla were most numerous in the medial and lateral parvocellular zones. Small numbers of double labeled SS- and TH-containing cells were detected in various parvocellular regions following either medullary or spinal injections.

PVH neurons with long descending projections are not biochemically homogeneous, with OXY-, VAS-, TH-, and perhaps SS-staining cells each contributing to both projections. Because the total number of doubly-stained neurons identified in these experiments constitute only small percentages of the total number of PVH cells labeled with true blue following spinal or medullary injections, it is likely that neurons containing other putative transmitter substances are involved in these projections. ([1]Swanson, LW & HGJM Kuypers, JCN (in press)

180.2 ACTIVATION OF THE HYPOTHALAMO-NEUROHYPOPHYSEAL SYSTEM: REGIONAL ANALYSIS UTILIZING THE TRITIATED 2-DEOXYGLUCOSE METHOD. D. Wells, J. Buggy, A. J. Beitz, and J. Coleman. Depts. of Physiology, Anatomy, and Psychology. Univ. of South Carolina, Columbia, SC 29208.

2-deoxyglucose is a glucose analogue which competes with glucose for uptake into cells but after phosphorylation cannot be further metabolized and thus remains trapped within cells. By combining radiolabeled 2-deoxyglucose accumulation in neurons during physiological stimulation with autoradiography of brain sections, Sokoloff and colleagues pioneered the technique of functional, in vivo analysis of regional cerebral metabolic activity. One limiting factor in resolution of regional cerebral metabolic activity on X-ray film is the energy of the isotope. Another major concern with the original technique is the high cost of the isotope required to produce adequate labeling of brain tissue for autoradiographic analysis. To improve on the original technique which used ^{14}C labeled 2-DG, we have tried several modifications of this method to study functional changes in the hypothalamo-neurohypophyseal axis. A new X-ray film (LKB ultrofilm) specifically designed for tritium autoradiography was recently introduced. The high sensitivity of this film made it possible to utilize tritium label with the 2-DG tracing technique. The use of ^{3}H-2DG reduced the cost of each experiment by more than half. Furthermore, the lower energy level of tritium versus ^{14}C label improved autoradiograph resolution since the distance beta particles could travel to affect silver grains was decreased. Finally, in situ fixation of the brain tissue by intracardiac perfusion has improved ease of sectioning and tissue quality while further improving resolution of the autoradiographs. When necessary, rats were outfitted the day before an experiment with chronic venous and arterial catheters and probes for electrical or chemical brain stimulation. ^{3}H-2DG was injected iv (167 uci/100 g BW) prior to a 45 mintue exposure period to experimental stimulation. The brain was frozen at -45°C and 15µ sections were collected from the cryostat on prewarmed coverslips. Sections and X-ray film were sandwiched between aluminum plates and exposed for 3 weeks. Four stimulus conditions increased activity in posterior pituitary and preoptic periventricular tissue (AV3V): water deprivation in Brattleboro rats with genetic diabetes insipidus, subcutaneous or intracerebroventricular injections of hypertonic NaCl, and electrical stimulation of preoptic periventricular tissue.

180.3 DIRECT EFFECTS OF GLUCOSE ON SOMATOSTATIN RELEASE IN VITRO FROM NEURONS IN THE MEDIAL BASAL HYPOTHALAMUS. A. Negro-Vilar and S.R. Ojeda*. Department of Physiology, University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

Neural regulation of energy homeostasis involves the hypothalamus to integrate signals related to metabolic needs. Insulin-sensitive glucoreceptor cells are located in the satiety center, in and around the ventromedial nucleus (VMH). In the rat, one of the responses to hypoglycemia and/or starvation is a lowering of plasma GH levels (Endocrinology 84: 814, 1969). Recent evidence indicates that this GH response may result from enhanced somatostatin (SRIF) release. The present experiments were designed to test whether glucose and/or insulin could directly modify release of SRIF from medial basal hypothalamic (MBH) fragments incubated in vitro. Tissues obtained from adult male rats were incubated in Krebs-Ringer bicarbonate glucose (5.5 mM) buffer, pH 7.4, under an atmosphere of 95% O_2, 5% CO_2. After a 15 min pre-incubation period, medium was changed and replaced by fresh medium for an additional 30 min incubation, during which release of peptides was evaluated. SRIF, LHRH and arginine vasopressin (AVP) were measured by specific RIA's. The results show that lack of glucose in the medium increased SRIF release (3-4 fold) from the MBH significantly. Only minor, non-significant increments in LHRH and AVP release were observed after glucose removal. Addition of glucose to the medium during the incubation at three doses (2, 5.5 and 11 mM) resulted in a step-wise reduction in SRIF release, with the largest dose of glucose reducing release of the peptide to control levels. Incubation of MBH fragments with a non-metabolizable glucose analog, 2-deoxy-glucose (2-DG) increased somatostatin release to values similar to those obtained in the absence of glucose. Moreover, pre-incubation of MBH fragments with 2-DG abolished the inhibitory effect of glucose on somatostatin release. When ME fragments (which contain only nerve terminals and no cell bodies) were incubated with or without glucose, no significant increments were observed in SRIF release, suggesting that the effects of glucose require the presence of neuronal cell bodies, perhaps located in the VMH. Incubation of MBH fragments with insulin (10^{-7} or 10^{-6}M) with or without glucose produced no consistent effects on SRIF release. However, in MBH fragments preincubated with 2-DG, addition of insulin to the KRB-glucose buffer during incubation induced a clear increase in somatostatin release. These results indicate that glucose can directly modulate somatostatin release from medial basal hypothalamic neurons, thereby influencing GH release and perhaps other central actions of somatostatin, and that the effects of insulin may be complex, probably involving glucose-dependent and glucose-independent mechanisms. Supported by NIH HD-09988 and AM-10073.

180.4 TONIC RELEASE OF IMMUNOREACTIVE SOMATOSTATIN FROM RAT HYPOTHALAMIC CELL CULTURES: MODULATION BY γ-AMINOBUTYRIC ACID. D.E. Vaccaro*, R. Gamse*, G. Gamse*, M. DiPace*, S.E. Leeman and T.O. Fox (SPON: C.C. Vito). Dept. of Physiology & Neuropathology & LHRRB, Harvard Med. Sch., and Dept. of Neuroscience, Children's Hosp. Med. Ctr., Boston, MA 02115.

The regulation of the secretion of immunoreactive somatostatin (IR-somatostatin) was studied using cell cultures of embryonic rat hypothalamus (Vaccaro et al., J. Neurobiology, 11, in press, 1980). The cultures were used approximately 2 weeks after plating and contained 1890±160 fmol (n=28) of IR-somatostatin. The IR-somatostatin was characterized by gel permeation and/or reverse-phase chromatography. The major portion of IR-somatostatin co-chromatographed with synthetic somatostatin in each case.

Hypothalamic cell cultures continuously release a percentage of their total content of IR-somatostatin in a "tonic" fashion (1.73±0.13%/3min; n=36). Release of IR-somatostatin was stimulated by exposing the cells to 60mM K^+ (5.0-fold) or veratridine (6.9-fold). Reducing the calcium concentration of the external medium (0.1mM) and adding cobalt (4.5mM) abolished K^+-stimulated release and, in other experiments, reduced the level of tonic release by 76%. When tetrodotoxin (TTX), which blocks the voltage-dependent Na^+ channels, was added to the medium tonic release was lowered 76%.

γ-Aminobutyric acid (50mM GABA) completely inhibited 30mM K^+-stimulated (release) and inhibited tonic release 72%. Bicuculline (50mM), a GABA antagonist, inhibited the action of exogenously administered GABA. When added alone to the cultures, bicuculline promoted a greater than 2-fold increase in IR-somatostatin release.

Previous studies have demonstrated that hypothalamic cell cultures exhibit GABA synthesis and GABA uptake. To study the release of GABA, cultures were preloaded with (^{3}H)GABA. 60mM K^+ stimulated a greater than 2-fold calcium-dependent release of radioactivity. Continuous release of radioactivity was measured. This could be inhibited greater than 30% by either 0.1mM calcium with 4.5mM cobalt or by TTX.

These results are consistent with the suggestion that endogenous GABA may function as a neurotransmitter to regulate the release of somatostatin from hypothalamic cells.

Studies supported by grants HD 10818 (T.O.F.) and AM 16510 (S.E.L.), NRSA (NINCDS to D.E.V.) and performed at the Mental Retardation Res. Ctr. (CHMC).

180.5 AN AUTORADIOGRAPHIC ANALYSIS OF THE EFFERENT CONNECTIONS OF THE SUPRACHIASMATIC NUCLEUS. Mitchell L. Berk and Judith A. Finkelstein. Dept. Anat., N.E. Ohio Univs. Col. Med., Rootstown, Ohio 44272.

The suprachiasmatic nucleus (SCN) of the hypothalamus has been implicated as a generator of circadian rhythms of many biological functions. In the present study, the efferent pathways by which the SCN could produce its effects were investigated with the use of the autoradiographic technique. Iontophoretic injections of ^{3}H-leucine were placed into the SCN of rats, which were allowed to survive for 2-8 days. Emulsion coated slides were exposed for 3-4 months prior to development.

The injections were small and centered in the SCN, but some cells of the adjacent anterior hypothalamic area and anterior periventricular nucleus were also labeled. Many labeled fibers are observed in the periventricular zone at the level of the medial preoptic area, anterior hypothalamic area, and the dorsomedial (DMH) and ventromedial (VMH) hypothalamic nuclei. At the level of the medial preoptic area, these periventricular fibers ascend into the thalamus and densely innervate the periventricular thalamic nucleus. From the periventricular region of the anterior hypothalamus, heavily labeled fibers course dorsolaterally to the ventrolateral border of the paraventricular nucleus. These fibers continue caudally into the periventricular zone adjacent to DMH and appear to send terminals to the medial part of DMH. Some fibers are also present along the periventricular border of the paraventricular nucleus.

The ventromedial part of the anterior hypothalamic area contains many labeled fibers, some of which project laterally, dorsal to the optic chiasm. Posteriorly, labeled fibers are concentrated at the ventrolateral margin of VMH, slightly fewer fibers between VMH and the arcuate nucleus, as well as some fibers dorsal to VMH, thereby encapsulating VMH with SCN fibers. Some fibers are observed to enter the external layer of the median eminence. Further caudally, the fibers at the lateral border of VMH sweep dorsomedially into DMH, join the periventricular fibers and continue dorsally and caudally into the posterior hypothalamic nucleus. These labeled fibers continue dorsally and caudally into the periventricular gray of the midbrain. The fibers ventral to VMH proceed posteriorly and can be traced to the fiber capsule underlying the mammillary complex.

180.6 EFFECTS OF LESIONS OF THE MEDIAL PREOPTIC NUCLEUS (MPN) ON COPULATION-INDUCED OVULATION. L.V. Rubens* and E. Terasawa (spon. J. Kemnitz). Wisc. Reg. Primate Research Ctr., Univ. of Wisc., Madison, WI 53706

Previously, we have shown that small lesions of the MPN, a periventricular structure immediately caudal to the organum vasculosum lamina terminalis, induce persistent estrus in the rat, are invariably associated with a complete abolition of progesterone-induced LH release in ovariectomized animals, and result in a drastic reduction of hypothalamic content of LHRH. Lesions of the suprachiasmatic nucleus (SCN), on the other hand, do not block the progesterone-induced LH surge, although such lesions sometimes result in persistent estrus. In the present experiment, in order to obtain further evidence of involvement of the MPN in LHRH release, effects of MPN and SCN lesions on copulation-induced ovulation were investigated. Rats were housed under standard laboratory conditions (lights on 0500-1900). Daily vaginal smears were taken, and animals showing regular cycles were used. Bilateral electrolytic lesions were made stereotaxically with tungsten electrodes under pentobarbital anesthesia. In sham animals, electrodes were lowered into the MPN but no current was passed. 5-8 weeks after surgery, animals exhibiting persistent vaginal cornification were placed with sexually active males overnight. Sham lesioned or lesioned animals showing vaginal cyclicity were placed with males on the night of proestrus. Mating was verified by a copulation plug on the cage floor and sperm in the vaginal smear. Animals which did not mate were placed with males for a 2nd night about 1 week later. The morning following mating, laparotomies were performed. If the ampullae were dilated, they were dissected, and the number of ova were counted under a microscope. Lesioned animals were killed and brains prepared for histological determinations. MPN lesions, of approximately 700 μm in diameter, involved midline structures over the anterior half of the optic chiasm, including the entire MPN, while the SCN were spared. SCN lesions, of approximately 900 μm in diameter, involved 80-100% of this nucleus, while sparing the MPN. 7 of 9 persistently estrous rats with MPN lesions mated on the 1st or 2nd trial. None of these animals ovulated. On the other hand, 6 of 11 persistently estrous rats with SCN lesions mated on the 1st or 2nd trial, and 4 ovulated. All 9 cyclic rats with lesions or sham lesions mated, and 8 of these ovulated. In SCN-lesioned rats, the number of ova per ovulating animal was 6.8 ± 2.1, whereas in cyclic rats the number was 11.1 ± 1.1. It is concluded that copulation-induced ovulation is mediated by neurons in the MPN or vicinity. These results provide further support for our previous hypothesis that neurons indispensible for release of LHRH reside in the vicinity of the MPN, and not in the SCN. (Supported by NIH Grants RR-00167 and HD-11355.)

180.7 PARAVENTRICULAR NUCLEUS OF THE HYPOTHALAMUS: ANATOMICAL EVIDENCE OF TEN FUNCTIONALLY DISCRETE SUBDIVISIONS. Edward Tongju Koh* and Juarez A. Ricardo* (SPON: A. Galaburda). Dept. of Psychology, Massachusetts Institute of Technology, Cambridge, Mass. 02139 and Dept. of Anatomy, Harvard Medical School, Boston, Mass. 02115.

The paraventricular nucleus of the rat hypothalamus (pvn) has classically been divided into two parts: magnocellular (mc) and parvocellular (pc). Evidence from many groups, including our own (Brain Res. 153:1, SNS 5:#1524), considered together, indicates that the pvn may be further divided into at least ten discrete neuronal groups, each having a distinct combination of inputs, outputs, and chemistry. Evidence for such a parcellation comes from autoradiographic (ARG), horseradish peroxidase (HRP), and immunocytochemical (PAP) experiments. (See refs. for protocols.)

The ten groups (most uncited findings are our own) are:

I] four mc groups, all projecting to the neurohypophysis; 1) medial, containing oxytocin (OXY), and 2) lateral, containing antidiuretic hormone (ADH) (mcm & mcl/ Brain Res. 108:187, J. Endocr. 67:461), 3) mc posterior fornical and anterior commissural (pfm & acP/ J. comp. Neur. 128:181), both containing OXY &/or ADH; and

II] six pc groups, none containing OXY or ADH; 1) dorsal (pcd) and 2) ventral (pcv), which project to the spinal cord (Exp. Brain Res. 35:315), 3) intermediate (pci) and 4) periventricular (pcp), which project to the median eminence (me/ SNS 5:#754 & #1580), 5) caudal (pcc/ horizontal, fusiform cells), which projects to the parabrachial area (pb) and possibly to me, (Brain Res. 88:403), and 6) pc posterior fornical (pfp), which projects to pb and to the caudal part of the nucleus of the solitary tract (nts).

Afferents to these groups are as follows: caudal nts projects to all pc groups but pcc (most heavily to pci), and possibly to pfm; afferents from pb involve the same six groups plus pcc.

As to transmitters or hormones used by pc groups, the only direct evidence deals with pcp, which, based on PAP staining, contains somatostatin (J.C. King, C. Scouten, & F.L. Snavely, pers. comm.); pci, which, like pcp, projects to me, does not. Since thyrotropin-releasing hormone may be present in the pvn (Science 185:267), it seems possible that it may reside in pci; or pci may contain a corticotropin-releasing factor and affect adrenocorticotropic hormone release (e.g., see Rec. Prog. Horm. Res. 34:357).

The fact that HRP injections in me, nts, and the spinal cord label only pc neurons of pvn conflicts with the notion that OXY- &/or ADH-containing fibers innervating those regions originate in pvn. The HRP method with diaminobenzidine as substrate may not be adequate in these systems; there may be undetected ADH- or OXY-containing pc neurons in pvn; or these fibers may not arise from pvn at all! (Supp. by grants MH 25515 & 5 T05 02220 [USPHS], BNS-7681227 [NSF], & Fellowship Award 04-75/0167 to J.A.R. from the Fundação de Amparo à Pesquisa do Estado de São Paulo, Brazil.)

180.8 IMMUNOCYTOCHEMICAL ANALYSES OF THE ACTH COMPONENT OF THE OPIOCORTIN SYSTEM IN NORMAL AND MSG TREATED ANIMALS. S.A. Joseph*, W. Pilcher* and K.M. Knigge (SPON: E. Boyd). Neuroendocrine Unit, University of Rochester School of Medicine, Rochester, NY 14642.

We have previously reported the distribution of the ACTH component of the central opiocortin system on Bouin's-fixed, 50μc Vibratome brain sections, using an antibody generated against synthetic ACTH$^{1-39}$. Perikarya are demonstrated immunocytochemically in the region of the arcuate nucleus, extending caudally to the level of the mammillary region of the hypothalamus. This dense fiber system innervates numerous areas of the hypothalamus. A component can be traced to the limbic system. These fibers project from the hypothalamus to amygdaloid nuclei in two separate bundles. A third efferent component is represented by a large dorsal bundle which issues from the hypothalamus and courses in the dorsal longitudinal fasciculus. It distributes to the midbrain and pontine periaqueductal grey. Neonatal treatment of mouse and rat with monosodium glutamate (MSG) produces a chemical lesion of the arcuate region of the hypothalamus. Animals with complete MSG lesion lack ACTH-immunoreactive perikarya in the bed nucleus as well as the entire fiber distribution of this system.

These data support the conclusion that the ACTH-immunoreactive perikarya in the arcuate region of the hypothalamus represent the bed nucleus of this system.

(Supported by RCDA to S.A.J. HD 00230A, HD 07926, and Program Project NS-15345.)

180.9 ORIGIN OF THE OPIOCORTIN SYSTEM IN RAT BRAIN. K.M. Knigge, S.A. Joseph* and W. Pilcher*. The Neuroendocrine Unit, University of Rochester, Rochester, N.Y. 14642.

An extensive fiber system in rat brain can be immunocytochemically demonstrated using antibodies generated against several peptides of the opiocortin family. Perikarya are seen variably in the mediobasal-arcuate area of the hypothalamus and are suspected to be the cells of origin of this system. This region was destroyed unilaterally from the retrochiasmatic area to the mammillary region using a deafferentation knife with a 1.0x1.2mm wedge-shaped blade. Two weeks later, animals were anesthetized and brains fixed with Bouin's solution by cardiac perfusion. Sections were cut at 50μm on a vibratome. The ACTH component of the opiocortin was revealed by the unlabeled antibody method using a primary antibody generated against synthetic $ACTH_h$ 1-39, conjugated to BSA at the C-terminal with carbodiimide. In all lesioned animals, fibers in hypothalamus, preoptic area, amygdala and dorsal longitudinal fasciculus (dlf) were eliminated almost completely on the side of the lesion. In midbrain and pons, fiber distribution was diminished. The ipsilateral component of the dlf descends with the mesencephalic nucelus of V and distributes to pontine and medullary grey along the floor of the 4th ventricle. The contralateral fibers distribute to tegmental nuclei. These results indicate that the ACTH-immunoreactive cells in the basal hypothalamus represent the bed nucleus of this opiocortin system. Fiber distribution in forebrain appears to be entirely ipsilateral; efferent outflow to the brainstem via the dlf has contralateral and ipsilateral components.

180.10 IMMUNOCYTOCHEMICAL LOCALIZATION OF LHRH IN HYPOTHALAMUS AND PINEAL GLAND USING DIFFERENT FIXATION SOLUTIONS. D.T. Piekut* (SPON: R. Snider). Neuroendocrine Unit, University of Rochester School of Medicine, Rochester, NY 14642.

It has been previously reported in this laboratory that immunoreactive material is visualized in the rat pineal gland using antisera generated against synthetic LHRH and analogs of LHRH. The substance seen immunocytochemically in the pineal gland may have a different structure or antigenic determinants different than the LHRH peptide found in hypothalamus. Effect of different fixation solutions on our immunocytochemical studies is presented. Animals were perfused with Bouin's or Zamboni's solution, brains were cut on a Vibratome at 30μm, and collected in phosphate saline buffer. Sections of hypothalamus or pineal were processed for visualization of LHRH or LHRH-like material using Sternberger B antiserum and the PAP method of immunocytochemistry. Immunoreactive material is demonstrated in sections of the pineal gland that have been fixed in Bouin's solution. Immunostaining is not seen in sections of pineal fixed in Zamboni's solution at pH 7.6, but it is visualized if the pH of Zamboni's solution is buffered to 3.5. More intense fiber and perikarya immunoreactivity is observed in sections of hypothalamus following fixation by Zamboni's solution as compared to Bouin's. When the pH of Zamboni's solution is buffered to basic pH values (8.7), an even greater amount of immunoreactive LHRH is observed; a reduction of LHRH reactive material is apparent in brains fixed with an acidic Zamboni's solution (pH 3.5). These immunocytochemical studies reveal a difference in LHRH immunoreactivity in hypothalamus and pineal gland using antisera generated against different LHRH conjugates, antisera generated against different analogs of LHRH, different fixation solutions, and fixation solutions at altered pH values.

181.1 LIGHT MICROSCOPIC AUTORADIOGRAPHIC DIFFERENTIATION OF MU AND DELTA OPIATE RECEPTORS IN RAT BRAIN. R.R. Goodman*, S.H. Snyder, M.J. Kuhar and W.S. Young, III. Dept. of Pharmacology & Experimental Therapeutics, and Psychiatry & the Behavioral Sciences, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Evidence supporting the existence of multiple opiate receptors has accumulated from binding studies and effects on smooth muscle (Kosterlitz, H.W., Lord, J.A.H., Paterson, S.J. & Waterfield, A.A., Br. J. Pharmacol., 179:333-342, 1980). The mu or morphine-like receptor has higher affinity for opiates than for enkephalins, while the opposite is true for the delta or enkephalin-like receptor. With techniques for in vitro light microscopic autoradiography of neurotransmitter receptors (Young, W.S., III, & Kuhar, M.J. Brain Res., 179:255-270, 1979), we have demonstrated a differential distribution of mu opiate receptors (labeled by [^{125}I][D-Ala^2, MePhe^4, Met(O)^5-ol]-enkephalin) and delta opiate receptors (labeled by [^{125}I][D-Ala^2, D-Leu^5]-enkephalin). The mu receptors display discrete localizations that in many regions are distinct from the more diffusely distributed delta receptors. High concentrations of mu receptors in the fourth layer of the cortex (an important area for the integration of sensory input), certain thalamic nuclei and the periaqueductal gray are all consistent with a role in antinociception. Delta receptors are more diffusely, localized with high concentrations in the second, third, fifth and sixth layers of the cortex, the striatum, the amygdala, the nucleus accumbens and the olfactory tubercle. These localizations are consistent with the evidence that delta agonists are sedating, seizure provoking and related to general behavior and reward. These autoradiographic localizations resemble regional variations in mu and delta binding (Chang, K-J., Cooper, B.R., Hazum, E. & Cuatrecasas, P. Mol. Pharmacol., 16:91-104, 1979).

181.2 ULTRASTRUCTURAL LOCALIZATION OF LEUCINE ENKEPHALIN IN THE SUPERFICIAL DORSAL HORN OF THE CAT. Ellyn J. Glazer and Allan I. Basbaum, Department of Anatomy, University of California, San Francisco, CA 94143.

The mechanism by which spinal endorphins modulate nociceptive transmission is unclear. Both pre- and postsynaptic models of opiate mediated inhibition of spinal nociceptors have been proposed. In the cat enkephalin-containing processes are densely distributed in laminae I and II of the superficial dorsal horn. Lamina I also contains numerous enkephalin cell bodies; fewer cell bodies appear in lamina II. To determine the synaptic circuitry through which enkephalin modulates spinal nociceptive input, the ultrastructural localization of leucine enkephalin immunoreactive processes was studied in the cat superficial dorsal horn. Cats were perfused with 4% para/.2% glut in 0.1M phosphate buffer. Sections through C1 and the trigeminal nucleus caudalis were sectioned transversely on a Vibratome, processed for enkephalin immunoreactivity by the PAP method, osmicated and flat embedded in Epon-Araldite. Control sections were incubated in specific enkephalin antisera preabsorbed with an excess of leucine enkephalin. The most commonly labeled profile was a small unmyelinated process which appeared in bundles containing predominantly unlabeled profiles. It was not possible to morphologically identify these processes as dendrites or unmyelinated axons. Enkephalin axon terminals in lamina I and II contained either small, round or a mixed population of small, round and large vesicles. The reaction product surrounded the small vesicles and filled the lumen of the large vesicles; the large vesicles in several terminals were peripherally displaced. Labeled axon terminals were associated with synaptic glomeruli. These complexes consist of a centrally located primary afferent terminal surrounded by axonal and dendritic profiles. Although enkephalin axons did not directly contact the primary afferent they were associated with non-vesicle-containing dendrites postsynaptic to the central terminal. This arrangement is consistent with an indirect opiate modulation of primary afferent terminals or a direct opiate inhibition of second order nociceptors. Outside the glomeruli enkephalin terminals were associated with dendrites, perikarya and axons. It could be determined that enkephalin axons were presynaptic to both dendrites and soma, but the polarity of axo-axonic relationships could not be established. There was, however, a frequent association of an enkephalin axon terminal with an unlabeled, flat vesicle containing profile. The latter was presynaptic to a dendrite. Since GAD immunoreactivity in the superficial dorsal horn has been demonstrated in profiles containing flat vesicles this arrangement may reflect a GABAergic-enkephalinergic interaction.

181.3 DISTRIBUTION OF ACTH- AND ENDORPHIN-RELATED PEPTIDES IN BOVINE BRAIN. J. Lépine*, A. Dupont* and F. Labrie* (SPON: F. Garcin Department of Molecular Endocrinology, CHUL, Quebec G1V 4G2, Canada.

Study of the distribution of β-LPH, β-endorphin, ACTH and their related peptides in anterior and intermediate pituitary lobes have shown the presence of the same peptides but in different proportions in the two tissues. We now report the distribution of the same peptides in different areas of bovine brain. Thirty structures of bovine brain frozen immediately after dissection at the slaughterhouse were extracted with 2 N acetic acid and lyophilized before measurement with specific RIAs for $ACTH_{1-24}$, β-endorphin, γ-LPH_{1-47}, γ-endorphin and α-MSH. The area preoptica, the habenula including the paraventricular nucleus of thalamus, and the septum are the most concentrated extrahypothalamic regions in β-endorphin immunoreactivity. The finding that ACTH and γ-LPH_{1-47} immunoreactivity in these structures parallel the distribution of β-endorphin suggests that neurons from these areas produce the biologically active peptides by cleavage of the precursor molecule. Study of the distribution of the endorphins, ACTH and α-MSH by gel filtration in extracts from the median eminence, hypothalamus and area preoptica shows that β-endorphin is the main opioid peptide present in the regions studied while its presumed precursor, β-LPH, is also present but in lower concentrations. Two main forms of ACTH are present in these regions: $ACTH_{1-39}$ and a low molecular weight immunoreactive material eluting ahead of α-MSH. This unidentified material is seen in equivalent concentrations in the area preoptica as well as in the posterior and median hypothalamus. However, $ACTH_{1-39}$ is the main form of ACTH in the median eminence and the anterior hypothalamus. Finally, γ-LPH immunoreactivity resolves into three peaks in all the structures studied: the first one corresponds to β-LPH, the second peak coelutes with γ-LPH while the last one elutes at a position slightly faster than the β-endorphin marker. In conclusion, these results show that neurons from the anterior, median and posterior hypothalamus, as well as from the median eminence, the area preoptica, the septum and the habenula, including the paraventricular nucleus of thalamus, contains β-LPH, ACTH, γ-endorphin and α-MSH in different concentrations. While the proportion of β-LPH, γ-LPH, β-endorphin and γ-endorphin immunoreactivity is the same in all brain areas, the distribution of $ACTH_{1-39}$ and lower molecular form of ACTH immunoreactivity shows wide variations. The present data indicate a differential processing of the 31K precursor molecule in various bovine brain structures.

181.4 OPIATE RECEPTOR REGULATION OF THE NIGROSTRIATAL PATHWAY. Paul L. Wood. Merck Frosst Lab., Dept. of Pharmacology, P.O. Box 1005, Pointe Claire-Dorval, Quebec, H9R 4P8.

A simple but sensitive and specific assay for the simultaneous measurement of striatal dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA), dopamine (DA) and 3-methoxytyramine (3-MT) was established and used to monitor opiate actions on nigrostriatal function. Mu, delta and epsilon receptor agonists were found to produce dose dependent elevations of striatal DOPAC and HVA indicating the presence of these receptors on nigrostriatal neurons. In addition, a species difference in the coupling of opiate receptor activation and DA release was observed. In the mouse, both intraneuronal metabolism and DA release were elevated after parenteral morphine while in the rat no such parallelism was observed. In contrast to mu, delta and epsilon receptor agonists, kappa receptor agonists did not alter dopamine metabolism in the striatum suggesting that these receptors are not involved in the regulation of these neurons. Agonist/antagonist analgesics also elevated DA metabolites at low doses; however, these actions were reversed at higher doses where the antagonistic activity of these agents prevails. Sigma receptor agonists also altered striatal DA metabolism but these actions were not reversed by naloxone, arguing against an opiate receptor mechanism.

In summary, our studies indicate that multiple opiate receptors are involved in the regulation of activity in the nigrostriatal pathway but that kappa receptors are not present on these neurons.

181.5 NON-COMPETITIVE INHIBITION OF THE BINDING OF ^{3}H-NALOXONE BY LEUCINE ENKEPHALIN - REVERSAL BY MORPHINE. Richard Rothman* and Thomas C. Westfall (SPON: V. Fischer). Departments of Pharmacology, University of Virginia School of Medicine, Charlottesville, Virginia 22908 and St. Louis University School of Medicine, St. Louis, Missouri 63104.

In the experiments to be described, the specific binding of ^{3}H-naloxone to rat brain membranes was determined in ice-cold 10 mM NH_4Ac, pH 7.7, at 4°C in the presence of 400 mM NaCl. Saturation binding experiments with ^{3}H-naloxone demonstrated that this ligand labels a single class of binding sites (K_d = 1.7 nM, R_t = 464 fmol/mg protein). By displacement of a fixed concentration of ^{3}H-naloxone, the Ki's of met-enkephalin, leu-enkephalin, etorphine, and morphine were calculated to be 190 nM, 1000 nM, 6.6 nM, and 100 nM, respectively. Scatchard analysis of the binding of ^{3}H-naloxone in the absence and presence of 30 nM etorphine demonstrated that in addition to a four-fold increase in the K_d, from which a Ki of 9 nM was calculated, there also occurred a 20% decrease in the number of binding sites. When this was taken into account, the true Ki of etorphine was calculated to be 14 nM. Similar experiments with 10 µM leu-enkephalin and 1 µM met-enkephalin demonstrated that these drugs were non-competitive inhibitors of the binding of ^{3}H-naloxone with true Ki's of 13 µM and 2.5 µM, respectively. In contrast, 200 nM morphine was a competitive inhibitor with a Ki of 60 nM, and, in addition, reversed the non-competitive inhibition caused by 500 nM leu-enkephalin. (Supported in part by USPHS-NINCDS 16215 and NIGMS 57055.)

181.6 CHARACTERIZATION OF GUANINE NUCLEOTIDE INTERACTIONS WITH OPIATE RECEPTORS IN RAT BRAIN. Steven R. Childers and Margaret Marsh* Dept. of Pharmacology, Univ. of Florida Coll. Med., Gainesville, Fla. 32610.

Recent evidence indicates that guanine nucleotides, in particular GTP, play an important role in regulating the binding of agonists to opiate receptors by selectively reducing opiate agonist and not antagonist binding to rat brain membranes. The mechanism of the GTP effect principally involves increased dissociation rates of agonists from receptor sites. In order to explore the relationship between the opiate receptor active site and the GTP regulatory site, rat brain membranes were incubated with various reagents to determine whether one site could be separated from the other. Protein modifying reagents such as N-ethylmaleimide (NEM) and iodoacetamide, and enzymes such as trypsin and phospholipase A, were effective in inhibiting ^{3}H-opiate agonist binding. At the same concentrations, these agents also inhibited the GTP effect on ^{3}H-agonist binding, reducing both the IC_{50} and maximum effect of GTP in inhibiting ^{3}H-dihydromorphine and ^{3}H-d-Ala enkephalin binding. Incubation of rat brain membranes with 250 µM NEM reduced ^{3}H-d-Ala enkephalin binding by 60%, while reducing the effect of 50 µM GTP on binding by approximately 80%. In order to selectively protect the opiate site from the actions of NEM, membranes were incubated with 0.2 µM d-Ala enk before NEM treatment, followed by extensive washing to remove both reagent and opiate. Protection with opiates resulted in only a 40% loss of binding with NEM; however, the GTP effect was completely eliminated up to 100 µM GTP. This "non-regulated" preparation of receptors exhibited over 90% of normal antagonist binding, normal IC_{50} values for unlabeled opiates, and normal sensitivity to sodium. These receptors were not affected by manganese, GTP or GMP-PNP in steady-state experiments. The GTP effect could be partially restored by incubation of membranes with 100 µM GMP-PNP prior to NEM treatment: while ^{3}H-d-Ala enk binding was still reduced by 60%, the effect of GTP was reduced only about 10-20% by NEM. Pre-treatment with both GMP-PNP and d-Ala enk parially restored both binding and GTP regulation. These experiments indicate that GTP regulates opiate receptor sites by binding to a protein which is physically distinct from the opiate receptor itself, and which may mediate the divalent cation effects on receptor interactions.

181.7 DIBUTYRYL CYCLIC AMP DECREASES SPECIFIC [^{3}H]-DIHYDROMORPHINE BINDING TO RAT MIDBRAIN HOMOGENATE. (D.A. Hosford, P.M. Iuvone* and H.J. Haigler, Dept. of Pharmacology, Emory Univ., Atlanta, GA 30322)

The intracerebral or intravenous administration of dibutyryl cyclic adenosine 3',5'-monophosphate (cAMP) reversed morphine-induced analgesia in mice (Ho et al., J. Pharmacol. Exp. Ther. 185, 336, 1973). In the rat mesencephalic reticular formation, morphine blocked the increase in firing evoked by a nociceptive stimulus (Haigler, Life Sci. 19, 841, 1976); this blockade by morphine was reversed by the microiontophoretic administration of dibutyryl cAMP (Hosford and Haigler, Neurosci. Abst. 5, 560, 1979). To determine if dibutyryl cAMP blocked the effect of morphine by interfering with its binding to membrane receptors, we tested the effects of dibutyryl cAMP, butyrate, and 3-isobutyl-1-methylxanthine (IBMX: a phosphodiesterase inhibitor) on the specific binding of [^{3}H]-dihydromorphine to brain homogenates prepared from rat midbrain.

Male Sprague-Dawley rats were decapitated and the brains were removed within 2 min. The midbrain was homogenized in ice-cold 50 mM Tris buffer (pH 7.4, 37°C); the homogenate was diluted and incubated for 30 min at 37°C with 2 nM [^{3}H]-dihydromorphine. Except for controls, one of the following was added to each of the homogenates: dibutyryl cAMP (100 µM), IBMX (100 µM) or butyrate (100 µM). All incubations were carried out in the presence or absence of levorphanol. Specific binding was calculated as the difference between binding in the presence and absence of levorphanol. Both dibutyryl cAMP and IBMX significantly decreased specific [^{3}H]-dihydromorphine binding. Butyrate had no effect on binding. Adenosine 5'-monophosphate (5'-AMP) did not decrease [^{3}H]-dihydromorphine binding to rat brain homogenate (Blume, Proc. Natl. Acad. Sci. 75, 1713, 1978). The decrease in specific [^{3}H]-dihydromorphine binding by dibutryryl cAMP, but not by its metabolites, butyrate and 5'-AMP, implies that the effect is caused by the cyclic AMP analogue. The mechanism underlying this effect remains to be determined. (Supported in part by NIH grant T32-GM-07415-03 [D.A.H.], NIH grant 5S07-RR05364 [P.M.I.], and NIDA grant 1-R01-DA-01344-04 [H.J.H.])

181.8 INHIBITION OF OPIATE RECEPTOR BINDING BY ADENOSINE 5'-DIPHOSPHATE David A. Brase, Dept. of Pharmacology, Eastern Virginia Medical School, Norfolk, VA 23501.

Studies by other investigators (Blume, *Life Sci. 22*: 1483, 1978; Childers & Snyder, *Life Sci. 23*: 759, 1978) have shown that opiate receptor binding, particularly of agonists in the presence of 100 mM NaCl, is reduced by GDP and GTP, but not by adenine nucleotides up to a concentration of 100 µM. Since some adenine nucleotides exist in cells in higher concentrations, their effects on specific (^{3}H)etorphine and (^{3}H)diprenorphine binding were studied, by preincubation of the adenosine compounds with rat brain homogenates in 50 mM Tris-HCl buffer (pH 7.4) ± 10 µM naloxone, followed by incubation with (^{3}H)-ligand (1 nM) for 20 min at 37°C. Incubations were terminated by placing the vials on ice, followed 5 min later by filtration through GF/C filters and two 8-ml washes with cold buffer. With a 5-min preincubation, 1 mM adenosine, AMP or cyclic AMP had no effect, but ADP and ATP caused about 40% and 20% inhibition of binding, respectively, of both etorphine and diprenorphine, either in the absence or presence of 100 mM NaCl. A 5-min preincubation with 1 mM ADP did not inhibit binding to a washed particulate fraction of rat brain. The inhibitory effect of ADP could be restored by adding the 40,000xg supernatant fraction from the homogenates back to the washed particulate fraction. The supernatant fraction, itself, was inhibitory to both agonist and antagonist binding, in the absence or presence of 100 mM NaCl. The inhibitory effect of the supernatant fraction was enhanced by boiling, not affected by trypsin, partially destroyed by potato apyrase, and completely removed from boiled supernatant by activated charcoal.

In homogenates, the inhibition by ADP increased with preincubation time (0-20 min) and with concentration (0.125-1.0 mM). At 1 mM, 2-deoxyADP and 1,N^6-ethenoADP mimicked ADP, whereas α,β-methyleneADP and β-thioADP completely blocked, and ATP partially blocked the inhibitory effect of ADP. Other adenosine-containing compounds that were tested at 1 mM, but failed to mimic or block ADP included: adenosine, AMP, ADP-glucose, ADP-ribose, NAD, and P^1,P^2-diadenosine 5'-pyrophosphate. Addition of α,β-methyleneADP just before (^{3}H)diprenorphine, after a 20-min preincubation with ADP, failed to reverse the inhibition of binding by ADP.

These studies indicate the possibility that ADP interacts with an unidentified soluble factor to produce an inhibitor of opiate receptor binding. It is tempting to speculate that this inhibitor is endogenous and may play a role in the regulation of opiate receptor function. Studies are in progress to further characterize the supernatant inhibitor and to compare its effects with those of ADP and guanine nucleotides. (Supported in part by NIH Biomedical Research Development Grant RR09028-03)

181.9 OPIATE AND PHENCYCLIDINE RECEPTORS IN RAT AND MONKEY BRAIN. Roberta M. Palmour,* Elizabeth Zobell* and Frank R. Ervin. Dept. Genetics, U. California, Berkeley and Dept. Psychiatry, McGill University, Montreal, Quebec, Canada H3A 1A1.

The existence of multiple brain opiate receptor subpopulations is substantiated by pharmacological studies, bioassay observations and direct binding data. At least 5 classes of opiate receptors--μ, σ, κ, δ, ε--have been proposed, but biochemical distinctions of the different classes of binding sites are incomplete. Using a rapid filtration assay, we have defined kinetic parameters and regional distributions of opiate and phencyclidine (PCP) specific receptors in rat and African green monkey brain. ^{3}H-etorphine (E) was used as a "generalized" opiate agonist and ^{3}H-naloxone as an antagonist. Saturation analysis reveals approximately equal numbers of agonist and antagonist binding sites in whole brain. Agonist binding sites are highest in limbic areas (hippocampus, amygdala, cingulate), moderate in striatum, thalamus and cortex and very low in cerebellum. Displacement of low concentrations (∿ 0.1 K_d) of ^{3}H-E by unlabelled enkephalin (D), endorphin (βE), N-allylnormetazocine (S), N-ethylketocyclazocine (K) yielded biphasic displacement plots and 2-component Hill plots, while displacements with E, M or N gave monocomponent plots. Biphasic plots were more pronounced in limbic and striatal regions than in whole brain. Displacement of low concentrations of ^{3}H-K, ^{3}H-DHM and ^{125}I-βE with homologous and analogous competitors allowed partial distinction of κ, μ and ε opiate receptors. Again effects were more pronounced in limbic and striatal regions.

In vervet monkey brain, ^{3}H-PCP binding is specific and saturable, having a K_d of 1.5 x 10^{-7} M and B_{max} of 350 fmol/mg protein. The regional order of binding is hippocampus > thalamus > cingulate/septum/amygdala > striatum/cortex. Specifically bound PCP is displaced by low concentrations of PCP, PCE and TCP, by moderate conceptrations of S, cyclazocine and ketamine, and by higher concentrations of K, naloxone, quipazine and amphetamine in rat brain membrane preparations. Cross-displacements suggest that ^{3}H-PCP does not label the σ receptor; definitive demonstration awaits availability of ^{3}H-S.

In a green monkey social group, low-dose chronic PCP (0.15 mg/kg/day) reduced affiliative and increased aggressive behavior in both treated and untreated animals. At higher doses, a subset of animals appears to show differential behavioral and neurological sensitivity to PCP. A potential receptor basis for this phenomenon is under study.

We thank NIDA for drugs and Dr. M. McGuire, Behavioral Sciences Fdn., St. Kitts for animals.

181.10 CHARACTERIZATION OF [^{3}H]MET- AND [^{3}H]LEU-ENKEPHALIN BINDING IN CAT CNS: EFFECTS OF LUMBAR RHIZOTOMY. G. J. Wastek, T. L. Yaksh and E. Richelson. Depts. of Psychiatry, Pharmacology and Neurosurgery, Mayo Foundation, Rochester, MN 55901.

[^{3}H]Met- and [^{3}H]leu-enkephalin binding were measured in various regions of cat brain and spinal cord using a microcentrifugation assay at 0°C. The $t_{½}$ association of these [^{3}H]opioids to both cat brain and spinal cord was ∿ 10 min for [^{3}H]met- and ∿ 17 min for [^{3}H]leu-enkephalin and the binding of both ligands equilibrated by 90 min. The association rate constants (k_1) for both [^{3}H]opioids at 0°C was ∿ 1-2 x $10^6 M^{-1}$ min^{-1}. The $t_{½}$ dissociation of these ligands from both brain and spinal cord at 0°C was ∿ 240 min giving dissociation rate constants (k_{-1}) of ∿ 4-6 x 10^{-4} min^{-1}. The dissociation constant (K_D) calculated from the ratio of these two kinetic constants for both [^{3}H] ligands was 0.3 nM. Scatchard analyses of saturation isotherms, using both [^{3}H]opioids in cat brain homogenates, revealed one population of binding sites with maximum binding (B_{max}) between 500-700 pmol/g prot. and K_Ds of 2-4 nM. Similar studies in the cat spinal cord revealed one population of binding sites for both [^{3}H]opioids with B_{max}s of ∿ 200 pmol/g prot. and K_Ds of 1-4 nM. Na^+(100 mM) reduced [^{3}H]opioid binding in both the brain and spinal cord to approximately one-sixth of control values for each ligand. Both met- and leu-enkephalin were more potent in inhibiting the [^{3}H]opioid binding than were naloxone or morphine (the least potent). The distributions of [^{3}H]met- and leu-enkephalin binding in the cat brain were as follows, with met- being uniformly higher than leu-enkephalin binding in all regions examined: septum, hypothalamus, hippocampus, thalamus, PAG, caudate > medulla, superior and inferior colliculi, MRF, pons > frontal, parietal, temporal and occipital cortices, cerebellar vermis and sciatic nerve. [^{3}H]Opioid binding varied between 200-300 pmol/g prot. in the dorsal and ventral regions of the cervical, thoracic and lumbar segments of the cord, with met- being uniformly higher than leu-enkephalin binding in all regions examined. Lumbar rhizotomy significantly decreased the binding of both [^{3}H]opioids in the lumbar dorsal region of the cord. These findings confirm and extend those of Fields et al. (Nature 284:351, 1980) in showing that opioids act directly on the terminals of small diameter primary afferents to selectively inhibit nociceptive input to dorsal horn neurons. 181.11 OPIATE RECEPTOR CHARACTERISTICS IN ETHANOL-TREATED MICE. P. L. Hoffman* and B. Tabakoff. Dept. Physiol. & Biophys., Univ. of Ill. Med. Ctr. and West Side V.A. Med. Ctr., Chicago, IL 60612.

Chronic ethanol treatment alters the function of several components of the striato-nigral feedback loop which acts to control dopamine (DA) synthesis. Thus, both DA agonists and antagonists are less effective in altering DA synthesis in ethanol-treated mice. Enkephalin-containing neurons have also been postulated to control DA metabolism in the striatum and our prior studies demonstrated that the striatal DA neurons of ethanol-treated animals are significantly less responsive to submaximal doses of morphine, in terms of DA metabolism, as compared to controls. We therefore examined the affinity and number of striatal opiate receptors in ethanol-treated animals. Male C57Bl mice were exposed chronically to a liquid diet containing 7% (v/v) ethanol and controls received a diet containing equicaloric amounts of sucrose. After seven days, the ethanol-consuming animals were given the control diet (withdrawal). The animals were shown to be tolerant to and physically dependent on ethanol. Opiate receptor function was examined at 24 hours after withdrawal, when withdrawal symptoms were no longer evident, by determining ^{3}H-dihydromorphine binding to striatal membranes. Scatchard analysis revealed a high- and low-affinity binding site, with K_D's of 0.47±0.07 nM and 2.52±0.48 nM, respectively, in control animals. Each portion of the Scatchard plot was corrected for the contribution of the other portion by computer analysis. The K_D of the high-affinity site in the ethanol-treated animals was 0.82±0.09 nM, and was significantly higher ($P<0.05$) than that in controls. No significant changes occurred in the B_{max} values for the high-affinity site. Determination of association and dissociation rate constants revealed that the decreased affinity of the high-affinity morphine-binding site in the ethanol-treated animals was largely due to a decreased association rate constant. We are currently examining the effects of Na^+ on morphine binding in control and ethanol-treated animals, since high Na^+ concentrations have also been found to affect the affinity of the opiate receptor for agonists. Furthermore, the possible relationship of changes in opiate receptor affinity to ethanol tolerance or dependence is being assessed by following the time course of the development and dissipation of the affinity change. Chronic ethanol exposure has been postulated to alter the physical properties of neuronal membranes, including lipid composition. Our results are in line with the hypothesis that such membrane changes may alter the function of the lipid-containing morphine receptor.

181.12 PHARMACOLOGICAL PROFILE OF THE FUMARAMIDO METHYL ESTER DERIVATIVE (βFNA) OF NALTREXONE. Susan J. Ward*, P. S. Portoghese* and A. E. Takemori* (SPON: Alice Larson). Depts. of Pharmacol. and Med. Chem., U. of Minn. Minneapolis, Minnesota 55455.

βFNA has recently been shown to possess reversible agonist and irreversible antagonist actions on the electrically stimulated guinea-pig ileal longitudinal muscle preparation. The pA_2 for the antagonism of βFNA's agonist actions by naloxone (NLX) was 8.06, similar to that for nalorphine-naloxone interactions. In contrast to any other opiate antagonist, βFNA selectively antagonised the agonist actions of morphine (M) yet was ineffective against the agonist actions of nalorphine. Since morphine-like and nalorphine-like compounds are considered to interact preferentially with μ and k receptors respectively, this data would suggest that βFNA possesses irreversible antagonist actions at the μ receptor and reversible agonist actions at the k receptor in the guinea-pig ileum preparation. The in vivo profile of βFNA supports this hypothesis.

βFNA, like other mixed agonist-antagonist compounds, did not demonstrate any agonist activity on the mouse tail flick test following peripheral administration. Some agonist action could be detected following icv administration (ED_{50}:4.8 nmol/kg) and this was antagonised by NLX. Following ip injection, βFNA readily antagonised the analgesic effects of both M and ethylketazocine (EK) (a pure 'k' agonist) and this antagonist action was apparent up to 4 days following a single administration. This ability of βFNA to antagonise EK-induced analgesia on the tail flick test is not inconsistent with the suggestion that βFNA possesses antagonist action only at the μ receptor since the agonist actions of EK in this test are probably mediated primarily by μ receptor interaction.

In the acetic acid writhing test, a less stringent analgesic assay in which mixed agonist-antagonist compounds are active, βFNA demonstrated an agonist action (ED_{50}:7.3 μmol/kg) that was antagonised by NLX. βFNA antagonised the analgesic actions of M in this test, but enhanced the analgesic actions of EK.

The unique importance of βFNA's selectivity of agonist and antagonist action lies in the irreversibility of only one of these actions. As such βFNA may prove to be an invaluable tool in the elucidation of receptor types in opioid binding assays. 182.1 FEEDING RESPONSES TO 2-DEOXY-D-GLUCOSE AND INSULIN AFTER DESTRUCTION OF THE AMYGDALOID COMPLEX IN THE RAT. Paula J. Geiselman, Michael G. Tordoff*, Carlos V. Grijalva, Stephen W. Kiefer, and Donald Novin. Brain Research Institute and Department of Psychology, UCLA, Los Angeles, CA 90024.

The lateral hypothalamus (LH) and the amygdaloid complex are functionally related in the control of food intake. The sequelae to LH destruction, however, have been studied more extensively. Rats sustaining LH damage no longer show enhancement of food intake in response to either 2-deoxy-D-glucose (2DG) or insulin. Comparable metabolic challenges have not been studied following amygdaloid destruction. The present experiment was, therefore, conducted to investigate the possible role of the amygdala in the mediation of glucostatic feeding.

Twelve male albino rats sustained electrolytic destruction of the amygdaloid complex, and an additional 12 rats were sham operated. Following recovery, free-feeding animals received intraperitoneal injections of 2DG (100, 200, and 400 mg/kg), subcutaneous injections of insulin (10 U/kg), or equal volumes of isotonic saline by similar routes. All tests were begun at light onset. Food was measured hourly for three hours and again at 24 hours postinjection.

Following injections of 2DG, control animals showed an increase in food intake during the first hour as a function of dosage. By the second hour, the lowest dose of 2DG (100 mg/kg) was no longer effective; but the other two doses (200 and 400 mg/kg) continued to increase food intake. By the third hour, the effects of 2DG had largely subsided in control animals. Rats with amygdaloid damage were unresponsive to 2DG until the third hour, at which time they showed an increase in food intake in response to the two larger doses only. During the 4th through 24th hours, both groups of animals showed alteration in food intake as an inverse function of dosage of 2DG. In response to insulin, however, there were no differences between the two groups: Both control and lesioned animals increased food intake throughout the initial three hours postinjection of insulin and decreased food intake during the remaining portion of the 24-hour period.

This study demonstrates that amygdaloid destruction has a dissociative effect on 2DG- and insulin-induced feeding behavior. These results are in contrast to LH damage, which alters both 2DG- and insulin-induced feeding.

182.2 EFFECTS OF VAGAL TRANSECTIONS ON PLASMA INSULIN AND GLUCOSE LEVELS IN NORMAL AND VENTROMEDIAL HYPOTHALAMIC LESIONED RATS. Bruce M. King, Glenn R. Phelps,* and Lawrence A. Frohman.* Department of Psychology, University of New Orleans, LA 70122, and Division of Endocrinology and Metabolism and Department of Medicine, Michael Reese Hospital, and University of Chicago, IL 60616.

Animals with ventromedial hypothalamic (VMH) lesions display marked elevations in plasma insulin levels both after a fast (Goldman, Bernardis, and Frohman, 1974; Hales and Kennedy, 1964; Han and Frohman, 1970) and in response to an oral glucose load (Steffens, 1970; Steffens, Mogenson, and Stevenson, 1972). In order to assess the role of vagally-mediated hyperinsulinemia in hypothalamic obesity, plasma insulin and glucose levels were assayed in vagotomized (n = 12) and sham-vagotomized (n = 10) female rats after a 6-hour fast and after a measured glucose meal (6 ml sweetened milk) both prior to and 10-14 days following VMH lesions (150 days after vagotomy). The vagotomized and sham-vagotomized animals displayed mean weight gains of 104.3 and 112.2 g, respectively, in the first 10 days after VMH lesions ($t = 0.88$, $p > .30$), but fasting insulin levels were significantly elevated only in sham-vagotomized animals ($p < .005$). Fasting glucose levels were not affected by vagotomy. VMH lesions enhanced the insulin response to oral glucose in both vagotomized and sham-vagotomized animals ($p < .005$). The glucose and insulin response to oral glucose was also markedly elevated by vagotomy ($p < .001$), both prior to and following VMH lesions. As vagotomy reduces gastric retention and increases intestinal transit of liquid loads (Ralph & Sawchenko, 1978; Snowdon, 1970), this effect was probably the result of more rapid absorption of glucose from the intestine. It is concluded that postabsorptive insulin hyperresponsiveness to an oral glucose load in VMH-lesioned animals is independent of vagal mediation, and that while fasting hyperinsulinemia is under vagal control, its elimination does not prevent the development of obesity.

182.3 TACTILE CONTROL OF FEEDING IN THE MALLARD (ANAS PLATYRHYNCHOS L.) H. Berkhoudt*(SPON: H.P. Zeigler). Dept. of Morphol., Zool. Lab., Leiden, The Netherlands 2300 RA.

Previous work has shown that the ingestive behavior of the mallard involves a continuous flow of inputs from mechano-receptors in the oral region. These inputs are used to control the organization of oromotor activity during the different phases of eating and drinking.

The central projections of oral afferents were determined by multi-unit analyses of central trigeminal structures. These studies provided somatotopic maps of the main sensory trigeminal nucleus and a second order trigeminal telencephalic relay, the nucleus basalis. Cinematographic analyses have suggested predictions as to the sequencing of input from different parts of the buccal region during pecking, straining and drinking. These hypotheses were tested by correlating beak movements, muscle activity and neural activity during ingestive behavior. Beak movements were monitored using strain gauges and EMGs recorded from serpihyoid muscle (tongue retractor muscle). Electroneurograms were obtained using chronic multi-unit electrodes implanted in somatotopically differentiated (beak and tongue) regions of the nucleus basalis.

During drinking, mechanoreceptor activity continued throughout the entire act (often for more than two sec.), reaching its highest level during water intake and gradually decreasing prior to swallowing. Mechanoreceptor activity during drinking was not correlated either with beak or tongue movements. The level of mechano-receptor activity during straining was low but correlated better with beak closure/tongue protraction. During pecking there was a clear-cut correlation between the different positions of the food items within the oral region and the occurring activity in different somatotopic regions of nucleus basalis. Multi-unit activity in these regions also correlated well with the occurrence of beak closure/tongue protraction movements. These results confirmed predictions as to the role of mechanoreceptors based upon morphological analyses of their topography and distribution.

182.4 POST-DYNAMIC PHASE OF FATTENING IN RATS WITH VENTROMEDIAL HYPOTHALAMIC LESIONS. J. D. Hallonquist and J. S. Brandes. Dept. of Psychiatry, Mount Sinai Hospital, Toronto, Ontario, Canada M5G 1X5.

Lesions of the ventromedial hypothalamus (VMH) of adult rats result in immediate hyperphagia accompanied by a rapid, negatively-accelerated increase in body weight reflecting increased fat stores. Following this 4 to 10 week "dynamic" phase, a permanent "static" phase is commonly reported in the literature. This phase is described repeatedly as consisting of normal food intake and an elevated body weight beyond which there is no further increase except that exhibited by normal rats of the same age.

In contrast to this description of a "static" phase, we report the absence of a post-dynamic plateau in body weight in female rats with large electrolytic lesions in the VMH area. Instead, beginning by the 11th. postoperative week, such rats showed a steady increase in body weight at a mean rate more than double that of operated control rats of the same age (1.6 vs. 0.7 g/day, $P < .001$). In several cases the post-dynamic phase weight gain amounted to 500 g. Experimental manipulation of the body weight of individual rats by food restriction during the post-dynamic phase suggests that in addition to an immediate elevation of a "set-point" for body weight that produces the dynamic phase, the lesions also induce an additional, gradual elevation of the set-point with age (i.e., a climbing set-point).

The characterization of this gradually developing obesity in rats with VMH-area lesions is especially important considering that most human idiopathic obesity also develops gradually. As a model for human obesity, this long-term effect of VMH area lesions may be more important than the immediate effects. Because normal rats increase fat stores slightly with age, the long-term effect of VMH area lesions may also reflect the acceleration of a normal process.

182.5 PITUITARY BETA-ENDORPHIN LEVELS AND NALOXONE EFFECTS ON FOOD INTAKE IN SEVERAL OBESITY SYNDROMES. M. W. Gunion* and R. H. Peters* (SPON: G. Ellison). Dept. of Psychology, Iowa State Univ., Ames, Iowa 50011.

Beta-endorphin (BE) has been implicated in some genetic obesities. Genetically obese mice (ob/ob) and rats (fa/fa) have elevated pituitary BE levels, and show enhanced suppression of food intake after injection of the opiate antagonist naloxone (Margules et al., Science, 202:988-991, 1978). In the present experiments the role of BE in several non-genetic obesity syndromes was examined. Adult female hooded rats received ventromedial hypothalamic lesions (VMH), dorsolateral tegmental lesions (DLT), parasagittal hypothalamic knife cuts (KC), intraventricular 5,7-dihydroxytryptamine (serotonergic neurotoxin; 5,7-DHT), ovariectomy (OVX), or control surgery. The effect of naloxone (0.5, 1.8, 6.8, or 25.0 mg/kg ip) on food intake was measured during daily four-hour food access periods while all animals were kept at control body weights. Intake was significantly decreased by 1.8 mg/kg (6%, $p<.05$), 6.8 mg/kg (13%, $p<.01$), and 25.0 mg/kg (20%, $p<.01$). The groups did not differ in this dose-dependent suppression.

Half of each group continued on this diet and feeding regimen after naloxone testing. The remaining half of each group was maintained on ad libitum wet mash (70% water) until all rats were sacrificed 4-6 weeks after naloxone testing. VMH and KC became very obese, and OVX and DLT moderately obese on wet mash (68%, 68%, 22%, and 16% above control, respectively; all $p<.01$). Pituitary beta-endorphin-like immunoreactivity (BELI) was decreased by 61% ($p<.01$) in both lean and obese KC rats (23.1 pg/mg), but was unaltered in other groups (mean of 59.8 pg/mg). Obesity had no effect on BELI. In a second experiment, female rats were made obese (69% above control; $p<.0001$) by maintenance for 6 months on palatable foods (sweetened milk, sweetened chow, and syrup-peanut butter slurry). These obese rats had pituitary BELI levels 36% ($p<.02$) above controls.

Feeding mechanisms involving opioid peptides do not appear to be of etiological significance in the syndromes examined. Changes in pituitary BE levels do not appear to be directly related to obesity. The enhanced naloxone suppression of food intake previously found in some genetically obese rodents may be due to obesity alone.

182.6 STRAIN DIFFERENCES IN BEHAVIOR EVOKED BY ELECTRICAL STIMULATION OF THE LATERAL HYPOTHALAMUS. G. Mittleman & E.S. Valenstein, Depts. Psych. & Neurosci. Lab., Univ. Michigan, Ann Arbor, Mich. 48109.

Electrical stimulation of the lateral hypothalamus (ESLH) has been shown to produce individual response differences that cannot be attributed to the neuroanatomical locus of the electrode (Valenstein, Cox & Kakolewski, Psych. Rev., 77:16-31, 1970; Wise, Physiol. & Behav., 6:569-572, 1971. It has been proposed that the response to ESLH may be significantly influenced by behavioral characteristics of the individual animal (Valenstein, Brain, Behav. & Evol. 2:295-316, 1969. The possibility that strain differences may underlie individual responses to ESLH has been raised by reports that hypothalamic self-stimulation rate is correlated with genetic background in rats (Lieblich, Cohen & Beiles, Physiol. & Behav., 21:843-849; Lipp, Brain Res. Bull., 4:553-559, 1979) and mice (Cazala, Cazals & Cardo, Brain Res., 81:159-167, 1974). Moreover, preliminary observations in this laboratory indicated that the incidence of evoking stimulus-bound (S-B) eating and drinking by ESLH was much higher in animals from a Long-Evans (Simonsen Lab, Gilroy, CA & Charles River, Wilmington, Mass.) strain than from a Sprague Dawley (Holtzman Co., Madison, WI) albino strain although these animals did not differ in daily food or water consumption or body weight. The purpose of this experiment was to systematically investigate these differences in behavior evoked by ESLH in Sprague Dawley (S-D) and Long Evans (L-E) rats.

Bipolar electrodes were implanted bilaterally in the lateral hypothalamus of 51 mature S-D male rats and 49 (L-E) male rats. All animals were tested for S-B eating and drinking on 7 separate sessions using an ascending series of stimulus intensities. Those reliably exhibiting eating or drinking in response to ESLH were classified as positive animals, the others as negative. Positive animals were given threshold tests (Bachus & Valenstein, Physiol. & Behav., 23:421-426, 1979) to determine the minimum current capable of evoking S-B behavior.

Results indicated that 56% of the L-E rats showed S-B eating or drinking while only 22% of the Holtzman rats were positive ($\overline{X}^2=10.93$, $p<.001$). Analysis of variance indicated that strain, but not electrode placement or their interaction, was the only significant determinant of the frequency of S-B behavior. Moreover, even though the probability of success was relatively low in the S-D strain, all 10 animals designated as positive at one electrode exhibited S-B behavior at the second electrode site. There were no significant differences in the current threshold for evoking S-B behavior in the positive animals from the two strains. The results support the hypothesis that characteristics of animals associated with strain differences can be a significant determinant of the behavior evoked by ESLH.

182.7 PERIPHERAL LOCUS FOR EPINEPHRINE AND AMPHETAMINE INDUCED ANOREXIA. Michael G. Tordoff,* Donald Novin and Mauricio Russek. Department of Psychology and Brain Research Institute, UCLA, Los Angeles, CA90024.

To test whether epinephrine and amphetamine produce their anorexic effects by activation of a peripheral satiety mechanism, each drug was administered to rats with selective vagotomies.

Groups of six rats were subjected to one of the four following procedures: 1. Total subdiaphragmatic vagotomy (TSV), 2. Destruction of the esophageal-hepatic branch of the vagus (EHV) 3. Esophageal-hepatic spared vagotomy (EHSV) which entailed destruction of both vagal esophageal trunks distal to the esophageal-hepatic branch, and 4. A sham operation as a control (SHM).

Commencing 24 days postsurgery and separated by 4 days, intraperitoneal injections of epinephrine chloride (0, 20, 40, 80, 160 µg/kg) were administered in a counterbalanced design. Tests began at the onset of the dark period of the vivarium light:dark cycle (0500:1700) with food and water intakes being recorded 1, 2, 3, and 24 hr later. In SHM and EHV animals, epinephrine administration resulted in a severe dose-related suppression of feeding in the first two postinjection hours. TSV and EHSV groups showed a similar, but significantly less severe, suppression which was clearest at the two highest doses.

Seven days after completion of epinephrine testing, all rats received in counterbalanced order 0, 0.1, 0.2, and 0.4 mg/kg amphetamine sulfate with injections separated by 3 days and consumption measured 0.5, 1, 2, 3, and 24 hr postinjection. As with epinephrine injections, TSV and EHSV groups showed a significantly milder dose-related decrease in food intake than the SHM or EHV groups. This was most apparent in the first postinjection hour after the 0.4 mg/kg dose. No effects of epinephrine or amphetamine were discernable on food intake later than 2 hr postinjection or on water intake at any time.

We interpret these results as evidence that epinephrine and amphetamine stimulate peripheral glucoreceptors, probably by induction of hepatic glycogenolysis. As total destruction of the vagus attenuated, but did not eliminate, the anorexia produced by epinephrine and amphetamine, we conclude that some, but not all, afferents from hepatic glucoreceptors travel via the vagus. The finding that EHV failed to attenuate drug-induced anorexia implies that these fibers are unimportant in glucostatic regulation.

(Supported by NS07687)

182.8 OROSENSORY MECHANISMS AND THE NEURAL CONTROL OF INGESTIVE BEHAVIOR IN THE RAT. M. Jacquin* & H.P. Zeigler, Biopsychology Dept., Hunter Col., CUNY, NY, NY 10021.

To clarify the roles of trigeminal orosensory and gustatory inputs in the neural control of ingestive behavior detailed analyses were carried out in rats subjected to trigeminal orosensory deafferentation (inf., and ant. sup. alveolar; lingual, sphenopalatine nerves) or gustatory deafferentation (chorda tympani, glossopharyngeal, pharyngeal branch of vagus).

Trigeminal deafferentation is followed by a syndrome of behavioral and morphological effects whose magnitude varies with the number of orosensory nerves sectioned. These effects include: (1) Incisor overgrowth and abrasions of the palate, lower lip and tongue; (2) A reduction in responsiveness to perioral stimuli which normally elicit biting, mouth opening and tongue extrusion; (3) Disruption of the sequential organization of eating and drinking and a reduction in consummatory efficiency; (4) A reduction in responsiveness to food and water; (5) A reduction in food intake whose magnitude and persistence vary with the texture of the available diets; (6) A reduction in water intake. The resumption of intake involves the development of alternative modes of feeding behavior (e.g., "scooping") or contorted drinking postures. After trigeminal deafferentation, intake remains insufficient to compensate for weight lost after surgery and the rats remain below control weight levels for prolonged periods. Our analyses indicate that the reduced intake seen after trigeminal deafferentation is not accounted for either by morphological changes in the oral region or decreases in consummatory efficiency but reflect a disruption of neurosensory processes mediating hunger and thirst. Preliminary data suggests that recovery is due to a combination of nerve regeneration and behavioral compensation.

Gustatory deafferentation is followed by a reduction in food intake whose magnitude and persistence vary with the taste of the available diets. Water intake is significantly reduced and weight is regulated below control levels. The effects of gustatory deafferentation are quantitatively and qualitatively different from those seen after trigeminal orosensory deafferentation suggesting a reevaluation of the role of these two sensory systems in the neural control of ingestive behavior.

182.9 INVESTIGATION OF SEROTONERGIC INFLUENCE ON CANCER-INDUCED ANOREXIA M. von Meyenfeldt, W. T. Chance, J. H. James* and J. E. Fischer*. Dept. Surgery, Univ. Cincinnati Med. Ctr., Cincinnati, OH 45267.

Cancer is often paralleled by anorexia and cachexia, which prohibit the use of aggressive and possibly-curative therapies. Our previous research has demonstrated the onset of anorexia 6 days after the injection (im.) of 5 X 10^4 Walker 256 carcinosarcoma cells in 60 to 80 g, female, Sprague-Dawley rats. This anorexia has also been correlated with increased plasma free tryptophan (Trp), brain Trp and brain serotonin (5-HT) turnover. Therefore, the role of CNS 5-HT in mediating cancer anorexia was investigated in 2 experiments employing intraventricular (ivt.) injections of the Trp-hydroxylase inhibitor, p-chlorophenylalanine (PCPA) in tumor-bearing (TB) rats. Two mg of DL-PCPA methyl ester HCl was administered (ivt., 8 ul) bilaterally, 2 days after the im. injection of W. 256 cells (5 X 10^4, n = 8) or saline (NTB, n = 8). Two additional groups (n = 8) received ivt. saline, 2 days after these im. injections. Food intake and body weight were monitored across the next 7 days of ad lib. feeding. The PCPA-TB group ate significantly more than did the S-TB rats on days 5 - 7 following the tumor treatment, with no differences being observed between PCPA-TB and NTB groups across these 3 days. Nine days after the injection of the tumor cells, the rats were sacrificed by decapitation. The brains were removed and blood collected for the fluorometric determination of 5-HT, 5-hydroxyindoleacetic acid (5-HIAA) and Trp. These biochemical analyses revealed decreased brain 5-HT and 5-HIAA in the PCPA-NTB group, while significant increases in 5-HIAA and brain Trp were observed in the S-TB group. Although plasma total Trp was decreased in both TB groups, free Trp was significantly elevated. In order to assess biochemical changes at a point that more closely coincides with the effect of PCPA, we next investigated the effects of ivt. PCPA treatment on both brain indoleamines and catecholamines (CA) 6 days after the tumor treatment. Two days following the im. injection of saline (n = 16) or 1 X 10^5 W. 256 cells (n = 16), PCPA (2 mg) was bilaterally-administered (ivt.) to half of each group of rats (120 - 160 g). The rats were sacrificed 4 days later, with brain hemisections frozen for the fluorometric determination of 5-HT and 5-HIAA and of CA by high pressure liquid chromatography. S-TB rats exhibited significantly decreased eating 5 days after tumor treatment. By day 6, PCPA-TB rats ate more than did S-TB rats, and there was no difference between groups PCPA-TB and S-NTB. Biochemical analyses indicated significant decreases in 5-HT in both PCPA-treated groups and 5-HIAA in the PCPA-NTB group. Analysis of CA indicated no depletions of norepinephrine or dopamine across any groups. Thus, these data implicate CNS 5-HT derangements in the mediation of cancer-induced anorexia.

182.10 STUDIES OF THE SITE OF ACTION OF NALOXONE IN SUPPRESSING FOOD AND WATER INTAKE IN RATS. Jeffrey G. Jones* and Judith A. Richter (SPON: J.I. Nurnberger), Depts. Pharmacology & Psychiatry, Indiana University School of Medicine, Indianapolis, IN 46223.

Naloxone causes a decrease in certain appetitive behaviors of the rat (Holtzman, J. Pharm. Exp. Ther. 181, 51, 1974). The site of action of naloxone in producing these effects is not known. This abstract summarizes several experiments done in an attempt to elucidate where and how naloxone produces these effects.

Bilateral injections of 15 µg/rat of naloxone into the lateral ventricles of cannulated, food and water deprived rats caused a significant ($p<.05$) decrease in food intake when compared to saline injected controls. Water intake in naloxone-treated animals did not differ significantly from that of saline-treated controls during the one hour tes t period. The total dose of naloxone given centrally, 15 µg, did not produce a change in eating or drinking if given peripherally. This suggests that naloxone exerts its effect on food intake at a central site.

In a second experiment, the effect of i.p. administered naloxone on food and water intake in rats with either a subdiaphragmatic vagotomy (vag) or a sham vagotomy (sham) was evaluated. A dose-related and significant suppression of water intake was seen after treatment with naloxone in doses of 1, 3, and 10 mg/kg in vag and sham rats. Although a significant suppression of food intake was seen in the sham rats, no suppression of food intake was seen in the vag rats at any dose of naloxone tested. This implies that the vagal nerve is necessary for mediation of naloxone's effect on eating.

A third experiment was done to test whether the vagal efferent fibers or the vagal afferent fibers were necessary for mediation of naloxone's effect. In rats pretreated with methyl atropine (5 mg/kg i.p.), naloxone (3 mg/kg i.p.) was equivalent to saline in that it did not decrease food intake during the one hour test period. The naloxone treated group did show a significant decrease in water intake.

These results suggest that the suppression of food intake by naloxone has a central site of action which is mediated by vagal efferents. The results also suggest that naloxone's effect on water intake is mediated by a different mechanism than that involved with food intake.

(Naloxone was generously supplied by Endo Laboratories).

182.11 PERIPHERAL MEDIATION OF OPIATE EFFECTS ON FEEDING IN RATS. G. K. W. Yim, M. T. Lowy*, M. P. Holsapple*, and M. B. Nichols*. Dept. of Pharmacology and Toxicology, Sch. of Pharmacy, Purdue Univ., W Laf IN

The reduction, by naloxone (Lowy et al., Life Sci. 26: 2113, 1980) and by dexamethasone (Lowy and Yim, The Pharmacologist 22: 1980), of 2-DG, food-deprivation (FD), and night feeding suggests opiate involvement in these hyperphagias. These studies were aimed at identifying the type(s) and location of the receptors involved in opiate-mediated feeding.

Three hr daytime rat chow consumption of non-deprived rats were elevated to 3.9 times control intake by 8 mg/kg sc of the µ receptor agonist, morphine sulfate. Feeding was increased to 4.9 times control by 4.0 mg/kg sc of the κ receptor agonist, ketocyclazocine. Meperidine (0.5-32 mg/kg) did not increase feeding. Levorphanol (1.0 mg/kg) elevated food intake to 2.1 times control, while its optical isomer, dextrorphanol (1.0 mg/kg) was ineffective. Loperamide, the peripherally effective opiate agonist which presumably does not pass the blood brain barrier, caused a 2.7 times increase in food intake. Naloxone (0.25 mg/kg sc) caused a 70% reduction of feeding induced by loperamide (10 mg/kg). Single doses of the opiate agonists did not increase 24 hr food intake. Instead, decreases were noted following high doses of some of the agonists. Six hr water intake was elevated to 4.7 times control by 16 mg/kg morphine; to 4.1 times control by 4.0 mg/kg ketocyclazocine; and to 6.7 times control by 1.0 mg/kg levorphanol. Dextrorphanol (0.33-3.0 mg/kg); meperidine (0.5-32 mg/kg); and loperamide (0.33-32 mg/kg) did not increase 6 hr water intake.

The injection of 100 and 400 µg naloxone into the lateral ventricles only decreased one hr FD-induced eating by 41 and 46% respectively. The sc injection of 250 µg of naloxone decreased 1 hr FD eating to the same extent (43%).

These results suggest that opiate mediated feeding involves stereospecific activation of peripheral opiate receptors of the µ and/or κ type. 182.12 SATIETY IS PRODUCED BY GASTRIC NUTRIENT CONTENT. J. A. Deutsch* and M. F. Gonzalez* (SPON: J. S. O'Brien). Department of Psychology, University of California, San Diego, CA 92093.

We have reported previously that satiety signals arise from the stomach and not the duodenum (Deutsch, J. A., W. G. Young, and T. J. Kalogeris, Science, 201:165, 1978). We have also demonstrated that two sets of signals contribute to this regulation. The nature of one of these signals has been shown to be the sheer volume in the stomach that operates at high levels of intake (Deutsch, J. A., M. F. Gonzalez, and W. G. Young, Brain Res. Bull., Suppl. 4, 1980). Here we show that the second signal operates at lower levels of intake and that it is generated by the content of nutrient present in the stomach.

Eleven rats (male, Sprague-Dawley) were implanted with gastric tubes and inflatable pyloric cuffs, and trained to drink a calorically dense liquid diet (Nutrico Standard Research Diet, ICN Pharmaceuticals, Inc.) when 15 h deprived. The mean intake after 15 min was 4.86 ml ± 0.30 ml (SEM). When the animals were counterinjected with normal saline with one half of the volume voluntarily taken by mouth the amount consumed was 4.91 ml ± 0.64 ml (SEM) which was not significantly different from the control level ($t = 0.45$, d.f. = 10, $P > 0.05$). However, when 5 ml were siphoned out of each of the subjects' stomachs, intake was elevated to a mean value of 8.50 ml ± 0.56 ml (SEM) ($t = 6.01$, d.f. = 10, $P < 0.01$). These results show that stomach volume is not a determining factor in the production of satiety at this level of intake.

In a second experiment we permitted seven of the rats to drink normally for 10 min. The pyloric cuffs were then inflated and intake was recorded 15 min later. When the rats were run under control conditions, they consumed a mean of 0.57 ml ± 0.30 ml (SEM) during this period. After a mean volume of 4.14 ml was siphoned off, this value was significantly increased to 3.64 ml ± 0.76 ml (SEM) ($t = 5.3$, d.f. = 6, $P < 0.01$). These results show that at levels where volume is not a factor, the stomach alone (and not the duodenum or the oropharyngeal cavity) generates messages concerning nutrient content that produce satiety.

182.13 INTERACTION OF HEPATIC AND CEREBRAL RECEPTORS IN THE CONTROL OF FEEDING STIMULATED AFTER RECOVERY FROM ACUTE GLUCOPRIVATION IN RATS. J. Granneman* and M. I. Friedman Dept. of Psychol., Univ. of Mass., Amherst, MA. 01003

Injections of insulin and 2-deoxy-D-glucose (2DG) stimulate feeding when food is witheld until after recovery of normoglycemia, 6 hours post-injection. Because the acute energy emergency produced by these injections has presumably abated by the time rats are given access to food, we investigated the possibility that enduring alterations in peripheral metabolism might trigger feeding under these conditions. Feeding after recovery from hypoglycemia is associated with depletion of liver glycogen. Intravenous infusion of fructose, a hexose that does not enter the brain, during hypoglycemia inhibited feeding after recovery from hypoglycemia in intact, but not hepatic-vagotomized rats. Further, food intake is highly correlated with liver glycogen under these conditions. These results suggest that fructose may inhibit feeding after recovery from hypoglycemia by antagonizing insulin-induced changes in hepatic metabolism. Hepatic production of glucose, however, is not necessary for delayed access feeding because adrenal demedullation, which abolishes 2DG-induced hyperglycemia and reduces insulin-induced depletion of glycogen, does not reduce feeding. Finally, intraventricular injections of 2DG stimulate food intake in intact and demedullated rats, suggesting that receptors in the brain may be sufficient to initiate feeding in this paradigm.

In summary, the results of these experiments suggest that receptors in the brain may trigger feeding in the delayed access paradigm, and receptors in the liver may inhibit this response. Finally, hepatic production of glucose, or depletion of glycogen per se, are not necessary to trigger feeding after recovery of normoglycemia. (NIH Grant AM-20022)

182.14 FEEDING RESPONSES IN RATS FOLLOWING APPLICATIONS OF MORPHINE TO THE VENTROMEDIAL HYPOTHALAMUS. F.S. Tepperman*, M. Hirst and C.W. Gowdey* Dept. of Pharmacology, The University of Western Ontario, London, Canada.

We have shown that after s.c. injections of several narcotic analgesics into rats, a period of behavioral depression occurred, followed by "stimulated" feeding activity[1], both phases being antagonized by naloxone. It was of interest to determine whether morphine injected into the ventromedial hypothalamus (VMH) would alter food intake. Cannulae were implanted stereotaxically into the VMH of adult male Sprague-Dawley rats which were maintained in a temperature- and light-controlled room for 7 days before infusions (at 1300 hr) of saline, or 4, 8 or 16 nMol morphine or 10, 20 or 40 nMol norepinephrine (NE) in 0.5 µl sterile saline. Food consumption and hourly core temperatures were measured for 3 hr. Drugs were given re a Latin square design on every 5th day with a saline control intervening (day 3). Food consumption was increased significantly after morphine cf. saline, and the amounts eaten were similar to those after NE, but morphine-stimulated feeding was slower in onset and persisted longer. Some morphine-treated rats showed transient behavioral depression preceding the feeding and all seemed more apprehensive during the feeding phase than NE rats. Core temperatures increased after morphine (more than after NE), the rise often persisting for the 3 hr observation period. In another experiment, both 1 and 2 nMol morphine increased core temperature, but only 2 nMol increased feeding. Naloxone (4 mg/kg s.c.) given 30 min before 8 nMol morphine reduced the "stimulated" feeding. Procaine (110 nMol) into VMH had no apparent effect on temperature or feeding. This study suggests that morphine elicits feeding by an action on opiate receptors in the VMH.

182.15 LATERAL HYPOTHALAMIC LESION INDUCED ADIPSIA PREVENTED BY A PREOPERATIVE RESTRICTED WATERING. Timothy Schallert. Department of Psychology, University of Texas at Austin, Austin, TX 78712.

Prior to receiving small lesions of the lateral hypothalamic area, rats were adapted to a schedule of daily 30-minute access to water for a period of several weeks, during which time they lost little or no body weight. A group was permitted ad lib access to water and just prior to surgery, was given a slightly reduced amount of food to match the weight loss of rats in the restricted watering group. Another group of rats was adapted to a schedule of daily 1-hour access to food for a period of several weeks, but had ad lib access to water. The body weight of an additional control group was reduced all at once just prior to surgery to match the slight loss observed in rats on the special feeding regimen.

After surgery, rats in the brain damaged control groups were aphagic and adipsic. In striking contrast, the rats adapted to a restricted watering schedule showed no adipsia; indeed, they drank water vigorously and chronically. The rats adapted to a restricted feeding schedule were adipsic but not aphagic. The results suggest that preoperative behavioral and physiological conditioning play a large role in recovery of function after brain damage.

182.16 CHRONIC CEREBROVENTRICULAR INFUSIONS OF ANGIOTENSIN II STIMULATE EXCESSIVE DRINKING BUT NOT SALT APPETITE IN DOGS. C. J. Brown*, T. N. Thrasher*, L. C. Keil* and D. J. Ramsay. Department of Physiology, University of California, School of Medicine, San Francisco, CA 94143 and Ames Research Center, NASA, Moffett Field, CA 94035

A salt appetite can be demonstrated in dogs following dietary sodium restriction. A group of eight dogs were given a choice of water or 0.3 M NaCl, a sodium concentration which was aversive to that population of dogs when sodium replete. The dogs were fed a low sodium diet for 5 days and given furosemide (20 mg im) on each of the first 3 days. This procedure decreased plasma sodium concentration from 142 ± 1 to 132 ± 2 mequiv/l and increased plasma renin activity from 3.5 ± 0.6 to 24.5 ± 1.9 ng/ml/3h by day five. On the 5th day the dogs consumed 406 ± 110 ml 0.3 M NaCl and 261 ± 73 ml water in a 4-h testing period.

A number of maneuvers designed to replicate the raised plasma angiotensin II and mineralocorticoid levels characteristic of sodium depletion were tested on salt appetite in sodium-replete dogs. Intravenous infusion of angiotensin II (20 ng/kg/min) in normal dogs, and in dogs pretreated for 5 days with either DOCA (30 mg/day) or aldosterone (5 mg/day) drank water but no salt. Similarly, peripheral administration of renin, acutely or chronically, failed to induce salt appetite.

A vigorous salt appetite has been shown to follow chronic, central administration of angiotensin II in rats. Dogs were prepared with chronic third ventricular cannulas. Angiotensin II (1 µg/kg/h at 1 µl/h) was infused for 7 days using osmotic minipumps (Alzet) and the dogs were offered a choice of water and either 0.3 or 0.45 M NaCl. A maintained, greatly increased water intake was observed for the seven day period. The dogs drank volumes of water between 50 and 100% of their body weights per day. This treatment reduced plasma sodium concentration between 20-25 mequiv/l and suppressed plasma renin activity and plasma vasopressin. Thus although central administration of angiotensin II acutely stimulates vasopressin secretion, it is not maintained, presumably due to dilution and expansion of the extracellular fluid. There was no evidence of salt appetite when compared to vehicle-infused controls.

Thus sodium-depleted dogs show a salt-appetite. This cannot be reproduced by either central or peripheral administration of angiotensin II to the salt-replete animal.

182.17 INSULIN INDUCES INCREASED MILK INTAKE BY SUCKLING RATS IN ABSENCE OF GLUCOPRIVATION. Christina L. Williams and Elliott M. Blass. Dept. Psychol., The Johns Hopkins Univ., Baltimore, MD 21218.

In adult animals insulin-induced glucoprivation is associated with an increase in food intake. Recently, R.C. Ritter et al. (Am. J. Physiol., 234:E617, 1978) have demonstrated that if food is returned to adult rats 6 hr after regular insulin administration, intake is elevated even though normoglycemia has been restored. Utilizing new techniques for studying milk intake during suckling and independent feeding in 5- to 20-day-old rats, we investigated the effects of insulin on these two forms of ingestive behavior 2 hr (during glucoprivation) and 6 1/2 hr (when normoglycemia was restored) after insulin treatment.

Consistent with earlier reports (Houpt et al., Am. J. Physiol. 225:58, 1973; Lytle et al., J. Comp. Physiol. Psychol., 77:388, 1971) we found that 8 hr food and suckling deprived 5- to 20-day-old rats did not increase their milk intake when the dam was returned 2 hr after insulin administration (.5-1.0 U/kg, s.c.); a time when pups' blood glucose levels were low. However, when the dam was returned to 8 hr deprived pups 6 1/2 hr after insulin administration, their milk intake was increased by 35-45% over saline-treated controls. This occurred when pups sucked milk from the nipples of an anesthetized dam that was periodically (once every 4 min for 40 min) injected i.v. with oxytocin (.002 U/inj.). Twenty-day-old pups treated with insulin and tested 6 hr later with another suckling test protocol (pups receiving milk through a tongue cannula while they sucked from their dam's nipples) actually consumed more milk ($\bar{X}$=10.0±.6% b.wt.)than saline-treated controls ($\bar{X}$=7.5±.5% b.wt.)before they reached satiety and stopped suckling. Although insulin treatment increased the rate and total volume of milk intake in suckling rats, the treatment had no effect on pups' latencies to attach to their mothers' nipples.

In contrast, insulin did not increase milk intake when pups ingested food independently of the dam. Regardless of whether insulin was given 2 or 6 1/2 hr prior to milk presentation (either through a tongue cannula or in a bowl) intake did not increase.

These data suggest: 1) Insulin can modulate the intake of young rat pups when milk is ingested by sucking, 2) This modulation only occurs after normoglycemia has been restored, and 3) Since insulin only alters the milk intake of pups when they are suckling and not when they are feeding independently of the dam, the physiological controls of these two ingestive behaviors may be different.

182.18 LATERAL HYPOTHALAMIC (LH) LESIONS PRODUCE EXTENSIVE BLOOD BRAIN BARRIER (BBB) DAMAGE AND CEREBRAL EDEMA. Peter H. Cooper[1], Donald Novin[1,2], and Larry L. Butcher[1,2]; Department of Psychology[1] and Brain Research Institute[2], University of California, Los Angeles; CA, 90024; U.S.A.

A large literature exists demonstrating that brain lesions disrupting the BBB allow for extravasation of serum proteins and for the development of cerebral edema (e.g., Olsson & Hossman, Acta Neuropath. 16: 103, 1970). Evans Blue dye (EB) has been found to be a particularly good marker for the extent of cerebral edema, and horseradish peroxidase (HRP, Sigma Type II) has been used similarly to assess BBB damage. Because of possible relevance for studies of eating and drinking, unilateral LH lesions were made electrolytically in rats. At various times after the ablations, either HRP (50 mg/kg) or EB (40 mg/kg) was administered intravenously. The brains were subsequently examined histologically for BBB involvement.

Two days after lesion induction, there was massive leakage of EB and HRP into the brain parenchyma surrounding the ablations, in some cases approximately 4 mm from the border of cavitation. Apparent BBB damage was seen dorsally in the ventrobasal thalamus, laterally in the internal capsule and in some cases in the adjacent cortex, rostrally in the ventral striatum, and caudally in the anterior substantia nigra and adjacent structures. Three to five weeks after LH ablations, as the volume of the electrolytic lesions decreased (Wolf & DiCara, Exptl. Neurol. 23: 529, 1969), the presence of EB and HRP in the tissue surrounding the cavitation was markedly reduced compared to that seen at shorter intervals, suggesting repair of the BBB.

Cerebral edema may contribute to the ingestive deficits of the LH syndrome by functionally impairing tissue not physically destroyed by the lesions. Repair of the BBB and reduction of edema may be a factor in recovery of function after brain damage. Preliminary evidence indicates that intracerebral administration of 6-hydroxydopamine also produces cerebral edema. As with electrolytic LH lesions, such edema may contribute to the total constellation of pathologic involvement after lesions produced by aqueous solutions of cytotoxins. 182.19 QUANTITATIVE BEHAVIORAL ANALYSIS OF NEUROPEPTIDES WHICH SUPPRESS FOOD INTAKE. J. Gibbs, L. Gray*, C.F. Martin*, W.T. Lhamon and J.A. Stuckey*. Cornell University Medical College and Bourne Laboratory, The New York Hospital, New York, NY 10605.

A growing list of brain-gut peptides has been reported to suppress food intake in rats after systemic administration. In order to determine if the suppressive effect of each peptide was due to a specific action on feeding behavior, we devised a method for reliably rating all behaviors emitted by rats at a test meal. The behavior of each rat was observed during and only during a 0.6 sec 'window' which was signalled by the occurrence of a low-volume background tone played regularly once every two sec by a prerecorded tape. During the 1.4 sec interval between each successive tone, one of 18 defined behaviors was recorded for later analysis; if no behavior could be instantaneously identified, none was recorded. Inter-rater reliability was examined by determining the rate of agreement between three individuals observing 12 rats eating a test meal: Correlations between scores by the three observer pairs were 0.91, 0.91 and 0.92. Test-test reliability was examined by determining the rate of agreement between scores by one individual observing 11 rats eating test meals on consecutive days: There were no statistically significant differences in scores across days.

Twelve adult male Sprague-Dawley rats were deprived of food but not water from 1000 to 1300 h. At 1300 h they were injected intraperitoneally with one dose of one peptide dissolved in 0.15M NaCl, or equivolumetric 0.15M NaCl as a control, and immediately offered liquid food (25% EC116, GIBCO) for 60 min. Cumulative food intakes were recorded at intervals during the test; behavior was rated as outlined above. Substance P (SP; 1-200 μgkg^{-1}), neurotensin (NT; 1-100 μgkg^{-1}), thyrotropin-releasing hormone (TRH; 10 μgkg^{-1}) and bombesin (BBS; 8 μgkg^{-1}) each produced potent suppressions of food intake; somatostatin (1-10 μgkg^{-1}) and pancreatic polypeptide (50-100 μgkg^{-1}) did not. Suppressions of food intake by SP, NT and TRH were always accompanied by abnormal behaviors (e.g. coarse wheezing, arching of back, 'treading' of forepaws after SP and NT) or disruption of the normal distribution of behaviors (e.g. after TRH, the percentage of behaviors represented by apparent sleep shifted from 71±3% to 24±6%, while grooming shifted from 4±1% to 24±3%. No abnormal behaviors or significant change in distribution of behaviors accompanied the suppression of feeding after BBS. These results: (1) support a satiety role for BBS, but not for SP, NT and TRH, and (2) indicate that a systematic behavioral assessment is required to evaluate putative satiety signals. (Supported by NIAMDD grant AM17240 and an Irma T. Hirschl Career Scientist Award.)

182.20 MIF-I SUPPRESSES DEPRIVATION-INDUCED WATER CONSUMPTION IN RATS. R. D. Olson, A. J. Kastin, G. A. Olson, B. M. King, T. K. von Almen*, M. C. Berzas*, M. L. Ibanez, and D. H. Coy*. Dept. of Psychology, University of New Orleans, New Orleans, LA 70122

To study the effects of several neuropeptides on fluid intake across five levels of incentive motivation, rats were deprived of water and given 8 grams of food for 12 hours prior to testing. Animals were given a 0.1 mg/kg i.p. injection of either MIF-I, (D-Ala^2, F$_5$Phe^4)-Met-enkephalin-NH$_2$, D-Phe^4-Met, enkephalin, dynorphin, naloxone, or the diluent vehicle, placed in their home cage for 10 min., and then given ad lib. access to the test solution in a repeated measures design with solutions counterbalanced over five days. The solutions included 20% sucrose, 10% sucrose, water, 0.01% quinine, and 0.02% quinine. Water consumption was measured every hour for 4 hours.

A mixed analysis of variance yielded significant results for all main effects and the peptides by water and hours by water interactions. For the 4-hr. test period, naloxone and D-Phe^4-Met-enkephalin produced reliable increases in water consumption while MIF-I produced a reliable decrease. These differences were obtained only with sucrose solutions, which were consumed in reliably greater amounts than the other solutions. Most fluid was ingested in the first hour for the sucrose and control fluids but no differences existed for the quinine solutions. The data clearly indicate that peptides modulate fluid consumption at positive levels of incentive motivation.

In addition to the highly reliable decrease produced by MIF-I, the increase produced by naloxone was of interest as we had some previous data to suggest that MIF-I and naloxone might act in a comparable fashion. To reconcile these findings, 0.1, 1.0, and 10.0 mg/kg of naloxone and MIF-I were administered as before but to independent groups of rats and intake measures were taken every 30 min. These data replicate and extend the above findings by showing that during the first 30-min. both naloxone and MIF-I suppress intake in a dose-dependent fashion, with MIF-I being more effective at each dose. The 0.1 mg/kg naloxone group increased consumption over time, however, and achieved a total consumption greater than that observed in the control animals. Perhaps the low dose generates a rebound effect during the 4-hr. testing period while a comparable phenomenon might occur with higher doses more than 4 hours after the injection. The two higher doses of naloxone and all doses of MIF-I produced marked suppression during the entire 4 hours. It appears that at very low doses naloxone increases consumption but at more commonly tested higher doses it has a suppressant effect. The very similar results produced by naloxone and MIF-I suggest that these substances might have a common course of action. Finally, in this experimental paradigm, MIF-I acted like naloxone.

182.21 PARALLEL CHANGES IN CONSUMMATORY BEHAVIOR AND PREABSORPTIVE INSULIN RELEASE FOLLOWING TASTE-LiCl ASSOCIATION. Kent Berridge*and Harvey J. Grill
Dept. Psychol., Univ. of Pennsylvania, Philadelphia, Pa. 19104

Oral infusions of glucose (2.53 M) concomitantly elicit an observable ingestive response and a preabsorptive insulin release (PIR). Plasma insulin levels begin to rise during the first min. and reach a mean peak of 1.5 ng/ml over baseline by the 4th minute. Conversely, oral quinine evokes behavioral rejection and a much smaller PIR (0.1 ng/ml). Following a single pairing of novel glucose and LiCl i.p., glucose no longer elicits an ingestive response but instead produces a quinine-like rejection. Our purpose was to examine whether the association of glucose with LiCl would inhibit the reflex PIR to glucose. Twenty-nine male rats (300-400g) were implanted with chronic oral and jugular cannulae. Two groups of four rats each were given 1 min. oral infusions of glucose and 0.2 ml blood samples were taken at -3,0,1,2,3,4,6 and 8 min.; the behavior of the rats was simultaneously videotaped. Following the infusion rats were given 0.15 M LiCl i.p. (1 ml/100g). This procedure was repeated on the next two days, except that LiCl was omitted on the last day. Duplicate plasma glucose (10 μl) assays and radioimmunoassays for insulin (20 μl) were performed. Presentation of oral glucose to naive rats (n=4) produced a normal PIR and elicited behavioral ingestion. A single pairing of oral glucose with LiCl eliminated the PIR to oral glucose and changed the behavioral response to vigorous rejection. These altered autonomic and somatic responses resemble those given by naive rats to oral quinine (.003 M; n=5). The glucose finding was replicated in a second experiment (n=4). These results cannot be explained by blood glucose dependent changes in insulin levels. Control experiments also exclude explanations invoking direct effects of LiCl on pancreatic function (n=6) or response habituation due to repeated exposures to oral glucose (n=4). These results demonstrate that the PIR to taste is susceptible to modification by experience and suggest a parallel relationship between autonomic and behavioral responses to tastes. (Supported by NIH grant AM-21397-03 and by the Diabetes Center, University of Pennsylvania.)

182.22 CHANGES IN TRIGEMINAL MOTOR NEURONAL EXCITABILITY CAUSED BY GLOBUS PALLIDUS LESIONS. F.J. Denaro*, J.S. Schneider and T.I. Lidsky (SPON: J.S.Stamm). SUNY,Stony Brook, N.Y.11794

The trigeminal system, because it controls jaw movement, is intrinsic to eating and drinking behaviors. These behaviors are severely disrupted by globus pallidus (GP) lesions. Although it is known that such damage produces a variety of sensorimotor problems, it is not clear the extent to which the trigeminal system is affected. The present experiment was intended to provide some of this information by assessing trigeminal functioning before and after GP lesions.

The excitability of trigeminal jaw closure motor neurons was measured in chronically prepared rats. Stimulating electrodes were implanted in the trigeminal mesencephalic nucleus (Mes 5). Mes 5 contains the cell bodies of 1A afferents which monosynaptically excite jaw elevator motor neurons. The threshold of the jaw closure reflex which results from electrical stimulation of Mes 5 served as an index of motor neuronal excitability. Reflex thresholds were calculated before and after the production of GP lesions. These lesions caused a dramatic drop in threshold indicating that these motor neurons became hyperexcitable. This effect lasted at least several weeks and persisted well after the lesion-induced aphagia and adipsia had dissipated.

Previously, we have shown that GP stimulation modulates the processing of sensory information originating from facial and perioral tissues (Labuszewski and Lidsky, Exp. Neurol., 1979, 65: 471-477). Numerous investigators have demonstrated that sensory information from these areas can have potent influences upon the excitability of trigeminal motor neurons (e.g. Sessle, Exp. Neurol., 1977, 54: 323-339). Taken together, these two findings make plausible the possibility that the GP lesion-induced increase in trigeminal motor neuronal excitability is due in part to altered influences by facial and perioral somatosensory inputs. To test this possibility, the effect of blocking somatosensory influences upon the jaw closure reflex was tested in normal and GP lesioned rats. Local anesthetization of the face caused no or a slight elevation of threshold in intact rats. In contrast, local anesthetization caused a striking increase of threshold in GP-lesioned rats.

These data indicate that the GP influences those components of the trigeminal system which control jaw movement. Moreover, one way in which this influence is exerted is via regulation of a somatosensory stimulus' access to motor neurons.

182.23 CONTINUOUS ENDORPHIN BLOCKADE DECREASES FEEDING AND DRINKING. Vicki J. Merriman,* & Larry D. Reid, Dept. of Psych., Rensselaer Polytechnic Institute, Troy, New York 12181.

This study follows earlier work of the effects of opioid antagonists on motivated behaviors. Naltrexone hydrochloride (NTX), for example, reduces intake of water among rats while hardly modifying responding for intracranial stimulation (ICS) (Cruz-Morales, Merriman, & Reid, Eastern Psychol. Assoc. Meeting, 1980; Maickel, Braude, & Zabik, Neuropharm., 1977). In this study rats were chronically administered NTX (across 6 days) either by periodic injections or by way of subcutaneously (sc) implanted osmotic minipumps for continuous delivery of small quantities of drug (Alza Corp.) while daily intakes of food and water were measured.

Five groups, of 8 male Sprague-Dawley rats each, were given a different drug regime. Four doses of NTX were delivered via the minipumps, with doses computed as 0.0, 0.068, 0.27, and 1.08 mg/day. The 5th drug condition was a daily sc-injection of NTX, 4.0 mg/kg/day, a dose equivalent in mg/kg to the highest minipump-dose. Subjects were weighed and food and water measurements were taken once a day. After 3 days of baseline, all subjects were anesthetized with ether and underwent a sham or actual implantation of a minipump. After 6 drug days, the pumps were removed, followed by 3 days of post drug baseline. Throughout the study, patterns of drinking were monitored using a drinkometer circuit.

Food intake was decreased by about 2, 10, 18, and 22% compared to predrug baseline for the 4 minipump-doses (0 to 1.08 mg/day) and <1% for the sc-dose, respectively. Water intake was decreased by <1, 2, 15, and 15% respectively, with the minipump-doses and <1% with the sc-dose. NTX of .27 and 1.08 mg/day reliably decreased both food and water intake ($ps < .05$), while the 0 minipump- and sc-doses produced insignificant decreases. Therefore, small doses, continuously delivered, successfully decreased consummatory behavior, while an equal or larger dose given as an acute injection did not.

These data fit into a growing body of evidence indicating that different antagonists of morphine-endorphin modify different kinds of motivated behavior. For example, NTX and naloxone reduce feeding and drinking (NTX in remarkably small doses) while large doses of NTX do not reliably modify pressing for ICS. Naloxone decreases and Win 44,441 increase pressing for ICS. Nalorphine reduces deprivation-induced drinking but does not reduce ad lib. intake of sugar-water. It is inferred that different opioid systems are links in the various motivational schema.

182.24 LESIONS OF THE SUBFORNICAL ORGAN INHIBIT ANGIOTENSIN-INDUCED DRINKING IN THE DOG. M. H. Reed*, T. N. Thrasher*, J. B. Simpson, L. C. Keil* and D. J. Ramsay. Department of Physiology, University of California, School of Medicine, San Francisco, CA 94143 and Ames Research Center, NASA, Moffett Field, CA 94035

The sub-fornical organ (SFO) has been implicated in many of the centrally mediated actions of circulating angiotensin in the brain. In particular, injections of angiotensin II directly into the SFO cause drinking, vasopressin secretion and an increase in blood pressure in rats. In the present study, a technique was devised to make lesions of the SFO in dogs. The effect of such lesions on drinking and vasopressin secretion brought about by angiotensin and hypertonic saline was studied.

Lesions were made with the dog placed in a stereotaxic apparatus. A 20 gauge cannula was placed in the III ventricle and 0.5 ml contrast medium injected. From the X-ray, precise coordinates for placing the lesioning electrode in the SFO were calculated. The position of the lesioning electrode was checked with a second X-ray and altered if necessary. After all observations had been made, the brain was fixed in formalin by perfusion, removed and later stained for Nissle substance. In the initial series of 12 dogs, complete destruction of the SFO was attained in 5 dogs.

The drinking response to angiotensin II (20 ng/kg/min, i.v.) was reduced from 222 $\pm$ 65 ml to 27 $\pm$ 24 ml over a 30 min test period following SFO lesions. When retested one month later, the drinking response to angiotensin II was still absent (20 $\pm$ 20 ml). Thus, the effect of the lesion was sustained for at least one month and the drinking response to angiotensin showed no tendency to recover. In contrast, drinking responses to 0.85 M NaCl were not affected by the lesion (315 $\pm$ 92 before and 269 $\pm$ 70 ml after the lesion). However the latency to drink was significantly lengthened from 10 $\pm$ 3 to 22 $\pm$ 3 min. Whether this increase in latency indicates that the SFO is involved in drinking responses to osmotic stimulation is uncertain.

The effect of SFO lesions on vasopressin responses to angiotensin and 0.85 M NaCl is more variable. This is due in part to the inhibitory effects of drinking itself on vasopressin secretion. However, it appears that complete lesions of the SFO suppress the capacity of brain to respond to these agents.

In summary, in the dog the drinking response to circulating angiotensin, but not to hypertonic saline, depends on the integrity of the SFO.

182.25 SPECIFIC INCREASE IN CARBOHYDRATE CONSUMPTION AFTER NOREPINEPHRINE (NE) INJECTION INTO THE PARAVENTRICULAR NUCLEUS (PVN). J.R. Tretter* and S.F. Leibowitz. Rockefeller Univ., New York, NY 10021. (SPON: R. L. Thompson)

While the phenomenon of increased feeding after PVN noradrenergic stimulation is believed to reflect a physiologically active system, little is known about the specific role this system has in the feeding process. The present study examined a possible function of NE in controlling the animals' elective consumption of particular nutrients. With the use of a self-selection feeding paradigm, results revealed that noradrenergic stimulation of the PVN, while increasing total food intake, also produces a specific enhancement in the animal's preference for carbohydrate, thus implicating NE is the process of balancing dietary nutrients.

Rats (350 g) with PVN cannulas were maintained and tested on one of several sets of 2 diets. These diets, simultaneously available, consisted of either: 1) lab chow powder mixed with various proportions of sucrose versus fat (Crisco or corn oil used with mineral oil to make diets isocaloric), or 2) pure protein (casein), starch (dextrin or corn starch), or sugar (sugar or dextrose), or various combinations of these constituents, mixed with corn oil, vitamins, minerals, L-cystine, and in a few cases cellulose to equate caloric density. These diets were tested under two different paradigms: a) The 2 diets were available ad lib; the drug or vehicle control tests, lasting 1 hr, were conducted in the day when a small amount (1-4 g) of spontaneous eating occurred. b)The food was restricted to a 6-hr period during the day. The drugs or vehicles were injected 1 to 3 times throughout this period, and food intake was measured hourly.

The basic phenomenon, that PVN noradrenergic stimulation specifically increases preference for carbohydrate (sweet or non-sweet), received preliminary support from initial experiments showing that NE elicited consumption of sugar cubes and 20% sucrose water but not saccharin water, and that NE increased preference for sugar cubes over lab chow pellets. The two main and more extensive experiments, using self-selection feeding paradigms and diets described above, yielded comparable results, although the 6-hr feeding schedule permitted more careful and continuous minitoring of the animals' total daily food intake pattern and generally revealed more stable effects. With all the various diets tested, PVN injection of NE consistently increased the rats' elective consumption of carbohydrate relative to other dietary constituents, and this occurred whether the carbohydrate was sweet or non-sweet. No differential effects on intake of protein or fat were observed. These results are consistent with those obtained with the α-adrenergic agonist clonidine (Fahrbach et al., this meeting), and preliminary experiments suggest a similar increased carbohydrate preference after injection of tricyclic antidepressants.

182.26 LOCAL INJECTION OF MORPHINE OR AN OPIATE PEPTIDE INTO THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS ELICITS FEEDING S. McLean* and B. G. Hoebel. Prog. in Neurosci., Dept. of Psychol., Princeton Univ., Princeton, NJ 08540.

Bilateral injections of morphine (2ug) or D-ala^2-met^5-enkephalinamide (DALA) (2ug, 4ug, and 8ug in 0.3ul) into the paraventricular nucleus of the hypothalamus elicited feeding in satiated rats. The 2ug dose of morphine produced a mean intake of 2.5 gm. of food pellets in the second hour after injection, compared to a mean of 0.5 gm. during the same time period after saline control injection. DALA increased food intake in a dose dependent manner. Morphine elicited feeding with a latency of 60-90 minutes; DALA initiated feeding within 30-60 minutes. Morphine's effect appeared to be receptor mediated because local injection of naloxone, 40 minutes following morphine, attenuated the feeding induced by morphine. It is concluded that exogenous opioids injected into the paraventricular nucleus can induce food intake with a long latency.

183.1 ACTION OF CYCLIC AMP ON APLYSIA NEURON R15. S. N. Treistman. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

We have previously reported that a long-lasting synaptic hyperpolarization produced in cell R15 after stimulation of the branchial nerve is augmented in the presence of the phosphodiesterase inhibitor, theophylline. Also, intracellular injection of guanylylimidodiphosphate (GMP-PNP), an activator of adenylate cyclase, causes a long-lasting hyperpolarization in R15, further suggesting that the synaptic event may be mediated by cyclic AMP. In this report, the biophysical effects of branchial nerve stimulation and cyclic AMP elevation are compared, in an attempt to further test the possibility that cAMP mediates the synaptic event, and to explore the conductance mechanisms that underlie the nucleotide action.

Maximal stimulation of the branchial nerve silenced R15 and the quasi-steadystate I-V plot indicated an increased slope conductance in response to hyperpolarizing pulses plus reduction or abolition of the negative slope resistance region (NSR) normally present in R15. By varying stimulus parameters, it was possible to activate inputs which acted primarily to decrease NSR, increase slope conductance, or both.

Cyclic AMP was elevated by four different routes: 1) perfusion with cAMP derivatives, 2) intracellular injection of cAMP derivatives, 3) intracellular injection of cAMP after perfusion with the phosphodiesterase inhibitor RO-1724, and 4) intracellular injection of guanylylimidodiphosphate (GMP-PNP). All caused burst reduction or silence in R15, and the I-V plot in all cases showed an increased slope conductance in response to hyperpolarizing pulses. The NSR was generally not reduced, except after GMP-PNP injection, where a reduction of NSR often occurred. Thus, cyclic nucleotide action in R15 appears to result mainly from an increased conductance, presumably to potassium ions, and it is this component of the synaptic response which is most likely to be mediated by cAMP in R15. The nucleotide-induced response in R15 is not due to a spike-related event such as an increased Ca^{2+}-mediated K^+-conductance since GMP-PNP injection into a clamped cell resulted in a silent cell when the clamp was removed, even though no action potentials had occurred.

183.2 ACTIVATION OF ADENYLATE CYCLASE BY A SUBSTANCE OF PROTEINOUS NATURE FOUND IN RAT SPINAL CORD. S. T. Bissen* and T. Ueda. Mental Health Research Institute and Dept. of Pharmacology, The Univ. of Michigan, Ann Arbor, MI 48109

We have recently described that the synapse-specific proteins, Proteins Ia and Ib, and adenylate cyclase are enriched in cervical and midlumbar segments of the rat spinal cord (Ueda, Stratford, and Larson, 1980; J. Neurochem., in press). The adenylate cyclase activity in the cell-free system of the spinal cord was not affected appreciably by the putative neurotransmitters dopamine, norepinephrine, serotonin, and histamine (0.1 mM), when assayed under the incubation conditions which allowed dopamine to stimulate adenylate cyclase in caudate nucleus (Kebabian, Petzold, and Greengard, 1972; Proc. Nat. Acad. Sci. 69, 2145). We now report that acid extracts of the spinal cord of matured rats contain a factor(s) of proteinous nature that can stimulate as much as 8-10 fold adenylate cyclase in the cell-free preparation of the cord. The stimulatory action of the factor(s) does not require exogenously added GTP or Ca++. The ability of the factor(s) to stimulate the adenylate cyclase is lost upon treatment with proteolytic enzymes but not with lipolytic or nucleolytic enzymes. Moreover, the activating substance is not dialyzable and is thermolabile under acidic and neutral conditions, suggesting that the substance is not a small peptide. The purification and further characterization of the substance are now in progress.

Supported by NIH Grant NS 15113.

183.3 ISOPROTERENOL EFFECTS ON CORTICAL ADENYLATE CYCLASE IN CA^{++}_1-SATURATED MEMBRANES. Scott R. Whittemore*, Yigal H. Ehrlich†, and Edith D. Hendley, Dept. of Physiol. & Biophys. and †Dept. of Psychiatry & Biochem., Univ. of Vermont College of Medicine, Burlington, VT. 05405.

Neurohormonal effects on adenylate cyclase (AC) have been examined in the absence of endogenous Ca^{++} since von Hungen and Roberts (Nature New Biology, 242:58, 1974) demonstrated enhanced epinephrine stimulated AC in the presence of EGTA. However, the interpretation of these findings in relation to physiological function is complicated as Ca^{++} is present intracellularly in micromolar concentrations. This study was initiated to investigate the interactions of neurotransmitters and Ca^{++} ions in mechanisms regulating AC activity. The effects of Ca^{++} on cortical AC have been reported to be dependent on calmodulin (CaM). Therefore, we have prepared fractions containing synaptic membranes from rat cerebral cortex, by osmotically shocking synaptosomes in the presence of 50μM $CaCl_2$. Using this procedure it has been shown that the membranes support endogenous Ca^{++}/CaM-dependent protein phosphorylation without addition of exogenous CaM (Ehrlich et al. J. Neurochem. vol. 5 (in press) 1980, Life Sci. 26:1965, 1980. Thus, these membranes contain bound CaM. Other experiments were carried out with excess EGTA (2mM) in the homogenization and osmotic-shock buffers. Basal AC activity produced 78 picomoles cAMP/min/mg protein. GTP (10μM), (-)-isoproterenol (ISO) (100μM), and ISO plus GTP stimulated basal activity 30%, 20%, and 100% respectively. Basal activity in membranes used with Ca^{++} buffer was 3-5 fold greater than that seen with EGTA prepared membranes and GTP always resulted in increased AC activity, as expected from the report of Brostrom et al. (Arch. Biochem. Biophys., 191:341, 1978). Addition of 100μM ISO produced small (13.9±5.4%) but consistent ($p<.05$, n=7) decreases in AC activity. This decrease in AC activity induced by ISO in Ca^{++} saturated membranes occurred in the absence of exogenously added GTP. AC activity in these membranes in the presence of GTP and ISO was always greater than basal activity. However, the effects of ISO in the presence of added GTP were variable. Out of 7 experiments, ISO had no effects in two, produced an increase in AC activity in two experiments, and a decrease in GTP stimulated AC in the remaining three. These results serve to demonstrate the complexity of interactions between various factors that affect adenylate cyclase activity in the presence of physiological concentrations of Ca^{++} ions, and indicate the need for further and more detailed characterization of this system. These experiments are in progress. Supported by Grants DA02747 from NIDA and PHS RO1-25811.

183.4 THE EFFECT OF CALMODULIN ON THE RESPONSE OF RAT CAUDATE TO CALCIUM AND DOPAMINE. M.T.Piascik*, R.J.Hitzemann* and J.D.Potter*. (SPON: G. Eckstein). Dept. of Pharmacol. and Cell Biophysics and Dept. of Psychiatry, Univ. of Cincinnati College of Medicine, Cincinnati, OH 45267

Recently it has been proposed that calmodulin may participate in dopamine receptor supersensitivity in the rat straitum (Gnegy et al., J.P.E.T. 202, 558, 1977) by making the striatal adenylate cyclase more sensitive to dopamine (Gnegy and Treisman, Fed. Proc. 39, 516, 1980). In the present study we have examined the effects of purified calmodulin on the basal and dopamine stimulated adenyl cyclase found in rat striatal microsomes. Cortical microsomes were used as a control. Both brain regions contained a basal adenylate cyclase which responded in a biphasic manner to changes in free Ca^{2+} concentration, $[Ca^{2+}]$, (half maximal stimulation=0.2μM $[Ca^{2+}]$, half maximal inhibition=0.8μM $[Ca^{2+}]$).However, the basal striatal adenylate cyclase was stimulated only two fold while the basal cortical adenylate cyclase was stimulated seven fold. These data suggest that the striatum contains an adenylate cyclase which,relative to cortex,is less responsive to Ca^{2+}.The lower Ca^{2+} dependent stimulation was not due to loss of calmodulin during preparation since addition of excess calmodulin (60μg/mg protein) resulted in only a 2.5 fold stimulation of basal adenylate cyclase. Although the adenyl cyclase of the striatum is relatively unresponsive to Ca^{2+} and calmodulin, the work of Gnegy et al. suggests that these modulators should play an important role in regulating the cyclase response to dopamine. Our data suggest otherwise. At 0.2μM $[Ca^{2+}]$, the dopamine EC_{50} was not changed by the addition of excess (64μg/mg striatal membrane) calmodulin. Depletion of calmodulin from these membranes by washing with 0.1 mM EGTA resulted in a significant loss in the sensitivity of the striatal cyclase to Ca^{2+} but did not change basal activity. Furthermore, the EC_{50} to dopamine was not changed in these membranes (EC_{50}=5μM) when compared to control (EC_{50}=6μM). In conclusion our data do not support the concept that calmodulin regulates the sensitivity of the striatal adenyl cyclase to dopamine. Thus it is unlikely that a change in calmodulin levels is responsible for the supersensitivity of the dopamine stimulated adenyl cyclase. 183.5 MUSCARINIC POTENTIATION OF DOPAMINE STIMULATED CYCLIC AMP ACCUMULATION IN RAT RETINA J.H. Brown and M.G. Rietow*, Division of Pharmacology, University of Calif. San Diego, La Jolla, CA 92093

Muscarinic agonists are among a group of agents previously thought to have no effect on adenylate cyclase, but more recently demonstrated to cause inhibition, particularly of hormone-stimulated adenylate cyclase. We have examinied potential interactions between dopamine (DA) and the choline ester, carbachol (CARB) on cyclic AMP accumulation in the retina. Intact retinas from adult rats were incubated in oxygenated Krebs Henseleit buffer pH 7.4 at 35°C, in the presence of 100 μM phosphodiesterase inhibitor, isobutylmethylxanthine, and then exposed to hormones for 2 min, frozen and assayed for cyclic AMP by competitive protein binding. DA (50 μM) increased the cyclic AMP concentration from 17 to 45 pmol/mg prot. CARB (30 μM) caused a smaller but significant increase in cyclic AMP to 27 pmol/mg protein. When the two agents were tested in combination they were found to be synergistic. Thus while additivity would predict that CARB plus DA produce a 30% greater response than DA alone, the response to DA was instead almost doubled in the presence of CARB. Two pieces of data indicate that this effect of CARB is mediated via muscarinic receptors: it was completely antagonized by atropine (10 μM) and it was mimicked by the muscarinic agonist oxotremorine (OXO). OXO (10 μM), like CARB, caused marked potentiation of the response to DA. Retinas depolarized by incubation in 57 mM K^+ medium also showed increased responsiveness to DA. This suggested the possibility that muscarinic effects on adenylate cyclase were mediated indirectly via release of another neurohormone. However, CARB still increased cyclic AMP and synergised with DA in retinas incubated in calcium-free, EGTA containing medium for 20 min, making a calcium dependent release unlikely. In brain slices adenosine (ADO) is released by depolarization and potentiates the effects of amines on cyclic AMP formation. ADO (100 μM) did not mimic the effects of CARB on basal or DA stimulated cyclic AMP formation in the retina. The data suggests that the acetylcholine containing cells of the retina may function to modulate aspects of dopaminergic neurotransmission mediated through adenylate cyclase. The molecular mechanisms that underly the dopaminergic-cholinergic interactions shown here remain to be elucidated.

This work was supported by USPHS grant HL 24441 from the NIH.

183.6 EFFECTS OF MUSCARINIC AND NICOTINIC AGONISTS AND ANTAGONISTS ON BRAIN REGIONAL CYCLIC NUCLEOTIDES. J.L. Meyerhoff, G.J. Kant, R.H. Lenox, L.L. Pennington* and D.R. Collins*. Dept. of Med. Neurosciences, Walter Reed Army Inst. of Res., Wash., DC 20012 and Dept. of Psychiatry, Univ. of Vermont, Burlington, VT 05405

We have previously reported that cholinergic agonists elevate cyclic AMP and cyclic GMP in several rat brain regions in vivo (R.H. Lenox, G.J. Kant, and J.L. Meyerhoff, Neurosci. Absts. 5: 1373, 1979). We have now compared the effects of muscarinic versus nicotinic agonists and also examined the effect of pretreatment with muscarinic or nicotinic blockers.

Male albino rats of the WRC strain, weighing between 250-300 grams were maintained in a light-cycled chamber. Two groups of rats were pretreated with methylatropine nitrate (0.5 mg/kg, ip) and later injected with either oxotremorine (2.0 mg/kg, ip) or saline. Another two groups were pretreated with atropine sulfate (60 mg/kg, ip) and later also injected with either oxotremorine or saline. In a second study, two groups were pretreated with saline injections followed by either an injection of nicotine (1.2 mg/kg, ip) or another saline injection. Another two groups were pretreated with mecamylamine (1.0 mg/kg, ip) followed by an injection of either nicotine or saline. Pretreatment always occurred 40 min prior to sacrifice and the second injection was given 10 min prior to sacrifice, which was accomplished by exposure to microwave irradiation (2.5 kw, 2450 MHz, 5 sec).

Following sacrifice and decapitation, trunk blood was collected for radioimmunoassay for prolactin and 21 brain regions were dissected for radioimmunoassay for cyclic AMP and cyclic GMP. Oxotremorine caused marked increases in cyclic AMP in the pituitary as well as in the hypothalamus, interpeduncular region and substantia nigra all of which were attenuated by pretreatment with atropine. Nicotine markedly elevated cyclic AMP in the pituitary and the interpeduncular region and caused significant increases in plasma prolactin as well. The nicotine-induced changes were attenuated by mecamylamine pretreatment.

The regional pattern of increase in cyclic GMP levels in the animals receiving oxotremorine is similar to the response following locomotor activity (Meyerhoff et al., Life Sci., 1979) consistent with the behavioral observation of tremor. The increases in cyclic GMP in the septal region, however, were not seen following locomotor activity alone. The tremors and the brain cyclic GMP increases were attenuated by pretreatment with atropine.

Nicotine lowered cyclic GMP in the cerebellum and decreased locomotor activity. These changes were attenuated by pretreatment with mecamylamine. Muscarinic and nicotinic agonists have marked effects on cyclic nucleotide levels in several regions of rat brain and these effects are attenuated by pretreatment with appropriate antagonists.

183.7 LOSS AND RESTORATION OF SENSITIVITY TO CATECHOLAMINES IN CULTURED BHK CELLS: INFLUENCE OF DANSYLCADAVERINE. A. Reggiani*, F. Vernaleone*, and G. A. Robison. Dept. of Pharmacology, University of Texas Medical School, Houston, Texas 77025

The adenine prelabeling technique has been used to further study the accumulation of cyclic AMP (cAMP) in BHK cells in response to isoproterenol (ISO) and PGE_1. Cyclic AMP rises and then falls in these cells in response to either agonist; the decline is due to hydrolysis by phosphodiesterase (PDE) and to the development of tachyphylaxis, i.e., a state of reduced responsivity to stimulation by agonists. Although ISO and PGE_1 clearly compete with each other insofar as the activation of adenylyl cyclase (AC) is concerned, PGE_1 has no influence on the rate at which tachyphylaxis develops to ISO. The evidence suggests that receptors must be activated in order for AC to be activated, but that the active receptors are inactivated at a rate independent of the extent to which they interact with the AC system.

When cells are exposed to 10^{-6}M ISO for 2 hours, and the ISO then removed, the maximum response to ISO is only 15% of that of control cells. After incubating in the absence of ISO for several hours, the response increases up to about 60% of control but no further, suggesting that about half of the inactivated receptors had been irreversibly lost (as indicated also by a comparable reduction in the maximum specific binding of ^{125}IHYP). We had previously found that when tachyphylaxis was induced in the presence of cycloheximide or actinomycin D, and the agonist then removed, responsiveness to ISO returned to 100% of control within 1 hour, suggesting a possible involvement of protein synthesis in the maintenance of tachyphylaxis. We have now found that dansylcadaverine (DC), which has no significant effect on protein synthesis but which is a potent inhibitor of transglutaminase and hence of endocytosis (Nature 238:162, 1980), produces a similar effect, i.e., DC does not prevent the initial development of tachyphylaxis, but does permit the complete restoration of responsivity to ISO after the ISO and DC have been removed. We conclude that the long-term loss of responsivity to agonists in these cells occurs in two stages, first the initial development of tachyphylaxis (conversion of active to inactive receptors) followed by the slower endocytotic uptake of inactive receptors, and protein synthesis does not seem to be involved in either process. We also conclude from studies of cells grown under different conditions that endocytotic activity depends more upon cell density (it is greater at high density) than on the rate at which the cells are growing. Supported by grants from the USPHS (GM 27378) and the Burroughs Wellcome Fund.

183.8 ENHANCED CYCLIC AMP ACCUMULATION IN RAT SPINAL CORD TISSUE SLICES FOLLOWING 6-HYDROXYDOPAMINE. D.J.Jones, L.F.McKenna* and P.M.Mason* Departments of Anesthesiology and Pharmacology, The University of Texas Health Science Center, San Antonio, TX 78284

Previous studies from this laboratory have demonstrated agonist specificity for cyclic AMP accumulation in rat spinal cord tissue slices (Jones and McKenna, Neuropharmacology, 1980). The presence of catecholamine containing neurons in spinal cord and their degeneration by 6-hydroxydopamine (6-OHDA) suggests that adrenergic denervation supersensitivity might be associated with the adenylate cyclase-cyclic AMP response in this tissue. The purpose of this study was to determine if there occurs an enhanced cyclic AMP response to catecholamines in spinal cord following 6-OHDA.

Three, seven, ten or 14 days prior to sacrifice rats were etherized and injected intracisternally with either a single or two, 0.20 mg doses of 6-OHDA in 0.01 ml of 0.1% ascorbate. Sham animals recieved vehicle only. Following sacrifice, spinal cords were removed and sliced on a McIlwain tissue chopper (300 μm) with subsequent incubation for one hour in oxygenated Krebs-Ringer bicarbonate buffer. Following this period, the slices were placed into incubation flasks for 15 min at which time various agonists were added. At the end of a 10 min incubation period tissue protein was denatured and cyclic AMP measured by radioimmunoassay.

One week following injection of 0.20 mg (x2) of 6-OHDA spinal cord norepinephrine (NE) levels were depleted over 95% from 619 ± 72 to 32 ± 10 ng/gm tissue. Depletion was also evident at 14 days. Consonant with depletion at 7 days and 14 days was an enhanced, concentration-dependent accumulation of cyclic AMP in response to NE. The enhanced response was reflected in an increase in maximal response only, without a change in the EC_{50}. In regional studies, enhanced accumulation of cyclic AMP in response to NE was evident as early as 3 days in the cervical cord. However lumbar spinal cord required at least 10 days for this response to develop suggesting a time course dependent on diffusion of 6-OHDA to the lumbar level. Enhanced cyclic AMP accumulation was also evident with iso proterenol. In addition the enhanced response to both NE and isoproterenol was potentiated in the presence of the phosphodiesterase inhibitor RO 20-1724. Pretreatment of animals with intracisternal 6-OHDA did not alter the response of spinal cord tissue slices to adenosine. This data suggests that adrenergic denervation supersensitvity, as evidenced by enhanced cyclic AMP accumulation, is evident in spinal cord tissue slices following 6-OHDA.
Supported by NIH grant NS 14546.

183.9 ISOPROTERENOL-INDUCED CYCLIC AMP INCREASES IN VIVO IN PINEAL AND OTHER RAT BRAIN REGIONS. G. Jean Kant, Vernice E. Bates, Robert H. Lenox and James L. Meyerhoff. Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington DC 20012 and Dept. of Psychiatry, Univ. of Vermont College of Medicine, Burlington VT 05405

Central β-receptors appear to be linked to cyclic AMP generating systems as determined primarily in in vitro studies. Tissue slices respond to isoproterenol (a β-agonist) with increased levels of cyclic AMP and this increase can be blocked by prior incubation with the β-antagonist propanolol. Recently the pineal β-receptor has been investigated in vivo and pineal cyclic AMP has been shown to increase after administration of isoproterenol. Since β receptors are found in many rat brain regions, we measured cyclic AMP levels in 10 brain regions of rats sacrificed by microwave irradiation 10 min after challenge with isoproterenol. The sensitivity of the pineal β-receptor has been shown to increase in rats maintained in continuous light and therefore in one experiment a group of rats was kept in continuous light for 3 weeks prior to isoproterenol challenge. All other rats were maintained on a 12 hr light-dark cycle (0600-1800). All rats were habituated to saline injection, handling, and to being placed in a plastic tube (similar to one used to immobilize the rats briefly during microwave sacrifice).

Rats were injected with saline or isoproterenol (10 mg/Kg i.p.), and sacrificed 10 min later by microwave irradiation at 2450 MHz using 2.5 Kw for approximately 5 sec. The heads were cooled on dry ice; the brain regions were dissected, weighed and sonicated in 50 mM sodium acetate buffer pH 6.2. The sonicates were centrifuged and the supernatants were stored at -70°C until assayed for cyclic AMP by radioimmunoassay. Isoproterenol significantly increased levels of cyclic AMP in the light-dark cycled rats in pineal, pituitary, cortex, hypothalamus, midbrain, frontal cortex, brainstem, and cerebellum.

In the animals kept in continuous light there was an enhanced cyclic AMP response to isoproterenol, suggesting the presence of supersensitivity.

183.10 IN VIVO CYCLIC AMP LEVELS IN RAT BRAIN REGIONS FOLLOWING KINDLING. Vernice E. Bates, James L. Meyerhoff, G. Jean Kant and Robert H. Lenox. Dept. of Medical Neurosciences, Walter Reed Army Institute of Research, Washington DC 20012 and Dept. of Psychiatry, Univ. of Vermont College of Medicine, Burlington, VT 05405

Kindling consists of repetitive intermittent low intensity electrical stimulation of subcortical structures, especially the amygdala. This results in progressive changes in electrical activity and behavior and eventually culminates in a generalized seizure in response to an electrical stimulus which previously had produced no effect.

Seizures induced by maximal electroshock or pentylenetetrazol result in increased brain levels of cyclic AMP (cAMP) immediately following a seizure. Iontophoretically applied cAMP has an inhibitory effect on CNS neurons and it has been suggested that the cAMP rise following seizures has an antiepileptic effect in the brain. However, the precise role of cAMP in these acute seizure episodes is not clear and their role in chronic seizure models such as kindling has not been evaluated. We were interested in determining whether regional levels of cAMP measured in vivo would be altered following amygdaloid kindling.

Bipolar amygdaloid electrodes were implanted unilaterally into 12 male Sprague-Dawley rats. Seven days later, daily electrical stimulation was begun in 6 experimental animals. Stimulation consisted of 1 second of 60 Hz biphasic square wave pulses at 400 μA using a Grass S88 constant current stimulator. Six sham kindled animals with unilateral amygdaloid electrodes were handled similarly but did not receive electrical stimulation. Animals were considered fully kindled when they had 3 consecutive days of stage 5 seizures. This occurred following a mean of 12 ± .5 stimulations. Following the last seizure, amygdaloid electrodes were removed from both kindled and sham kindled animals. Three days later all animals were sacrificed by microwave irradiation at 2.5 kilowatts at a frequency of 2450 ± 20 MHz. After sacrifice, brains were dissected and cAMP was assayed by a modification of the radioimmunoassay of Steiner et al. Regions assayed included amygdala, hippocampus, striatum, substantia nigra, midbrain, brainstem, cerebellum, thalamus, cingulate gyrus, pyriform cortex and frontal cortex.

Cyclic AMP levels were significantly decreased in the stimulated amygdala when compared to sham kindled animals ($p<.01$). No differences were found in other brain regions. These findings suggest a role for cAMP mechanisms in amygdaloid kindled seizures.

183.11 CYCLIC GMP BIOCHEMISTRY IN HIPPOCAMPUS: COMPARISON OF RAT AND GUINEA PIG. P.E. Kilbride*, D.A. Kinscherf*, A.C. Blank* and J.A. Ferrendelli (SPON: T. Lysz). Div. of Clin. Neuropharm. and Depts. of Neurol. and Pharm., Washington Univ. Med. Sch., St. Louis, MO. 63110.

Over the past several years there have been numerous investigations of cyclic nucleotides in nervous tissues. Most of those concerned with mammalian brain have examined whole brain or cerebral cortex, cerebellum and/or striatum, and there have been fewer studies of other regions of CNS. Since hippocampus is now becoming an area of brain of increasing interest and study, we have examined cyclic nucleotide biochemistry in this structure to prepare for and facilitate future investigations. This report summarizes our results of studies on cyclic GMP biochemistry in rat and guinea pig hippocampus.

Levels of cyclic GMP in rat and guinea pig hippocampi rapidly frozen, in situ, were 0.41 ± 0.08 and 0.71 ± 0.12 pmoles/mg prot, respectively. In animals frozen during metrazol-induced convulsions, cyclic GMP levels increased 4-fold to 2.74 ± 0.47 in guinea pig hippocampus, but only 2.5-fold to 0.98 ± 0.09 in rat. Incubated slices of rat and guinea pig hippocampi had levels of cyclic GMP similar to basal levels, in vivo, 0.49 ± 0.03 and 1.06 ± 0.24 pmoles/mg prot, respectively. Exposure of tissue slices to 64 mM K^+ elevated cyclic GMP levels 20-fold in guinea pig hippocampus, but only 2-fold in rat.

In an attempt to explain the marked difference between rat and guinea pig, we measured cyclic GMP phosphodiesterase (PDE) and guanylate cyclase activities in hippocampi from the two animals. Both had similar cyclic GMP-PDE activity, 38 ± 2 and 40 ± 2 nmoles GMP formed/mg prot/min in the rat and guinea pig, respectively. Guanylate cyclase activity in particulate fractions of hippocampal homogenates was also similar to the two animals and was approximately 14 pmoles cyclic GMP formed/mg prot/min. However, guanylate cyclase activity in soluble fractions from guinea pigs was twice as great as that in rat, 114 vs. 63 pmoles cyclic GMP formed/mg prot/min. The apparent Km·GTP for this enzyme was about the same (ca. 25 μM) in the two animals.

These results demonstrate that cyclic GMP biochemistry in CNS may differ markedly among animal species. The striking difference in cyclic GMP regulation between rat and guinea pig hippocampus may be, partially, a result of lower soluble guanylate cyclase activity in rat tissues.

183.12 IDENTIFICATION AND CHARACTERIZATION OF cAMP AND CALCIUM DEPENDENT PHOSPHOPROTEINS IN RAT BRAIN SYNAPTIC MEMBRANES. L. P. Kleine*, R. G. Sorensen* and H. R. Mahler. Dept. of Chemistry, Indiana University, Bloomington, IN 47405

We have previously reported on the phosphorylation of substrate proteins in synaptic membranes (SM) from rat brain by endogenous cAMP and Ca^{+2}-dependent protein kinases [De Blas, Wang, Sorensen and Mahler (1979) J. Neurochem. 33, 647-659]. Both systems affect a variety of substrates in the 50,000 to 60,000 dalton range. Also, there exist at least four components in this region that bind 8-azido-[^{32}P]cAMP. We have therefore, initiated a detailed analysis of these phosphorylatable and cAMP binding components in SM. Our aim is to elucidate possible identities between phosphoproteins and cAMP binding components and between Ca^{+2}- and cAMP-dependent phosphoproteins.

We have identified and characterized these cAMP and Ca^{+2}-dependent phosphoproteins by means of two-dimensional techniques as well as by peptide mapping of ^{32}P-labeled proteins using [^{32}P]-γ-ATP and 8-azido-[^{32}P]cAMP as donors. The possible relationships of these proteins to the regulatory subunits of type I and II protein kinases were explored by comparison with authentic regulatory subunits from muscle and brain. Inhibitory effects of ACTH (~10^{-5} M) and its fragment peptides [Zwiers, Schotman and Gispen (1980) J. Neurochem., in press] have been studied in collaboration with H. Zwiers and W.H. Gispen, State University of Utrecht, The Netherlands. (Supported by Research Grant NS 08309 from the NIH.)

183.13 A CYCLIC NUCLEOTIDE-INDEPENDENT PROTEIN KINASE FROM RAT BRAIN.
R. F. Alderson* and P. Y. Sze (SPON: B. E. Ginsburg). Dept. of Biobehavioral Sciences, Univ. of Connecticut, Storrs, CT 06268.

Two soluble forms of protein kinase from rat brain (all tissue anterior to the cerebellum) have been separated by DEAE-cellulose chromatography with a linear NaCl gradient (50 mM Tris acetate, pH 7.4 - 1 mM DTT-2 mM EDTA), using histone as the substrate. The first peak elutes at 0.08 M NaCl, and the second peak elutes at 0.2 M salt. This elution profile remains the same whether midbrain, striatum, or cerebral cortex is used. Peak II protein kinase is totally dissociable by cAMP. Peak I contains a protein kinase that is not dissociated or stimulated by cAMP and is not inhibited by the endogenous inhibitor of cAMP-dependent protein kinase. The peak I protein kinase has been further fractionated on ATP-agarose and hydroxyapatite columns. The highly purified enzyme exhibits the following characteristics in addition to its lack of response to cAMP: (1) binding to ATP-agarose in the absence of cAMP; (2) incapable of binding ^{3}H-cAMP; (3) not stimulated by cGMP; (4) with a substrate preference in the order protamine > casein > phosvitin > whole histone; (5) requiring an optimal Mg^{+2} concentration at 10 mM. These properties are consistent with the criteria for a cyclic nucleotide-independent protein kinase. Its M.W. has been estimated as 90,000 from gel filtration. When tested on midbrain tryptophan hydroxylase, this kinase results in the activation of the midbrain enzyme in the presence of ATP and Mg^{+2}.

From the DEAE-cellulose elution profile, the protein kinase characterized in this study appears to be similar to the "protamine kinase" described by Inoue et al. from rat whole brain which is also cAMP-independent (Inoue et al., BBRC, 228, 50, 1973). In bovine cerebellum, another soluble cAMP-independent protein kinase with M.W. 64,000 has been identified which elutes at 0.2 M NaCl from DEAE-cellulose and is detectable only in the presence of high Mg^{+2} concentrations (Takai et al., JBC, 252, 7603, 1977). This protein kinase may be present in brain regions other than the cerebellum (Raese et al., Commun. Psychopharmacol., 3, 295, 1979). Thus, at least two soluble cyclic nucleotide-independent protein kinases may exist in brain tissue. The relative distribution and function of the two protein kinases in various brain regions remain to be determined.

184.1 BEHAVIORAL TOLERANCE TO THE STIMULANT EFFECTS OF DIETARY L-TYROSINE. G. B. Freeman*, J. R. Ieni*, J. Soblosky*, and J. B. Thurmond. Neuropsychopharm. Program, Univ. of Louisville, Louisville, Kentucky 40292

Behavioral and brain neurochemical changes were assessed in mice maintained on L-tyrosine supplemented 12% protein diets for 2, 5, 10, or 14 days. Male CF-1 mice were fed a semi-synthetic 12% casein diet for 1 week, then switched to a diet modified by the addition of 4% L-tyrosine supplement. Measures of territorial aggressive behavior and locomotor activity were obtained before and after the dietary supplement was administered. Compared to control animals maintained on 12% casein, resident mice fed the L-tyrosine supplement displayed an increase in the number of attacks on intruders and shorter attack latencies.

The strongest stimulating effect of L-tyrosine on aggressive behavior was observed after 2 days on the dietary supplement. The ability of L-tyrosine to induce changes in behavior was considerably diminished following longer periods of maintenance on the diet, suggesting the development of behavioral tolerance. No unusual changes in weight gain were noted as a function of maintenance on the diets and no ill effects were observed.

Other groups of mice maintained on 12% casein (controls), or administered the L-tyrosine supplement, were sacrificed for analyses of brain tyrosine, norepinephrine, dopamine, serotonin, and certain metabolites of these monoamines. In contrast to the reduced behavioral effects after 14 days, neurochemical changes induced by addition of L-tyrosine to the diet were sustained over the two-week period.

184.2 DIFFERENCES IN (i) BEHAVIOUR, (ii) BRAIN AMINO ACID DISTRIBUTION AND (iii) REVERSIBILITY BY THIAMINE BETWEEN THIAMINE-DEFICIENT AND PYRITHIAMINE-TREATED RATS. Edith Hamel*, Roger F. Butterworth, François B. Jolicoeur* and André Barbeau. Clinical Research Institute of Montreal, Montreal, Quebec, Canada.

Male Sprague-Dawley rats (200-225 g) were fed a thiamine-deficient diet or treated with the central thiamine antagonist pyrithiamine. Thiamine-deficient rats were subjected to a series of neurobehavioural tests including a detailed analysis of gait as previously described (Can. J. Neurol. Sci., 6: 209, 1979), as was that of the appropriate pair-fed and ad libitum controls. Thiamine-deficient rats lost their righting and weight shift reflexes and their gait was found to be ataxic. These abnormalities were also present in the PTh-treated rats; however, these rats also lost their traction and forelimb extension reflexes and were severely cataleptic. Administration of thiamine (diet + injections of 20 µg/100 g body wt.) promptly reversed all the neurological abnormalities of the thiamine-deficient group but was without effect on the symptomatic PTh-treated rats.

Amino acid concentrations were determined in many regions of the CNS of the symptomatic thiamine-deficient and PTh-treated rats together with appropriate controls as already described by us (J. Neurochem., 33: 575, 1979). Glutamate, Aspartate, GABA and Glycine were significantly decreased in the cerebellum, brain stem and spinal cord of the thiamine-deficient group. Aspartate, Glutamate and GABA concentrations were diminished in the cerebral cortex and brain stem of the PTh-treated rats, the cerebellum and spinal cord being spared. Glycine levels were unchanged by PTh treatment.

These results clearly show that chronic thiamine-deficiency induced by dietary deprivation of the vitamin and that produced by treatment with the central thiamine antagonist pyrithiamine exert their CNS effects by different mechanisms, as shown by the differences in behaviour, regional vulnerability, amino acid changes and reversibility of symptoms by thiamine administration.

184.3 COMPARISON OF THE EFFECTS ON BODY TEMPERATURE OF THE RABBIT OF ALANINE WITH THAT OF SERINE, GLYCINE AND TAURINE. J.M. Lipton and J.R. Glyn* (SPON: W.G. Clark). Depts. of Physiology and Neurology, University of Texas Health Science Center at Dallas, Dallas, TX 75235.

Serine, glycine and taurine cause dose-related hypothermia and delay the onset of temperature increases induced by leukocytic pyrogen (LP) or prostaglandin E_2 (PGE_2). Alanine, another small neutral amino acid, is transported by similar mechanisms and shares neuronal inhibitory properties with serine, glycine and taurine (Cutler, R.W.P. & Coull, B.M., In: Taurine and Neurological Disorders, 1978, p. 95; Curtis, D.R., Hosli, L. & Johnston, G.A.R., Nature, Lond. 215:1502, 1968). Since alanine also lowers body temperature in the rat (Sgaragli, G.P. & Pavan, F., Neuropharmacology 11:45, 1972), the present experiments compared the effects of alanine on body temperature with those produced by the other amino acids. Intracerebroventricular (icv) injections of alanine (0.5-2.0 mg) caused no change in body temperature at an ambient temperature (T_a) of 30°C; a small decrease at T_a = 23°C; and a greater, dose-related decrease at T_a = 10°C. Alanine was additive with glycine and taurine in producing hypothermia at T_a = 10°C. With serine, alanine was slightly subadditive, like previous results in which serine appeared to be subadditive with glycine and taurine. 2 mg icv alanine significantly reduced both LP fever and PGE_2 hyperthermia. Therefore alanine, glycine and taurine appear to act at similar sites in the central thermoregulatory pathway, with serine possibly acting at other sites as well. (Supported by National Institutes of Neurological and Communications Disorders and Stroke Grant NS 10046.)

184.4 HALOTHANE INDUCED RELEASE OF GABA-T FROM RAT BRAIN SYNAPTOSOMES. S-C. Cheng and E.A. Brunner*. Dept. Anesthesia, Northwestern Univ. Med. Sch., Chicago, IL 60611. Volatile anesthetic agents inhibited GABA disposal($^{14}CO_2$ from [1-^{14}C]GABA) with intact synaptosomes but not with solubilized synaptosomal GABA-T (Cheng and Brunner, Biochem. Pharmac., 28:105, 1979). A direct correlation between inhibition of GABA disposal and of Complex I of the electron transport chain (Miller et al., Anesth. Analg. 53:132, 1974) has not been established. Volatile anesthetics also released proteins from beef heart mitochondria (Richter et al., Biochim. Biophys. Acta, 543:106, 1978). One of them was aspartate aminotransferase. We question if a similar release of GABA-T might occur from synaptosomes. Rat forebrain synaptosomes were prepared by fractionating the crude mitochondria between 0.9-1.2M sucrose and resuspending the synaptosomes in 0.32M sucrose. Aliquots were incubated for 1 hr at 30° in the absence (C) or presence (H) of halothane. After incubation, C and H suspensions were centrifuged to yield clear supernatants (C_S and H_S) and sediments (C_P and H_P). The sediments were resuspended again in 0.32M sucrose. Samples from each of these were tested for GABA-T activity in an assay previously described. Halothane was introduced in two ways: (1) it was vaporized into N_2 in a Copper Kettle and diluted with 40%O_2:60%N_2, and (2) liquid halothane was added to the center-well of a calibrated 25ml flask. The halothane concentration in the gas phase above the synaptosomes was calculated assuming a synaptosome/gas partition coefficient of 2.0. This value was derived from the total volume of the flask, the volume and protein concentration of the synaptosomes and the protein/wet weight ratio and the halothane partition coefficient of brain tissue (Ikeda, Anesthesiology, 37:87, 1972). The specific activity of GABA-T of the initial synaptosomal suspension was 0.72 µmole/hr/mg protein. Both C and H fractions lost some GABA-T activity at various halothane concentrations. In paired experiments, H and H_P lost more activity than C and C_P respectively. The additional losses were dose-related. Activities of H_S and C_S were highly variable. The presence of GABA-T activity in these supernatants confirmed the loss of protein from the synaptosomes and may reflect leakage of protein or rupture of synaptosomes. The amount of protein released was very small and this could account for the instability of released GABA-T in H_S and C_S. The loss in GABA-T activity in H_P, when compared to C_P, was dose-related and showed a 10% effect in the range of ED_{50} for halothane. This might account for the correlation of ED_{50} for halothane to ID_{10} for GABA disposal (Cheng, in GABA - Biochemistry and CNS Function, p. 161, 1979).

184.5 VALPROATE INTERACTIONS WITH GABA INHIBITION IN HYPOTHALAMIC TISSUE CULTURES. H.M.Geller. Dept. of Pharmacology, CMDNJ-Rutgers Medical School, Piscataway, NJ 08854

Explant tissue cultures of newborn rat tuberal hypothalamus have been utilized in order to examine whether valproate (dipropyl acetate) acts to potentiate GABAergic inhibition. Cultures were prepared from newborn rats and maintained in roller tubes until 3-4 weeks of age. At this age, many neurons are spontaneously electrically active and respond to locally applied GABA with a depression in firing rate. Additionally, putative GABAergic (picrotoxin-and bicuculline-sensitive) inhibition can be evoked with focal electrical stimulation. In these experiments, the activity of 37 neurons in 17 cultures was recorded extracellularly with 3 M NaCl filled micropipettes. Action potentials were amplified, discriminated and fed to a computer for on-line histogram construction. Inhibitions were evoked electrically (0.1 msec pulses, 10-30 V) or with repeated pulsed iontophoretic application of GABA (5-10 sec, 1-50 nanoamperes). Peri-event histograms were used to quantify drug-or electrically-induced inhibition and to quantify changes in inhibition produced by perfusion of sodium valproate (0.1-4 mM). Potentiation of GABA inhibition by valproate was observed in only 8 neurons (22%) while a reduction of inhibition was observed in 12 (32%); the remaining 17 showed no change or irreversible alterations in firing rate. Thus, these data utilizing hypothalamic cultures do not support the hypothesis that valproate actions are mediated by an acute potentiation of GABA. Alternately, valproate actions may be regionally specific, with the hypothalamus being relatively unaffected. Further experiments utilizing other brain regions are necessary to assess this possibility. Supported by NIH NS 15468 and NSF BNS 79-14003.

184.6 FURTHER STUDIES ON THE BINDING OF β-ALANINE TO SYNAPTOSOME-ENRICHED FRACTIONS OF RAT CENTRAL NERVOUS SYSTEM. L. M. Orensanz* and Gloria Corrochano* (SPON: F. V. DeFeudis). Dept. de Investigación, Centro Especial Ramón y Cajal, Madrid-34, Spain.

Using techniques which permit biochemical identification of neurotransmitter receptors in the mammalian brain we have previously demonstrated a sodium-independent specific binding of β-alanine to synaptosome-enriched fractions of rat brain. The present experiments were undertaken to study in more detail the characteristics of this sodium-independent β-alanine binding.

Experiments were conducted in rat tissue containing brain stem plus spinal cord. Specific [^{3}H]β-alanine binding, that is, that obtained by subtracting from the total bound radioactivity the amount not displaced by high concentrations of unlabeled β-alanine, was higher in crude synaptosomal fractions than in frozen/thawed synaptosomal fractions or synaptic membranes. Bound radioactivity was analyzed by thin layer chromatography and was shown to migrate as authentic β-alanine. Binding rose linearly when increasing amounts of tissue were added to the incubation medium. In the 2-160 nM concentration range binding occurred by a double affinity mechanism, the highest affinity having a binding constant, K_D, of 5×10^{-8} M and binding capacity, B_{max}, of 380 f-moles per mg protein. Compounds capable of inhibiting the uptake of β-alanine in rat spinal cord slices, at 2.5×10^{-4} M, did not affect the specific binding of 5 nM [^{3}H]β-alanine, while specific binding was abolished by compounds which have no effect on the uptake, such as glycine or DL-2,3-diaminopropionic acid. In addition, specific binding was not detectable to similarly prepared fractions from liver and spleen.

The present results may indicate that specific receptors may be implicated in the binding of β-alanine to synaptosome-enriched fractions of rat brain stem and spinal cord. The observed iontophoretic depressant action of β-alanine in these regions may be linked to interaction with these receptors.

184.7 ENDOGENOUS INHIBITORS OF GABA-AGONIST BINDING FROM SYNAPTOSOMAL FRACTIONS OF RAT BRAIN. L. M. Yunger. Dept. Biol. Res., Smith Kline & French Labs., Philadelphia, PA 19101

Pretreating synaptic plasma membranes with 0.2 to 0.05% Triton X-100 produced a 5- to 50-fold increase in GABA agonist binding, depending on the brain area and ligand used. This increase appears to be due to release of endogenous inhibitors which mask the high affinity GABA agonist binding sites. These inhibitors are not equally distributed in brain; for example, the potency of inhibitors in the buffer eluate from hippocampal synaptic plasma membranes is almost 7 times that from cerebellar membranes. Since at high concentrations these endogenous inhibitors can block low affinity GABA agonist binding as well, this may account for the very low GABA agonist binding observed in fresh hippocampal homogenates (44 fmol ^{3}H-muscimol bound/mg protein) compared to fresh cerebellar homogenates (490 fmol ^{3}H-muscimol bound/mg protein). We have partially characterized inhibitors of GABA agonist binding (1) which are eluted into the hypotonic medium when synaptosomes are lysed (H_2O fraction) and (2) which are eluted into the first buffer wash of the synaptic plasma membranes (buffer fraction). Inhibitors from both fractions are heat stable, and, once heated, are stable at 4°C for at least 7 days. Approximately 95% of activity is lost from the H_2O fraction and 60% of activity is lost from the buffer fraction on dialysis (3500 to 12000 pore size). Most of the dialyzable activity in the H_2O fraction appears to be GABA. The inhibition of GABA agonist binding produced by either fresh or dialyzed H_2O and buffer fractions was not affected by pretreating the membranes with 10 μM diazepam. At present, it is not known if the non-dialyzable inhibitors correspond to those which have been described in the literature.

184.8 HOMOCYSTEINE INDUCED CONVULSIONS: ENHANCEMENT BY VITAMIN B_6 AND INHIBITION BY HYDRAZINE. R.W. Hurd*, E.J. Hammond*, B.J. Wilder. (Spon: A.J. Dunn) Department of Neuroscience, University of Florida, and Neurology Service, VA Medical Center, Gainesville, FL 32610.

Intraperitoneal injections of homocysteine in animals have been shown to produce tonic-clonic convulsions and electrographic seizures which resemble seizures in humans. Some patients with homocystinuria also have seizures. The actual mechanism of seizure induction in both humans and experimental animals are, however, obscure.

We studied the effects of pretreatment with the B_6 vitamers, pyridoxal phosphate, pyridoxine (50 mg/kg) and the B_6 antagonist hydrazine sulfate (50 mg/kg) in mice receiving injections of homocysteine thiolactone (5.5 mM/kg). Both pyridoxal phosphate and pyridoxine significantly decreased the latency ($P < .01$) and increased the severity, lethality, and duration of homocysteine induced convulsions. Hydrazine, which is normally a convulsant, prevented the tonic component of the homocysteine convulsions ($P < .001$) and increased the latency to the clonic component ($P < .01$). These data indicate that a vitamin B_6 dependent step is critically involved in the metabolic changes which precede homocysteine seizures.

Supported by the Epilepsy Research Foundation of Florida.

184.9 A COMPARISON OF THE EXCITATORY EFFECTS OF L-ASPARTATE AND L-GLUTAMATE ON PURKINJE CELLS IN VITRO IN THE CEREBELLAR CORTEX OF GUINEA PIG. Sandra L. Morzorati, William J. McBride and Robert C.A. Frederickson, Departments of Psychiatry and Biochemistry, Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN 46223.

Neurochemical evidence (Nadi et al., J. Neurochem. 28: 661, 1977) has shown that the level of aspartate decreases in the cerebellum of rat following a single injection of 3-acetylpyridine, which destroys the inferior olivary nuclei and thus the cerebellar climbing fibers. From this data, it was proposed that aspartate may be the excitatory transmitter released from climbing fibers onto Purkinje cells. This hypothesis was supported by the fact that the microiontophoretic application of L-aspartate produced an increase in the firing rate of all Purkinje cells tested in vivo in rat (Morzorati et al., Society for Neuroscience Abstracts, 4: 448, 1978).

A number of advantages have been cited for using the thin slice preparation over the intact animal preparation. Thus we have adopted the in vitro technique in which to study the sensitivity of Purkinje cells to L-aspartate (Asp) and L-glutamate (Glu), the transmitter possibly released from granule cells. Thin sections of the guinea pig cerebellar vermis (300-500 µm) were sliced parallel to the long axis of the folia using a tissue chopper and placed in a perfusion chamber. Multibarrelled micropipettes served both to record extracellularly and to eject the amino acids. Preliminary results showed that the microiontophoretic application of Asp and Glu produced an increase in the spontaneous firing rate of all Purkinje cells tested. The excitatory effects of both amino acids were dose dependent and characterized by a rapid onset. The 'doses' (current x ejection time) necessary to produce half maximal responses to Asp and Glu on a single cell were obtained from linearized dose-response relationships. Subsequent potency ratios showed Purkinje cells to be more sensitive to Glu than Asp. These same dose-response relationships were generally found to be non-parallel, implying different mechanisms of action (and thus different receptor sites) for the two amino acids. These data indicate that the thin cerebellar slice is a useful tool in our hands, and that Asp may be an excitatory transmitter in the mammalian cerebellum. (Supported in part by PHS Grants NS 13925 and MH 00203 and a grant from Eli Lilly and Co.).

184.10 EXCITATORY AMINO ACID STIMULATION OF CEREBELLAR CYCLIC GMP IN THE RAT. P.J. Roberts* and G.A. Foster* (SPON: W.G. Van der Kloot). Dept. of Physiol. and Pharmacol., Sch. Biochem. and Physiol. Sci., Southampton Univ., Southampton, SO9 3TU, England.

The postsynaptic actions of several types of neurotransmitter are mediated, or modulated through the cyclic nucleotides, cyclic AMP and cyclic GMP (cGMP). The cerebellum contains high concentrations of cGMP, and recently it has been demonstrated that during a short period of postnatal development, glutamate is able to elicit very large increases in cGMP in rat cerebellar slices. In this study, we have investigated the cerebellar cGMP response in tissue slices (0.5 x 0.5 mm) from 8-day old female rats. After a 90 min pre-incubation, slices were exposed to agonists for 5 min and cGMP concentrations determined by radioimmunoassay. L-glutamate produced a dose-related increase in cGMP with the half-maximal response occurring at approximately 1 mM. With respect to other agonists, a rank order of potency was observed similar to that for excitation of mammalian spinal neurons, i.e. NMDA > 4-fluoroglutamate > DL-homocysteate > (±)-ibotenate > L-glutamate = L-aspartate = kainate > dihydrokainate. The proposed excitatory amino acid antagonist, L-glutamate diethylester inhibited the stimulation by glutamate, aspartate and NMDA, while D-α aminoadipate and DL-α-aminosuberate were inactive. The stimulation of cGMP by kainate did not attain the same maximal response as that with L-glutamate, suggesting partial agonism or different sites of action. When L-glutamate (1 mM) was combined with kainate however, a marked synergism was observed with an apparent increase in sensitivity to kainate of approx. 35 fold. This finding may have implications for the neurotoxic actions of kainate.

184.11 HIGH-AFFINITY BINDING OF L-[^{3}H]GLUTAMATE TO HIPPOCAMPAL SYNAPTIC MEMBRANES IN THE ABSENCE OF SODIUM. Linda L. Werling* and J. Victor Nadler. Dept. Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Considerable evidence suggests that glutamate serves as the transmitter of several excitatory projections to the rat hippocampal formation, in particular the perforant path fibers and commissural-ipsilateral fibers that arise from CA3 pyramidal cells. We have therefore attempted to identify binding sites that might correspond to physiologically relevant glutamate receptors by use of hippocampal synaptic membranes. Freshly-prepared synaptic membranes were washed 3-5 times with H_2O to remove endogenous glutamate and were incubated with L-[^{3}H]glutamate (45Ci/mmol) in a 1.4 ml volume of tris-HCl buffer. Non-specific binding was determined from parallel incubations with 0.1 mM non-radioactive glutamate and accounted for less than 20% of the total binding. Preliminary studies with 20 nM [^{3}H]glutamate revealed a sharp pH optimum around 6.5 and an optimal incubation temperature of 38°C. At 4°, 25° or 38°C, specific binding reached a plateau in less than 5 min, but when the incubation was continued for 20 min or longer a substantial and progressive increase in specific binding was obtained. Preincubation of the synaptic membranes for 30-60 min at 38°C in the absence of glutamate increased specific binding at 5 min of incubation, but preincubation at 4°C did not. These findings suggest that specific binding can be increased by two processes, one temperature-dependent and the other substrate-dependent.

When synaptic membranes were incubated for 5 min with a range of L-[^{3}H]glutamate concentrations (1-1000 nM), specific binding was found to be saturable. A biphasic Scatchard plot was obtained, suggesting the possibility of two distinct populations of binding sites. Apparent K_D values were: 13 nM and 580 nM, with corresponding B_{max} values of 4.2 pmol/mg protein and 70 pmol/mg protein. Hill plots gave two lines with slopes of about 1.2, supporting the existence of positive co-operativity. In displacement studies no striking pharmacological differences have emerged between the two presumptive sites. Both are relatively stereospecific for L-glutamate and interact with a number of excitatory amino acids and excitatory amino acid antagonists, but neither N-methyl-DL-aspartate nor kainate at a concentration of 0.1 mM displaces L-[^{3}H]glutamate from either site. Our results are consistent with a role for these synaptic membrane binding sites in glutamatergic transmission. (Supported by NIH grant NS 16064 and NSF grant BNS 78-13051.)

184.12 THE LATERAL OLFACTORY TRACT TRANSMITTER MAY BE NEITHER GLUTAMATE NOR ASPARTATE. D. J. Braitman, N. Hori*, C. R. Auker and D. O. Carpenter. Physiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Aspartate (Asp) and glutamate (Glu) are principal candidates for the excitatory neurotransmitter released by the lateral olfactory tract (LOT) in prepyriform cortex of the rat. Both are present in this region and are released on stimulation of the LOT. However, identity of action of the natural transmitter with exogenous Glu and/or Asp has not yet been demonstrated.

In a prior study (Fed. Proc. 39:281, 1980) we found that bath perfusion of 2-amino-4-phosphonobutyric acid (APB), a presumed specific Glu antagonist, markedly decreased the amplitude of LOT-stimulated field potentials in rat prepyriform cortex slices. We used a similar preparation attempting to establish the identity of action of the LOT transmitter and either Glu or Asp. In the current study we recorded single unit activity from the pyramidal cell layer of prepyriform cortex. We attempted to prove identity of action by blocking, with APB, both the LOT-stimulated activity and the activity evoked by ionophoretic application of various amino acids including Asp and Glu.

Tangential slices (200-400 u thick) of rat prepyriform cortex, including the LOT, were cut by hand and preincubated at 35°C in modified oxygenated Kreb's-Ringer solution. Individual slices were placed in a total immersion chamber, and an electrode was driven into the pyramidal cell layer until an extracellular single unit response evoked by LOT stimulation was recorded. A seven-barrel glass ionophoretic electrode was then driven into the zone of termination of the LOT fibers onto the apical dendrites of the pyramidal cells (100-200 u superficial to the recording tip). The barrels were filled with 1 M L-Glu, 1 M L-Asp, 1 M N-methyl-D-aspartate (NMDA), 1 M DL-homocysteate (HC), 1 M L-cysteate (Cys), 10^{-2} M kainic acid (KA), or 0.5 M NaCl, each at pH 7-8.

Single units driven by LOT stimulation were also excited by ionophoretic application of all six amino acids. Bath perfusion of 10^{-3} M APB blocked the activity evoked by LOT stimulation but was ineffective in blocking the responses evoked by L-Glu, L-Asp, or L-Cys. However, responses to the three other excitatory amino acids—NMDA, HC, and KA (which do not naturally exist in brain)—were markedly reduced by bath perfusion of 10^{-3} M APB. We tentatively conclude that (1) neither Asp nor Glu is the endogenous LOT transmitter, and (2) Glu, Asp, and Cys act at different receptor sites than do NMDA, HC, and KA.

184.13 EFFECTS OF KAINIC ACID, N-METHYL-d-ASPARTATE AND GLUTAMIC ACID DIETHYL ESTER ON UPTAKE OF 2-DEOXYGLUCOSE IN THE RAT BRAIN. N.H. Diemer[1]*, K.E. Sørensen[2]* and I. Divac[3]. 1) Institute of Neuropathology, University of Copenhagen, 2) Institute of Anatomy B, University of Aarhus, 3) Institute of Neurophysiology, University of Copenhagen.

Intraperitoneal injections of kainic acid (KA, 12-13.3 mg/kg) produced a characteristic change in distribution of uptake of [^{14}C]2-deoxyglucose (2-DG). In other animals, silver impregnated (degenerated) neurons were found after intracranial injections of ninogram amounts of KA in those brain formations which had relatively high uptake of 2-DG. Neither N-methyl-d-aspartate (26.7 mg/kg) nor glutamic acid diethyl ester (1200 mg/kg), also injected intraperitoneally, had a visible effect on distribution of 2-DG uptake.

184.14 CYCLOPROPANE ANALOGS OF GAMMA-AMINOBUTYRIC ACID: EFFECT OF RESTRICTED CONFORMATION ON RECEPTOR BINDING. James C. Schaeffer, Layton L. McCoy* and Mark S. Wassermark*. Dept. of Chemistry, University of Missouri, Kansas City, Missouri 64110.

Gamma-aminobutyric acid (GABA) is an extremely flexible molecule that can exist in a variety of conformations. In order to investigate the possibility that different GABA binding sites interact preferentially with different conformational states, we have synthesized two cyclopropane analogs of GABA. Cis-2-(aminomethyl)-cyclopropane-1-carboxylic acid (CIS-cGABA) was prepared in six steps from methyl acrylate and ethyl chloroacetate while trans-2-(aminomethyl)cyclopropane-1-carboxylic acid (TRANS-cGABA) was prepared from the same starting materials in eight steps.

The GABA receptor assay of Enna, Collins and Snyder (Brain Research, 1977), using 1 mM unlabeled GABA as the displacing ligand, was employed to assess the effect of restricted conformation on sodium-independent receptor binding. CIS-cGABA, TRANS-cGABA, and GABA gave I_{50} values of 30μM, 0.38μM, and 0.073μM, respectively. These data, coupled with the previously demonstrated preference of the GABA receptor for trans-4-aminocrotonic acid over the corresponding cis isomer, strongly suggest that the trans staggered conformation of GABA is preferred by its postsynaptic receptor. Recently, Johnston, Allan, Kennedy and Twitchin (Alfred Benzon Symposium 12) have prepared independently the same cyclopropane GABA analogs and reported similar binding results. However, they found that TRANS-cGABA bound slightly better than GABA while we have found that GABA binds five-fold better than TRANS-cGABA. In contrast to the data of Johnston, et al., our results may indicate that the binding site is a narrow crevice that cannot well tolerate the extra methylene of the cyclopropane ring.

The ability of the cyclopropane analogs to inhibit sodium-dependent GABA reuptake was also investigated. Like Johnston, et al., we have found both isomers to be poor inhibitors of GABA reuptake.

184.15 SEROTONIN AND ENKEPHALIN CO-EXIST IN NEURONS INVOLVED IN OPIATE AND STIMULATION-PRODUCED ANALGESIA IN THE CAT. A.I. Basbaum, E.J. Glazer, H. Steinbusch* and A. Verhofstad*. Department of Anatomy, University of California, San Francisco and Department of Anatomy and Embryology, Catholic University, Nijmegen, The Netherlands.

Profound analgesia can be produced by electrical stimulation of the serotonin (5HT)-containing nucleus raphe dorsalis (RD), raphe magnus (NRM) and paragigantocellularis (PGL) (located lateral to NRM). Recently we reported significant numbers of enkephalin (ENK)-immunoreactive neurons in RD and PGL of the cat. In this study we describe neurons in these nuclei which contain both 5HT and ENK. ENK and 5HT were sequentially localized on the same section by a combined immunoperoxidase-immunofluorescence technique using specific antisera generated against either leucine-enkephalin-BSA or serotonin-BSA conjugates. Cats were pretreated with colchicine (III ventricle) and an MAO-inhibitor and were perfused with buffered 4% paraformaldehyde/0.2% glutaraldehyde. The brainstems were embedded in paraffin, serially sections at 10 microns and sequentially processed for ENK immunoperoxidase (PAP) and 5HT immunofluorescence.

Both 5HT and ENK labeled neurons are found throughout the rostral caudal extent of the RD. Two 5HT cell types were observed. Small, round neurons appear in the midline; larger multipolar neurons extend laterally into the periaqueductal grey (PAG), beyond the cytoarchitectural boundaries of the RD. ENK neurons of the RD are concentrated on the midline; others are found throughout the PAG. The specific 5HT immunofluorescence fills both the cytoplasm and nucleus of labelled neurons. In contrast the enkephalin peroxidase reaction product is limited to the cytoplasm. These different staining characteristics made it possible to distinguish a population of double-labeled neurons, showing both cytoplasmic peroxidase reactivity and nuclear fluorescence. A population of these double-labeled neurons was found within the midline RD intermingled with neurons containing only serotonin or enkephalin. The PGL also contains three populations of neurons: an enkephalin group, a serotonin group and a group containing both serotonin and enkephalin.

A comparison of the 5HT- and/or ENK containing cell groups of the rostral medulla with the known origin of descending pathways in the spinal dorsolateral funiculus reveals a variety of potential descending modulatory systems. These include 5HT-cells of NRM, ENK and 5HT cells of PGL and cells of the nucleus reticularis magnocellularis located dorsal to PGL which contain neither 5HT nor ENK. This study suggests that the analgesic action of RD and rostral medullary electrical stimulation reflects a simultaneous activation of 5HT and ENK neurons.

184.16 RELEASE OF METHIONINE ENKEPHALIN FROM CAT MESENCEPHALON AND SPINAL CORD IN VIVO. Tony L. Yaksh, and Robert P. Elde. Dept. of Neurosurgical Res., Mayo Fdn., Rochester, MN 55901 and Dept. of Anatomy, Univ. of Minnesota, Minneapolis, MN 55455.

Methionine enkephalin like radioimmunoreactivity (MELA) found within cells of the spinal cord and brain may reveal one of the transmitters for intrinsic opioid systems. To investigate the properties associated with the release of MELA from the mesencephalic aqueduct (MA) and spinal cord, cats were anesthetized with chloralose urethane, and prepared for perfusion by inserting a 22 ga inflow cannula into the caudal aspect of the third ventricle and an outflow catheter into the mouth of the aqueduct. To perfuse the spinal cord, an infusion catheter (PE-10) was inserted through the cisterna magna to the caudal edge of the lumbar enlargement. Outflow was collected by a second concentric catheter whose tip lay at the level of the thoracic cord. Artificial CSF contained albumin (120 μg/ml) and bacitracin (300 μg/ml). Samples were collected on ice and immediately lyophilized prior to radioimmunoassay. The mean resting levels of MELA was .8 ± 0.1 ng/ml and 1.3 ± 0.2 ng/ml for the MA and spinal cord superfusates, respectively. Bilateral stimulation of the sciatic and infraorbital nerves at high but not low intensity produced over a 2 fold increase in the levels of MELA in both the MA and spinal perfusates. That the elevated levels of MELA were not due to alterations in blood pressure as evidenced by the failure of vasoxyl, i.v., to alter enkephalin levels in cord or MA perfusates. Cold block at C-3 had no effect on the elevated levels of MELA in spinal perfusates, but reduced the release otherwise evoked from the MA. Column chromatography of pooled samples of ventricular and spinal perfusates prior and during high intensity stimulation revealed that the MELA activity was isographic with authentic methionine enkephalin. This in conjunction with the relative specificity of the antisera (cross reacts with leu-enk, less than 0.6%) strongly suggests that the material observed in the perfusate was methionine enkephalin. Results suggest 1) that the MELA activity in brain was dependent upon the activation of rostrad transmission systems, while the activity of MELA systems in the spinal cord were directly activated by afferent input and did not depend upon a descending link for their activity and 2) that the MELA systems in the central gray are activated by sensory input of diverse somatotopic origin. The observation of the increase in levels of MELA in regions where enhanced exogenous levels of opiate activity produce significant elevations in the nociceptive threshold, strongly suggests that high intensity somatic stimulation results in the activation of an intrinsic modulatory circuit. (This work was supported by Mayo Fdn., NS 14629 and DA 02148).

184.17 OPIOID PEPTIDES INHIBIT DRINKING BEHAVIOR AND THE PRESSOR RESPONSE TO HYPERTONIC SODIUM CHLORIDE. Joan Y. Summy-Long and Lillian M. Rosella*, Dept. of Pharmacology, College of Medicine, PA State University, Hershey, PA 17033.

Enkephalins inhibit angiotensin II-stimulated drinking behavior and pressor response by a naloxone-sensitive mechanism (Pharmacologist 21:288, 1979). Studies were designed to determine if endogenous opioid peptides inhibit: 1) drinking induced by relative cellular dehydration or hypovolemia and 2) the pressor response to intracerebroventricularly (IVT) administered hypertonic sodium chloride (NaCl). Adult male Sprague Dawley rats (300-400 g) were anesthetized with sodium pentobarbital and a cannula positioned in the left lateral cerebroventricle. In drinking experiments animals were placed in individual metabolism cages with food and water available ad libitum. Five days after surgery rats received 20% polyethylene glycol (PG; M.W. 20,000) or 1 M NaCl (HS) subcutaneously (15 ml/kg) at 9 a.m. Food and water were withheld for 3 hr (HS) or 6 hr (PG) after injection. Artificial cerebrospinal fluid (CSF, 10 µl) with or without β-endorphin (β-ED; 1 or 5 µg) was administered IVT 5 min prior to water access. Drinking onset and volume consumed for 2 hr were measured for each rat. Differences were evaluated by analysis of variance and Newman Keuls t. β-ED delayed ($p<0.05$) drinking onset (min ± SEM) stimulated by PG (CSF 4 ± 2 < β-ED 1 µg 78 ± 12, β-ED 5 µg 94 ± 12) and HS (CSF 6 ± 2 < β-ED 1 µg 33 ± 5 < β-ED 5 µg 71 ± 4). After drinking began animals receiving β-ED and HS consumed a volume similar to controls (CSF-HS) within 45 min. In other experiments blood pressure was continuously monitored directly from a femoral artery in conscious rats 2 days after surgery. Repeated (hourly) injection of 10 µl 1 M NaCl IVT to the same animal resulted in similar pressor responses (HS ↑ 32 ± 3 mmHg; CSF-HS ↑ 29 ± 2 mmHg; $p>0.05$, paired t, n9). Leucine^5-enkephalin (LE; 100 µg/5 µl) administered 15 sec prior to the second HS, IVT injection significantly reduced the pressor response (HS ↑ 31 ± 3 mmHg > LE-HS ↑ 13 ± 3 mmHg; $p<0.01$, paired t, n7). β-ED (0.5 µg/5 µl) produced a similar inhibition (HS ↑ 30 ± 4 mmHg > β-ED-HS ↑ 16 ± 2 mmHg; $p<0.01$, paired t, n6). Naloxone prevented LE and β-ED inhibition of the pressor response to HS, IVT. Opioid peptides inhibit: 1) drinking behavior stimulated by both intracellular dehydration and hypovolemia and 2) the pressor response to 1 M NaCl, IVT.

184.19 CHRONIC STRESS INDUCES INCREASED BRAIN IMMUNOREACTIVE β-ENDORPHIN CONTENT, WHICH IS PREVENTED BY HYPOPHYSECTOMY. M. West*, V. Havlicek, V. Sundmark*, Dept. of Physiology, University of Manitoba, Winnipeg, R3E OW3.

Several studies have noted that experimental models of acute stress promote analgesia in rats, which is partially naloxone-reversible. Goldstein (Proc. Can. Fed. Biol. Soc. 17, 1974) has suggested that mild sustained nociception would be an optimal stimulus for the central release of endorphin. We studied the effect of chronic stress on the brain content of immuno-reactive (ir) β-endorphin, and the modulation of such an effect by previous hypophysectomy (hypox). Experiments were performed in Sprague-Dawley male rats (200-250 gm.) separated into 4 groups; sham hypox (SH); sham hypox and stress (SS); hypox (H) (by the oropharyngeal route); and hypox and stress (HS). Chronic stress was administered by placing rats on a warm plate at 50°C. for 2 min. four times daily for 7 days. Rats were sacrificed 18 hours following the last stress, by microwave irradiation. Three brain regions normally high in β-endorphin content were studied; hypothalamus, thalamus, and amygdala. Ir β-endorphin was measured by a double-antibody radioimmunoassay. Gel filtration of brain extracts in our laboratory has shown that 98% of β-endorphin immunoreactivity co-elutes with synthetic β-endorphin. Only a minor peak co-elutes with β-LPH.

Following chronic stress, ir β-endorphin content was increased in the regions studied. Prior hypox eliminated the stress-induced increase; in fact hypox rats had lower than control content of ir β-endorphin, as previously reported from this laboratory.

	ir β-ENDORPHIN CONTENT (ng/gm tissue) Mean ± S.E.M.			
Brain Region	SH	SS	H	HS
Thalamus	91 ± 17	153 ± 14[a]	45 ± 5	51 ± 6[b]
Hypothalamus	652 ± 123	2645 ± 935[a]	217 ± 13	285 ± 56[b]
Amygdala	63 ± 15	178 ± 53[a]	24 ± 5	37 ± 12[b]

a - significant difference between groups SH and SS $p<.05$, non-paired t test

b - no significant difference between groups H and HS.

The data suggest that chronic stress induces the mobilization of β-endorphin from the pituitary to the brain and that hypox eliminates this physiological response. (Supported by the MRC of Canada).

184.20 DEVELOPMENT OF A COMBINED HPLC - FLUOROMETRIC QUANTITATIVE ASSAY FOR ENKEPHALINS. K. M. Wu*, J. W. Sloan* and W. R. Martin. Department of Pharmacology, University of Kentucky, Coll. of Med., Lexington, Kentucky 40536.

Several techniques using UV, electrochemical or fluorometric methods have been used for detecting enkephalins in HPLC effluent. Here we are reporting a sensitive method for identifying enkephalins by a precolumn labelling technique in a HPLC - fluorometry system. A Waters C_{18} HPLC column and a Shoeffel GM 970 fluorometer were used. The elution was accomplished with 0.05M pH 7.4 Tris buffer (A) and 100% methanol (B). Two gradients were employed at a flow rate of 2 ml/min. In the first, the starting concentration ratio of A to B was 65:35 and the final ratio was 0:100. The second differed from the first in that the starting Tris - methanol ratio was 40:60. Starting at the injection of the sample, linear gradient was performed for 60 minutes at an ambient temperature of 21 ± 1°C. Enkephalins were reacted with fluorescamine in 0.05M, pH 7.4 phosphate buffer and 20 µl of this product was injected into the column. The effluent was excited at 390 nm and fluorescence detected at 470 nm. The retention times with their standard errors for fluorescamine reacted leucine-enkephalin and methionine-enkephalin were respectively 16.01 ± 0.04 minutes and 13.89 ± 0.03 minutes using the first gradient and 12.15 ± 0.04 minutes and 10.13 ± 0.08 minutes using the second-gradient. D-ala methionine-enkephalinamide was distinguished from methionine- and leucine-enkephalins using the 60:40 gradient in that it had a longer retention time than both. The least detectable amount was at least 2.5 ng. Standard calibration curves were linear. This combination of HPLC and precolumn derivatization procedure using fluorometry is a simple, economic and sensitive method for identifying and measuring opioid pentapeptides.

184.21 LEVELS OF A CEREBROSPINAL FLUID ENDORPHIN ARE ELEVATED IN PLACEBO RESPONDING CHRONIC PAIN PATIENTS

Barney E. Miller, William L. Byrne, Merry Noel, Alberte Ungar
Department of Biochemistry

Kit Mays, William E. North, Johathan Lipman, Shaila Karkera
Department of Anesthesiology

Our working hypothesis was that chronic pain patients should have lower than usual concentrations of at least one CSF endorphin during pain and prior to pain relief by a non-drug method and this endorphin should become elevated over the patient's usual baseline level.

We obtained CSF from 2 groups of patients; chronic lower back pain patients (n=20) and pain free elective surgery patients (n=14). All the chronic pain patients underwent a diagnostic spinal examination (DSE) at the University of Tennessee Pain Clinic. The DSE is briefly: lumbar puncture, CSF withdrawal, warmed normal saline (NS) injected followed by graduated doses of drug. The DSE is terminated if complete pain relief is achieved after any step.

Radioreceptor assay of this lumbar CSF following gel filtration chromatography indicated multiple opioid-like components. The major endorphin activities did not correspond to β-endorphin, met or leu-enkephalin. The levels of one component, Peak B, was correlated with the pain status of the patients. The CSF endorphin reported in 1975 (Terenius and Wahlström) and named Fraction I is chromatographically similar to Peak B.

It was found that those chronic pain patients who experienced an auto-analgesia during a pre-drug step of the DSE were members of a sub-population of the chronic pain patients. This sub-group was defined in terms of CSF Peak B concentrations. The CSF Peak B levels of the non auto-analgesia chronic pain patients (n=11) was significantly lower than those of both the pain free group and auto-analgesia chronic pain group ($p < .01$ and $p < .025$ respectively by the Mann Whitney U-test).

This auto-analgesia was usually reported to the doctor just after intrathecal injection of NS. This auto-analgesia may be referred to as a "placebo" pain relief response.

We now believe that a precise knowledge of the time course relationship between both the "placebo" stimulus and pain relief is crucial to the interpretation of Peak B levels and their role in the process of auto-analgesia (placebo response). We believe that the variability of the Peak B levels in the CSF of the placebo responding chronic pain patients could result subsequently to an uncontrolled environment cue. Present studies in progress involve multiple CSF sampling and more detailed pain assessment using a modified DSE. This approach may help elucidate the factors responsible for Peak B level variations in chronic pain patients.

184.22 AVERMECTIN B_{1a} INCREASES THE NUMBER OF GABA RECEPTORS IN THOROUGHLY-WASHED RAT BRAIN MEMBRANES. S. S. Pong* and C. C. Wang. Merck Institute for Therapeutic Research, Rahway, NJ 07065.

Avermectin B_{1a} (AVM), an antiparasitic macrocyclic lactone, reduces lobster muscle membrane resistance by opening the chloride channels (Fritz et al., PNAS, 34: 351, 1979) and blocks transmission from interneurons to motor neurons in the ventral cord of the parasitic nematode Ascaris (Kass et al., PNAS in press). Both actions are reversible by picrotoxin. The drug also stimulates GABA release from mammalian brain synaptosomes (Pong et al., J. Neurochem. 34: 351, 1980) and enhances ^{3}H-diazepam binding to the brain membranes (Williams and Yarborough, Eur. J. Pharmac., 56: 273, 1979) as well as the solubilized receptor complex in the membranes (Pong and Wang, unpublished); the enhanced binding is partially blocked by bicuculline, and unaffected by picrotoxin. When rat brain membranes were thoroughly washed with phosphate buffer through 5 to 7 cycles of freezing, thawing and centrifugation for assays of ^{3}H-GABA binding, AVM (10 μM) was found to increase significantly specific GABA binding by 40-80% without much effect on the non-specific GABA binding. The stoichiometry of drug effect appears to be complicated; AVM at 0.1 to 1.0 μM showed slight inhibition on GABA binding, but became stimulatory at concentrations above 1 μM with a linear dose dependence. Scatchard analysis indicates that AVM (10 μM) does not alter the apparent dissociation constant (23-26 nM) of GABA binding but increases the number of GABA binding-sites from 3.3 to 5.2 pmoles per mg protein. Bicuculline (10^{-4}M) completely blocked the original and the AVM-stimulated GABA binding, whereas picrotoxin (10^{-4}M) antagonized very specifically the AVM-stimulated GABA binding with an IC_{50} value of 4 μM. The AVM-stimulated GABA binding is also chloride-ion dependent; substitution of Tris-Cl with Tris-citrate or Tris-acetate in the reaction mixture resulted in total loss of the stimulatory effect of AVM. The optimal concentration of Cl^- was about 60 meq. for the drug action. These results suggest that the AVM action is very closely associated with the chloride ion channel or that AVM may have exposed a new population of GABA receptors which are sensitive to picrotoxin and dependent on Cl^- for ligand binding.

184.23 IMMUNOCHEMICAL COMPARISONS OF L-GLUTAMIC ACID DECARBOXYLASE FROM DIFFERENT SPECIES. Y.Y.T. Su*, J.-Y. Wu and D.M.K. Lam. Cullen Eye Institute and Dept. of Cell Biology, Baylor College of Medicine, Houston, Texas 77030.

L-Glutamic acid decarboxylase (GAD), the enzyme involved in the synthesis of GABA, has been purified from catfish brain and antisera against this enzyme were produced from rabbits. The species specificities of GAD were examined immunochemically using antisera against catfish GAD. The antibodies were found to cross-react with GAD from brains of goldfish, chick, frog and turtle in immunodiffusion tests. Enzymes from rabbit, rat, bovine, drosophila and crayfish did not show precipitin bands by these tests. Enzymes from crayfish, frog, chick, drosophila and goldfish were inhibited to different degrees by anti-GAD but bovine, rabbit or rat enzymes were not inhibited. The results from microcomplement fixation tests were consistent with those from enzyme inhibition and immunodiffusion tests. These immunochemical comparisons indicate that GAD from lower vertebrates and some invertebrates can be studied immunologically using antibodies against catfish GAD. Antibodies against mouse brain GAD, which have also been produced, cross-react only with the enzymes from mammals, chick and frog. Thus with the combination of the antibodies against mouse brain GAD and catfish brain GAD, it is now possible to study immunologically the GABA-ergic systems of almost all the vertebrate species and also some invertebrate species. Localization of GAD containing neurons in the chick retina using these antibodies were compared.

185.1 RECEPTOR CHANGES FOLLOWING SHOCK AVOIDANCE. D.R. Cherek, J.D. Lane, M.E. Freeman* and J.E. Smith. Psychiatry Research Unit, Department of Psychiatry, LSU Medical Center, School of Medicine, Shreveport, LA 71130.

Shock avoidance has been used to study the effects of stress upon brain neuronal systems. This research project was initiated to determine if different lengths of exposure to shock avoidance and shock presentation resulted in changes in brain acetylcholine, benzodiazapine or dopamine receptors. Pairs of Fisher (F-344) littermate rats were exposed to one or four 8 hour sessions of electric footshock presentation. One of each littermate pair was placed in a chamber containing a response lever. Responding on this lever was maintained by a signaled Sidman avoidance schedule with an R-S and S-S interval of 40 seconds. The last 20 seconds of this interval was signaled by a flashing light and clicker. Each lever press during the first 20 seconds postponed shock presentation for 40 seconds and terminated the flashing light and clicker. The other member of the littermate pair was placed in an identical chamber with no lever present and was also presented with the flashing light and clicker. If the avoiding animal failed to emit a lever press for 40 seconds, both rats of the pair received an electric footshock (1 mA 500 msec). Four pairs were exposed to one 8 hour session and four pairs to four consecutive 8 hour daily sessions. Following the termination of the first or fourth session, both animals of the pair were sacrificed by decapitation and the heads stored at -70°C. Brains were removed at -20°C, and dissected into cortical regions, striatum, hippocampus and diencephalon. Tissue from four animals from each treatment condition was pooled and total particulate membranes prepared. The resulting membrane suspension was incubated at the appropriate time and temperature in the appropriate buffer with either 0.6 nM [^{3}H] QNB in the presence or absence of 10 µM atropine or 30 pM or 0.03 mM or .35 mM 350 pM [^{3}H] spiperone in the presence or absence of 1 µM (+)-butaclamol or 3 nM [^{3}H] diazepam in the presence or absence of 3 µM clonazepam. Although there were many differences when comparing avoider and yoked-shock animals, the most striking results were observed in the cortical regions. When comparing the yoked-shock animals with their avoiders after 32 hours, muscarinic acetylcholine receptors were increased, while benzodiazepine receptors were decreased. High affinity dopamine receptors did not appear to vary while low affinity dopamine receptors increased in the frontal cortex (mesolimbic system) and decreased in other regions. These changes probably result from emotional and conditioning components of this paradigm. (This project was supported in part by USPHS Grants DA-01999-04 and MH-31835.)

185.2 RECEPTOR CHANGES FOLLOWING CONDITIONED EMOTIONAL RESPONSE. J.D. Lane, M.P. Sands*, J.E. Smith and D.R. Cherek. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Conditioned emotional response (CER) is thought to be an animal model for anxiety. CER has frequently been used to evaluate behavioral-drug effects with anxiolytics clearly attenuating the emotional response. To evaluate the neurochemical changes associated with this paradigm, groups of three littermate Fisher F-344 rats were food deprived and shaped to lever press in a standard operant chamber. Lever pressing was maintained by a variable interval (VI) 1 min schedule of food presentation. Following stabilization of responding, one hour classical conditioning sessions were initiated. Classical conditioning consisted of presenting conditioned stimulus (tone) of varying lengths (2 min-10 min) and unconditioned stimulus (foot shock, 1 mA, 500 msec) approximately 8 times during each session. UCS was presented at the end of CS. One rat of each group received this classical conditioning for 10 sessions. To isolate the conditioning component from the shock history and animal activity, the other two littermates received either CS (tone) or USC (shock) only. On test day, the CS was presented to the triads for 15 minutes while lever pressing was maintained by the food presentation schedule, afterwhich the animals were decapitated and stored at -70°C until analysis. The pre-tone and post-tone responding on the VI1 schedule were compared. The CER animal responded very little (<<1 res/min) after tone presentation, while both controls continued at pre-stimulus rates (circa 15 res/min). Brains were dissected into discrete cortical and subcortical areas and total particulate membrane fractions were prepared. Membrane suspensions were evaluated for binding of tritiated QNB, spiperone, muscimol and diazepam in the presence or absence of atropine, (+)-butaclamol, GABA or clonazepam, respectively. When comparing the CER animals with their shock-only controls, frontal and associative cortical areas had decreased benzodiazepine and increased muscarinic acetylcholine receptors. These receptor data are correlated with multiple neurotransmitter utilization (turnover) in the same regions. This data is consistent with CER being a model for studying emotional behavior in the absence of an aversive stimulus. (supported by USPHS Grant MH-31835)

185.3 INTERACTION OF NEUROTRANSMITTER SYSTEMS IN THE MEDIATION OF HYPOTHERMIA IN THE MOUSE. C. L. Melchior and B. Tabakoff, Dept. of Physiology & Biophysics, Univ. of Ill. Med. Ctr. and West Side V. A. Med. Ctr., Chicago, IL 60612.

Hypothermia occurs in the mouse in response to agonists of the central noradrenergic, dopaminergic, serotonergic, and cholinergic systems. In order to determine how these neurotransmitter systems interact, we examined the effects of agonists of different systems in mice in which selective amine depletions were made with neurotoxins.

C57Bl mice were intraventricularly injected with 10 µl of artificial cerebrospinal fluid (CSF) or CSF containing 50 µg of 6-hydroxydopamine (6-OHDA) to deplete catecholamines or 75 µg of 5,7-dihydroxytryptamine (5,7-DHT) to deplete serotonin. All of the mice given 5,7-DHT and half of those given 6-OHDA were injected with 25 mg/kg of desmethylimipramine i.p. 45 mins. prior to the central injections to protect against noradrenergic depletion. The animals were tested for their temperature response to agonists of various systems 1-3 weeks after the neurotoxin treatment. Drugs were presented in a randomized block design with at least 48 hrs. between the i.p. injections. Body temperature was measured with a rectal probe before and every 15 mins. for 2 hrs. after injection. At the end of the experiment, the animals were sacrificed and the brains analyzed by a spectrophotofluorometric procedure for levels of norepinephrine, dopamine, and serotonin.

The α-adrenergic agonist clonidine produced a greater and longer lasting fall in body temperature in 5,7-DHT-treated mice than in CSF-treated animals. In contrast, the hypothermia induced by the serotonin precursor 5-hydroxytryptophan was blocked in the 5,7-DHT group but exacerbated in animals with norepinephrine depletion. These results suggest a reciprocal inhibitory action between noradrenergic and serotonergic neurons.

The hypothermic response to the muscarinic cholinergic agonist oxotremorine was attenuated by 6-OHDA treatment, indicating a noradrenergic link in cholinergic-induced hypothermia.

The fall in body temperature caused by the dopamine agonist piribedil was blocked in the 5,7-DHT group. This supports the idea that there is a serotonergic link in dopamine hypothermia. Although the mice given 6-OHDA did not show as great a fall in temperature as controls, they were far more activated. The activity of these animals may explain, at least in part, the diminished temperature response. In contrast, animals given DMI-6-OHDA to produce predominantly a depletion of dopamine manifested a greater sensitivity to the hypothermic actions of piribedil.

Supported by grants from NIAAA (2696), NIDA (2024, 1951), State of Illinois DMH&DD (8083-13) and the Medical Research Service of the Veterans Administration.

185.4 BEHAVIORAL EFFECTS OF YOHIMBINE: ANTAGONISM BY ANXIOLYTICS. Ronald G. Browne, Dept. Pharmacol., Central Research, Pfizer Inc., Groton, CT 06340

Yohimbine, a naturally occurring alkaloid, is known to be a selective antagonist of presynaptic α- noradrenergic receptors. In man, this agent produces a number of effects including stimulation, hallucinations and anxiety. The clinical observation that yohimbine-induced "anxiety" could be reversed with diazepam suggested the present study where attempts were made to antagonize the discriminative stimulus properties of yohimbine with various anxiolytics.

Twenty-four male Sprague-Dawley rats weighing 250-300 g at the start of the experiment were trained to discriminate 3.2 mg/kg of yohimbine hydrochloride from saline in a 2 lever operant procedure. Fifteen minute sessions were conducted five days per week beginning 30 minutes after drug or saline administration. The rats were required to press the left lever under a FR-10 schedule of reinforcement on those days when yohimbine was administered, and to press the right lever during saline sessions. Incorrect responses were recorded but had no programmed consequence. Discrimination accuracy was established when the animals consistently emitted their first FR-10 responses on the appropriate lever. Following about 40 training sessions all animals were reliably discriminating yohimbine from saline as evidenced by having selected the correct lever in 9 out of 10 consecutive sessions.

Twice weekly test sessions were conducted in order to examine the similarity between yohimbine and various drugs, as well as to attempt antagonism of yohimbine's discriminative stimulus properties. The results of generalization testing indicate that piperoxane, another presynaptic α_2 antagonist with anxiogenic properties in man, produces yohimbine-like discriminative effects. In contrast to yohimbine and piperoxane, clonidine and prazosin were discriminated as saline, suggesting that yohimbine's discriminative properties are mediated through α_2 receptors.

When the rats were pretreated with diazepam, a dose related antagonism of yohimbine's stimulus properties was observed. Thus, all animals selected the saline appropriate lever following the simultaneous administration of 17.8 mg/kg of diazepam and 3.2 mg/kg of yohimbine. A partial antagonism of yohimbine cueing was also obtained with meprobamate, phenobarbital, chlordiazapoxide, and clonazapam. These results suggest that yohimbine discrimination in rats may be a useful model for detecting agents with anxiolytic activity.

185.5 DOSE-DEPENDENT TOLERANCE TO A BEHAVIORAL EFFECT OF NICOTINE. Glenn Daniel Todd* and John Dougherty. Depts. of Pharmacology and Psychiatry, University of Kentucky and Veterans Administration Medical Center, Lexington, Kentucky 40511.

We have previously reported that tolerance to the suppression of lever pressing by nicotine developed according to two time courses: rapidly (within hours) and slowly (over days) when 200 µg/kg (first 9 days) and then 350 µg/kg (next 10 days) of the base were injected i.p. twice daily at intervals of 1,2,4, or 8 hours on successive days (Soc. Neurosci. Abstr., 5:665, 1979). As an extension of that study, we now report the effects of chronic injections of higher doses (500 and 650 µg/kg/inj base) on the slowly developing tolerance to the effects of the first daily injection. Twenty male albino Wistar rats, divided into 4 groups of 4-6 rats each, were maintained at 80% of their free-feeding weight by limiting water access and were injected twice daily at the four dosing intervals listed above, with each injection followed by a 30-minute session of water-reinforced lever pressing according to an FR50 schedule.

We previously found that tolerance to the initial suppressant effect of the first daily injection of nicotine on responding developed slowly over successive days at doses of 200 and 350 µg/kg/inj (400 and 700 µg/kg/day). When the dose was increased from 350 to 500 µg/kg/inj (1000 µg/kg/day), the suppression of responding at the beginning of the session was lengthened, as was previously found when the dose was increased from 200 to 350 µg/kg/inj. However, unlike the findings at lower doses, tolerance at this increased dose was not evident after 12 days. Increasing the nicotine dose further to 650 µg/kg/inj (1300 µg/kg/day) produced an additional slight lengthening of the suppression duration. Tolerance at this dose was also not seen over four days of dosing. Dosing was stopped at this largest dose because of progressive weight loss and the increasing appearance of fasciculations and muscular rigidity.

These data indicate that the tolerance that slowly develops to a behaviorally suppressant effect of nicotine over a period of days is dose-dependent and does not occur with doses at or above 500 µg/kg/inj. These data are consistent with other research findings that show a lack of tolerance to the body weight lowering effects of the drug in rats. More significantly, our findings are compatible with the development of certain types of cigarette smoking patterns in which initially increasing smoking rates are followed by long periods of stable smoking frequency.

185.6 EFFECTS OF CLONIDINE ON ACTIVITY AND LEARNING IN 6-HYDROXYDOPAMINE AND NORMAL DEVELOPING RAT PUPS. B.A. Shaywitz, A.S. Wolfe*, D.J. Cohen*, J.G. Young*, G.E. Anderson* and M.H. Teicher. Lab. Develop. Neurobiol. and Develop. Neurochem., Yale Univ. Sch. Med. New Haven, CT 06510.

Intracisternal administration of 6-hydroxydopamine (6-OHDA) (preceded by desmethylimipramine) to neonatal rat pups results in selective reduction of brain dopamine (DA) to concentrations 10-25% of controls, hyperactive motor activity which abates with maturity and persistent cognitive deficits. Such behavior may result from a predominance of noradrenalin (NA) compared to DA and should be attenuated by reduction in NA activity. We have examined the effects of clonidine (CD), an agent which at low dosages will decelerate the utilization of NA and inhibit the firing rate of NA neurons in the locus coeruleus via inhibitory autoreceptors, an action which would be expected to reduce the hyperactivity and the cognitive deficits. Normal and 6-OHDA pups were treated with saline, or CD (50 µg/kg-low dose, 500 µg/kg-high dose) given 30 minutes prior to observation. Activity levels were significantly affected by age averaging 36.8%, 35.0% and 22.7% for 12, 19 and 26 days respectively; activity was also significantly influenced by dose averaging 28.4% at 0 dose, 39.4% for low and 26.7% activity at the high dose. Activities averaged 32.5%, 45.1% and 32.9% at 12 days, 17.7%, 53.8% and 33.6% at 19 days and 35%, 19.4% and 13.6% at 26 days for 0, low and high doses respectively. This indicated a significant age X dose interaction, with the low dose increasing activity at 12 and 19 days, while the high dose had no effect at 12 or 19 days, and both doses reduced activity at 26 days. Reduction of activity by 34% over the hour long observation period (habituation of activity) was observed for pups receiving 0 or the high dose, but habituation of activity was not demonstrated for those receiving the low dose. Avoidance learning in a shuttle box at 28 days was not affected by the low dose but increased by 82% indicating a significant impairment by the high dose. Interactions between CD and 6-OHDA were not observed for either activity or the avoidance task.

The impaired habituation of activity after low doses of CD indicates a role for NA mechanisms, with similarities to the dorsal bundle extinction effect proposed by Mason and Fibiger. Furthermore, our results underscore the important role of dopamine and noradrenalin in the ontogeny of motor activity and avoidance learning but suggest that the development of other neural systems (serotonin, GABA, substance P) may also influence the response to CD.

185.7 CHRONIC AMPHETAMINE INFLUENCES STIMULUS FILTERING. Venera Bruto, Hymie Anisman and Larry Kokkinidis. Carleton University and University of Saskatchewan.

When permitted to explore a multiarmed maze, mice tend to visit most frequently those arms least recently entered (spontaneous alternation). When treated with amphetamine (3.0-7.0 mg/kg) mice exhibit perseverative responding (i.e., successive visits between two arms). Following repeated drug treatment (5 - 10 mg/kg for 5 - 10 days) the perseverative pattern of responding ordinarily elicited by amphetamine is eliminated; however, alternation responding does not appear either. Rather, mice exhibit a random pattern of responding. Such behavior was evident even when mice were tested in the nondrug state. The effects of chronic amphetamine did not appear to be due to reduced effectiveness of the drug. Specifically, if mice were preexposed to the maze, thereby reducing the alternation tendency, the perseveration induced by amphetamine was maximized. Thus, doses that ordinarily reduce alternation to chance levels, induced marked perseveration follow apparatus preexposure. In contrast, preexposure did not influence behavior of mice that received chronic amphetamine. It is suggested that NE depletion provoked by chronic amphetamine treatment results in deficits of filtering information. As a result mice chronically treated with amphetamine do not adequately attend to apparatus cues and are unaffected by previous experience in the maze.

185.8 COMPARATIVE ASSESSMENT OF EQUILIBRIUM PERFORMANCE OF RHESUS AND CYNOMOLGUS MONKEYS: EFFECTS OF ATROPINE. C. T. Bennett, N. E. Lof*, D. N. Farrer*, and J. L. Mattsson*. USAF School of Aerospace Medicine, Brooks AFB, Texas 78235.

The primate equilibrium platform (PEP) consists of a small restraining chair that is pitched forward and backward from horizontal by a computer-driven, random signal (band-passed 0 to 0.4 Hz). Six M. mulatta (rhesus) and six M. fascicularis (cynomolgus) monkeys were trained by mild shock reinforcement to operate a control stick to maintain themselves in a relatively horizontal position. Cynomolgus monkeys took an average of approximately six weeks longer than rhesus monkeys to reach a similar level of performance. Previous clinical screening of the effects of atropine sulfate indicate rhesus to be approximately 5 to 10 times more sensitive, in terms of mydriasis and muscular weakness. The effects of four doses of atropine on performance in the PEP were tested. As expected, as atropine doses increased, the PEP performance decreased, with rhesus performance changing at lower doses than fascicularis.

185.9 SEIZURES INDUCED BY CHRONIC GABA ELEVATION WITH γ-ACETYLENIC GABA. S.E. Bachus, A.B. Young & E.S. Valenstein; Depts. Psych. & Neurol., Univ. Michigan, Ann Arbor, Michigan 48109.

The GABA transaminase inhibitor γ-Acetylenic GABA (GAG), reported to elevate brain GABA levels (Jung et al., Neurochem. 28: 717, 1977), has been proposed as an anticonvulsant (Schecter et al., GABA-Biochemistry & CNS Functions, ed. P. Mandel & F.V. De Feudis, Plenum, p. 43, 1979) and also tested clinically as a treatment for Huntington's Chorea (Böhlen et al., Brain Res. Bull.4:692, 1979) and tardive dyskinesia (Casey et al., Brain Res. Bull. 4:698, 1979). Two cautions have been noted: seizure-protection does not persist as long as does maximal GABA elevation (Wood et al., Neurochem. Res. 2:707, 1977); and single high doses of GAG can cause seizures (Schecter & Grove, Brain Res. Bull. 4:712, 1979). We now report results which indicate that chronic low doses of GAG can induce seizures during a period while brain GABA levels are declining to baseline values.

Male Sprague-Dawley and Long Evans rats with lateral hypothalamic electrodes (N=8) were administered daily i.p. injections of 50 mg/kg GAG. Grand mal tonic-clonic convulsions were observed during electrical self-stimulation and programmed stimulation: regularly at 23 hrs, occasionally at 8-12 hrs, but never at 4 hrs post-injection (when GABA elevation is maximal) or after saline injections. Seizures were first seen after the second or third daily GAG injection, and thereafter observed regularly for as long as 16 days. 8 naive rats without electrodes were then monitored during 8 days of GAG treatment. Spontaneous seizures were detected during the 20-24 hrs post-GAG period in 5 rats.

To test the hypotheses that these seizures might be due to below-baseline GABA during GAG withdrawal or to development of GABA receptor subsensitivity, naive rats were sacrificed at 4 hrs post-GAG (N=6), at 23 hrs post-GAG (N=6), and at 23 hrs post-saline (N=6) on the third day of treatment. GABA levels (Enna & Snyder, J. Neurochem. 26:221, 1976) and GABA synaptic receptors (Williams & Risley, J. Neurochem. 32:713, 1979) in frontal cortex were assayed. GABA levels were significantly elevated at 4 hrs post-GAG ($\bar{X}$=12.60 μmole/g) relative to saline ($\bar{X}$=5.55 μmole/g), and still slightly though no longer significantly elevated at 23 hrs post-GAG ($\bar{X}$=7.10 μmole/g). GABA receptor sensitivity, however, did not differ significantly at any time period. Localized brain changes in GABA might provide an explanation for the appearance of seizures after low doses of chronic GAG treatment. Meanwhile, the possibility of inducing spontaneous seizures with GAG treatment should be seriously considered before recommending the clinical use of this drug.

185.10 ACUTE AND CHRONIC NALTREXONE TREATMENT: DIFFERENTIAL EFFECT ON MORPHINE-INDUCED LOCOMOTOR ACTIVITY AND ANALGESIA. J.M. Ng Cheong Ton*, R.S. Blair*, L.J. Holmes* and Z. Amit. Dept. of Psychology, Concordia University, Montreal, Quebec, Canada.

Three studies were conducted to investigate the opiate receptor's role in morphine's biphasic effects on locomotor activity (LA) and morphine's analgesic properties.

In the first study, naltrexone (2 mg/kg) injected subcutaneously (S.C.) 2 hr prior was found to attenuate both the excitatory and the depressive actions of morphine (1, 4 or 8 mg/kg, S.C.) on LA in an open-field. These results suggest that the opiate receptor mediates the biphasic effects of morphine.

It has been shown that chronic treatment with opiate antagonists increase the number of opiate receptors. In the second study, we examined the effect of chronic naltrexone treatment on morphine's biphasic effect on LA. Animals were injected daily with naltrexone (10 mg/kg, S.C.) for 24 days. Three days after the termination of naltrexone treatment, animals were treated with morphine (1, 4 or 8 mg/kg, S.C.) and open-field LA was recorded. Naltrexone was found to shift the biphasic activity curve to the right. The shift appears to have resulted from an increase in the duration of depression for naltrexone treated animals.

In the third study, animals received naltrexone and morphine treatments identical to those in the second study. Following the morphine injection, animals were placed within a plexiglas cylinder on a hot-plate every 15 min for 90 min. Paw-lick and escape latencies were recorded. Naltrexone potentiated morphine's effect on paw-lick but not escape latencies.

The observation that chronic naltrexone treatment did not potentiate all effects of morphine suggests that only specific opiate receptor populations were affected.

185.11 FOOD INTAKE ALTERS BEHAVIORAL EFFECTS OF NALOXONE. Diane Snell and R. Adron Harris. Depts. Psychology and Pharmacology, Univ. Missouri and Truman V.A. Hospital, Columbia, MO 65212

Few studies have evaluated the behavioral effects of chronic administration of narcotic antagonists. The present investigation explores the effects of repeated administration of naloxone as a function of food intake. In food deprived rats, neither single nor repeated injections of naloxone or naltrexone produced any alteration of food-reinforced responding (Harris, JPET 213: in press, 1980). It was noted, however, that following one injection of 30 mg/kg of naloxone, which itself had little effect, free feeding animals performing on a shock avoidance task became so sensitive to subsequent injections that administration of as little as 0.1 mg/kg of naloxone lead to disruptions in performance. This lead us to postulate that repeated administration of naloxone might lead to sensitivity in free feeding animals but not in food deprived animals. In order to test this hypothesis, rats were trained to avoid shock under a continuous avoidance schedule. Naloxone was administered twice/week to free-feeding rats until they became sensitized to the drug. Sensitivity was measured by increase in shock rate. Animals were considered sensitized when their shock rates were at least 3 times higher than their control rates for 5 consecutive injection days. Following 6 injections of 0.3 mg/kg of naloxone none of the rats were sensitized. The dose was then increased to 3.0 mg/kg, which lead to sensitization in some of the rats, while others required 10 mg/kg to produce a disruption in performance. When the rats became sensitized, they were reduced to 80% of their free-feeding weights. Injections of naloxone were continued twice/week until the rats showed little or no disruption in performance in response to the same dose of naloxone which had produced sensitivity when the rats were free feeding. At this time the animals were given free access to food and sensitivity to the behavioral effects of naloxone was reinstated. In contrast, mice given 17 daily injections of 3 mg/kg of naloxone did not show alterations in hot plate latency or in the hyperalgesic activity of naloxone as measured by the hot plate test. The effects of chronic administration of higher doses of naloxone on the hot plate test as well as results obtained with other tests will be presented. In summary, chronic administration of naloxone sensitized free-feeding rats to behavioral effects of the drug, while no sensitivity was detected in rats which were food deprived. In addition, free feeding animals which had been sensitized were no longer affected by naloxone when their body weights were reduced. This points to a critical role of dietary factors in the regulation of sensitivity to narcotic antagonists. Supported in part by V.A. Research and PMAF.

185.12 LIMBIC NEUROTRANSMITTER CHANGES CORRELATED WITH INTRAVENOUS OPIATE SELF-ADMINISTRATION. J.E. Smith, C. Co*, M.E. Freeman*, M.P. Sands* and J.D. Lane. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

The self-administration of opiates has been shown to result from their rewarding properties. This study was initiated to determine if limbic neuronal systems are involved in opiate reward. The turnover rates for dopamine (DA), norepinephrine (NE), serotonin (5-HT), aspartate (Asp), glutamate (Glu), glycine (Gly) and gamma-aminobutyric (GABA) were measured in rats intravenously self-administering morphine (I) and in yoked-morphine infused (II) and yoked-vehicle infused (III) littermates. Eleven litters of three (conditions I-III) male F-344 rats were implanted with chronic jugular catheters and two littermates in each group made physically dependent upon morphine with hourly automatic infusions. One of the physically dependent rats was then allowed to self-administer morphine (10 mg/kg) by lever pressing. The other two littermates in each group received simultaneous yoked infusions. After stable baselines of self-administration were obtained an average interinjection interval was calculated for each self-administering animal. At 60 min (N=5 litters) or 90 min (N=6 litters) prior to a predicted self-infusion, 0.5 mCi of [^{3}H]-tryptophan, 1.0 mCi of [^{3}H]-tyrosine, and 0.2 mCi of [^{14}C]-D-glucose were injected through the jugular catheter and the litter sacrificed by immersion in liquid nitrogen at the predicted self-administration time. The brains were removed at -20°C and the frontal-pyriform cortex (FPC), nucleus accumbens (NA), septum (S), hippocampus (HI), amygdala (A) and hypothalamus (HY) dissected from serial coronal sections at -20°C. Content and turnover rates were determined by previously described procedures (Smith et al, Prog. Neuro-Psychopharm., 2, 359-367, 1978; Freeman et al, Anal. Biochem. in press). Passive morphine infusion (yoked-morphine vs yoked-vehicle) resulted in the following turnover changes: decreases in DA in the S, increases in NE in the HI, decreases in 5-HT in the FPC and S, increases in Asp in the FPC, S and HI and a decrease in the NA, increases in Glu in the FPC, S and HI and decreases in the NA and A, an increase in Gly in the S and increases in GABA in all areas except the S. The effects of morphine self-administration (comparison of the self-administration group with the yoked-morphine group) showed the following turnover changes: DA to be increased in the FPC and S, NE increased in S and HI, 5-HT increased in the FPC and S and decreased in the NA, Asp and Glu increased in all areas except the septum and GABA increased in the FPC, HI and A and decreased in the NA. Limbic neuronal systems appear to be involved in morphine reinforcement processes. (Supported in part by USPHS Grant #DA-01999-04 and MH-31835.)

185.13 PHARMACOLOGICAL DISSOCIATION OF SHAKING BEHAVIOR PRODUCED BY MET-ENKEPHALIN, TRH and SEROTONIN. Eugene G. Drust*, Robert S. Sloviter and John D. Connor. Department of Pharmacology, Pennsylvania State University, College of Medicine, Hershey, PA 17033.

A pharmacological comparison was made of shaking behavior produced by intracerebroventricular injection into rats of met-enkephalin (ME), thyrotropin-releasing hormone (TRH) and serotonin (5-HT). ME caused dose-dependent shakes in the dose range of 1-500 µg. Shakes occurred within 1-2 min after injection; virtually all shakes were observed in the first 5 min period after injection. TRH produced dose-dependent shakes in the dose range of 10 ng to 1 µg. TRH shakes began within 2-4 min after injection; the duration of the shaking response to TRH was dose-dependent (5-30 min). Shakes induced by intraventricular administration of 5-HT were studied in rats pretreated with the monoamine oxidase inhibitor, tranylcypromine (20 mg/kg, ip, 30 min before 5-HT) as described previously (Drust et al., Pharmacology 18: 299, 1979.

The role of 5-HT mechanisms in shaking behavior was examined by pretreating rats with p-chlorophenylalanine (pCPA), 5,7-dihydroxytryptamine (5,7-DHT) or methysergide (MS). None of these treatments significantly affected ME or TRH shakes, indicating that 5-HT mechanisms are probably not involved in these effects of ME or TRH. In contrast, 5-HT shakes were significantly potentiated by 5,7-DHT pretreatment and significantly decreased by pCPA or MS. The opiate receptor antagonist naloxone significantly inhibited ME shakes but had no effect on TRH or 5-HT shakes. The effects were also studied of pretreatment with the catecholamine neurotoxin, 6-hydroxydopamine (6-OHDA), or the tyrosine hydroxylase inhibitor, α-methyl-p-tyrosine (α-MpT), on the shaking behavior produced by these substances. While 6-OHDA or α-MpT pretreatment had no significant effect on 5-HT shakes, TRH shakes were decreased by both 6-OHDA and α-MpT. ME shakes were not significantly affected by α-MpT pretreatment but were significantly potentiated after 6-OHDA. This suggests that central catecholamine mechanisms may be involved in shakes produced by ME and TRH; however, the possibility exists that 6-OHDA and α-MpT produce some of these effects by mechanisms unrelated to catecholamines.

These data indicate that shaking behavior produced by these substances is apparently elicited by 3 different mechanisms. In light of the proposed role of ME, TRH and 5-HT as neurotransmitters or neuromodulators and the presumed existence of separate receptors for these compounds, the shakes produced by these substances may be useful as quantitative models of central enkephalin, TRH and 5-HT activity, respectively.

185.14 COMPARATIVE EFFECTS OF LITHIUM ON DRUG-INDUCED AND LESION-INDUCED DOPAMINERGIC SUPERSENSITIVITY. Eliot L. Gardner, Ira Hirschhorn, Thomas F. Seeger*, Michael Weiss* and Maynard H. Makman*. Depts. of Psychiatry, Neuroscience, Biochemistry and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, N.Y., 10461.

We have previously reported (Seeger and Gardner, Soc. Neurosci. Abstr. 5: 662, 1979) that chronic lithium (Li^+) administration attenuates the development of mesolimbic dopaminergic (DA) behavioral supersensitivity. A similar blocking effect of Li^+ on nigrostriatal DA supersensitivity has also been reported (Pert et al, Science 201:171, 1978). However, these studies dealt only with drug-induced DA supersensitivity, leaving open the possibility that the demonstrated effects are unique to the drug-induced condition. The present study was designed to test for an effect of Li^+ on the development of lesion-induced DA supersensitivity. Rats received unilateral 6-hydroxydopamine lesions of the substantia nigra to produce DA denervation supersensitivity of the ipsilateral striatum. Half of the animals were given Li^+ carbonate in their food (1600 mg/kg of powdered chow) for three weeks, starting one week before surgery. Control rats received powdered chow without Li^+. Animals were tested for rotational behavior following systemic administration of apomorphine (2 mg/kg) after three weeks of Li^+ treatment and, again, four weeks after termination of Li^+ treatment. The Li^+-treated animals showed behavioral supersensitivity after three weeks of Li^+ chow, but at only 65% of the magnitude shown four weeks after the termination of the Li^+ treatment, when they were completely (control level) supersensitive. Control animals were equally supersensitive at the end of three weeks of control chow as four weeks later. Partial attenuation of supersensitivity after three weeks was also indicated by biochemical studies of striatal DA-stimulated adenylate cyclase. Thus, while Li^+ significantly attenuated the development of lesion-induced DA supersensitivity, the effect was incomplete. We also observed only a partial attenuating effect of Li^+ on the development of chronic haloperidol-induced DA behavioral supersensitivity, as measured by DA-mediated intracranial self-stimulation. Thus, while chronic Li^+ attenuates both the magnitude and time-course of both lesion-induced and neuroleptic-induced DA supersensitivity, the effect is neither complete nor permanent. The impermanence of the effect has also been confirmed by biochemical studies, in which we find that chronic Li^+-treated animals become fully supersensitive, in terms of increased ^{3}H-ADTN binding, when taken off the daily Li^+ regimen.

185.15 THE EFFECT OF LITHIUM ADMINISTRATION ON APOMORPHINE INDUCED ROTATION FOLLOWING UNILATERAL DESTRUCTION OF THE NIGRO-STRIATAL PATHWAY IN THE RAT. M. Gruenthal* (SPON:J.A. Simmons). Dept. of Psychol., Washington Univ. St. Louis, MO 63130.

Previous reports have indicated that combined lithium-haloperidol administration may prevent the development of haloperidol induced behavioral supersensitivity to apomorphine (Pert, A. et al., Science, 201:171, 1978). The present study was conducted to examine the effect of lithium administration on the development of apomorphine induced contralateral rotation following unilateral denervation of the striatum, a phenomenon which appears to be due to the development of postsynaptic receptor supersensitivity (Creese, I. et al., Science, 197:596, 1977).

Male albino rats (sixty days old) received unilateral intra-nigral injections of either 6-hydroxydopamine or of the vehicle alone. Beginning 24 hrs. after surgery subjects received daily injections of either lithium chloride (2meq/kg i.p.) or isotonic saline for 14 days. Seven days after the last injection all subjects received apomorphine (0.25mg/kg sc.) and 10 min. later were placed in automated rotometers for a period of 15 min.

Rats in the lesion-lithium group did not differ from subjects in the lesion-saline group with respect to apomorphine induced contralateral rotation. Preliminary observations, however, suggest that rats in a similar lesion-lithium group show decreased apomorphine induced contralateral rotation, relative to saline treated subjects with lesions, when apomorphine is administered 3 to 12 hrs. following the last lithium injection. These data suggest that lithium administration may transiently supress, but not permanently eliminate, development of the behavioral consequences of lesion induced supersensitivity.

186.1 RESPIRATION IN ASTROCYTES FROM PRIMARY CULTURES AND ESTABLISHED CELL LINES DURING EXPOSURE TO ALTERED OSMOLARITY. James E. Olson and David Holtzman*, Dept. of Pediatrics & Neurology, Stanford University School of Medicine, Stanford, CA 94305.

During maturation isolated brain mitochondria become resistant to morphologic alteration and to respiratory inhibition in media of increased osmolarity (Holtzman et al., J. Neurochem 33:453-460, 1979). These properties, which may be confined to a sub-population of whole brain mitochondria, appear coincident with astrocyte maturation. To investigate the proposed localization of these hyper-osmolar resistant mitochondria in astrocytes, we have measured the rates of oxygen consumption in astrocytes from primary culture suspended in media of varying osmolarities. These results are compared with similar studies using cell lines of type II pneumocytes and 3T3 mouse-embryo fibroblasts.

Astrocytes from dissociated neonatal rat brain were grown for two weeks in an Eagle's minimal essential medium supplemented with vitamins, amino acids, and 20% calf serum. The confluent cultures were then grown for an additional five days with 0.25 mM dibutyryl cyclic AMP added to this medium. At the end of this time, cells were suspended in a respiration medium (pH 7.3) which included glucose 55 mM, KCl 2.7 mM, $CaCl_2$ 1.0 mM, $MgCl_2$ 0.50 mM, Na_2HPO_4 8.0 mM, KH_2PO_4 1.5 mM, and variable concentrations of NaCl ranging from 0-822 mM. Basal respiration, phosphorylation-independent respiration (5µM oligomycin added), and maximally uncoupled respiration (20-80µM dinitrophenol added) were measured polarographically using a Clark platinum cathode assembly.

Basal rates of respiration in medium of normal osmolarity (137 mM NaCl) were between 25-30 n at. equiv O/mg protein min for all cell types. The basal rates were reduced by about 50% in the 0 NaCl medium. Basal rates in the pneumocytes fell significantly in each of the hyper-osmolar solutions (NaCl of 274, 548, and 822 mM). Basal rates in astrocytes were constant from 137 to 822 mM NaCl. The respiratory rates in the presence of a maximally-inhibiting concentration of oligomycin were depressed in hypo-osmolar media compared to normal medium in pneumocytes more than in the astrocytes. In hyper-osmolar media up to 548 mM NaCl, oligomycin inhibited rates were increased 2-3 fold in astrocytes compared to a 50% increase in pneumocytes. In both astrocytes and pneumocytes peak uncoupled respiratory rates were found in media of normal osmolarity.

186.2 AN IMMUNOCYTOCHEMICAL STUDY OF ASTROCYTES ASSOCIATED WITH THE RAT SUPRAOPTIC NUCLEUS. Adrienne K. Salm* and Glenn I. Hatton (SPON: R. A. Pax). Department of Psychology and Neuroscience Program, Michigan State University, East Lansing, MI 48824.

Astrocytic neuroglia associated with the rat supraoptic nucleus was investigated using immunohistochemical techniques. Recent evidence (Cell Tiss. Res. 1977, 181, 59-72) for a functional role of neuroglia in hypothalamic magnocellular hormone release prompted further investigation of the astrocytes in this area.

The unlabeled antibody method of Sternberger (1974) was used to demonstrate immunoreactivity to glial fibrillar acid protein (GFAP) antiserum. (The antiserum was kindly provided by Dr. E. A. Zimmerman.) GFAP is only found in fibrous and protoplasmic astrocytes. Hypothalamic tissue from 12 normal adult male rats was studied in 60 µm, 10 µm, and 6 µm unembedded vibratome or paraffin embedded sections. Immunoreactivity was visualized with 3,3'-diaminobenzidine. This revealed a group of morphologically distinct astroglia, the cell bodies of which lie primarily between SON cell bodies and the pial surface of the brain. The cells are easily distinguishable from all labeled neuroglia encountered in other areas of the hypothalamus, including the internal median eminence, periventricular subependymal region and the medial paraventricular nuclear region. Unlike the latter groups, which display a stellate morphology, the SON astrocytes have extremely long and thin processes which radiate outward in a predominately dorsolateral direction. However, some of these processes are interposed between the SON and the optic tract. The cell bodies of these astrocytes form a tightly packed lamina along the pial surface, diminishing in number as they extend laterally toward the periamygdalar cortex. Astrocytic fibers exhibit their most dorsal extension in the area neighboring SON, where they project for distances up to three times the depth of the nucleus.

At its most caudal extent SON appears to be almost totally surrounded by astrocytic processes except where capillaries exit dorsally from the nucleus. These capillaries are also seen ensheathed by long, thin neuroglial processes. Glial processes have also been observed forming a reticulum around cell bodies of SON neurons.

186.3 EFFECT OF DOPAMINE ON PROTEIN SYNTHESIS IN A RAT GLIOMA CELL LINE. L. Roel, V. May*, and K. Braas*, Dept. of Anatomy, Northwestern Univ., 303 E. Chicago Ave., Chicago, IL 60611.

Intraperitoneal (ip) administration of L-dihydroxyphenylalanine (L-DOPA) causes massive disaggregation of rat brain polysomes and inhibition of protein synthesis in vivo (Life Sci. 22: 1887, 1978). Polysome disaggregation occurs between 1 hr and 2 hr after L-DOPA administration, and is temporally correlated with the rise in brain dopamine (rather the rise in *L-DOPA, 3-O-*methyl DOPA, or the depletion of brain S-adenosylmethionine). In addition, pretreatment of animals with Ro4-4602 (800 mg/kg), an L-Aromatic Amino Acid Decarboxylase inhibitor, prevents the L-DOPA-induced brain polysome disaggregation. These findings suggest that the brain polysomal disaggregation following L-DOPA administration is mediated by dopamine.

In order to determine whether observed brain protein synthesis effects are occurring in neurons or glia, studies employing C6 cells (a rat glioma cell line) were conducted. In these studies, C6 cells were grown in Falcon petri dishes, in an atmosphere of 95% air, 5% CO_2 in Ham's F-10 medium supplemented with 10% fetal calf serum and 0.1 µg/ml gentamycin. Confluent cultures were incubated with dopamine hydrochloride (in a final concentration of 1×10^{-5} M), and at various times thereafter, 0.5 µCi ^{3}H-lysine was added to the culture medium. Thirty min later, incubation media were poured off, cells washed once with 5 ml ice cold saline, and cells harvested in 5 ml ice cold 5% trichloroacetic acid (TCA). Incorporation of ^{3}H-lysine into TCA precipitable protein was determined by standard procedures.

Dopamine in concentrations of 10^{-5} M depressed incorporation of ^{3}H-lysine into TCA precipitable protein 25-50%. The maximal effect occurred at 2 hr after addition of dopamine to the media. Protein synthesis rates returned to control values between 4 and 6 hrs after addition of dopamine to the medium. The effect of amphetamine on protein synthesis in C6 cells was also examined under conditions similar to those described above. Results indicate that protein synthesis is inhibited 30-40% 2 hrs after addition of 1×10^{-5} M amphetamine to the medium. Studies are being conducted to determine whether dopamine and amphetamine have similar effects on protein synthesis in a neuroblastoma cell line.

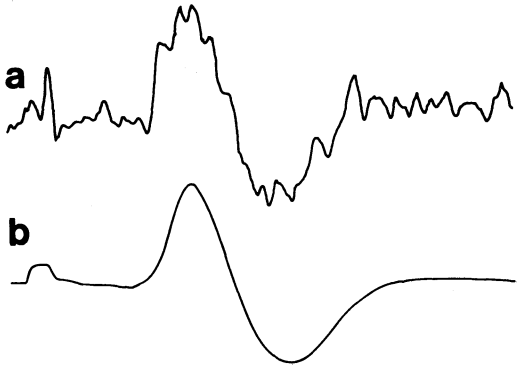
186.4 MAGNETIC MEASUREMENT OF INTRACELLULAR CURRENTS IN ISOLATED FROG SCIATIC NERVES. John P. Wikswo, Jr.*, John P. Barach* and John A. Freeman (SPON: Frank R.Freemon). Department of Physics and Astronomy and Department of Anatomy, Vanderbilt University, Nashville, Tenn. 37235.

We have developed a Supeconducting Quantum Interference Device (SQUID) magnetometer with a minature room-temperature toroidal pick-up coil that has sufficient sensitivity and frequency response to measure the magnetic field associated with the action potential of an isolated frog sciatic nerve (Wikswo, Barach and Freeman, Science 208:53, 1980). The nerve is immersed in Ringer's solution and is threaded through the ferrite core of the toroidal pick-up coil. The coil typically has a diameter of 2.6 mm and has 10 to 30 turns of No. 38 copper wire. The time-dependent magnetic field of the nerve induces currents in the pick-up coil that are detected by the SQUID. Recent improvements to the instrument provide a magnetically shielded environment for the SQUID in a liquid helium storage dewar so that the measurements of the weak magnetic field (100 picotesla) can be made in a typical laboratory. The (a) trace shown below is the output of the SQUID magnetometer electronics with a 1.0 Hz to 2 kHz bandwidth for a frog sciatic nerve threading the toroid. The (b) trace is an average of 1024 responses and clearly demonstrates that high quality magnetic measurements can be made on isolated nerves. Detailed theoretical calculations indicate that the intracellular currents provide the dominant contribution to the extracellular magnetic field, so that this technique provides a non-invasive measurement of the currents flowing inside a nerve.



186.5 Cl^- AND Na^+ EXCHANGE TRANSPORT PROPERTIES IN PRIMARY ASTROGLIAL CULTURES FROM RAT BRAIN. H.K. Kimelberg and S. Biddlecome*, Albany Medical College, Albany, N.Y. 12208.

We have previously reported (Neurosci. Abst. 5, 293, 1979) that Cl^- transport in primary monolayer astroglial cultures from rat brain (at least 80% pure by immunocytochemistry, Neurosci. Abst. 5, 759, 1979) shows kinetic properties consistent with much of the Cl^- being transported by a mediated process similar to the $Cl^- \leftrightarrow HCO_3^-$ exchange system described for red blood cells and other tissues. In further support of this concept we now find that the rate of efflux of $^{36}Cl^-$ from these cells is less in Cl^- and HCO_3^- free media and is increased when Cl^- or HCO_3^- is added back to the medium. Furthermore, addition of choline chloride to detached cells suspended in a Cl^--free, lightly buffered medium causes alkanization of the medium consistent with either intracellular HCO_3^- or OH^- exchanging with external Cl^-. As previously reported (Neurosci. Abst. 5, 293, 1979), the internal Cl^- concentration of around 30mM in these cells is some 3 times greater than expected from equilibration with an average measured membrane potential of -70mV. Since addition of furosemide, an inhibitor of Cl^- transport in other systems, decreases not only the initial rate of Cl^- uptake but the final steady state Cl^- levels by 3 to 5 fold this high $[Cl^-]_i$ could be a consequence of the Cl^- anion exchange system. Also, comparison of steady state Cl^- levels, measured with $^{36}Cl^-$, in a HCO_3^- buffered and HEPES buffered medium shows that $[Cl^-]_i$ levels were some 20% lower in a HCO_3^- buffered medium, suggesting that uptake of HCO_3^- competed with uptake of Cl^-.

These data indicate that the presence of an anion exchange system, perhaps operating in parallel with a much slower conductive system for Cl^-, results in a higher $[Cl^-]_i$ than expected from passive distribution. In other tissues, however, especially in secretory or absorptive epithelium, there is evidence that active transport of Cl^- involves co-transport with Na^+. In our astroglial cultures, however, the rate of uptake and final steady state levels of Cl^- measured with $^{36}Cl^-$ are unaffected by substitution of choline for Na^+ in the external medium. Also, it appears that Na^+ transport in astroglial cells includes a neutral $Na^+ \leftrightarrow H^+$ exchange system since addition of Na^+ to detached cells in a Na^+-free medium caused acidification of the medium. This acidification was partly inhibited by 10^{-4}M amiloride, as was uptake of $^{22}Na^+$ in cells pretreated with ouabain to raise $[Na^+]_i$. Thus, these studies suggest the presence of neutral homo- and hetero- ion exchange systems in astroglial cells which could have profound consequences on ion transport in the brain without markedly affecting the electric potentials developed across astroglial cell membranes. (Supported by NINCDS grant 13042).

186.6 ORTHOGONAL ARRAYS OF PARTICLES IN FREEZE-FRACTURED HYPOTHALAMO-NEUROHYPOPHYSIAL GLIA: DISTRIBUTION AND RELATIONSHIP TO INTERCELLULAR JUNCTIONS. James D. Hatton and Mark H. Ellisman. Dept. of Neurosciences, U. Calif. at San Diego, La Jolla, CA 92093

Orthogonal arrays of 65A particles have been demonstrated in the plasma membranes of several non-neural cell types. However, their relationship to other membrane specializations has not been carefully studied. Such a study might be especially useful in a system where non-neural cells react to physiological stimuli. Using freeze-fracture techniques, we have investigated membrane specializations of the glia of the hypothalamo-neurohypophysial system of the rat. In the paraventricular (PVN) and supraoptic (SON) nuclei, astrocytes in areas of high neuronal density (i.e., magnocellular regions) display orthogonal arrays of 65A particles solely near gap junctions, suggesting a function associated with the glial syncytium. Astrocytes in areas of lower neuronal density (i.e., parvocellular regions) contain additional arrays on membranes not displaying gap junctions. Arrays are especially numerous on astrocytic perivascular end-feet in both nuclei and on the laminations of the pial-glial limitans ventral to the SON. Ependymal cells near the PVN show arrays both on their lateral surfaces (displaying gap junctions) and their apical surfaces (facing the CSF). Tight junctions are not noted on astrocytes or ependymal cells of the dorsal third ventricle, but are noted on both the somas and myelin lamellae of oligodendroglia. Both of these latter membranes occasionally contain gap junctions as well; however, orthogonal arrays are never noted on oligodendroglia.

Pituicytes are the specialized glial cells of the pituitary which are similar in strucuture to the astrocytes of the CNS. The plasma membranes of pituicytes in the neurohypophysis display gap junctions, complex junctions, and tight junctions. Orthogonal arrays are noted near the first two of these, but not near the last. Arrays in the neural lobe appear in highest densities on membranes adjacent to subpial or perivascular spaces. Pituicyte membrane bearing orthogonal arrays appears infrequently near the neural stalk, increasing towards the distal end of the neural lobe. The distribution of orthogonal arrays in this system, as well as in other systems in which they have been noted, suggests a polarization of membrane activity, possibly providing for "trans-astrocytic" movement of substances.

Supported by NIH grant NS14718 and a grant from MDAA to M.H.E.

186.7 BIOCHEMICAL GENETICS OF GLYCOGEN METABOLISM IN CULTURED GLIAL CELL LINES. C. J. Cummins*, W. D. Lust, and J. V. Passonneau. Laboratory of Neurochemistry, NINCDS, NIH, Bethesda, MD, 20205.

The metabolism of glycogen may be predominantly glial in the mammalian brain. We have employed several glial cell lines to characterize the rate of glycogen formation and breakdown, the activities of the regulatory enzymes, and the role of cyclic nucleotides in glycogenolysis. Five glial preparations are considered: (1) primary cultures of neonatal rat astrocytes (RPA); (2) herpes virus transformed RPA cells, (HSV-TRPA);(3) SV-40 transformed adult mouse astrocytes;(4) & (5) glia derived from methylnitrosourea induced tumors in situ (B9 &B82).

The RPA and HSV-RPA cell lines show essentially the same features of glycogen metabolism: the rate of glycogen synthesis is rapid after feeding, accumulating up to 200 nmoles/mg protein at 2.5 hrs, and thereafter the level of glycogen decreases. The maximal level of glycogen is dependent on both the density of the cultures and the concentration of the extracellular glucose. Active ("a") and inactive ("b") forms of both glycogen synthase and phosphorylase exist, and the ratios of "a" to "b" forms are comparable to rat brain. Agents that increase the levels of cAMP promote the typical features of glycogenolytic cascade: quantitative conversion of phosphorylase "b" to "a", and the rapid degradation of glycogen.

B9, B82, and S22 all exhibit a deficient glycogen metabolism and appear not to accumulate significant glycogen. Phosphorylase activities for the B9 cell line are essentially similar to the HSV-RPA, but the active form of glycogen synthase is essentially absent, implying a defect in synthase phosphatase system. The active form of synthase is also low in in the B82 cell line, and the levels of active and inactive phosphorylase are essentially absent suggesting a pleiotropic effect on the metabolism of glycogen. For the S22 cell line, glycogen synthase activity is essentially similar to the HSV-RPA. However, the phosphorylase is found entirely in the active form. Thus, glycogen does not accumulate because the rate of breakdown exceeds the rate of formation, implying a defect in the phosphorylase phosphatase step.

186.8 INCORPORATION OF ^{3}H-LEUCINE BY A REACTIVE GLIAL CELL POPULATION IN THE LESIONED NEWT OPTIC NERVE. Linda L. Phillips and James E. Turner, Dept. of Anat., Bowman Gray Sch. of Med., Wake Forest Univ., Winston-Salem, NC 27103.

The glial cell population of the newt optic nerve has been shown to react to lesion within 30 minutes after injury (Soc. for Neurosci. Abst. IV:399, '78). This response involves a qualitative increase in filaments and cytoplasmic vesicles which has been associated with glial hypertrophy and lytic enzyme distribution (Soc. for Neurosci. Abs. V:431, '79). The purpose of this study was to determine if the apparent increase in such organelles is accompanied by an increase in amino acid incorporation into the glia. All newts were anesthetized, injected with 50μCi of ^{3}H-leucine (sp. act. 58.5 Ci/mmol.) in 200μl dH_2O and left optic nerves of the experimentals transected. Animals were sacrificed at 30 minutes post-lesion, along with sham-operated and unlesioned controls. Nerves were processed for liquid scintillation spectroscopy and light microscopic autoradiography. Results showed that lesioned and contralateral nerves from experimental animals had a 3.5 fold higher uptake of ^{3}H-leucine at 30 minutes post-lesion than the unlesioned controls (40.53 and 46.53 counts/min/μg protein in experimentals compared to 12.58 counts/min/μg protein in controls). Autoradiographic silver bromide grains were of higher density (41.0 ± 3.5 and 32.0 ± 2.6 grains/$\mu m^2 \times 10^3$) in the central neuroglial core of the lesioned and contralateral nerves than in the neurons of the nerve periphery (16.0 ± 2.7 and 18.0 ± 1.9 grains/$\mu m^2 \times 10^3$) at 30 minutes post-lesion. These central glial grain densities were significantly increased ($p<0.02$) over both sham-operated (11.0 ± 2.2 grains/$\mu m^2 \times 10^3$) and unlesioned (19.0 ± 3.5 grains/$\mu m^2 \times 10^3$) controls, while the peripheral neuronal densities were not different in the experimental and control groups. These results indicate that (1) lesion induces an increase over controls in both uptake and incorporation of an amino acid precursor to protein synthesis and (2) the contralateral optic nerve also reacts to lesion with an increased uptake and incorporation of amino acids during the early stages of Wallerian degeneration. These observations may be correlated with glial filamentous hypertrophy and lysosomal production in the newt optic nerve during the first 30 minutes post-lesion.

186.9 BIOCHEMICAL PROPERTIES OF RAT GLIOMA TRANSPLANTED TO NUDE MOUSE. Y. Noda* and S. Hirano*. School of Medicine, University of Toho, Ohmori, Ohta-ku, Tokyo, Japan.

We studied the biochemical properties of neoplastic glial cells induced primarily in rat cerebral cortex by transplacental administration of ethylnitrosourea. Tumor cells were secondarily transplanted subcutaneously to the nude mouse. 1). The pattern of free amino acid content between the secondary glioma and rat brain cortex showed substantial differences. Glycine and alanine were higher, while glutamate and aspartate were lower in the glioma than in the rat cortex. In addition, the GABA content of the glioma was below our detection limits. 2). The incorporation of ^{14}C and ^{15}N from ^{14}C-U-glucose and ^{15}N-$(NH_4)_2SO_4$, respectively, into free amino acids were determined in secondary glioma and the host brain cortex of the nude mouse. The incorporation of ^{14}C to glutamate was the highest of all amino acids examined in both tissues. Aspartate and alanine were higher in the glioma than in the cortex. Notable incorporation of ^{15}N to glutamine was found in both tissues. A disproportionately high quantity of ^{15}N was incorporated into glutamine as compared to glutamate in the glioma versus the cortex. This indicates that glioma have a higher synthetic activity for glutamine than do neurons. 3). Slices of the secondary glioma tissue showed less oxygen consumption than slices of the cortex, without showing a potassium stimulating effect. 4). The utilization of glycolytic pathways was fundamentally different in the glioma and neuronal tissues. Glioma tissues showed higher activity in the pentose phosphate pathway than in the Embden-Meyerhof pathway.

187.1 CYTOCHEMICAL IDENTIFICATION OF NEURONAL AND NONNEURONAL CELLS IN MIXED AND PURIFIED CHICK EMBRYO RETINAL CULTURES. R. Adler[+], P. J. Magistretti[++*], A. G. Hyndman[+], and W. J. Shoemaker[++]. [+]Dept. of Biology, Univ. of Calif., San Diego and [++]The Salk Institute, La Jolla, CA 92093.

Different retina (NR) monolayer cultures can be generated by appropriate combinations of substrata and media. Cell suspensions from 8-day chick embryo retina undergo considerable clumping before attaching to substrata of low adhesiveness. These "clumped" cultures develop process-bearing (PB) cells with either Horse (HS) or Fetal Calf (FCS) serum, whereas only the latter supports development of "flat" cells, which migrate out of the clumps and generate a confluent carpet. Highly adhesive substrata, on the other hand, allow clump-free and flat cell-free cultures, rich in PB cells. To further extend this characterization as to the neuronal or nonneuronal identity of the cells, these cultures have been analyzed using i) ^{3}H-thymidine (^{3}HT) incorporation, as an indicator of mitotic activity, and ii) tetanus toxin (TT) binding, generally considered a neuronal "marker". Four culture conditions at day 1,3 and 6 in vitro were studied: i) highly adhesive substratum such as a) polyornithine or b) A30-0 collagen (Adler et al, Dev. Biol. 69: 424-435, 1979) in presence of optic lobe extracts, ii) low adhesive substrata, in presence of a) FCS or b) HS. Each dish was incubated with 1 µCi/ml of ^{3}HT. ^{3}HT was washed out 24 hours later and the cultures stained for TT immunofluorescence and processed for autoradiography. Main findings are: i) Neuronal identity of PB cells in clump-free and flat cell-free cultures is indicated by the fact that 100% of them are ^{3}HT(-), and 95% or more are TT(+). A significant number of small, process-free cells appears ^{3}HT(+) after 1 day in vitro, but their number decreases markedly when the labelling is applied at later in vitro stages; ii) After 1 day in vitro, cell clumps present on low adhesive substrata show TT(+) cells as well as ^{3}HT(+) cells both with FCS and HS. In FCS cultures, flat cells emerging from clumps between days 3 and 6 appear always TT(-), and are ^{3}HT(+) in the vast majority of the cases. The presence of ^{3}HT(+) cells within clumps in HS cultures at all the stages examined suggests that flat cell promotion by FCS does not result exclusively from its mitogenic properties. TT(+) PB cells are found within as well as outside cell clumps in both FCS and HS cultures. Preliminary experiments indicate that similar results are obtained when equivalent cultures are prepared using chick embryo optic lobe cell suspensions. Supported by USPHS grant EY-02854 from the National Eye Institute (to R.A.), and by grants from the March of Dimes Birth Defects Foundation (1-691) and NIAAA (AA-34504) (to W.J.S.). P.J.M. is a recipient of a Swiss National Sciences Foundation fellowship.

187.2 NEURONAL "BIRTH" AND DEVELOPMENT IN PURIFIED MONOLAYER CULTURES FROM CHICK EMBRYO RETINA. A. G. Hyndman and R. Adler. Dept. of Biology, Univ. of Calif., San Diego, La Jolla, CA 92093

It is now possible to obtain flat cell-free, purified neuronal cultures from 8-day chick embryo retina. They can be supported by media containing either fetal calf serum, horse serum or the serum-free supplement "N1" (Bottenstein et al., Exp. Cell Res. 125: 183-190, 1980) when cultured on highly adhesive collagen or polyornithine (PORN)--although the latter substratum must be pre-exposed to serum before cell seeding if serum-free medium is used. These different culture conditions were quantitatively compared using as parameters: i) total number of process-bearing neurons; ii) relative numbers of different neuronal classes (types A-F), using a classification based on neuronal polarities, and iii) neuritic development. Different tissue extracts added to the N1 medium, promoted both neuronal survival and neuritic development, without inducing detectable changes in the relative proportion of neuronal classes. When extracts from chick embryo optic lobe or telencephalon were added to the medium, however, a new cell type could be recognized. These "G" cells represent no more than 1% of the total number of neurons, and are characterized by a "super-long" neurite which is some 20-fold longer than neurites from other cell types.

Cultures from 6-day chick embryo retinas contain neurons and "neuroepithelial-like" cells. Autoradiographic analysis of ^{3}H-thymidine-labeled cultures provided evidence that some retinal neurons are "born" in vitro. Short thymidine pulses label almost exclusively the neuroepithelial-like cells, but with longer pulses increasing numbers of process-bearing, neuronal cells also appear labeled. Work is in progress to test the hypothesis, that some neuroepithelial cells undergo a last mitotic cycle, become postmitotic and differentiate as neurons in vitro.
Supported by USPHS grant EY-02854 from the National Eye Institute.

187.3 NEURONAL REPLICATION OF HERPES SIMPLEX VIRUS (HSV) IN VITRO IN THE ABSENCE OF VIRAL THYMIDINE KINASE. R.W. Price and R. Rubenstein*. Lab. of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center, New York, NY 10021.

Accumulating evidence supports the central role of neurons in the survival and spread of herpes simplex virus (HSV) in the human community. Experimental studies in animals have demonstrated that sensory and autonomic neurons are infected by HSV after inoculation of peripheral target tissues, that virus remains latent for prolonged periods in sensory and autonomic ganglia, and that virus in these ganglia can be reactivated. It has been speculated that the viral gene product, thymidine kinase (TK), may be important in latency and reactivation by facilitating viral DNA synthesis in non-dividing neurons in which only minimal (repair-related) DNA synthesis occurs.

In order to determine whether HSV TK is required for viral replication in neurons, we compared replication of a TK deficient viral mutant (TK^-) of HSV type 1 with the parent (TK^+) strain in two in vitro neuronal cell culture systems: 1. dissociated superior cervical ganglion (SCG) neurons, and 2. PC12 pheochromocytoma cells induced to neuron-like differentiation by NGF. In dissociated SCG neurons the kinetics of HSV replication, as judged by cytopathology, viral antigen expression and viral titers, were approximately equal for both the TK^- and TK^+ strains. Addition of the HSV inhibitor acyclovir, which requires the viral TK enzyme for its antiviral action, completely inhibited TK^+ virus replication but inhibited only slightly the TK^- virus. When methotrexate (MTX) was added to the culture medium, replication of TK^- virus was inhibited while TK^+ replication was unaffected. Results of studies of infection of PC12 cells were quite similar. In addition, TK activity was also measured in the PC12 cells during infection. No increase in either viral or cellular TK activity accompanied infection by TK^- virus, while viral TK activity was induced by TK^+ virus.

These results indicate that the metabolic machinery required for viral DNA replication is available or can be induced in isolated neurons, and that viral replication in these cells does not require virus-coded TK. The results of studies with MTX suggest that the de novo pathway involving thymidylate synthetase participates in DNA synthesis under these conditions, but further studies are needed to more precisely clarify both cellular and viral contributions.

187.4 RESPONSE OF SCHWANN CELLS IN VITRO TO ADDITION OF PURIFIED ZONAL FRACTIONS DERIVED FROM RAT CNS TISSUE. L.N. Minier and G.H. De Vries. Biochemistry Dept., Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298.

Previous work from this laboratory and others has indicated that some factor(s) most likely associated with the mammalian axolemma has the ability to induce multiplication within a relatively quiescent population of Schwann cells maintained in vitro. Currently a method is available for the osmotic disruption and subsequent isolation of axolemmal and myelin membranes from brain using continuous sucrose gradients in a zonal centrifuge rotor. The resultant fractions from such a method were employed in efforts to determine the position and nature of a potential Schwann cell mitogen(s) derived from neuronal and/or nonneuronal membranes. White matter from rats of varying ages was homogenized and CNS myelinated axons were obtained utilizing flotation in a buffered salt-sucrose medium (Brain Res. 147:339, 1978). Purified myelinated axons were disrupted by hypotonic shock and were applied to a 20%-50% linear sucrose gradient in a Beckman Ti14 zonal rotor and were centrifuged to equilibrium. Aliquots of the resulting fractions were washed extensively in balanced salt solutions and then were added to cultures of rat Schwann cells for varying periods of time. Dispersed cultures of Schwann cells were obtained by the enzymatic and mechanical dissociation of dissected sciatic nerves from newborn rats. The growth of fibroblasts in these cultures had been arrested by the addition of the antimitotic agent cytosine arabinoside during the early stages of culture. After removal of the drug, tritiated thymidine was added as a single pulse for incorporation by mitotically active cells. The cells, on coverslips, were then processed for light microscope radioautography.

Initial evidence indicated that the addition of purified membranes from the zonal fractions caused a general increase of the mitotic index over control values when a twenty four hour labeling period was employed. Within a certain level of variation, the resting level of unstimulated cells was only half that of cells that had been stimulated by the presence of neuronal and nonneuronal membranes. The morphology of stimulated cells did not appear to be altered during the exposure to the mitotic signal in the culture medium. This is in contrast to the effects produced by the addition of cholera toxin to Schwann cell cultures; this known mitogen caused Schwann cells to assume a more flattened, polygonal shape from their normal bipolar, spindle morphology. (Supported by National Multiple Sclerosis Society Grant FG526A-1 and NIH Grant NS10821).

187.5 DEVELOPMENT OF BENZODIAZEPINE AND GABA RECEPTORS IN MOUSE CNS PRIMARY CELL CULTURE. D.B. Shibla, M.A. Gardell* and J.H. Neale. Dept. of Biology, Georgetown University, Washington, D.C. 20057.

CNS neurons obtained from fetal mice at 13.5-14.5 days of gestation, dissociated mechanically and grown in primary cell culture for three weeks become functionally mature. Receptors for benzodiazepines and GABA develop in both tissue cultured brain and spinal cord. The development of these receptors *in vitro* seems to parallel their development *in vivo*. The binding characteristics of ^{3}H-diazepam (^{3}H-DZP) in membrane homogenates prepared from cultured cells correspond closely with the binding characteristics of this ligand on membrane homogenates prepared from adult tissues. For ^{3}H-DZP binding in adult whole brain the K_D is measured at ~8.4 nM and the B_{max} at ~2.315 fmol/µg protein. The K_D for ^{3}H-DZP binding to cultured brain homogenates is ~8.7nM and the B_{max} is ~3.115 fmol/µg protein. Dissociated cell culture thus provides a model system for the study of receptor development and for a study of the effects of chronic drug treatment on receptor development.

We have evaluated the effects of chronic (1 µM) diazepam exposure to mouse whole brain grown in primary cell culture for three weeks and find no significant change in either the binding affinity of ^{3}H-DZP or the total number of ^{3}H-DZP receptors on these cells. We are currently investigating the effects of chronic diazepam treatment on GABA receptors as well as the effects of long-term exposure to GABA on the development of both benzodiazepine and GABA receptors.

187.6 K^+ - STIMULATED RELEASE OF ^{3}H-GABA FROM PRIMARY MONOLAYER CULTURES. B. R. Pearce*, D. N. Currie*, R. Beale*, G. R. Dutton, R. Hussey* and R. Pigott*. Department of Biology, The Open University, Milton Keynes, MK76AA, UK, and Department of Pharmacology, College of Medicine, University of Iowa, Iowa City, IA 52242.

In order to investigate the release properties of putative neurotransmitter substances from primary monolayer cultures of perikarya isolated from brain regions of the rodent, we have designed and built a novel perfusion apparatus which allows the simultaneous study of efflux from two cultures each grown on 22 mm sq. glass coverslips [apparatus and methodology to be described in detail].

The data obtained demonstrate that in neuron-enriched cultures [85%; Brain Res. 183, 241 (1980)] of cerebellar perikarya which were prelabelled with ^{3}H-GABA, Ca^{+2} - dependent [5 mM] release with K^+ depolarization [50 mM] was observed. This phenomenon was abolished by *cis*-1-3-aminocyclohexanecarboxylicacid [ACHC, 1 mM], a specific inhibitor of neuronal GABA uptake, in the prelabelling medium. In addition, results obtained from different experiments could be pooled, meaned and standard errors calculated. For example, values of $P<0.001$ for the Ca^{+2} - dependent, K^+ - depolarized ^{3}H-GABA efflux [compared to background values] were obtained in three different experiments. Finally, this perfusion apparatus was designed to minimize the perturbing effects of media changes on both cell retention and cell surface disturbances known to cause non-specific release of putative neurotransmitter substances.

This work was supported by a grant from the British MRC [GRD]. B.R.P. was supported by an SRC scholarship. ACHC was a gift of Dr. N. Bowry, St. Thomas' Hospital Medical School, London.

188.1 AN ENERGY DETECTION MODEL FOR AUDITORY THRESHOLD TO PULSE STIMULI. Ronald L. Seaman. Biomedical Research Branch, Engineering Experiment Station, Georgia Institute of Technology, Atlanta, Georgia 30332

A model has been developed for detection of pulse stimuli (e.g., clicks) by the auditory system. The model is based upon energy detection in the frequency domain and is similar in some respects to models of energy detection in the time domain. Input is the frequency spectrum of the pulse stimulus given by its Fourier transform. Frequency-domain formulation has led to a straightforward analysis which shows the dependence of threshold intensity on pulse duration T_p.

The model comprises three separate elements. An ideal filter element with a passband from LF to UF represents the auditory system's frequency range. A detector element uses an absolute-value function as the nonlinear process of detection. An integrator element sums energies of the frequencies from LF to UF. The model's output is this summed energy which represents the response to a pulse input. The response is considered to be threshold when it is equal to a fixed, constant value.

In its simplest form, the model predicts that the relative threshold is a function of only $UFxT_p$, where UF is the upper frequency limit of response. When plotted against $UFxT_p$, there are two distinct regions of the threshold curve which become straight lines on a log-log plot. For small T_p, the slope is exactly -1; for large T_p, approximately -1/5. Transition between regions is gradual and occurs over roughly $0.3<UFxT_p<2$.

This derived threshold trend with $UFxT_p$ matches available experimental data. The shape of the threshold can be used to determine the auditory-system upper frequency limit by using pulse stimuli. This capability may be useful for experimental and clinical measurements.

188.2 ON THE ROLE OF AUDITORY NERVE INTER-FIBER DISCHARGE TIMING IN THE PERCEPTION OF PITCH. M. W. White*, G. E. Loeb, and M. M. Merzenich (SPON: K. Brown). Coleman Memorial Laboratory, UCSF, San Francisco, CA 94143 and Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Evidence for the combined role of temporal and spatial information in the encoding of complex spectral stimuli has been reported (Young, E.D., and Sachs, M.B., J. Acoust.Soc.Am. 66:1381, 1979). Various features of the temporal information might be utilized by the auditory nervous system. We here consider evidence that the auditory system is, in fact, sensitive to inter-fiber timing information and to which normally occurring aspects.

Electrical stimulation of the eighth nerve in cat causes strongly phase locked nerve fiber responses for stimuli up to 6 kHz. However, in frequency discrimination tests, implanted subjects were unable to utilize this phase locked information for frequencies above 500-1000 Hz (Eddington, D.K., Ann. Otol.Rhinol. Laryn. suppl. 53:1-39, 1978). Simmons (Arch. Otolaryng. 84:24-76, 1966) obtained similar results when stimulating a single group of eighth nerve fibers. In contrast, Simmons also discovered that his subject was highly sensitive to small changes in inter-pulse timing if each of the two pulses excited a different group of fibers. Inter-pulse timing changes of only 0.2-0.3 msec were detectable.

A neural network that performs a temporal cross-correlation between inputs from neighboring fibers would be highly sensitive to changes in inter-fiber discharge times. Because inter-fiber timing is a strong function of stimulus frequency and not amplitude (for phase locked frequencies, Greenwood, D.D., Psychophysics and Physiology of Hearing, Ed. E.F.Evans and J.P.Wilson, Academic Press, NY, 1977, pp. 43-54), such a neural network could be useful in pitch perception. In particular, it would be capable of relatively accurate and precise frequency discrimination over a wide dynamic range and in the presence of multiple frequency acoustic stimuli. We will discuss the relationship of this new model of pitch perception to other models and to existing psychophysical and neurophysiological data.

188.3 BRAINSTEM PROCESSING OF AUDITORY INFORMATION TO GENERATE A CENTRAL REPRESENTATION OF PITCH. G. E. Loeb, M. M. Merzenich, and M. W. White*. Coleman Memorial Laboratory, UCSF, San Francisco, CA 94143 and Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

A growing body of psychophysical evidence points to the existence of a central neural representation of the sound frequencies presented to a listener from which a decision about the overall pitch (and, perhaps, location) of the source is made on the basis of pattern recognition (Goldstein, J.L., J.Acoust.Soc.Am. 54:1496, 1973). However, the two existing theories of pitch perception (on the basis of cochlear place or neuronal phase-locked periodicity) cannot generate such a representation without supposing that complicated signal extraction processes such as Fourier analysis, template matching, or auto-correlation are occurring in the first few synaptic relays.

A new theory suggests that pitch could be extracted from the relative timing of activation of pairs of auditory nerve fibers sampling the basilar membrane motion at points some distance apart in the cochlea (White, Loeb, and Merzenich, this session). We here suggest a specific neuronal pathway which could perform the necessary calculation at a single synaptic level and which gives immediate rise to a three dimensional perceptual map function suitable for a pattern recognition determination of the pitches and spatial origins of multiple, simultaneous sound sources over a very wide dynamic range.

The critical requirement is for a convergent neuron capable of detecting the synchronicity of arrival of signals from two basilar membrane sites with a resolution of 10-20 μsec. Neurons capable of such fine temporal detection (cross-correlation) are already known to exist in the medial superior olive (MSO), where they subserve binaural sound localization by inter-aural delay detection. We suggest that the same neurons could actually perform a four-way synchronicity detection by convergence from pairs of anteroventral cochlear nucleus (AVCN) neurons phase locked to equally spaced points of basilar membrane motion in each cochlea. A given MSO cell would then be optimally stimulated by the existence of a certain sound frequency (giving rise to a unique spatio-temporal pattern of basilar membrane motion) at a certain position in space (causing a unique inter-aural delay). Physiological and psychophysical data supporting this notion and other testable predictions of this hypothesis will be discussed along with the implications for the design of an auditory prosthesis.

188.4 RESPONSES OF PRIMARY AUDITORY FIBERS TO COMBINED NOISE AND TONAL STIMULI. C. D. Geisler and D. G. Sinex.* Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706. Responses to tonal stimuli, with and without added noise of different bandwidths, were obtained from anesthetized cat auditory-nerve fibers using glass micropipettes. When low-pass noise with a cut-off frequency at least one octave below best or characteristic frequency (CF) was used, every neuron tested showed a suppression of the tonal response. This suppression did not cause a general reduction of neural responsiveness to all sounds, but rather took the general form of a frequency-specific reduction in the effective intensity of the tonal stimuli. That is, the principle effect of the noise was to shift the position of the rate-intensity curves to higher intensities without changing the shape or magnitude of the curves (cf. Javel, et al. J. Acoust. Soc. Amer., 63:1093, 1978). The suppression mechanism(s) involved thus adjust the sensitivity of these fibers to cover higher intensity ranges in the presence of noise. The frequency of the most severely affected tones was always at or near best frequency, in confirmation of previous work (Kiang and Moxon, J. Acoust. Soc. Amer. 55:120, 1974). The suppression gradually dropped off to zero as the frequency of the tones was decreased. The suppression is a direct but highly nonlinear function of the intensity and bandwidth of the noise. One of the most striking characteristics of the low-frequency noise was its great power: the activity of all neurons were affected by it, with suppressions of up to 40 dB being exhibited by some neurons.

The effects on tonal responses of wide-band noise were quite variable, sometimes causing suppression similar to that induced by the low-pass noise and sometimes causing only "strong-signal capture" effects (Rhode, et al. J. Neurophysiol., 41:692, 1978). By contrast to low-pass noise effects, low-frequency tones often caused suppression of the responses to the wide-band noise alone, particularly in neurons with low rates of spontaneous activity.

A model of noise-induced suppression has been developed. Each sound produces both an excitatory effect that is sharply tuned at best frequency and a suppressive effect that has its lowest threshold at best frequency but is more broadly tuned. The magnitude of the suppression is frequency-dependent, with the greatest effect seen at best frequency. Stimuli near best frequency mainly stimulate excitatory mechanisms, while tones with frequencies either above or below that also cause appreciable and sometimes dominant suppression. The balance between the excitatory and suppressive mechanisms determines the neural response.

Supported by NIH Grants NS-12732 and NS 06195.

188.5 NEUROANATOMICAL MAPPING OF EIGHTH-NERVE FIBER PROJECTIONS FOLLOWING EXPERIMENTALLY-INDUCED COCHLEAR PATHOLOGY. G.K. Martin*, R.P. Wise* and B.L. Lonsbury-Martin (SPON: J.M. Miller). Dept. Otolaryngology, Univ. Washington Sch. Med., Seattle, WA 98195.

In the auditory system, afferent projections from the cochlea have been demonstrated by intracochlear injections of the tritiated amino acids leucine and proline which are taken up by the primary spiral ganglion cells in an unknown manner and label axonal terminals in the cochlear nucleus (CN). The results of these investigations have confirmed and extended the findings of many previous anatomical studies using classical degeneration techniques to describe innervation patterns to the CN. The purpose of the present study was to examine the feasibility of employing intracochlear injections of tritiated leucine to trace the remaining functional cochlear nerve-fiber projections to the cells of the CN following ototraumatic insults to the cochlea. To the extent that uptake of these tracers can be related to cochlear histopathology, these methods provide a powerful means to assess cochlear function in pathological ears. In order to assess the general applicability of autoradiographic tracers in revealing cochlear damage, we studied healthy guinea pigs that received end-organ damage resulting from one of the following experimental manipulations: exposure to intense sound, ototoxic poisoning, or mechanically-induced injury. Following one of these insults, subjects were allowed varying survival periods prior to the intrascalar injection of tritiated leucine. In all cases, the left cochlea of each experimental animal was injected with 50 µCi of [^{3}H] leucine dissolved in 5 µl physiological saline via the round window. Following a 24-hr survival period, animals were deeply anesthetized, perfused with 10% neutral buffered formalin and the brain and cochleas removed. A block of brainstem containing the CN complex was placed in a 30% sucrose solution for complete fixation and then frozen sectioned in the transverse plane. All tissues were processed for standard autoradiography and exposed for 4 wks. Sections were developed, stained, and examined microscopically for the presence of silver grains overlying the CN. All cochlear tissues were processed for midmodiolar sectioning or examined with a plastic embedding technique. All animals showed substantial damage as revealed by absence of projections to CN corresponding to regions of cochlear insult. In the most severely damaged ears that received neomycin poisoning, projections to CN were virtually absent although significant numbers of spiral ganglion cells remained. These preliminary results suggest that unmyelinated dendrites may play a significant role in the uptake of tritiated leucine following intracochlear injection.

188.6 MET-ENKEPHALIN-LIKE IMMUNOREACTIVITY IN EFFERENT NERVE FIBERS IN THE GUINEA PIG COCHLEA. J. Fex and R. A. Altschuler, Lab. Neuro-otolaryngology, NINCDS, NIH, Bethesda, MD 20205.

The distribution of Met-enkephalin-like immunoreactivity in the guinea pig cochlea was determined using the indirect immunofluorescence technique with antisera against Met-enkephalin. Two kinds of preparations were used, I and II. In both I and II, NIH strain guinea pigs were deeply anesthetized and perfused transcardially with 4% paraformaldehyde solution. The cochleae were removed and perfused with the fixation fluid. The bony cochlear spiral was dissected free from surrounding bone and vascular stria. I: The indirect immunofluorescence technique was carried out directly on the cochlear spiral. One to 2 mm segments of the organ of Corti were removed, forming surface preparations, and mounted for observation and photography under epifluorescent and ordinary illumination. II: The cochlear spiral was mounted in OCT and 10 micron cryostat sections were cut to give cross sections of the organ of Corti. The sections were incubated for immunofluorescence, observed and photographed.

Met-enkephalin-like immunoreactivity was found in unmyelinated fibers in the fascicles of the intraganglionic bundle immediately peripheral to the spiral ganglion. In the organ of Corti, the immunoreactivity was found in fibers of the inner spiral bundle and tunnel spiral bundle, in low tunnel crossing fibers and as patches at the bases of inner and outer hair cells.

We conclude that the cochlea of the guinea pig contains Met-enkephalin-like immunoreactivity in efferent nerve fibers. We have no evidence that hair cells or auditory nerve fibers contain any Met-enkephalin-like substance.

188.7 CENTRAL TERMINATIONS OF FUNCTIONALLY IDENTIFIED AUDITORY AND VESTIBULAR AFFERENTS. Hironori Koyama*, E. L. Leverenz*, R.A. Baird, and E.R. Lewis. Electronics Research Laboratory, University of California, Berkeley CA 94720.

After functional identification, individual afferent fibers from the auditory and otoconial organs of the bullfrog inner ear were injected iontophoretically with the fluorescent dye Lucifer Yellow and traced to their central terminations. The results to date are consistent with those of previous projection studies of auditory and vestibular populations in the frog (Gregory, K.M., Brain Behav. Evol. *5*: 70-88, 1972; Matesz, C., Neuroscience *4*: 2061-2071, 1979; Nieuwenhuys, R. & Opdam, P., in Frog Neurobiology (Springer): 811-855, 1976; Fuzessery, Z.M. & Feng, A.S., Soc. Neurosci. Abstr. *5*: 141, 1979), but refine the resolution to that of individual, functionally identified afferents. Three functional classes have been identified: auditory (responding to airborne sound), vibratory (responding to substrate-borne vibration), and vestibular (responding to head position, linear acceleration). Auditory afferents (from the amphibian and basilar papillae) and vibratory afferents (from the saccular macula and the striola of the lagenar macula) project to the dorsal medullary lobe. Vestibular afferents (from the utricle and the lagena) project to the cerebellum and to the medulla just ventral to the dorsal medullary lobe.

The central projections of the amphibian papilla occupy the lateral side of the dorsal medullary lobe in the immediate vicinity of the VIIIth nerve, and extend no more than 0.5 mm along the rostral-caudal axis. The projections of the basilar papilla units occupy the dorsal region of the dorsal medullar lobe, generally medial to the projections of the amphibian papilla, and extend approximately 1.5 mm caudally from the level of the VIIIth nerve. The projections of vibratory afferents occupy the lateral side of the dorsal medullary lobe, just ventral to the projections of the amphibian papilla, but extend well beyond them (approximately 2 mm) caudally from the level of the VIIIth nerve. Projections of the lagenar vestibular afferents occupy a region of the medulla immediately ventral to the projections of the vibratory fibers and immediately dorsal to those of the utricular afferents. Both lagenar and utricular vestibular projections extend approximately 4 mm caudally from the level of the VIIIth nerve and rostrally to the cerebellum. No afferent fibers of any type were found to project to the contralateral side.

188.8 HORSERADISH PEROXIDASE DEMONSTRATION OF MOTONEURONS TO THE STAPEDIUS MUSCLE IN THE RHESUS MONKEY. Norman L. Strominger, Steven M. Silver*, Timothy C. Truscott and Jerome C. Goldstein*, Dept. of Anatomy and Division of Otolaryngology; Albany Medical College of Union University, Albany, New York 12208 and Samaritan Hospital Troy, New York.

The stapedius muscle was exposed in a series of rhesus monkeys using an endaural transmastoid approach with the aid of an operating microscope. The incus and head of the malleus were removed for better visualization of the contents of the middle ear. Horseradish peroxidase (20%-50%; Sigma Type VI) was injected into the stapedius through a micropipette. Dried flakes of the enzyme also were tattooed into the muscle belly in some cases. Animals were perfused transcardially 2-3 days postoperatively with 0.9% saline followed by 8% gluteraldehyde. Tetramethyl benzidine was used as the chromagen in the last several cases. Sections, cut in one of the three major planes were counterstained with neutral red or thionin.

After initial experiments demonstrated the completely ipsilateral disposition of stapedial motoneurons, subsequent cases were done bilaterally. A total of 20 muscles were injected. Labeled perikarya were located in the tegmentum immediately surrounding the facial nucleus. In some cases labeled cells occupied the facial nucleus itself; our data indicate that this was due to uptake of enzyme by fibers of the facial nerve. Labeled perikarya often were located in the tegmentum a distance superior to the facial nucleus along the course of the facial roots. Occasional cells were located at the interface between the rostral end of the facial nucleus and the lateral superior olivary nucleus.

188.9 AUTORADIOGRAPHIC DEMONSTRATION OF EIGHTH NERVE PROJECTIONS IN RANA PIPIENS. Peter G. Aitken. Section of Neurobiology and Behavior, Division of Biological Sciences, Cornell University, Ithaca, N.Y. 14853

Approximately 10nL of tritiated proline solution (25uC/uL) were injected into the left eighth nerve ganglion of each of 5 Rana pipiens. Postinjection survival at 18°C was for 48 hrs (2 frogs), 72 hrs (1 frog), or 96 hrs (2 frogs). Paraffin-embedded brains were sectioned frontally (3 frogs) or horizontally (2 frogs) at 15u, mounted on slides, and coated with Kodak NTB-3 emulsion. Exposure at 4°C was for 45 days (1 frog) or 28 days (4 frogs). Slides were developed in Kodak D-19 and lightly stained with cresyl violet. The results described were essentially identical in all animals.

The labeled region, as determined by microscopic examination under both dark- and brightfield illumination, was limited to one contiguous area ipsilateral to the injected nerve, extending from slightly caudal to the entry of nerve X to the ventrolateral portion of the cerebellar granular layer; projections covered the caudal, ventral, and dorsal nuclei of nerve VIII described by other authors. At their caudal limit, projections formed two separate, thin bands bordering the fasciculus solitarius on its medial and dorsolateral edges. More rostrally, the bands enlarged, fused, and extended dorsally to become limited by the pial surface laterally and the ventricle medially. Ventrally, the projections were limited by the fasciculus solitarius, descending spinal tract of nerve V, and a line drawn from the fasciculus solitarius to the sulcus limitans. Rostral to the entry of nerve VIII, the ventral boundaries seemed to be the sensory nucleus and descending tract of nerve V; these boundaries were difficult to determine exactly because the limits of the labeled region were less sharp than was seen more caudally. Projections continued into the cerebellar peduncle, cerebellar nucleus, and the ventrolateral portion of the cerebellar granular layer, i.e., that portion bordering the cerebellar nucleus.

No projections were seen to the superior olive, contralateral cerebellum, cerebellar molecular layer, reticular formation, spinal nucleus of nerve V, or motor nuclei of any cranial nerves.

This research was supported by an N.I.H. Postdoctoral Fellowship and by N.I.H. Grant NS-09244.

188.10 EFFERENT INNERVATION OF THE ORGAN OF CORTI: ASSYMETRICAL TOPOGRAPHIC PROJECTIONS. John J. Guinan Jr. and W. Bruce Warr. Eaton-Peabody Lab., Mass. Eye and Ear Infirmary, Boston, MA 02114, and The Boys Town Institute for Communication Disorders in Children, Omaha, NE 68131

Warr and Guinan (1979, Brain Res. 173:152-155) have shown that olivocochlear cells in the lateral part of the superior olivary complex (LSOC) project bilaterally to the region under inner hair cells, whereas olivocochlear cells in the medial part of the superior olivary complex (MSOC) project bilaterally to the region under outer hair cells. We have used the same anterograde tracing methods (brainstem injections of 35-S-methionine followed by cochlear autoradiographs) to compare the projection patterns along the length of the organ of Corti of injections centered in different parts of the LSOC and MSOC.

LSOC injections show a clear ipsilateral topographic projection with more medial injections producing patterns of silver grains located more basally in the cochlea. A comparison of the tonotopic organizations of the cochlea and LSOC periolivary cells shows that this ipsilateral olivocochlear projection appears to connect regions of similar best frequencies. On the other hand, all of our LSOC injections produced silver grain patterns in the contralateral cochlea which were predominantly in the apex. Warr (1975, J. Comp. Neurol. 161:159-182) found that LSOC olivocochlear neurons which projected to the contralateral cochlea were located in the lateral part of the LSOC; some spread of injected 35-S-methionine to this lateral part of the LSOC occurred in all of our LSOC injections. Since both the apex of the cochlea and the lateral part of the LSOC are "low frequency" regions, the projections of LSOC olivocochlear neurons to the contralateral cochlea might also be between regions of similar best frequencies.

MSOC injections produced silver grain patterns which ranged from widespread distributions which were fairly symmetrical in both cochleas to distributions which were concentrated in a narrow region of one cochlea and were widespread in the other cochlea. We have not yet found a clear pattern of topographic projections from the MSOC to either cochlea.

188.11 INTRACELLULAR RECORDING AND STAINING IN CAT COCHLEAR NUCLEUS. W. S. Rhode*, P. Smith and D. Oertel. Dept. of Neurophysiology, University of Wisconsin Medical School, Madison, Wisconsin 53706.

Cells in cat cochlear nucleus (PVCN, DCN) were studied electrophysiologically and stained with horseradish peroxidase. Units were usually characterized extracellularly by their characteristic frequency (CF), threshold at CF, poststimulus time histogram (PST) for a 25 ms tone at CF, interval histogram, rate curve and response area when conditions permitted. A current pulse was used to enter the cell and intracellular responses were recorded to swept frequency tones. PST responses were used to classify cells according to the categories of Pfeiffer (Exp. Brain Res., 1:220, 1966).

An octopus cell (Osen, J. of Comp. Neurol., 136:453, 1969) exhibited a marked onset component followed by a slow sustained discharge. Small bipolar cells (8-9 μm) were sustained choppers and capable of discharge rates of 800-900 /s. Fusiform cells showed transient chopping or pausing responses. Giant cells (DCN) did not respond to auditory stimuli probably due to barbiturate anesthesia (E. F. Evans and P.G. Nelson, Exp. Brain Res., 17:402, 1973).

Many units exhibited chopper behavior. Sustained choppers were most often found in the PVCN and transient or weak choppers in the DCN. The latter exhibited lower maximum discharge rates and no tendency to phaselock to low frequency tones. Nearly every possible combination of PST types have been seen: onset-chopper, buildup-chopper, and pause-builder-chopper implying that categories based on PSTs are not always clear.

Supported by N.I.H. grant NS12732.

188.12 OBSERVATIONS ON TONOTOPIC ORGANIZATION WITHIN THE RAT SUPERIOR OLIVARY COMPLEX AND COMPARISONS TO HIGHER AUDITORY STRUCTURES USING 2-DEOXY-D[1-^{3}H] GLUCOSE. J. Coleman, W.J. Clerici, A. Ryan*, A.J. Beitz, J. Buggy, and M.N. Huhns*. Dept. of Psychology, and Depts. of Physiology and Anatomy, School of Medicine, and College of Engineering, Univ. of South Carolina, Columbia, SC 29208.

Tonotopic organization is believed to occur at numerous locations within the central auditory pathways. This may be construed as a multiple representation of the basilar membrane in which divergence or convergence of information can be emphasized in particular brain areas. In the present study, the labeled 2-deoxyglucose method was used to investigate selected auditory regions where binaural processing is believed to occur. Awake restrained male albino rats catheterized 24 hr previous were monaurally or binaurally presented with constant pure tone stimuli at 1, 2, or 8 kHz at various intensity levels. Animals were given intravenous injections of 2-deoxy-D[1-^{3}H] glucose, sacrificed 45 min later, and the brain removed in unperfused or perfused cases. Frontal or parasagittal sections 15-30 μm thickness were exposed to X-ray film and later stained with thionin. Differential optical densities observed could be validated and quantified using a computer image processing system.

Major subdivisions of the superior olive complex, inferior colliculus, medial geniculate body and auditory cortex showed preferential activity to pure tone stimulation. Little or no distinctive activity was observed in controls with ears plugged. A prominent focus of activity occurred in the caudal part of the lateral superior olive (LSO) adjacent to the facial nerve. At 1 kHz, this activity was concentrated in the ventrolateral tip of LSO; 8 kHz stimulation produced maximal activity at the dorsal hilus of LSO. There was a greater response to binaural than monaural stimulation at the same intensity levels. The medial nucleus of the trapezoid body showed a band of activity at the dorsal or dorsolateral margin to 1 kHz stimulation and deeper bands to more intermediate frequencies. Diagonal banding observed in the superior paraolivary nucleus appeared particularly prominent at 8 kHz. The darkest bands in the auditory system appeared in the inferior colliculus. Multiple bands were observed in the medial geniculate body including the ventral and dorsal nuclei. Active bands observed in cortex including the primary area varied in width and depth. Results indicate selective banding patterns to pure tones at major levels of the auditory system and suggest potential for parallel and convergent processing. (Supported by NIH AG-1571).

188.13 AN EVALUATION OF THE ORIGINS IN THE BRAIN STEM OF THE SHORT LATENCY AVERAGED AUDITORY EVOKED RESPONSES IN THE ANAESTHETIZED DOG. S. J. Whidden* and R. W. Redding*(SPON: B. L. Bird)
School of Veterinary Medicine, Auburn University,Auburn,AL.36830

The origins in the brain stem of the short latency averaged auditory evoked responses in the anaesthetized dog were evaluated by surgical ablation(under visual control) of parts of the brain stem. Five normal adult dog's short-latency(<8msec) auditory evoked responses (A.E.R.) to clicks (70 dB S.P.L.) were recorded(512 averaged) after aspiration of different brain stem structures. Ten clicks per second were presented monaurally to the right ear and recordings were amplified, filtered(.32 Hz-3.2kHz), and averaged (512). These auditory evoked responses were analyzed statistically and assimilated into different models for each population after a given surgical procedure.The surgical suboccipital approach to the brain stem was used to expose the caudal aspect of the cerebellum, the dorsal aspect of the medulla and the fourth ventricle. The head was flexed nearly at a right angle to the cervical vertebrae. Bilateral precollicular decerebration was carried out by aspiration of both medial geniculate bodies rostral to the superior colliculi. Midbrain and later rostral medulla were aspirated,as well as the cochlear nucleus. After each of these lesions, a subsequent successful recording was obtained in all five of the manipulative surgical groups.

The results indicate that medial geniculate aspiration produced a decrease in amplitude of Wave IV, while WaveV remained nearly constant, and Wave VI was not clearly visible. With caudal colliculus aspiration, Wave IV seemed to decrease in amplitude , while Wave V was not clearly visible . With most of the brain stem removed, Wave III was not discernible. With the complete aspiration of the brain stem only Wave I remained in a reduced state. Based on these results it is possible to propose general locations for the generation of these potentials in the dog.

188.14 THE DISTRIBUTION OF ACTIVITY IN THE AVIAN AUDITORY SYSTEM TO MONAURAL SOUND STIMULATION EXAMINED WITH [14C]2-DEOXY-D-GLUCOSE AUTORADIOGRAPHY. W.R. Lippe* and R.B. Masterton. Depts. of Otolaryngology and Neurosurgery, Univ. of Virginia Medical Center, Charlottesville, Virginia 22908.

The laterality of auditory input at each level of the avian auditory system was studied using [14C]2-deoxy-D-glucose (2-DG) autoradiography. One to three week old chicks sustained unilateral basilar papilla removals. Three to seven days later they received injections of [14C]2-DG (16 μCi/100gm., IV) and were immediately exposed to 90 dB (SPL) broadband white noise stimulation. After 45 minutes of sound exposure they were sacrificed and autoradiographs were prepared from cryostat-cut frozen sections according to the procedure of Sokoloff et al. (J. Neurochem., 1977, 28, 897). The autoradiographs were then examined to determine the relative amount of 2-DG uptake contralateral vs ipsilateral to the remaining ear throughout the auditory system.

The distribution of 2-DG indicates that each hindbrain auditory structure except n. laminaris receives entirely or predominantly monaural input. In n. angularis, n. magnocellularis and the superior olive, the uptake of 2-DG occurs ipsilateral to the normal ear whereas in the nuclei of the lateral lemniscus there is uptake contralateral to the normal ear and only slight uptake ipsilaterally. In contrast, 2-DG uptake in n. laminaris occurs bilaterally and correlates with the known spatial segregation of afferent input to this structure (Lippe, Steward and Rubel, Brain Res., 1980, in press).

In contrast to hindbrain auditory structures, 2-DG uptake in midbrain and forebrain structures indicates that these structures receive binaural input which is only slightly dominated by input from the contralateral ear. In MLd ('inferior colliculus'), n. ovoidalis ('medial geniculate') and Field L ('auditory cortex'), the general pattern of 2-DG uptake is similar: the uptake is bilateral with only a slightly greater amount contralateral to the normal ear. The districution of 2-DG within MLd also suggests the presence of subfields in this structure which differ in dominance of binaural vs monaural input. This suggestion is further supported by the finding that pure tone stimulation results in high levels of 2-DG uptake at several separate areas within MLd.

188.15 INGENIOUS USE OF PHASE BY THE OWL AUDITORY SYSTEM. Andrew Moiseff and Masakazu Konishi. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

A class of cells in owl's midbrain auditory nucleus (MLD) is known to respond to sounds from restricted regions of space. These cells have small spatial receptive fields, and are arranged anatomically to form a "neural map" of auditory space. We have exploited the organization of these cells to examine the role of interaural-time, -phase, and intensity differences in the extraction of directional information from sound. In this study we combine free-field and dichotic sound stimuli.

Single units were recorded with glass insulated Pt-Ir microelectrodes. The receptive fields were mapped using a free-field loudspeaker. Threaded plugs containing miniature speakers were then inserted into threaded tubes previously implanted into the ear canals allowing the presentation of dichotic stimuli. The phase of tone (in the range of 6-8 kHz) or noise stimuli delivered to each ear was varied, keeping intensity and arrival time constant, and the number of spikes resulting from each stimulus counted.

The results indicated that the responses of all MLD cells with restricted receptive fields varied as a function of interaural-phase differences. For example, cells with frontal receptive fields preferred zero phase difference between the two ears, whereas, cells having lateral receptive fields preferred the phase of the signal delivered to the ear contralateral to the receptive field to lag behind the signal delivered to the ipsilateral ear. The magnitudes of the preferred phase differences, which were within the physiologically relevant range, were correlated with the azimuth of the receptive fields. These data indicate that the owl auditory system is capable of using interaural-phase differences to determine the direction of high-frequency sounds.

(Supported by a Helen Hay Whitney Postdoctoral Fellowship to A.M., and NS 14617 to M.K.)

188.16 THE EFFECTS OF INTERAURAL TIME DELAY ON HIGH FREQUENCY CELLS IN THE CAT INFERIOR COLLICULUS. S. Kuwada*, T.C.T. Yin, and Y. Sujaku*. Dept. of Neurophysiology, University of Wisconsin Medical School, Madison, Wisconsin 53706.

A classical view of sound localization is that interaural time differences are the salient cue in the localization of low frequency (≲1500 Hz for humans) signals along the azimuth whereas interaural intensity differences are important in localizing high frequency stimuli. For sinusoidal tones the psychophysical, physiological and acoustical findings provide strong support for this duplex theory. However, results of recent psychoacoustical studies suggest that interaural time differences may also play a role in localizing high frequency signals. Human listeners in a dichotic situation can reliably lateralize complex high frequency signals (e.g. amplitude modulated) on the basis of interaural time differences alone.

We report here preliminary data on high frequency sensitive neurons in the central nucleus of the inferior colliculus (IC) which support the contemporary psychoacoustical findings. Platinum-and gold-plated microelectrodes were used to record extracellular single cell activity in barbiturate anesthetized cats. The stimulus to both ears was a train of high frequency sinusoidal tones which were gated on and off rapidly with a trapezoidal envelope. The carrier frequency was chosen to be within the response area of the neuron under study and the frequency (100-500 Hz) of the envelope was controlled by specifying the on-off time. The stimuli to both ears were identical except that the onset of the train to one ear was delayed in steps with respect to the other ear. The response of high frequency sensitive (>3000 Hz) IC neurons to such a stimulus was a cyclic function of interaural delay with a period corresponding to that of the envelope frequency. This response pattern closely resembles the commonly seen cyclic response of low frequency sensitive neurons to changes in interaural delay at the period of the stimulating frequency when pure tones are employed. Control experiments in which the carrier frequency was varied over a wide range demonstrated that these neurons were indeed sensitive to the high frequency component of the signal.

These data suggest that high frequency sensitive neurons are sensitive to changes in interaural time delay in a manner similar to their low frequency counterparts. These results are in accord with the recent psychoacoustical experiments demonstrating that time cues also play a role in the localization of high frequency signals.

188.17 THE INFERIOR COLLICULUS OF MICE SUSCEPTIBLE TO AUDIOGENIC SEIZURES STUDIED WITH 2 DEOXYGLUCOSE AUTORADIOGRAPHY OR MULTIPLE UNIT RECORDINGS. J.F. Willott, N. Mogharreban*, and S.M. Lu*. Dept. of Psychol., Northern Illinois Univ., DeKalb, IL 60115.

Previous lesion-behavior studies have shown the inferior colliculus (IC) to be critical for the occurrence of audiogenic seizures (AGS) in mice. The present study therefore employed [^{14}C] 2-deoxyglucose (2DG) autoradiography or electrophysiological (multiple-unit) records to examine neural activity in the IC of two inbred mouse strains--the DBA/2 strain (susceptible to AGS) and the C57BL/6 strain (AGS resistant). For autoradiography, a 21-day-old mouse was injected with 5μCi 2DG and decapitated 20 min. later. The brain was removed, frozen, and sectioned in a cryostat. Subjects were DBA mice that had AGS induced (either wild running attacks only or full tonic convulsions) by exposure to intense broad band noise shortly before decapitation; C57 mice matched for noise exposure; mice of both strains exposed only to ambient sounds (in a glass chamber); and anesthetized mice of both strains, noise-exposed or exposed only to ambient sound.

In unanesthetized C57 mice, all IC nuclei were generally well labelled in both ambient sound- and noise-exposed animals. In DBA mice, the ventral portion of the central nucleus (ICC) showed limited uptake of 2DG irrespective of the occurrence or severity of AGS or acoustic conditions. Beneath the area of reduced uptake was a band of activity along the ventral IC border. Uptake of 2DG was also reduced in the external nucleus in DBA mice. Anesthetized mice showed reduced 2DG uptake, but noise exposure was associated with some increased labelling.

Multiple-unit records, obtained using high intensity stimulation in lightly anesthetized mice, found neurons showing abnormal afterdischarges (ADs) in the DBA IC (ADs have been correlated with susceptibility to AGS in previous studies). Most AD neurons were located near the area of transition to reduced 2DG uptake seen in the ICC of DBA mice. However, even here, the incidence of neurons displaying ADs was rather low.

These results indicate that (1) Although there are hyperactive (AD) neurons in the IC of DBA mice, there is not an abnormally high overall level of neural activity associated with AGS, as indicated by 2DG uptake. It appears that AD neurons comprise a relatively small subpopulation of IC neurons. (2) In DBA mice, the lack of difference in IC activity as a function of AGS suggests that paroxysmal activity associated with AGS arises in areas to which the IC projects, not within the IC itself. (3) The concentration of AD neurons in the ICC near the area of reduced 2DG uptake is consistent with previous studies showing a relationship between partially impaired sensitivity of the auditory system and susceptibility to AGS.

188.18 AUDITORY CENTERS IN THE ELASMOBRANCH BRAIN: DEOXYGLUCOSE LOCALIZATION AND EVOKED POTENTIAL RECORDING. Jeffrey T. Corwin and R. Glenn Northcutt. Dept. Neurosci., Sch. of Med., and Scripps Inst. Oceanogr., U.C.S.D., La Jolla, CA and Div. of Biol. Sci., Univ. of Michigan, Ann Arbor, MI.

An evolutionary branch point that appeared 400 million years ago is the most recent ancestral link between the elasmobranchs and all of the more modern jawed vertebrates. Yet, these groups still share many bodily traits. Some of the shared traits might be results of recent convergent evolution, but theory holds that the common characters that are widely distributed throughout these groups are most likely hereditarily linked through ancient ancestral forms. Therefore, by studying systems in elasmobranchs and comparing them to systems in other vertebrates we can infer the age of certain traits and some aspects of the primitive systems from which they arose.

In this inferential manner we have begun to approach the early evolution of the vertebrate auditory nervous system by investigating the brain of a modern elasmobranch, Platyrhinoidis triseriata. Candidate acoustic centers were identified through autoradiography of frozen sectioned brains from rays which had received ^{14}C-2-deoxy-D-glucose intravenously at 0.2 μCi/gm body wt. Following injections animals were exposed to 90 minutes of either intermittent airborne noise bursts or silence in a sound isolation chamber. Clear experimental increases in radioactivity were observed in the anterior and descending octaval nuclei of the medulla and a mesencephalic nucleus believed to be the torus semicircularis. Less distinct increases were apparent in the cerebellar auricles, the medial diencephalon, and the telencephalic dorsal pallium.

The electrical activity of these centers was then investigated through field potentials evoked by airborne clicks at +45 dB re 1 μbar. The prussian blue marking technique was used in the direct histological verification of recording sites. These experiments confirmed the acoustic activity of the medullary, cerebellar, and mesencephalic centers identified in autoradiography, but the forebrain centers have not yet been confirmed. In summary, this elasmobranch has specific auditory relay centers in at least the medulla and the midbrain. These appear to be partially separate from vestibular and lateral line centers and at least partially homologous to auditory relays in other vertebrates. While the auditory brainstem has been modified in many groups, these results suggest that the basic relay centers may already have existed 400 million years ago.

188.19 EFFERENT PROJECTIONS OF THE VENTRAL NUCLEUS OF THE LATERAL LEMNISCUS: AN AUTORADIOGRAPHIC STUDY. D.L. Griffith*, M.H. Cooper, and L.C. Massopust. Departments of Anatomy and Otolaryngology, St. Louis University School of Medicine, St. Louis, MO 63104.

The efferent projection system of the ventral system of the lateral lemniscus was investigated in the laboratory rat (Rattus norvegicus albinos) using an autoradiography technique. Tritiated leucine at a concentration of 50 μ Curies/μl was injected iontophoretically into the ventral nucleus of the lateral lemniscus (VNLL) of rats weighing between 290-325 grams with a micropipette which had an opening at its tip of approximately 70 μm. Following a survival period of five days the rats were intracardiacally perfused and the brains were processed for autoradiography according to the method of Cowan et al. (1972). The sections stained with cresyl violet acetate were studied under light field illumination for the topography of nuclear arrangement and under dark field illumination for the course and terminations of the efferent projection system of the VNLL.

Axons from the VNLL projected to a variety of structures both rostrally and caudally to the ejection site as well as to structures at the same level. Rostrally axons either ascended ipsilaterally in the lateral lemniscus or crossed the midline through the reticular formation to the contralateral lateral lemniscus. Terminal fields were present in the dorsal nucleus of the lateral lemniscus, inferior colliculus, and medial geniculate nucleus of both sides. The concentration of reduced silver grains was more prominent in the ipsilateral structures than in the contralateral structures. Within the dorsal nucleus of the lateral lemniscus the terminal fields were divided into two distinct zones, one dorsal and the other ventral. Caudal to the ejection site descending axons project to the cochlear nucleus of both sides. These axons reached the cochlear nucleus by traversing the reticular formation dorsally as well as ventrally. Labelled axons were also present in a separate group which was placed ventral to the reticular formation. At the level of the ejection site labelled axons crossed the midline through the reticular formation to the contralateral ventral nucleus of the lateral lemniscus.

188.20 FOREBRAIN MECHANISMS IN SOUND LOCALIZATION: THE ROLE OF THE MEDIAL GENICULATE. Peter W. Judge* and Jack B. Kelly. Department of Psychology, Carleton University, Ottawa, Ontario, Canada, K1S 5B6.

Previous studies of sound localization by the rat have shown that large bilateral lesions of auditory cortex fail to produce the severe deficit in performance expected from studies of other species such as dog, cat or monkey (Kelly, J.B., Neuroscience Abstracts, 4:7, 1978). Even though auditory cortex is not essential for sound localization in the rat, it is possible that this function is mediated by other forebrain projections, for example, from medial geniculate to subcortical structures. In order to further clarify the role of the forebrain in sound localization, the effects of bilateral lesions of the medial geniculate were examined. Brain damaged and normal rats were trained to localize sounds in space in a two choice maze with variable speaker positions. Tests were carried out with speakers separated by 180 or 60 degrees and included single presentations of short duration noise pulses at the beginning of each trial. The stimuli contained either a broad band of frequencies (2kHz-32kHz) or narrow bands of high or low frequencies (around 32kHz or 2kHz). Histological analysis of brain damaged animals revealed massive lesions of the medial geniculate nucleus in every case. Damage to midbrain structures was minimal. The extent of damage to other forebrain structures such as hippocampus or other thalamic nuclei was variable from animal to animal. Pronounced deficits in performance were found especially under conditions of high frequency localization. Deficits were also noted under other stimulus conditions. However, with broad band and low frequency stimuli high levels of performance were found in spite of large lesions of the medial geniculate in a number of individual cases. These results indicate that while the medial geniculate is not essential for sound localization in the rat, deficits following forebrain lesions may be revealed under appropriate stimulus conditions.

188.21 GIANT SPINE-POOR PYRAMIDAL CELLS IN AUDITORY CORTEX OF YOUNG AND AGED CATS. Anne S. Kaplan and Arnold B. Scheibel. Brain Research Inst. and Dept. of Anatomy, University of California, Los Angeles, CA 90024.

In studying the auditory cortex of aged (12-18 years) cats, we have discovered a population of unusually large and spine-poor pyramidal cells. These have been found in Golgi-stained, 120 μ thick coronal sections of the mid-ectosylvian gyrus, and in adjacent 10 μ thick Nissl-stained sections. The auditory giant pyramids (AGPs) are comparable in size (750-2600 μ^2 in cross-sectional area; 40-75 μ high by 20-25 μ wide) to the Betz and Meynert (1,2) cells of motor and visual cortices. Like these other giants, AGPs are found sparsely distributed in Layer V. In Golgi sections, each AGP has a wide skirt of basilar dendrites, and sends a thick (6-8 μ), mostly unbranched apical dendrite towards the pial surface. This shaft bifurcates in Layer III. Unlike Meynert cells, which are found in primary receptive cortex, AGPs are found most frequently in the auditory association areas AII and SF (suprasylvian sulcus).

Surprisingly, these AGPs are essentially spine-free. For example, they have fewer than 10 spines between the origin and bifurcation of the apical shaft, a distance which may exceed 400 μ. Cells of similar morphology, but with spiny apical shafts (25-250+ spines), invariably have smaller somata (400-850 μ^2).

In young adult cats (1.5-2 years), AGPs may also be found. There are fewer AGPs in young than in old cats, as confirmed by blind counts of giant somata in Nissl-stained sections. Also, the inverse relationship between size and spininess is less absolute in the young cat: occasional spiny giants (800-1000 μ^2) are found, and even the largest AGPs may be somewhat spinier than their aged counterparts. Most young cells having the dendritic morphology of the AGPs are densely spined, but have surprisingly small somata (200-550 μ^2).

The dendritic arrays of giant cells in both young and old cats are quite lush and extensive, and are free of the nodularities and distortions which typify dying neurons (3). Thus, the unique spine-free nature of the AGPs and their increase in number with age, does not seem to indicate an absence of viability.

188.22 FREQUENCY ORGANIZATION OF AUDITORY CORTEX IN THE GREATER GALAGO. K.A. FitzPatrick, C. Welt, J.F. Brugge, T.A. O'Conner and B. Sprague*. Dept. of Neurophysiology, Waisman Center, Univ. of Wisconsin, Madison, Wisc. 53706.

Microelectrode techniques have been used to map the frequency organization of the auditory cortex of the greater galago (Galago crassicaudatus). Best frequencies of neurons and neuron clusters were recorded under sodium pentobarbital anesthesia. Their distributions were reconstructed in serial histological sections stained by the Nissl method. Auditory responsive cortex extends from the lateral surface of the superior temporal gyrus into the lateral fissure. It occupies much of the superior temporal plane in this prosimian. A primary field (AI) is present occupying a part of the dorsal and lateral surfaces of the superior temporal gyrus. Area AI contains a complete representation of the basilar membrane with low frequencies represented rostrolaterally and high frequencies caudomedially in the field. Another complete frequency representation is found posterior to AI in the posterolateral field (PL). Here low frequencies appear laterally whereas high frequencies are found medially contiguous with the representation of the highest best frequencies in AI. A rostral field (R) lies anterior to AI. We have mapped only a partial representation of the membrane in R. Its low frequency representation is contiguous with that in AI. Higher best frequencies (up to 12 kHz) are represented progressively more rostrally within R. The caudomedial field (CM) lies medial to AI and PL deep on the superior temporal plane. Its border is marked by a gradual or abrupt decline in best frequency from the highs which predominate at the medial sides of both AI and PL. Both high and low best frequencies are present in CM, but no obvious frequency organization is present. A few auditory responsive cells are encountered lateral to AI on the gyral surface. No particular frequency organization is evident. Fields AI, R, PL and CM appear to be homologous to areas completely or partially mapped in the rhesus and owl monkeys (Merzenich and Brugge, '73; Imig et al., '77).

188.23 TONOTOPIC ORGANIZATION AND DENDRITE ORIENTATION IN PRIMARY AUDITORY CORTEX OF THE RABBIT. E.M. Glaser and N.T. McMullen, Dept. of Physiol., Univ. of Maryland Sch. of Med., Baltimore, Md. 21201

We have been studying the frequency map in rabbit auditory cortex in order to determine whether its topography is related to the spatial orientation of the dendrites of its individual auditory neurons. Our experiments have been performed on urethanized Dutch Belted and New Zealand rabbits. The stimuli were slowly fluctuating tone bursts delivered at a 1/sec rate to the left, right, and both ears in a rotating sequence. Multiunit PSTs and average evoked potentials (AEPs) were observed with glass-coated microelectrodes that were advanced through the cortex along tangential tracks in the frontal plane. (See McMullen and Glaser, Soc. Neurosci. Abstr., 5,26, 1979 for details.) At 300 μm intervals within the responsive auditory area, we determined both best frequency and aural dominance by judging the vigor of the multiunit and AEP responses. In eight animals it was possible to make three or four parallel electrode penetrations 500 μm apart with each penetration passing through about 4 mm of 'mappable' cortex. Data were obtained from an average of about 50 sites per animal. We have found that: (a) The primary auditory area (as defined by its responsive and histological properties) is organized such that there is a generally monotonic decrease of best frequency from high (30-35 kHz) dorsally to low (ca. 400 Hz) ventrally. (b) The isofrequency contours are oriented in an anteroventral to posterodorsal direction. (c) The high (>15 kHz) frequency area is more extensive anteriorly while the area for frequencies below 3 kHz is more extensive posteriorly. (d) The largest part of the primary area is devoted to frequencies between 5 and 15 kHz. We have also obtained good evidence for a second auditory area dorsal and anterior to the primary one. Its best frequencies range from 1 to 10 kHz and are mapped with the low frequencies more dorsal than the high. With respect to aural dominance, we have found that 80% of the multiunit responses are contralaterally dominant and 20% ipsilaterally dominant. The responses exhibit binaural interactions that may be classified as summating (33%) or suppressive (67%). Alternating bands of response suppression and summation are sometimes seen. After electrophysiological mapping, the brains were processed according to the Golgi-Cox Nissl method. Using a computer microscope we have studied five pyramidal and five nonpyramidal neurons in layer IV of the primary auditory area of one such brain. A dendritic stick analysis was employed. The pyramidal cell basal dendrites show a clear preference for an anterior posterior orientation. There is also a good indication of a similar orientation of the dendrites of the nonpyramidal neurons. The results suggest that dendrites in layer IV are oriented similarly to the isofrequency contours.

188.24 SOUND INDUCED HEAD ORIENTING IN UNRESTRAINED CATS, S.E. Fish. Dept. Neurobiology, North Eastern Ohio Univ. Col. of Med., Rootstown, OH 44272.

Cats will orient their heads toward a sound source of interest to them but this behavior is difficult to quantify in freely moving animals. A technique was developed to study the cat's orienting behavior and data were collected to document it.

A small lightweight projector was developed which could be fastened firmly to a cat's head. The position of a small spot of light emanating from the projector was photographed to determine the orientation of the subject's head in relation to a sound source (30hz square wave clicks, 75Db). Sound sources were baited with freshly killed (cervical dislocation) mice which the cats were allowed to capture and eat. Trials were run in the dark and the cats "hunted" (with great enthusiasm) for all of their food in this manner.

The two cats were able to orient their heads to within a few degrees both horizontally (mean error, 1.84° and 3.77°) and vertically (mean error, 3.25° and 5.25°) of a sound source. The horizontal figures are comparable with the cat's horizontal auditory localization ability. There was a significant tendency for a systematic error in vertical orienting that was not evident in the horizontal orienting. The cats tended to orient below targets positioned above them and above targets positioned below them. This systematic error was not correlated with stimulus duration and remains unexplained. After a momentary sound stimulus the cats were observed to maintain their accurate orientation to its position while approaching it.

These data document the prominent role for head orienting in auditory localization and predatory behaviors of the cat.

188.25 INFLUENCE OF SEMICIRCULAR CANAL AMPULLA, DUCT, AND UTRICULAR SHAPE ON ENDOLYMPH FLOW DYNAMICS C.M. Oman and E.N. Marcus*
(Spon. L.S. Frishkopf) Res. Lab. of Electronics, M.I.T.
Cambridge, MA 02139

Theoretical descriptions of endolymph flow and cupula motion have traditionally been made employing a model (van Egmond, et al, J. Physiol. 110: 1 - 17, 1949) in which the entire membranous canal is represented as a hollow, thin torus of constant, circular cross section. The resulting 2nd order differential equation relating endolymph angular displacement about the center of the canal to head angular acceleration has two coefficients, π/Δ and θ/π. However, the cross section of an actual canal varies significantly in the ampulla and utricle. The effect of this variation has been considered only for simple variations in canal geometry (Van Buskirk, W.C., Ann. Biomed. Eng. 5: 1-11, 1977; Oman, C.M., Vestib. Function and Morphology, T. Gualtierotti, ed. Springer, N.Y., Ch.14, 1980). We have developed a more general theoretical model describing Newtonian endolymph flow where the canal lumen varies continuously in size and shape in a gradual fashion through the duct, ampulla, and utricle. Endolymph flow is more accurately described by a 2nd order differential equation with three coefficients, rather than by the traditional two coefficient model. The three coefficients (and hence the canal time constants and gain factor) analytically depend on the average of the inverse cross sectional area of the canal lumen (taken around the canal circumference) and also on the average inverse squared cross sectional area. To investigate the behavior of these functions for an actual canal, an optical technique was devised which was used to make the necessary dimensional measurements in the dissected, fixed canal of the skate, Raja erinacea. The numerical results obtained indicate that in most species, the inverse area functions (and hence canal response characteristics) are dominated by the influence of the narrow duct and ampulla cross sections, and by the fraction of the canal circumference which they occupy. The long time constant and the amount of cupula motion produced per unit head velocity (gain factor) should be heavily influenced by the relative length of the utricle and ampulla dilations. On the other hand, the short time constant of the model is nearly independent of the fraction of the canal torus occupied by the duct. One cannot legitimately "adjust" the two coefficients of the traditional model differential equation to allow for the presence of the ampulla and utricle, as has sometimes been claimed.

188.26 TRANSFER CHARACTERISTICS OF ANTERIOR SEMICIRCULAR CANAL AFFERENTS IN THE ANESTHETIZED GERBIL. A.A. Perachio and M.J. Correia.
Depts. of Otolaryng. and Physiol. & Biophys., University of Texas Medical Branch, Galveston, Texas 77550.

Experiments were performed on 21 gerbils anesthetized with urethane and maintained on ketamine. Recordings were made from either the right or left vestibular nerve using stereotaxically guided glass micropipettes driven through the intact cerebellum. Using the rotational null point technique (Estes et al., J. Neurophysiol., 38:1232-1249; 1975), ampullary afferents from the anterior (n = 22) and horizontal (n = 22) semicircular canals were functionally identified. Responses of those afferents to single and complex sinusoidal oscillations were obtained over a stimulus bandwidth of 0.01 Hz to 5.0 Hz. Spontaneous discharge was also recorded. All tests were performed with the animal's head held so that the horizontal semicircular canals were in the plane of rotation, and coplanar with the earth horizontal plane. Unit responses were dichotomized based on the CV of the spontaneous discharge. Anterior ampullary units with CV $\leq$ 0.1 had a mean firing rate (± SEM) of 83.04 ± 8.1 Impulses/s ($I \cdot s^{-1}$) and a mean (± SEM) gain and phase re velocity of 0.077 ± 0.02 $I \cdot s^{-1}/deg \cdot s^{-1}$ and 42.94 ± 1.7 deg at 0.1 Hz; and 0.078 ± 0.02 $I \cdot s^{-1}/deg \cdot s^{-1}$ and 6.79 ± 1.0 deg at 1.0 Hz. Those units with CV > 0.1 had a mean firing rate (± SEM) of 48.29 ± 6.1 $I \cdot s^{-1}$, and a mean (± SEM) gain and phase of 0.154 ± 0.02 $I \cdot s^{-1}/deg \cdot s^{-1}$ and 55.14 ± 4.12 deg at 0.1 Hz and 0.166 ± 0.05 $I \cdot s^{-1}/deg \cdot s^{-1}$ and 29.06 ± 3.3 deg at 1.0 Hz. Comparable data for horizontal ampullary afferents include: (A) CV $\leq$ 0.1, mean (± SEM) firing rate 73.34 ± 2.87 $I \cdot s^{-1}$; mean (± SEM) gain and phase of 0.224 ± 0.06 $I \cdot s^{-1}/deg \cdot s^{-1}$ and 50.42 ± 5.07 deg at 0.1 Hz; and 0.312 ± 0.07 $I \cdot s^{-1}/deg \cdot s^{-1}$ and 14.48 ± 2.9 deg at 1.0 Hz, (B) CV > 0.1, mean (± SEM) firing rate 42.83 ± 6.73 $I \cdot s^{-1}$; mean (± SEM) gain and phase of 0.467 ± 0.08 $I \cdot s^{-1}/deg \cdot s^{-1}$ and 59.78 ± 2.8 deg at 0.1 Hz; and 0.914 ± 0.15 $I \cdot s^{-1}/deg \cdot s^{-1}$ and 29.45 ± 1.8 deg at 1.0 Hz.

The above findings on the response characteristics of horizontal canal afferents confirm those of Schneider and Anderson (Brain Res., 112:61-76; 1976). The new data on anterior canal afferents indicate that, for rotation in a plane nearly orthogonal to the vertical semicircular canals, the gain slope remains constant over the range 0.1 to 1.0 Hz while the phase angle of the response is comparable to that of horizontal canal afferents.

(Supported in part by NASA Contract NAS9-14641.)

188.27 ADAPTATION OF AN OTOLITH-SPINAL REFLEX DURING PROLONGED EXPOSURE TO ALTERED GRAVITY. D.G.D. Watt and H.A. Zucker*. Aviation Med. Research Unit, McGill Univ., Montreal, Canada H3G 1Y6.

Previous studies have demonstrated that gastrocnemius-soleus emg activity occurring 50 to 150 msec after the onset of a sudden fall is predominantly otolith-spinal in origin. Further experiments have shown that the size of this response may be reduced significantly by rotating the gravity vector 90° relative to the body, or by eliminating it entirely, as in parabolic flight in an aircraft. These experiments seek to identify any adaptive changes which might occur during prolonged 90° rotation of the gravity vector.

Three subjects were exposed to sudden, unexpected vertical falls of 15 cm while surface emg activity was recorded from their left calf muscles. Each was then suspended horizontally in the supine position and tested in the same way every 60 to 90 min for 8 hrs, substituting for gravity with bungee cords running from the waist to the wall. It should be noted that subjects were never allowed out of the supine position during this period, but were encouraged to remain active, and do such things as hop "up and down" on the wall. Vertical testing was then repeated immediately after returning to the upright position, and every 90 min thereafter for 3 hrs.

All subjects demonstrated the expected reduction of the otolith-spinal response on assuming the supine position (area of rectified and averaged response 15-30% of normal). All showed a steady, systematic increase of the response with time, however, with about 50% recovery by 8 hrs. The effect of returning to the vertical position was more complicated, consisting of an early suppression of the reflex, followed quickly by larger than normal responses and then a return to normal.

These results demonstrate neural adaptation to rotation of the gravity vector, comparable to changes seen in the vestibulo-ocular reflex during vision modification experiments involving reversing prisms or magnifying lenses. However, the present findings extend this phenomenon to the otolith organs and the peripheral musculature, and seem to indicate that adaptation can occur in the absence of any obvious sensory conflict. The latter finding is supported by the complete lack of motion sickness symptoms in these (and other) subjects while adaptation was occurring. This is very different from reversing prism experiments, in which nausea, etc. develops rapidly in most subjects.

(Supported by M.R.C. Canada, Grant MA 5837).

188.28 MORPHOPHYSIOLOGY OF SUPERIOR VESTIBULAR NUCLEUS NEURONS PROJECTING TO THE CEREBELLUM IN THE CAT. AN INTRACELLULAR HRP STUDY. A. Mitsakos*, H. Reisine, and S.M. Highstein. Dept. Neurosci., Albert Einstein College of Medicine, Bronx, N.Y. 10461

The superior vestibular nucleus (SVN) was explored with glass microelectrodes loaded with HRP in anesthesized, paralyzed cats. The IIIrd nucleus and both vestibular nerves (VN) were electrically stimulated. SVN neurons projecting to the cerebellum (VCb) were identified morphologically by their axonal trajectories. All VCb neurons receive monosynaptic EPSPs and di- or polysynaptic IPSPs following ipsi- and contralateral VN stimulation respectively. We imply that VCb cells are functionally Type I.

VCb neuronal somas are oval to round (long dia. 28-55μ) and lie centrally or lateral and dorsal in SVN. Axon hillocks of VCb neurons are located on the medial, dorsal or lateral soma.

VCb axons (d=2.5-4.5μ) traverse SVN in a dorsal or lateral direction before exiting SVN laterally. Two axonal trajectories are followed. Some VCb axons travel laterally across the restiform body towards the ipsilateral flocculus. Others travel dorsal, then medial curving around the brachium conjunctivum toward the ipsilateral fastigial nucleus. Other VCb axons course toward the fastigial nucleus while a thin collateral (d=1.5μ) travels toward the ipsilateral flocculus.

VCb neurons emit 3 to 7 primary dendrites with 2 to 3 disproportionally thicker dendrites, more heavily branched. Secondary and tertiary dendrites are both tortuous and straight, exhibit a few spines, short appendages with bulbous heads, and distal beaded branchlets. The dendritic aborization of VCb neurons is polarized along a rostro-caudal axis, covering a small field in SVN. This orientation is less pronounced than that of the typical radiate dendritic tree of SVN vestibulo-ocular neurons.

This study reveals the characteristic dendroarchitectonic appearance of VCb neurons and their axonal trajectories following two distinct courses.

188.29 RESPONSE CHARACTERISTICS OF VESTIBULO-CORTICAL NEURONS TO ROTATIONS OF THE ALERT CAT IN THE DARK AND LIGHT. A.K. Sestokas* (SPON: M. Terman). Dept. of Psychology, Northeastern University, Boston,Ma.,02115.

While much is known about the processing of vestibular afferent signals in the brainstem, relatively little is known about the representation of this information by primary vestibulo-cortical neurons. The present investigations were undertaken to study the response characteristics of these cortical neurons to sinusoidal rotations in order to facilitate comparison with response properties of brainstem vestibular neurons. Recently, it has been reported that at rotational frequencies above 0.1 Hz single cell activity in primary vestibular cortex of the cat and monkey modulates in phase with head angular velocity, essentially imitating the activity of vestibular cells in the brainstem (Becker,Deeke and Mergner; Buettner and Büttner; Pflügers Archiv,373 Supplement,R87,1978). Furthermore, in monkey most primary vestibulo-cortical neurons also respond to optokinetic stimulation. The nature of visual input to cat vestibular cortex (anterior suprasylvian gyrus, ASSG) was investigated in this study by comparing responses of ASSG neurons during rotations of the cat in the dark with those in the light. Extracellular activity was recorded from restrained, alert cats during sinusoidal rotation at four frequencies between 0.18 and 0.75 Hz. These recordings confirm previous reports of Type I (activation by ipsilateral rotation, inhibition by contralateral) and Type II (activation by contralateral rotation, inhibition by ipsilateral) responses whose peaks were in phase with maximum head velocity. However, unlike the brainstem, cortical response patterns were often markedly distorted reproductions of the sinusoidal stimulation. Firing rates tended to increase much more rapidly during activation than they decreased during inhibition. Moreover, identical rotations in the light produced higher discharge rates and often accentuated the non-linearities causing a phase advance relative to activity in the dark. The influence of visual inputs in the ASSG was most evident in those cells which showed very weak responses to rotations in the dark. These neurons exhibited large amplitude, tightly coupled responses to head angular velocity only during rotations in the light. This is unlike activity described for the vestibular nuclei or vestibular cells in the thalamus and suggests that these cortical cells may receive a visual input other than that known to impinge on vestibular nuclei.

189.1 EFFECT OF CHRONIC SALT TREATMENT ON THE ChAT ACTIVITY IN HYPOTHALAMIC MAGNOCELLULAR NUCLEI OF RATS. Dieter K. Meyer* and Cinda J. Helke. (SPON: Juan M. Saavedra). Laboratory of Clin., Science, NIMH, Bethesda, Md. 20205.

Choline acetyltransferase (ChAT) activity (a specific marker for cholinergic neurons) has been found in the supraoptic (SON) and paraventricular (PVN) nuclei which are responsible for the synthesis and release of vasopressin(AVP). The bulk of the ChAT activity in the SON appears to be in neurons which are intrinsic to the nucleus. Pharmacological studies have demonstrated that stimulation of hypothalamic cholinergic receptors alters the release of AVP (Endocrinology 101: 411, 1977). More recent in vitro studies suggest that cholinergic neurons mediate the release of AVP due to osmotic stimuli (Endocrinology 105: 367, 1979). Therefore, the purpose of this study was to investigate the ChAT activity (as a marker of the activity of cholinergic neurons) in magnocellular nuclei under conditions of chronic osmotic stimuli and to correlate the data with pituitary AVP levels.

Male Sprague Dawley rats were sacrificed (3,7 or 14 d) following chronic substitution of either 1% or 2% NaCl solution for drinking water. The SON, PVN, arcuate nucleus and dorsal hippocampus were microdissected and assayed for ChAT activity. Controls consisted of age matched rats supplied with normal drinking water.

Replacement of drinking water with 1% saline for 3, 7 or 14 d had no effect on ChAT activity in the hypothalamic nuclei investigated while 2% saline treatment reduced the ChAT activity in the SON at 7 and 14 d (to 84 and 67% of control) and in the PVN and arcuate nucleus at 14 d (to 59 and 58% of control, respectively). At no time was a decrease in ChAT activity observed in the dorsal hippocampus indicating the specificity of the effect. No change in ChAT was observed in any of these areas in salt substituted adrenalectomized rats (5 d). Thus, these effects do not appear to be due to nonspecific stress.

The AVP content of the posterior pituitary was decreased by 7 and 14 d of 1% saline treatment (70 and 60% of control). Two percent saline decreased the AVP content to 10% of control at 3 d of treatment, this decline was sustained at 7 and 14 d.

These results support the hypothesis that cholinergic neurons are involved in the regulation of AVP release due to osmotic stimuli.

189.2 ANTICONVULSANT ACTIVITY OF β-ENDORPHIN IN THE SEIZURE SENSITIVE MONGOLIAN GERBIL. J.G. BAJOREK*, D.H. CATLIN*, and P. LOMAX. Department of Pharmacology, School of Medicine and the Brain Research Institute, UCLA, Los Angeles, CA 90024.

The opioid peptides, enkephalins and endorphins, were originally reported to induce electrographic seizures in rats. However, in the Mongolian gerbil, a natural genetic model of epilepsy, met-enkephalin (100-200 µg) injected intraventricularly (i.c.v.) did not change the incidence of seizures, nor did it modify the severity or duration of the attacks, or produce extensive epileptogenic electrographic discharges, although it did produce single paroxysmal spikes at a rate of 0.16 Hz. Intraventricular injection of β-endorphin (1-10 µg) reduced the incidence (51%) and severity (55%) of the natural seizures, as defined by characteristic behavioral and electrographic criteria. Naloxone (1 $mg.kg^{-1}$ i.p. 15 min previously) blocked these effects of β-endorphin indicating the involvement of opiate receptors. In addition to the anticonvulsant effect, β-endorphin induced consecutive periods of synchronization of the EEG to 6 Hz; concurrently the animals would flatten themselves down in the cage and clonic movements of the extremities occurred (LPS seizures). These LPS seizures comprised 9.4%-19.4% of the time in the period during which the animals were observed. Significant reductions in grooming (81%) and exploratory rearings (65%) are also evident. These effects were all dose dependent and were blocked by naloxone (1 $mg.kg^{-1}$ i.p.). Naloxone by itself has been shown to increase the incidence of the natural seizures in these animals. From these several observations it might be concluded that endogenous opioid peptides may modulate the seizures in the gerbil. There was evidence of an increase in intermittent abnormal spiking in the cortical EEG, which was increased, not decreased, by naloxone. It is of interest to try to disassociate the anticonvulsant and the LPS effects of β-endorphin and to localize the site at which the LPS effect originates. The lack of cortical paroxysms would tend to indicate a subcortical origin. Supported by ONR Contract N00014-75-C-0506.

189.3 HORMONAL MODULATION OF CENTRAL AND PERIPHERAL COMPONENTS OF "FAST" AND "SLOW" SKELETAL NERVE-MUSCLE SYSTEMS IN XENOPUS LAEVIS. G. Schneider*, N. Rubinstein*, F.P. Zemlan* and S.D. Erulkar Depts. Pharmacology and Anatomy, University of Pennsylvania Medical School, Philadelphia, PA 19104

Administration of exogenous androgens to male Xenopus laevis produces stereotyped sexual behavior including the "clasping" of the female during amplexus. The muscles of the front legs primarily involved in this action are the m. sternoradialis and the m. flexor carpi radialis. Using antibody staining techniques, we have shown that these muscles contain both slow tonic and fast twitch fibers. There is a sexual dimorphism; muscles from males contain higher numbers of slow fibers than those from females. The nerve in the m. sternoradialis has a multimodal distribution with respect to both fiber diameter and conduction velocity. In order to test neuronal effects of the androgens, the isolated spinal cord of Xenopus was used and the properties of neurons involved in clasp behavior studied in different hormonal states using intracellular recording techniques. Recordings were obtained from the nerve to m. sternoradialis in both castrated and sexually active (induced by testosterone or anterior pituitary administration) males. Dorsal root stimulation elicited a long latency diffuse response from neurons in cords from both castrated and induced males; the response was of shorter latency and more sustained in the latter. The most striking changes occurred in response to paired stimuli to the dorsal root. Testosterone administration to the bath caused a shortening of the latency, a reduction of the recovery period, an increased facilitation and a broadening of the interstimulus interval over which facilitation took place. Furthermore the pattern of activation was changed, the response to the second stimulus becoming more synchronized and periodic. Intracellular recordings from identified neurons in cords from induced animals revealed the existence of neurons that responded predominantly with repetitive discharge and after-depolarizing potentials, although our sample is small. The apparent effect of these changes brought about by the androgens is to allow more neurons to fire at faster repetition rates. Therefore hormones appear to modulate directly patterns of neural discharge in the cord consistent with the observed behavioral response. Moreover it is an interesting possibility that the differing patterns of neural input may influence the muscle fibers to change the character of myosin from slow to fast or vice versa. However a direct effect by the hormones on the muscle itself has not been excluded. (Supported by NS 12211).

189.4 EFFECT OF DELTA-9-TETRAHYDROCANNABINOL ON HIPPOCAMPAL EXCITABILITY IN ADULT MALE RATS. Michael R. Foy, Timothy J. Teyler and Richard M. Vardaris. Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272 and Kent State University, Kent, Ohio 44242.

Rodent hippocampal physiology has been shown to be altered following administration of behaviorally psychoactive doses of delta-9-tetrahydrocannabinol (delta-9-THC), one of the major psychoactive constituents of marihuana (Vardaris, Teyler and Weisz, Brain Res. Bull., 1977, 2, 181-187). Previous work has also demonstrated the modulating effects of gonadal steroids on in vitro hippocampal slices of normal adult rats (Vardaris and Teyler, Neurosci. Abs., 1978, 4, A1145) and castrated/ovarectomized rats (Teyler, Foy and Vardaris, Neurosci. Abs., 1979, 5, A1568). Due to the chemical similarity between delta-9-THC and the estrogenic steroids, further examination of the effect of delta-9-THC on hippocampal function may provide information concerning the physiological effect of this agent.

In vitro hippocampal slices were prepared according to standard methods (Teyler, Brain Res. Bull., 1980, in press) and tested in response to 1, 10 and 100 pM concentrations of delta-9-THC suspended in PVP applied in a random order. Electrophysiological measures were taken at 10 and 20 minutes following addition of drug to the bathing incubation media. CA1 excitability to monosynaptic stimulation of Schaffer collateral afferents displayed the greatest enhancement of extracellular population spike amplitude to 10 pM delta-9-THC. The 100 pM concentration resulted in a depression of population spike amplitude with respect to pre-drug controls, wheras the 1 pM concentration had little or no effect.

Within the examined dose range (1 pM, 10 pM and 100 pM), delta-9-THC initiated both excitatory and depressant postsynaptic responses. These results are consistent with the results of a similar study in the intact rat wherein hippocampal CA1 population responses to monosynaptic activation also displayed an inverted-U function over a 2-16 mg/kg dosage range (Weisz, Vardaris, Gunnell, and Teyler, unpublished). The time course of these actions was quite rapid, suggesting a membrane effect of this lipophilic drug. The initiation of both excitatory and depressant responses may be due to differential interractions with steroid receptors and/or neurotransmitters. These results indicate that delta-9-THC modulates the excitability of the rodent hippocampus and may do so by acting through mechanisms that can be studied in the in vitro preparation.

189.5 MELATONIN BINDING IN THE PINEAL GLAND: SPECIFICITY AND EFFECTS OF EXOGENOUS MELATONIN. W.R. Holloway*, L.J. Grota, & G.M. Brown. Dept. Psychiatry, Univ. Roch. Sc. Med., Roch., N.Y. 14642, and Dept. Neurosci., McMaster Univ., Hamilton, Ontario, Canada.

We have previously reported the presence of a melatonin (Mel) binding material in the rat pineal gland (PG)(Holloway et al., Neurosci. Absts.,1979,5,1515) using a semi-quantitative double antibody procedure (Holloway et al.,J. Histo. Cyto.,1980,28,255). Specific anti-Mel antibody (A-Mel) and FITC-labeled IgG were the first and second antisera, respectively. A CdS photometer measured fluorescence intensity (FI). With this method we found low levels of occupancy (30%) 1.5hr after lights-on with the maximum (100%) occurring 1.5hr after lights-off. In the following experiments we provide information oabout the specificity of this material and the influence of exogenous Mel on its binding ability.

Adult male rats on a 12:12 LD cycle were killed 1.5hr after lights-off, when the binding material is saturated with Mel. Cryostat sections of PG were incubated with A-Mel containing 0,1,10 or 1000 ng Mel/ml or with identical amounts of competing substances (N-acetyl-serotonin(NAS), serotonin(5-HT), and 5-Methoxy-tryptophol(5-M-ol)). 10 ng Mel/ml produced a significant fall in FI. NAS had a displacement curve identical to Mel. 5-HT and 5-M-ol did not displace Mel. These data indicate that indoles with an N-acetyl group on the terminus of the side chain will compete with Mel for binding sites.

Other studies have investigated the influence of Mel **in** vivo on the binding pattern of this material. Male rats were injected IP with Mel (MI) or vehicle (VI) 0.5 hr after lights-on (1mg/rat) and killed 1,6,or 11 hr later. MI animals had high plasma Mel levels at 1hr (16,500 pg/ml), returning to normal 11 hr later. Mel binding in the PG was markedly altered by the Mel treatment. VI rats had low FI at 1 hr, rising through the day to high levels 11 hr later. Mel injection prevented this rise. A second group of rats were injected with Mel (50ug), vehicle, or were not disturbed (NI) 1.5 hr before lights-out and killed 1, 3, or 9 hr later. MI rats had high plasma Mel 1 hr after injection (211 pg/ml), but at 3 and 9 hr they were identical with VI and NI rats. Mel treatment altered the pattern of Mel binding in the PG. Whereas NI rats had high FI at all sampling points, MI rats had significantly lower FI 1 and 3 hr after treatment, with a rise 9 hr later. VI rats exhibited a pattern of FI identical to the MI animals. The effect of repeated daily injections of Mel or vehicle on the binding properties of this material is under investigation.

189.6 MELATONIN INHIBITION OF THE RESPONSE TO LHRH BY AN ENRICHED GONADOTROPH CELL PREPARATION. J. E. Martin, D. McKeel* and C. Sattler*. Departments of Pharmacology and Pathology, Washington University Medical School, St. Louis, MO 63110.

Melatonin, a secretory product of the pineal gland, can suppress the neonatal rat pituitary LH and FSH responses to LHRH. This action of the indole has been shown both in intact animals and in pituitary cultures, thus clearly demonstrating the pituitary gland as a target tissue of the pineal hormone. The present study has examined the effect of melatonin on an enriched gonadotroph cell preparation to determine whether the indole interacts directly with the gonadotroph or requires other pituitary cells to mediate inhibition of gonadotropin release. Monodispersed anterior pituitary cells were prepared from 15-day-old female rats by a modification of the procedure of Hopkins and Farquhar (J. Cell Biol. 59:276, 1973). This procedure, in contrast to certain other methods tested in our laboratory for monodispersion, produced cells maximally responsive to both LHRH and melatonin and comparable to those dissociated with collagenase in our earlier studies. The dispersed cells were fractionated by velocity sedimentation on a 1-3% BSA gradient. LH, FSH, TSH, PRL and GH concentrations in cell lysates of each fraction were measured by double antibody radioimmunoassay. The percentage of LH-, TSH- and PRL-containing cells was determined by immunohistochemistry. In 3 separate gradient fractionations, both procedures revealed a highly reproducible elution profile with a peak of gonadotroph cells enriched 5-10-fold over the unfractionated mixture. The gonadotroph peak was clearly separated from lactotrophs and somatotrophs but did contain some thyrotroph cells. Enriched gonadotrophs were cultured overnight in serum-containing medium, washed free of serum, and then incubated for 5h with increasing concentrations of LHRH either alone or in the presence of melatonin. Controls were incubated in medium only. LHRH-induced LH release by the enriched gonadotrophs was indistinguishable from that observed with unfractionated cells with regard to both dose-response relationships and percent of total LH released. Melatonin (1 μM) significantly suppressed the LH response to 0.1, 1, and 10 nM LHRH by 100%, 62%, and 43%, respectively. This inhibition was equivalent to results obtained with the unfractionated cells. These findings indicate that melatonin acts directly on the gonadotroph to inhibit responsiveness to LHRH. The availability of partially purified target cells of the pineal hormone will facilitate further studies of its mechanism of action. (Supported by NIH Grant HD11854).

189.7 EVIDENCE THAT INHIBIN CAN SUPPRESS FOLLICLE STIMULATING HORMONE (FSH) RELEASE AT THE HYPOTHALAMIC LEVEL. M.D. Lumpkin*, A. Negro-Vilar, P. Franchimont* and S.M. McCann (SPON: P. Shore). Dept. of Physiol., U. Tx. Hlth. Sci. Ctr., Dallas, Texas 75235.

Crude or semipurified inhibin extracts from the gonads of male and female mammals have been shown to suppress preferentially the secretion of FSH both in vitro and in vivo by a pituitary site of action. We report here that inhibin preparations purified from ram rete testis fluid (RTF) preferentially inhibit FSH secretion in the adult male rat by a hypothalamic mechanism. In three experiments, Sprague-Dawley male rats (300-400 g) were implanted with third ventricular (3V) cannulae. After one week of recovery, silastic jugular cannulae were implanted to facilitate blood sampling in unanesthetized animals. Also at this time the animals were bilaterally orchidectomized (ORDX), to be used 24 h later. Inhibin preparations dissolved in saline or the vehicle were injected into the 3V in a volume of 4 μl over a 1 min period. In the first experiment, 30 μg of a highly purified inhibin extract (RTF 38) or saline were given at time 0 and blood collected at 1,2,4,6,8,10 and 24 h post-injection. FSH levels increased steadily throughout the 24 h period in controls. Inhibin-treated ORDX rats showed significantly depressed FSH levels at 4 h ($p<.005$), 6 h ($p<.001$), 8 h ($p<.0025$) and 10 h ($p<.05$). By 24 h, the inhibin-treated group had FSH values near control levels. Plasma LH levels were not significantly different at any point, although both groups experienced a slight decline for up to 8 h. In a second experiment, 3V injection of an inhibin preparation with much lower (25%) potency, given at the same dose as above, failed to suppress FSH or LH levels significantly. This experiment is viewed as a pertinent control which shows that the osmolarity of the injected extract is not a factor in inducing hormonal alterations. In a third experiment, an inhibin preparation (RTF_1A) of lesser potency was given at a 3.3 fold higher dose. FSH levels at 2 ($p<.025$), 4 ($p<.05$) and 6 h ($p<.005$) were significantly lower than in vehicle-injected ORDX rats. Slight but significant decrements were seen in LH levels 2 and 4 h after inhibin treatment. An LHRH challenge (25 ng/100 g BW) was given at 6 h post-injection. Both LH and FSH at 15 and 45 min reached similar peak levels in inhibin and saline groups, thus arguing against a pituitary site of action of the 3V-injected inhibin. Moreover, systemic injection of an inhibin preparation at a dose 2.5 fold higher than the dose given centrally, failed to modify either FSH or LH levels for up to 8 h or responses to LHRH at 15 and 45 min post-challenge. These results provide the first evidence that inhibin in the male can preferentially suppress FSH release by a hypothalamic site of action, in addition to its well known pituitary site of action. Supported by NIH HD-09988 and AM-10073.

189.8 IPSILATERAL HYPOTHALAMIC HEMI-ISLANDS BLOCK INCREASES IN SERUM FSH FOLLOWING HEMI-CASTRATION. D.M. Nance, M. Wilkinson and W.H. Moger*. Dept. of Anatomy and Physiol. & Biophys., Fac. Med., Dalhousie University, Halifax, Nova Scotia, B3H 4H7.

Hemiorchidectomy of prepubertal male rats produces a selective increase in serum FSH with little or no change in serum LH levels (Moger, Biol. Reprod. 17, 661, 1977). This dissociation in LH and FSH secretion suggest additional mechanisms may stimulate FSH release. Since hypothalamic hemi-islands have been utilized to provide evidence that compensatory adrenal growth is mediated neurally (Holzwarth & Dallman, Brain Res. 162, 33, 1979), a similar procedure was used to test for a possible neural mechanism mediating the increase in FSH following hemiorchidectomy.

In two separate studies hypothalamic hemi-islands or sham surgeries were produced in prepubertal male rats with an extrudable Halász type knife (1.5 mm radius). Animals were then sham castrated or else hemi-castrated on the contralateral or ipsilateral side with respect to brain surgery. Following either an 8 or 21 day interval between surgery and collection of serum, hemi-castrated animals given sham knife-cuts showed a significant increase in serum FSH, relative to sham animals with intact testes. Also, animals given hypothalamic hemi-islands and hemi-castrated on the contralateral side showed a marked increase in serum FSH and were comparable to hemi-castrated animals with sham brain surgeries. However, hypothalamic hemi-island rats which were hemi-castrated on the ipsilateral side failed to show an increase in serum FSH and were similar to sham operated controls. Preliminary in vitro determination of pituitary sensitivity to GNRH indicated no difference between the ipsilateral and contralateral hemi-castrated animals with hypothalamic hemi-islands.

Since serum LH levels were found to be comparable among all the groups, these data verify a clear dissociation between LH and FSH secretion. In addition, the observed differences between contralateral and ipsilateral hemi-castrated animals with identical brain surgeries can only be accounted for by postulating that FSH release is, in part, under direct neural control.

Research Support: Faculty of Medicine, Dalhousie University, MRC Grants # MA5401 and MA7131.

189.9 ELECTROCHEMICAL STIMULATION OF THE PREOPTIC AREA AND LH RELEASE IN THE RAT: THE EFFECTS OF FERROUS AND FERRIC CATIONS.
A.J. Carrillo and K.L. Evans.* University of Texas Health Science Center at San Antonio, San Antonio, Texas 78284.

It is well known that electrochemical "stimulation" (ECS) of the medial preoptic area (MPOA) in the rat results in the release of LH. It is also known that this neuroendocrine effect is associated with the deposition of iron cations from the electrode tip to the surrounding neural tissue (Everett and Radford, 1961). This study was designed to further investigate the effect of depositing cations into the MPOA on the release of LH. In all cases, female rats on the day of vaginal proestrus were anesthetized with nembutal (37 mg/kg) and brain surgery performed (1400-1600 h). In one group ECS (100 uA anodal DC x 60 sec) of the MPOA was carried out with a stainless steel electrode (N=10). A sham group (N=9) had 200uA anodal DC x 60 sec passed through a platinum electrode. Blood samples for LH determination (RIA-NIAMDD) were obtained from the jugular vein at 0, 1 and 2 h post ECS. ECS of the MPOA resulted in a significant ($p<0.01$) elevation of plasma LH (0 h 39±12 ng/ml; 1 h 821±110 ng/ml; 2 h 368±52ng/ml). Sham stimulation did not have any effect on plasma LH levels (0 h 38±5 ng/ml; 1 h 54±10 ng/ml; 2 h 59±19 ng/ml). Two other rats underwent ECS of the POA and the brains were rapidly removed, frozen and cut in a cryostat and the sections stained for the presence of ferrous (Turnbull's blue) and ferric (Prussian blue) ions. This staining revealed both cations to be present in the ECS site. Other groups of rats had 1 ul of the following solutions infused into the MPOA: $FeCl_2$ (31.1 mM; 47.0mM; and 62.2 mM); $FeCl_3$ (20.7 mM, and 41.4 mM); $MgCl_2$ (62.2 mM) and $CuCl_2$ (62.2 mM). The smallest concentrations of the iron solutions corresponded to the number of equivalents of iron that were calculated to have been deposited from the stainless steel electrode tip during ECS (6.2×10^{-8} equivalents). Blood samples were collected as before for LH determination. Only infusion of $FeCl_2$(41.1 mM and 62.2 mM) and $FeCl_3$(41.1mM) resulted in a significant ($p<0.05$) rise in plasma LH levels when compared to the sham group. However, this stimulatory effect on LH release was significantly ($p<0.01$) less than that detected after ECS. The other solutions had no significant effect on LH release when compared to sham controls. These data suggest that ECS deposits both ferrous and ferric ions and that only iron cations infused into the MPOA can stimulated LH release. However, the effect of ECS on LH secretion cannot be attributed solely to the release of iron ions.

189.10 COMPRESSED SPECTRAL ARRAYS OF THE AMYGDALA, PREOPTIC AREA, AND ARCUATE NUCLEUS IN CYCLING AND OVARIECTOMIZED RATS.
J. F. Masken and R. J. Morgan. Department of Physiology and Biophysics, Colorado State University, Fort Collins, Colorado 80523.

Adult female Sprague-Dawley rats were implanted with chronic electrodes in the corticomedial amygdala (AMY), medial preoptic area (POA) and arcuate nucleus median eminence area (ARC) in order to study electrical activity in these areas during the estrous cycle and following ovariectomy. Electrical signals from the three areas were recorded simultaneously on analog tape for ten minutes of each half-hour from 8:00h through 16:00h on each day of the estrous cycle. The animals were then bilaterally ovariectomized, allowed to recover, and recorded in similar fashion for four more days. The analog signals were digitized and analyzed for spectral density (1-32 Hz). Very little activity above 12 Hz was observed during estrus and diestrus-1 in any of the three areas (AMY, POA, or ARC). Higher frequencies, e.g. 12, 16, 24, and 28 Hz began appearing during diestrus-2, becoming more evident during proestrus. When the rats were ovariectomized and recorded, the power spectra of the three areas, i.e. AMY, POA, and ARC, showed frequencies similar to those seen during proestrus in the intact animals.
Supported by NIH Grant HD 09363-03.

190.1 VISUAL SPATIAL FREQUENCY AND ATTENTION: EVOKED POTENTIAL EVIDENCE FOR INTERACTION. Richard Coppola, NIMH, Bethesda, MD 20205 and Istvan Czigler*, Institute for Psychology, Budapest, Hungary

Previous evoked potential (EP) studies involving patterned and homogeneous field visual stimulation have shown attention by light intensity interactions. Other studies designed to investigate the presence of specific channels for size (spatial frequency) and orientation within the visual system have also shown effects of selective attention. Because in these studies pattern responses were simultaneous with luminance changes we undertook to investigate spatial frequency and attention while eliminating luminance change as a variable.

Vertical gratings at six spatial frequencies from .25 to 8 cycles/degree with either a sine wave or a square wave luminance profile were generated on a CRT display at a contrast of 44%. The screen went from a blank homogeneous field to the grating within 2 msec. The luminance change from the blank screen to the pattern was less than .005 ft-lamberts and was undetectable by a trained observer. Grass gold disk electrodes were placed on the midline at Oz and Cz with two electrodes spaced equally between them. The visual stimuli were presented concurrently with a series of different intensity tone bursts. The subjects were given instructions intended to direct their attention to either the visual patterns or the tones. Averaged evoked potentials time locked to the appearance of the gratings were recorded from 16 subjects. Half of the subjects had EOG electrodes placed at the outer canthi of each eye in order to control for eye movements. The EPs were measured using mean amplitudes for time bands of 100-200, 200-300, and 300-400 msec.

Analysis of variance indicated a significant attention by spatial frequency interaction for both sine and square wave. The most prominent aspect of the effect was the presence of a late positive component (400 msec) during the pattern attention condition which was missing for the tone attention condition. This component decreases with increasing spatial frequency. It is largest at vertex and diminishes at the more posterior leads. This result might suggest a greater saliance of lower spatial frequencies for visual processing.

190.2 NORMAL AND SCHIZOPHRENIC P300 LATENCY AND AMPLITUDE TO BACKGROUND, NOVEL, AND TARGET VISUAL STIMULI. A. M. I. Wagman, K. Keller*, A. Summerfelt and H. A. Burton*. Neuroscience Program, Maryland Psychiatric Research Center, P.O. Box 3235, Baltimore, MD 21228.

Eleven normals and 11 outpatient schizophrenics were tested on a visual evoked potential procedure that involved the presentation of background, novel, and target stimuli designed to differentially affect the P300 component. Slides were flashed for 8 millisec in 5 blocks of 40 stimuli, with intertrial intervals ranging from one to three sec. Background stimuli (vertical black and white stripes) comprised 40% of the total number of stimuli, while targets (black and white checkerboards) and novels (colored abstract art) each comprised 20% of the total. The order of presentation of the stimulus types was randomized, and subjects were instructed to respond to a touch switch upon seeing a target. Six electrode placements were used (left and right frontal, central, and occipital). P300 component amplitude (from pre-stimulus baseline) and latency were measured for each type of stimulus at each electrode site. Analysis of variance revealed significant ($p<.01$) group differences for both P300 latency (longer for schizophrenics) and amplitude (lower for schizophrenics), stimulus type differences for both latency (longest for novels) and amplitude (smallest for backgrounds, intermediate for novels, and largest for targets), and placement differences for amplitude (largest centrally and smallest occipitally). Analysis of the first few trials of the novel stimulus type is in process as a replication of the Courschene et al. (1975) effect. Because of the high between-subject variance, none of the interaction terms reached significance. However, one trend was apparent: for normals, across the three stimulus types, P300 amplitude was higher on the left at the frontal location and higher on the right at central and occipital placements. For schizophrenics, P300 amplitude was higher on the right at frontal and central placements and higher on the left at occipital locations.

190.3 MIDDLE LATENCY AUDITORY EVOKED POTENTIALS IN PATIENTS WITH TEMPORAL LOBECTOMIES. E. J. Hammond*, J. Bruni*, and B. J. Wilder. Neurology Service, VA Medical Center, Gainesville, Fl 32602.

The diagnostic use of human evoked potentials depends on identification of their generator sites. We recorded middle latency auditory evoked potentials in four patients before and after right temporal lobectomy for intractable epilepsy. Bilateral recordings were made from scalp locations C_3 and C_4 referred to P_Z; simultaneous recordings were obtained from these locations referred to linked earlobes. Stimuli were binaural clicks. In all patients a prominent positive potential at 28-30 ms (corresponding to the component P_a) was recorded pre-operatively. In three patients all tissue 6 cm from the anterior tip of the temporal lobe was excised. In these patients the P_a component was present before and after the operation. Although the exact extent of the primary auditory cortex (Heschl's gyri) was not determined electrophysiologically at the time of the operation, Heschl's gyri are generally located within the area of excision in these patients. In the fourth patient, the lobectomy extended past the primary auditory cortex into auditory association cortex (10 cm from the anterior tip of the temporal lobe). In this patient the P_a component was not present over the operated side.

This experiment suggests that the auditory P_a (P30) potential is not generated in the primary auditory cortex, but in a more posterior area of the temporal lobe.

190.4 ANALYSIS OF HUMAN AUDITORY BRAINSTEM RESPONSES TO CLICK TRAIN STIMULI P. J. Ainslie*, and J. R. Boston. Auditory Systems Laboratory, Carnegie-Mellon University, Pittsburgh, PA 15213

The temporal characteristics of click stimuli used to evoke auditory brainstem responses (ABRs) are important in determining the response. Recent studies have suggested that the use of high stimulus rates and click pair stimuli may have diagnostic significance. The purpose of this investigation was to examine the effects of the temporal characteristics in normal human subjects. ABRs were recorded from the scalp for monaural click train stimuli. Trains of one to four clicks with interclick times of 2, 4, 7, 15.4, 30.8 and 61.6 msec were presented to four subjects at 67 dBSL. Trains were separated by at least 110 msec for interclick times of 2, 4, and 7 msec and by at least 180 msec for interclick times of 15.4, 30.8 and 61.6 msec. Responses to each click in the click train stimulus were estimated using a linear model to cancel overlapping responses to other clicks in the train. Specifically, the response to the nth click of the click train was derived by subtracting the response recorded for n-1 clicks from the response recorded for n clicks, with all responses recorded during the same experimental session. The technique is based on two assumptions: 1) there is small variation among responses within an experimental session for a given subject for a constant stimulus condition, and 2) the response to the second click of a click pair does not affect the response to the first click (no backward masking effects.) Changes in the ABR to successive clicks in the click train were examined by comparing the response to each click, estimated as described above, to the response to one click. Several quantitative methods of comparison were evaluated, including cross-correlation, peak amplitude and peak latency measures. In particular, a wave peak corresponding to Jewett wave V was examined for changes in peak latency and peak to following trough amplitude as a function of click position. Wave V latency in derived responses to each click of the click train following the first click increased with respect to the wave V latency for the ABR to the first click. This latency increase depended on the interclick time and the number of preceding clicks. Latency changes were complete in the response to the last click of the click train for all interclick times except 2 msec. Amplitude changes also depended on interclick time and the number of preceding clicks. The variability in the amplitude data obscured any trends. Some additional data were acquired using noise or tone bursts preceding a click to compare the effects on the ABR generators of these stimuli to those of a click.

190.5 SIGNAL DISPERSION WITHIN A HIPPOCAMPAL NEURAL NETWORK IN THE RABBIT AND RAT. J. M. Horowitz, J. L. Giacchino* and K. S. Kott*. Dept. of Animal Physiol., Univ. of Calif., Davis, CA 95616.

Previous studies have described averaged evoked potentials (AEPs) recorded from populations of hippocampal neurons in the cat after stimulation of the fornix. Following single shock stimulation an AEP has the form of a damped oscillatory waveform lasting several hundred milliseconds. In the cat these AEPs have been related to post-stimulus time (PST) histograms of single pyramidal cells and to a model including an ongoing level of excitatory input to the pyramidal cell population (Intern. J. Neurosci. 5:113-123, 1973; Comput. Biol. Med. 5:283-296, 1975). The intent of the present study was to determine if PST histograms for single cells in the rat and rabbit hippocampus could also be related to oscillatory AEPs.

Tungsten microelectrodes were used to record PST histograms from hippocampal cells following commissural or fornix stimulation. Recording techniques were similar to those described previously for the cat. Rabbits and rats were anesthetized with sodium pentobarbital. A single unit was isolated using a WPI window discriminator and PST histograms were constructed using a Tracor-Northern digital signal analyzer. Following fornix stimulation in the rabbit and rat PST histograms showed multiple peaks, with successive peaks having a smaller amplitude and broader width. Commissural stimulation in the rabbit evoked similar PST histograms.

These results rule out the hypothesis that in the rat and rabbit each peak in an AEP is due to excitation of separate subpopulations of excited neurons, as PST histograms show that for a single shock one cell was excited to fire 2 to 4 times. As in the cat, the AEPs and PST histograms can be interpreted in terms of a network of pyramidal cells and inhibitory interneurons within the hippocampus. The first peak of the AEP reflects, at least in part, the excitation of pyramidal cells, and successive peaks reflect rebound excitations of some of the same pyramidal cells. The decreasing height and greater width of later peaks in both AEPs and PST histograms is attributed to dispersion of the signal as it circulates around the loop of pyramidal cells and interneurons. Rebound excitation occurs each time in the cycle there is a period of decreased interneuron activity so that the ongoing background activity excites pyramidal cells. (When background activity is reduced, as in hippocampal slices, previous studies have shown this type of damped oscillatory activity is absent). The network was simulated using differential-difference equations.

190.6 ENDOGENOUS POTENTIALS GENERATED IN THE HUMAN HIPPOCAMPAL FORMATION AND AMYGDALA BY RARE EVENTS. Eric Halgren, Nancy K. Squires*, Charles L. Wilson, John W. Rohrbaugh*, Thomas L. Babb, Paul H. Crandall*. Brain Res. Inst., Mental Retard. Res. Ctr., Depts. of Psych. and Surg./Neur. (J.W.R. at Dept. of Psychiat., U. Nebraska, Omaha NE).

Long-latency potentials can be recorded from the human scalp that depend upon the cognitive context in which a stimulus occurs but are independent of the sensory characteristics of the stimulus. Typically these potentials ("N2","P3" and "slow-wave") occur when the subject is actively attending to the stimuli and the evoking event is rare. Recordings were obtained from 6 adults with bilateral electrodes chronically implanted in order to locate epileptogenic foci for possible surgical removal. Implantation was undertaken only after failure of more conservative techniques and with informed consent. Large endogenous scalp potentials are evoked by tone pips of two different fixed pitches presented at random intervals. The subject counts silently the 'rare' tones (comprising 20% of the total) randomly interspersed amongst the more frequent tones. We find that this task evokes large potentials in the hippocampus, hippocampal gyrus, and amygdala. The potentials evoked by rare tones are much larger than those evoked by frequent, even though the tones are of identical intensity and duration. Similar potentials are evoked by rare visual stimuli randomly intermixed with the more frequent stimuli of equal luminance, contour and contrast. In the auditory task, the limbic potentials are greatly attenuated if the same stimuli are presented while the subject is reading a book and explicitly instructed to ignore the tones. Our data strongly indicate that these potentials are locally generated: they are large, often exceeding 100 microvolts in amplitude, and sometimes exceeding 150; they can be recorded between two electrodes situated within the same medial temporal lobe, with tip separation as small as 1.0 mm; and, phase-reversals are commonly observed between different limbic sites. Direct evidence that locally-generated synaptic flows are present during these potentials are concurrent changes in limbic unit-activity. These data may permit investigators of endogenous scalp potentials to infer the effects of their manipulation on specific neural events in specific brain regions, which in turn can be related to the large body of knowledge concerning the structure and function of these regions in animals and humans. Current studies are attempting to determine whether some component of the scalp-potentials is in fact a passively volume-conducted reflection of the much larger limbic-generated potentials.

190.7 HIPPOCAMPAL PYRAMIDAL CELLS DEPOLARIZE ON THE NEGATIVE PHASE OF DENTATE THETA RHYTHM IN URETHANE ANESTHETIZED RATS. S.E. Fox. Dept. of Physiol., Downstate Med. Ctr., SUNY, Brooklyn, NY 11203.

Rats were anesthetized with urethane (1.5 g/kg). Concentric bipolar stimulating electrodes (400 μm o.d.) were stereotaxically placed in the ventral hippocampal commissure. Recording macroelectrodes (150 μm nichrome--referred to skull screw) were placed in the right hippocampal formation under electrophysiological control, to record slow waves and evoked field potentials (0.1 Hz to 10 KHz) from the molecular layer of the dentate and the basal side of CA1. Theta rhythm of about 4 Hz ($>$ 0.5 mV p-p in the dentate) occurs spontaneously in such animals and is phase-reversed between two electrodes so placed. Theta rhythm can also be evoked by mild tactile stimuli. The left hippocampus was exposed by suction and covered with mineral oil. Glass micropipets filled with 3M KCl (30-90 MΩ) were inserted through a wax seal. All other openings were sealed with dental cement. Intracellular recordings ($\geq$40 mV membrane potential) were made during theta rhythm from CA1 and CA3 pyramidal cells (identified by depth and characteristic responses to commissural stimuli). Extracellular theta rhythms and membrane potential (21 to 106 cycles per cell) were normalized for cycle duration, then averaged, and crosscorrelation functions were computed.

Seven of the eight cells recorded thus far (5 in CA1, 3 in CA3) have shown membrane potential oscillations phase-locked to extracellular theta rhythm averaging from 1 to 3 mV p-p. In all these cases the maximum depolarization occurred within 45° of the maximum negativity of the dentate theta rhythm. That is, intracellular theta rhythms in CA1 and CA3 were 170° ± 30° ($\bar{X}$ ± s.d.) out of phase with extracellular theta rhythm from dentate, making them approximately in phase with CA1 theta rhythm. There was suggestive evidence for measurable phase-locked changes in conductance during theta rhythm in two of the three cells tested. The other cell was a CA3 cell which also showed no intracellular theta rhythm ($<$ 0.5 mV p-p).

Fujita and Sato (J. Neurophysiol. 27: 1011, 1964) and Artemenko (Neirofiziologiya 4: 531, 1972) previously reported oscillations of pyramidal cell membrane potentials phase-locked to theta rhythm in curarized rabbits, but they disagreed on the phase relation. These results agree with those of Artemenko, and disagree with Fujita and Sato. The present work is part of an attempt to determine the synaptic mechanisms of theta rhythm generation, and to discover explanations for the complexities introduced by these and several other recent studies which appear to be contradictory.

190.8 EFFECTS OF HEMICHOLINIUM-3 AND CHOLINE ON HIPPOCAMPAL ELECTRICAL ACTIVITY DURING IMMOBILITY VS. MOVEMENT. Daniel J. Green* and Terry E. Robinson. Psychology Department and Neuroscience Laboratory, 1103 E. Huron, University of Michigan, Ann Arbor, MI 48109.

Earlier studies have suggested that there may be two neurochemically distinct inputs to the hippocampus, each of which is capable of producing hippocampal rhythmical slow activity (RSA or theta; e.g. Vanderwolf, JCPP, 1975, 88, 300). The RSA which may occur during behavioral immobility is abolished by systemically administered atropine (i.e. it is atropine-sensitive), while the RSA which invariably accompanies behaviors such as walking, running, or swimming in rats is not abolished by systemic atropine (i.e. it is atropine-resistant). However, in these previous experiments large doses of atropine sulfate (20-50 mg/kg, i.p.) have been required to abolish atropine-sensitive RSA. This raises the question as to whether the effects of these doses of atropine are due to possible non-specific toxic effects of the drug, or to the specific blockade of cholinergic synapses. The approach we took to answer this question was to manipulate brain cholinergic activity in ways other than through the use of post-synaptic receptor antagonists, and to determine if such manipulations had the effects predicted by previous studies with atropine.

We found that the immobility-related RSA (IRSA) elicited by electrical stimulation of the reticular formation in urethanized rats (which is known to be atropine-sensitive) was severely attenuated by intraventricular injections of hemicholinium-3 (HC-3; 7.5μg in 1.5μl saline into each lateral ventricle). HC-3 depletes brain acetylcholine, presumably by inhibiting the uptake of choline into cholinergic terminals. A subsequent systemic injection of choline chloride restored electrical stimulation-elicited IRSA in the majority of rats. Systemically administered choline has been reported to elevate brain acetylcholine. Intraventricular injections of the vehicle had no effect on hippocampal electrical activity. In contrast, HC-3 had no deleterious effects on the movement-related RSA (MRSA) recorded from freely moving rats during behaviors such as walking or struggling. Therefore, atropine-sensitive IRSA is also HC-3 sensitive, and atropine-resistant MRSA is also HC-3 resistant. These results support the hypothesis that there are at least two pharmacologically-distinct neurochemical systems capable of producing hippocampal RSA. It is suggested that acetylcholine is necessary for the production of IRSA, but is not necessary for the production of MRSA. An as yet unidentified noncholinergic system appears sufficient to produce MRSA. It is interesting to speculate that the effects of choline on hippocampal electrical activity reported here may relate to recent reports that choline administered to humans enhances performance on some learning tasks.

190.9 BEHAVIOR MODULATION OF HIPPOCAMPAL RESPONSE IN CA1 REGION OF THE RAT: MODEL AND EXPERIMENTS. L. S. Leung. Inst. Medical Physics TNO, 45 Da Costakade, Utrecht, The Netherlands.

Average evoked potentials (AEPs) were recorded in the hippocampal CA1 region in rats following electrical stimulation of the stratum radiatum (Schaffer collaterals). In a sequence of behavioral states characterized by increasing peak frequency of the EEG (e.g. awake immobility, head movement only, walking), the AEPs showed (1) decreasing initial peak amplitude, (2) increasing frequency of oscillation with (3) decreasing damping (Neurosci. Abstr., 5:277, 1979).

To account for these results, a previous model (Biol. Cybernetics, 31:219, 1978) has been extended and simulated with an analog computer. The model consists of a population of interneurons (INT) inhibiting a population of pyramidal cells (PYR). PYR are assumed to excite INT after a static, saturation type nonlinearity which passes on the excitation but not the inhibition of PYR. Therefore PYR excitation results in INT excitation and ends in PYR inhibition, simulating the responses in the anesthetized rat. In the awake rat, noise input from the brainstem provides a linearizing effect such that inhibition of PYR is followed by the disexcitation of INT, and then disinhibition of PYR (equivalent to excitation), and so forth. The feedback loop is completed and oscillation occurs. Increasing input from the brainstem, assumed to correspond with the sequence of behavioral states from immobility to increasingly vigorous movements, or with tetanizing the brainstem with increasing stimulus intensity, provides further linearization and results in the gradual change of the three AEP characteristics mentioned above. The model further predicts: (1) A decrease of response oscillation frequency if the intensity for evoking the AEP is increased; this has been observed experimentally. (2) For the intrinsic hippocampal circuit, a frequency response that peaks at 20 - 50 c/s, corresponding to the frequency range of the hippocampal fast EEG. (3) With high (recurrent inhibitory) feedback gain, a low amplitude limit cycle of 50 - 60 c/s. The latter is similar to the high frequency afterdischarges following a tetanus of high frequency of the hippocampus.

190.10 ABNORMALITIES IN EEG AND SPATIAL PERFORMANCE FOLLOWING INTRA-HIPPOCAMPAL INJECTIONS OF NEUROTOXINS. R. J. Sutherland, I. Q. Whishaw and B. Kolb, Department of Psychology, The University of Lethbridge, Lethbridge, Alberta, Canada, T1K 3M4.

Kainic acid, colchicine, or ferric chloride were microinjected into the dorsal hippocampus in rats. We found that kainic acid preferentially destroyed the CA3 and CA4 cell layers, colchicine preferentially destroyed the granule cells in the fascia dentata, and ferric chloride preferentially destroyed the CA1 cell layer.

The effects on EEG of unilateral intra-hippocampal microinjection of these neurotoxins were assessed in freely-moving rats implanted with recording electrodes bilaterally in the dorsal hippocampus and frontal neocortex. Injections of kainic acid or ferric chloride into dorsal or ventral hippocampus generated electrographic and behavioural seizure activity during the first 24 hr. On subsequent days, hippocampal and neocortical EEG activity returned to pre-injection levels. Colchicine did not have an immediate effect on EEG, but beginning 2-3 days after injection there was a marked and long-lasting decline in the amplitude of hippocampal theta activity recorded ipsilaterally to the injection site.

In other rats, pre-treated with kainic acid, colchicine, or ferric chloride unilaterally in the dorsal hippocampus, EEG profiles through the hippocampus and overlying cortex were obtained in an acute recording session. Normal hippocampal theta activity was found in both dorsal and ventral generators after destruction of CA3 and CA4. Theta amplitude was reduced if significant damage was produced in CA1 or the dentate granule cells. Following ferric chloride injection, normal theta activity was found in both hippocampal generators, but to date the destruction of the CA1 cells has not been complete.

In rats injected bilaterally in the dorsal hippocampus with kainic acid, colchicine, or ferric chloride, a disruption of performance was demonstrated in the Morris open-field water maze. The deficits in this spatial task are correlated with the abnormalities in hippocampal EEG profiles.

190.11 ARE RHYTHMICAL SLOW WAVES IN THE EEG RELATED TO MEMORY CONSOLIDATION? A RE-EXAMINATION. K.-P. Ossenkopp and C. H. Vanderwolf. Dept. Psychology, Univ. Western Ontario, London, Canada, N6A 5C2.

We have reinvestigated the claim of Landfield et al. (Science, 1972, 175, 87-89) that the EEG theta rhythm is related to memory consolidation. Rats with bipolar electrodes in the neocortex and hippocampus were given one training trial with footshock (1 ma) in a step through passive avoidance task. Neocortical and hippocampal EEG as well as general activity were monitored for 30 min following the footshock. High levels of hippocampal theta and associated motility in this post-shock period predicted poor passive avoidance performance on retests over the next 3 days ($r = -.79$, $n = 10$, $p < .01$) whereas high levels of neocortical 6 - 9 Hz spindles and associated alert immobility predicted good passive avoidance performance on the retests ($r = +.80$, $n = 10$, $p < .01$). Experiments were also carried out in a two-way shuttle-box. In both learning tasks hippocampal theta activity correlated with immediately concurrent motor activity while 6 - 9 Hz neocortical spindles or low voltage fast activity occurred during alert immobility. Further, frequent 6 - 9 Hz spindles predicted good performance in the passive avoidance situation where the correct response is immobility, but did not predict good performance in the shuttle-box where the correct response is running. We conclude that hippocampal theta activity and 6 - 9 Hz neocortical spindles are related to motor activity and not to memory consolidation.

190.12 PREDICTION OF P300 AMPLITUDE AND LATENCY FROM A COGNITIVE TEST BATTERY. A. T. Summerfelt, K. Keller*, A. M. I. Wagman and F. Funderburk*, Neuroscience Program, Maryland Psychiatric Research Center, P.O. Box 3235, Baltimore, MD 21228.

Nine normal and 13 schizophrenic subjects were tested on a battery of cognitive tasks and on an evoked potential procedure designed to differentially affect the P300 component. An attempt was made to predict P300 amplitude and latency from the cognitive variables. The cognitive tests included the Purdue Pegboard, Wisconsin Card Sort, Halstead Categories, Full Range Picture Vocabulary, Tapping Test, Tactual Performance Test, and Memory for Designs. A one way ANOVA between groups revealed differences on several Wisconsin variables (sets, cards, % error, efficiency), (normals better than schizophrenic), and set 5 of the Halstead (HCT5) (schizophrenic better than normal). There was no difference in age or IQ between groups, while the education of schizophrenics was slightly higher than for normals (15 yrs. vs. 12.9). Results of the evoked potential procedure, which involved the random presentation of background, novel, and target stimuli, are discussed elsewhere (Wagman, Keller, Summerfelt, and Burton, 1980).

The correlation matrix of all variables suggested a selection of cognitive variables relatively uncorrelated with each other but which significantly loaded on P300 amplitude and latency. These included from the Wisconsin, the number of sets completed (Wsets), the number of cards to criterion, set interruptions, and percent error; HCT5; from the Tactual Performance Test, scores from the non-dominant hand (Tnon), from both hands (Tboth) and the memory test; and the Memory for Designs (MFD). An all possible subset regression with Mallow Cp criterion, using these variables to predict P300 amplitude and latency for six electrode locations (left and right frontal, central, and occipital) revealed (with a strict criterion of $F>4.35$ df 1/20 for significance) that only MFD was a predictor of P300 amplitude, and only for target stimuli. MFD, Tnon, and Tboth were predictors of P300 latency. Separate stepwise regressions averaging across electrode placements for either amplitude or latency with coding for group and group X variable interaction, showed that MFD accounted for 33% of the target amplitude variance, while no other cognitive variable was a significant predictor of amplitude. Several group X variable interactions were significant with respect to P300 latency. These included Wsets, MFD, Tboth, and Tnon. In each case, the interaction was carried by the normal's linear trend, while the schizophrenics showed no relationship. In all comparisons the linear trend indicated that poor cognitive performance was associated with either decreased P300 amplitude or increased P300 latency.

190.13 ELECTROCORTICAL FREQUENCY DIFFERENCES IN HYPERACTIVE, LEARNING DISABLED, MIXED TYPE AND NORMAL BOYS. Phillip Holcomb*, Roscoe A. Dykman*, Peggy T. Ackerman* and D. Michael Oglesby* (spon. E. Powell), Behavioral Sciences Laboratory, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72205.

In a previous paper (Dykman et al., J. Ner. and Men. Dis.,167: 288, 1979) we have contrasted differences in the behavioral performance of four groups of boys (hyperactive, learning disabled, learning disabled and hyperactive, and normals) engaged in a visual search conditioning task. We now report Principle Component analyzed EEG results obtained in the same paradigm.

Forty boys (WISC IQs>90) between 7 and 10 years of age severed as subjects. Group membership criteria were: Conners' teacher rated hyperkinesis scores of ≥ 15 for hyperactive and mixed type boys (<15 for all others); and Wide Range Achievement Test and Gray Oral Reading standard scores of ≤ 90 for learning disabled and mixed type boys (>90 for all others). On each trial subjects were awarded one penny for pressing the correct (one of twelve) transparent display windows behind which appeared one of 12 ASCII symbols (e.g., +, -,*,#). Over the experimental session visual fields progressed (as the child solved each successive search problem) from two to twelve simultaneously displayed symbols. EEG data (C_1,C_2,P_3,P_4, linked ear lobes; down 3 db at 1 and 100 hertz), which were recorded for one second pre and one second post stimulus onset, were Fourier transformed and averaged (Varian 100/F computer) over trials. Twenty frequency values (1 to 20 hertz) were submitted to a principle components analysis and subsequent component scores were analyzed with repeated measures analyses of variance.

Four components accounted for 87% of the variance. Component 1 which revealed primary activity between 16 and 20 hertz (beta) and secondary activity between 8 and 10 hertz (alpha) produced significant ($p<.05$) effects for group (control>mixed>hyper> learning disabled), pre vs. post stimulus onset (pre>post) and a pre-post onset by electrode site interaction. While Components 2,3 and 4 were less revealing , Component 3 (primary activity between 7 and 10 hertz) did produce significant pre-post onset and electrode site by pre-post onset effects similar to one.

These results agree with those of Grunewald-Zuberbier et al. (EEG and Clin. Neurophy., 38:149, 1975), who reported decreased alpha blocking and lower beta levels for hyperactive than non-hyperactive boys. The current study further suggests that: one, it is a combination of both alpha and beta frequencies that are responsive to group differences; and two, that learning disabled children are similarly (to hyperactives) depressed on this EEG component.

190.14 EEG FACTORS DERIVED THROUGH SPECTRAL ANALYSIS. Duilio Giannitrapani. Veterans Administration Medical Center, Perry Point, MD 21902.

A systematic evaluation of the degree of independence of EEG components has been attempted by subjecting EEG spectral analysis data to factor analysis. For this purpose the EEG of 56 11 to 13 year-old normal subjects was obtained from 16 scalp positions during 8 different behavioral states, each of 8 sec duration. Fast Fourier analysis was performed to obtain power density estimates for each of 17 bands (0 to 34 Hz), each 2 Hz wide, and averaged for the 8 conditions. A total of 272 variables (16 scalp positions X 17 frequency bands) was used in the factor analysis.

After preliminary analysis, principal component analysis with Varimax rotation of 10 factors was employed. The following rotated factors were obtained: Factor 1, loaded primarily on 29 Hz bilaterally; Factor 2, loaded primarily on 5 and 7 Hz and less on 9 Hz bilaterally: Factor 3, loaded primarily on 13 Hz and less on 15 Hz bilaterally; Factor 4, loaded exclusively on 15 and 17 Hz bilaterally; Factor 5,loaded primarily on 23 to 27 Hz in Fronto-Temporal areas on the left side; Factor 6, loaded exclusively on 11 Hz activity bilaterally; and four other factors accounting for minor portions of the variance.

The structure of the factors indicates a relative frequency-specific rather than brain-area specific factor structure. Factor 1, accounting for the greatest variance, relates to 29 Hz activity earlier found in greater amplitude in younger people, in females and in a portion of a schizophrenic sample. Some of the factors relate to traditional clinical EEG parameters (Factor 6, dominant alpha; Factor 2, theta activity). Other factors could be interpreted as representing newly discovered relationships with higher cortical functions (Factor 3, verbal functions; Factor 4, numerical functions) since in a previous study with the same data 13 Hz power was demonstrated to relate to verbal intelligence and 15 to 17 Hz to numerical processing. Factor 5 has an as yet unidentified role. The desirability of studying narrower band widths to resolve the composition of factors within the 2 Hz band width of this study is discussed.

190.15 AN EEG METRIC OF POST-SYNAPTIC DOPAMINE RECEPTOR ACTIVATION IN MICE. R. L. Lloyd* and P. K. Randall* (SPON:D.F.Lindsley).

On-going electrical activity was recorded from cortex and striatum of C57BL/6J mice following injections of the dopamine (DA) agonist apomorphine, and antagonist, haloperidol. Behavioral akinesia following 2mg/kg haloperidol was associated with large increases in striatal amplitude recorded from bipolar electrodes (1mm tip seperation) in anterior caudate. Power spectral analysis revealed a mean increase in power (1-15Hz) of the striatal signal of 254% 1 hr. following injection. Apomorphine, however, tended to reduce power 45-70% within 30min (3mg/kg); a time course similar to that of behavioral effects of apomorphine (e.g. stereotypy). However, 90 min following 3.0mg/kg apomorphine (IP), these animals, which manifested stereotypy earlier, underwent a rebound effect which was behaviorally and electrophysiologically similar to the effects of haloperidol: there was a decrease in motility, and catalepsy could be evoked. Ninety min following injection, striatal electrical power increased 272% over pre-injection levels. This effect could be produced with very small (IP) doses of apomorphine (0.01-0.05mg/kg), including high amplitude striatal signals, decreased motility, and catalepsy. Within 20 min striatal electrical power increased 43%.

These drugs also affected the simultaneous cortical EEG, with a slowing in frequency following 2.0 mg/kg of haloperidol. One hour after injection, the power spectrum changes from a difuse profile in the range 2-9Hz to a tightly constricted profile with a predominant frequency between 1.6-3.2Hz. The power in the band 0-3.25 Hz increased at this time by an average of 151%. During catalepsy, however, the predominant frequency shifted to a slightly higher range (3.25-6.0Hz) which increased in power by 202%. Following catalepsy, the EEG returned to the lower range predominating before catalepsy. Similarly, 90 min following 3.0 mg/kg apomorphine, the power in the 0-3.25Hz range increased by 216%.

These results are consistent with the selective effect of low doses of DA agonists upon the more sensitive presynaptic autoreceptors which would result in reduced DA release. The resulting DA deficit in the neostriatum would produce behavioral and electrophysiological effects similar to postsynaptic receptor blockade with haloperidol and suggests that recording of striatal gross-potentials may provide a convenient metric for post-synaptic DA receptor activation.

190.16 DEVELOPMENTAL CHANGES IN EEG PATTERNS OF NARCOLEPTIC DOBERMAN PINSCHERS. Arthur Foutz, Theodore L. Baker and William D. Dement, Stanford Sleep Disorders Center, Stanford, CA. 94305.

Narcolepsy is a disease occurring in humans and in several equine and canine breeds. It is usually characterized as a disorder of rapid-eye-movement sleep (REM) because many of the pathological manifestations suggest abnormal intrusion of REM into the waking state. For example, previous polygraphic studies of adult narcoleptic dogs in our laboratory have indicated: (1) sudden attacks of cataplexy (a REM-like inhibition of skeletal muscles) during periods of intense emotionality (2) REM-like desynchronized EEG during cataplexy, sometimes coupled with rapid eye movements and muscle twitches (3) sleep-onset REM periods. Experimental breeding of narcoleptic Doberman pinshers from our canine narcolepsy colony has yielded 35 puppies (6 litters) all of which have exhibited symptoms of narcolepsy within 4 wks. to 6 mos. of birth. We studied one male and one female (littermates) at intervals from 13 wks. to 16 mos. and a young adult male from a previous breeding of the same parents. EEG, EOG and EMG were recorded with implanted electrodes, and EEG signals were digitized and submitted to spectral analysis with a PDP-11 computer. Dogs were recorded during normal sleep-waking cycles and during cataplectic attacks elicited by play or food. The unanticipated finding of this study was that narcoleptic puppies showed not only the typical REM-like EEG patterns during cataplexy, but also periods of high amplitude slow-wave EEG activity. During some attacks, the EEG tracing consisted almost entirely of slow-wave EEG activity, which was indistinguishable from EEG recorded during normal non-REM sleep (NREM) periods. In some cases, a catapletic attack would initiate sustained, complete NREM sleep which did not spontaneously terminate. At other times, catapletic attacks were brief and consisted of alternating periods of both types of EEG patterns. In contrast, the young adult Doberman and the puppies re-recorded at 13 months showed only the REM-like EEG pattern during cataplexy. Catapletic attacks recorded in the more mature dog were much briefer and ended spontaneously. These findings indicate that narcolepsy may be manifested as a more generalized disorder involving both REM and non-REM sleep in the immature dog. Current studies are focused upon understanding developmental processes whereby narcolepsy becomes primarily a REM disorder in the adult dog.

191.1 SYNAPTOGENESIS IN THE VISUAL CORTEX OF NORMAL AND 6-OHDA-TREATED RATS. M. E. Blue*, J. G. Parnavelas and A. R. Lieberman* (SPON: H. Feit). Dept Cell Biology, Univ. Texas Health Sci. Ctr., Dallas, TX 75235 and Dept. of Anatomy, Univ. Coll. London, London, U.K.

The formation of synapses and their morphological maturation were studied by electron microscopy in the visual cortex of albino rats of several postnatal ages. The analysis was conducted on photographic montages of strips of cortex 50µm wide and extending from the pia to the white matter. The morphological features of all synapses were characterized and their positions were plotted on a scale map of the cortical strip on which the extent of the layers was marked.

There were few synapses (on the average 30 per montage) present in the visual cortex of animals 12 hr. of age, with the majority being located in the deep parts of the cortex. Synapses contained a few vesicles and appeared immature in their morphology; Gray's type I contacts predominated. There was a 6-fold increase in the number of synapses between 12 hr. and day 6 of postnatal life. At day 6, the distribution of synaptic contacts remained uneven, with the highest densities present in areas corresponding to layers I, IV and V/VI. Synaptic morphology was more mature and Gray's type I contacts remained the prevalent variety. Synaptogenesis continued at a high rate during the second postnatal week, and at day 14 there were approximately 3 times as many synapses as there were at day 6. The total number of synaptic contacts increased markedly during the third week, and by day 21 the number and morphological features of synapses resembled those of adult rats.

In addition, the influence of norepinephrine on cortical synaptogenesis was examined in rats that received intraperitoneal injections of the neurotoxin 6-hydroxydopamine (6-OHDA) in early postnatal life. Animals received an injection of 50µg/g body weight on each of the first two days and an injection of 100µg/g body weight on the third postnatal day; vehicle injected littermates were used as controls. Photomontages of 50µm strips of visual cortex were prepared from the 6-OHDA-treated animals and from their control littermates. Preliminary results from two ages (days 4 and 6) during the first week of postnatal life showed that there was a significantly higher number of synapses present in the visual cortex of animals whose cortical noradrenergic afferents were previously lesioned compared to their control littermates. However, at day 14, the number of synapses present in the cortex of lesioned and control animals were approximately equal. Further experiments are in progress to accurately describe the process of synaptogenesis in the visual cortex devoid of noradrenergic afferents.

191.2 SYNAPTOGENESIS IN CHICK SYMPATHETIC GANGLIA. Kathleen A. Hruschak*, Victor L. Friedrich, Jr. and Ezio Giacobini (SPON: S. Maxson). Dept. of Biobehavioral Sciences, The University of Connecticut, Storrs 06268.

Chicks at the four ages: 10 days in ovo, 1 and 30 days after hatching and adult (360+ days after hatching) were fixed by perfusion and the lumbar paravertebral ganglia, L1-L4, were prepared for electron microscopy.

Total ganglionic volume increases progressively from 0.01 mm^3 per ganglion at 10 days in ovo to 0.09 mm^3 at 1 day after hatching to 0.13 mm^3 at 30 days after hatching to 0.80 mm^3 in the adult. The neuropil/soma compartment increases 100 fold over this period from .0046 mm^3 at 10 days in ovo to 0.46 mm^3 in the adult. The rate of increase is the greatest in the interval before hatching and is substantially less, subsequently.

The number of synapses per unit area (synaptic density) of ganglionic tissue (in thin sections) was determined for each of the four ages. At 10 days in ovo, synapses are sparse (240 synapses/mm^2); their density is only ten per cent of the adult value. The synaptic density increases over 17 fold from 10 days in ovo to 1 day after hatching (4200 synapses/mm^2) demonstrating that synapses are formed rapidly during the last week of incubation (days 10 to 21 in ovo). The synaptic density decreases approximately 50% from 1 day after hatching to adulthood with the greatest decrease, 35% (2800 synapses/mm^2) occurring between 1 and 30 days after hatching. In the adult, the synaptic density is very low, 2200 synapses/mm^2. This decline in synaptic density probably reflects a dilution of the synapses into a progressively larger total ganglionic volume. In addition, the rate of synaptogenesis may decrease substantially shortly after hatching. This issue will be resolved when the determination of total numbers of synapses based on synaptic density, currently in progress, is completed.

Our results indicate that synaptogenesis appears to be most intense between 10 and 21 days in ovo, and may decrease substantially after hatching.

191.3 CORRELATION OF ACETYLCHOLINE RECEPTORS WITH ENDPLATE ACETYLCHOLINESTERASE AND NERVE TERMINAL PROCESSES AT DEVELOPING FROG NEUROMUSCULAR JUNCTIONS. K. Morrison-Graham* (SPON: M. S. Letinsky). UCLA School of Med., Dept. of Physiol., Ahmanson Lab. of Neurobiology, and the Jerry Lewis Neuro-Muscular Research Center, Los Angeles, CA. 90024.

The distribution of acetylcholine receptors (AChR) relative to the nerve terminal arborization and endplate acetylcholinesterase (AChE) was examined in the cutaneous pectoris muscle of Rana catesbiana bullfrogs from late-staged tadpoles to 7 month old post-metamorphic frogs. The muscle was removed and the AChR stained with tetramethylrhodamine-labelled α-bungarotoxin. Photographs of junctional receptors were taken, and the nerve terminal and postsynaptic AChE stained with the NBT/AChE method (Letinsky & DeCino, J. of Neurocytology, 1980).

In general, within any given terminal arborization, the distribution of AChE and AChR correspond closely with the NBT-stained nerve terminal processes. However, several different staining patterns were also observed, including: 1) most frequently, an absence of receptor staining underneath a growing tip (an axonal process extending approx. 5 µm past the confines of the endplate AChE and resembling the growth cones seen in tissue culture); 2) faint receptor staining under the initial part of a long growing tip (10-20 µm) without detectable AChE; 3) postsynaptic gutters revealed by AChE staining which were devoid of the normal overlying nerve processes and without demonstrable AChR; and 4) differences in the AChR staining intensity within an individual endplate. In addition, along NBT-stained processes which were varicose in appearance, the AChR and AChE staining patterns were similar with both being present under the varicosities but absent under the fine interconnectives. These differences in AChR, AChE, and nerve terminal staining patterns suggest ongoing growth and remodeling at established neuromuscular junctions. These were present at all ages studied, however, they were more prominent in the first weeks following metamorphosis when there is a rapid elimination of multiple innervation.

191.4 SYNAPTIC DENSITY IN THE TECTUM: EFFECTS OF NUMBER AND SIZE OF OPTIC AFFERENTS. Adrienne E. Lynch,* John J. Brunette,* and Stephen A. George. Biol. Dept. and Neuroscience Prog., Amherst College, Amherst, MA 01002.

The tissues of triploid amphibians contain larger but fewer cells than normal diploids, so that structures such as eye and brain are of comparable size in diploids and triploids. Thus, animals of different ploidy provide a suitable system for studying how the number and size of afferent fibers influence the density of synapses formed by these afferents.

We counted the number of myelinated optic nerve fibers in 40 nerves from diploid (2N) and triploid (3N) Xenopus at 5 stages from mid-larval (stage 53) to post-metamorphic (stage 66). We measured the cross sectional areas of a sample of 3368 fibers from 16 of these nerves at stages 56 and 66. Differences in the number of fibers in 2N's and 3N's were maximal at the earliest stages. For example, at stage 53 the 2N nerves averaged 369±31 myelinated axons (mean ± S.E.), compared to 227±39 for 3N's. In contrast, differences in fiber area were greatest at later stages. For example, at stage 66, the average area of 3N fibers was 18% greater than the 2N average.

To assess the role of axon size and number in synaptogenesis, we exchanged left eye rudiments between 2N and 3N embryos at stage 28, and prepared controls that received transplants of the same ploidy. Synapses in both tecta of 5 postmetamorphic animals from this series were counted in mosaics of electron micrographs covering the full depth of the tectal neuropil. Three measures of synaptic density were calculated: the average number of synapses per μm^3 (N_V); the total number of synapses under 1 μm^2 of tectal surface (N_a); and the number of synapses per tectal cell nucleus (N_n). All three measures of density were strongly influenced by the ploidy of the optic nerve input. For example, N_V for 2N innervation was $1.27 \pm .09$ synapses/μm^3 while N_V for 3N optic nerves was $0.89 \pm .06$ ($p<.02$). However, there were no substantial differences in any of these measures of density when the ploidy of the tectum was used as the dependent variable (e.g. $N_V = 1.09 \pm .18$ synapses/μm^3 in 2N tecta, compared to $1.01 \pm .09$ in 3N tecta, $p>.4$).

Though it is not surprising that a reduction in the number of inputs during development (e.g. 3N input to 2N tectum) would lead to a reduction in synaptic density, it is noteworthy that synaptic density can be increased above normal levels (e.g. for 2N input to 3N tectum) by differences in the size and number of inputs that do not involve gross changes in the amount of tissue in the input pathway.

191.5 FREEZE FRACTURE OF DEVELOPING NEUROMUSCULAR JUNCTIONS IN THE TADPOLE. K. Lynch*, C.-P. Ko, D.W. Pumplin and C.D. Harris*. Uniformed Services Univ. and Sec. on Funct. Neuroanat., LNNS, NINCDS, NIH, Bethesda, MD, and Univ. of Md. Med Schl., Baltimore, MD.

The rectus abdominis muscle of the tadpole is a mixed muscle which persists through metamorphosis. Due to the ease with which its neuromuscular junctions (NMJs) can be freeze fractured, we feel that it holds great promise for the ultrastructural study of neuromuscular development.

In R. pipiens, the muscle appears at about stage 24 (about 10 days) of embryonic development. Over several days, nerves enter the ventral body wall and muscle fibers develop, aligned in 5 or 6 tiers. The nerve bundles run along the boundary lines between adjacent tiers, dorsal to the myotendinous junctions. NMJs were located by staining for acetylcholine receptors (AChRs) with rhodamine-labeled α-bungarotoxin and for cholinesterase activity. The NMJs first appear near the myotendinous junctions and along the course of a few nerves that branch from the main trunks.

During the 2 to 3 months after embryonic development, NMJs become less frequent at the myotendinous junctions and larger and more numerous in the central part of each muscle tier. Freeze fracture of tadpole muscles during this period shows innervation sites which usually contain several nerve endings. Large P-face particles (interpreted as AChRs) in the postsynaptic membrane are concentrated in raised plaques separated by particle-free zones. Junctional folds, where present at all, are very shallow. No Schwann cell processes are evident between nerve and muscle. The presynaptic P-face contains particles that we interpreted to be active zone particles. In some NMJs, these are scattered or in short, randomly oriented double rows. In others, longer double rows are aligned on regularly spaced transverse ridges. The presence of ridges does not correlate with differences in terminal shape or receptor distribution. Where two or more nerve endings run parallel at a single innervation site with such ridges, their ridges are in register and appear to lie over shallow junctional folds. Cross-fractures and thin sections show that the nerve endings contain abundant synaptic vesicles and all other typical NMJ organelles. Freeze-fractured NMJs resembling those on frog twitch fibers have been seen in mature frog rectus abdominus; no slow junctions have yet been identified.

Our findings show some of the structural changes that lead to mature innervation of an amphibian muscle. The main changes observed were a shift in the position of the NMJs within the muscle, a shift from multiple to single innervation, enlargement of the junctions, and the appearance of active zones and junctional folds.

191.6 DENERVATION-INDUCED CHANGES IN ACETYLCHOLINE RECEPTORS AT GOLDFISH RETINOTECTAL SYNAPSES COMPUTED FROM INTRACELLULAR RECORDINGS IN TISSUE SLICES. John A. Freeman, Dept. of Anatomy, Vanderbilt University, Nashville, TN 37232, U.S.A.

In order to quantitate changes in the localization and density of nicotinic acetylcholine receptors (nAChR's) occurring during optic nerve denervation and reinnervation, intracellular recordings were made from neurons in tectal slices obtained at various times after optic nerve crush. The dendritic surfaces of individual tectal neurons, identified under Nomarski optics, were mapped iontophoretically for their sensitivity to ACh (Freeman, J. A., Soc. for Neuroscience, 5: 2495, 1979). In normal slices, ACh sensitivity was localized to 3 discrete zones corresponding to the regions of optic nerve synapses. The density of nAChR was estimated to be 1,500-3,500 molecules/μm^2 synaptic membrane from

$$p = 4\ A\ R_t/(\pi^2\ b\ r\ N_a\ V_t)$$

where A is Avogadro's number, R_t =moles ^{125}I-αbungarotoxin bound/slice volume V_t, N_a=areal density of synapses ($9X10^6/cm^2$, Norden and Freeman, Soc. for Neuroscience, this meeting), r=radius of synaptic disk (0.2μm) and b=fraction of nicotinic synapses (0.5, Oswald, Schmidt, Norden and Freeman, Brain Res., 187: 13, 1980). The Stoke's radius of the solubilized nAChR has previously been determined to be 80 Å (Oswald and Freeman, J. Biol. Chem. 254: 3419, 1979). Taken together, these density and size measurements suggest that acetylcholine receptors are packed very tightly at retinotectal synapses, probably constituting the major protein component of the subsynaptic membrane, and that the nAChR might be important for the structural integrity of the synapse, as previously postulated (Freeman, Nature, 269: 118, 1977). Following denervation 50% of nAChR's are rapidly lost. During reinnervation localized high density receptor aggregates reappear at synaptogenic sites. The detailed temporal relationship between receptor aggregation, seen with DTAF-alpha bungarotoxin, and synaptogenesis is presently being studied. Preliminary results suggest that regenerating fibers induce receptor clustering.

191.7 DEVELOPMENT OF ORGANOTYPIC CULTURES OF NEONATAL RAT HIPPOCAMPUS R. L. Beach, S. L. Bathgate*, A. Y. Kwan* & C. W. Cotman. Dept. Psychobiology, Univ. of Calif., Irvine, CA. 92717.

To facilitate progress on cellular mechanisms of the development of plasticity of hippocampal neurons we have developed and characterized an organotypic culture system of hippocampus. Transverse slices of neonatal hippocampii were maintained in culture for up to 3 months. Explants were grown on polylysine coated coverslips for subsequent staining. Cell types in these cultures were positively identified with a number of specific markers. Neurons and neurites were labelled via immunofluorescence and immunoperoxidase techniques utilizing tetanus toxin and antitoxin. Astrocytes were identified by their reaction with antibodies to glial fibrillary acidic protein. Antigalactocerebroside was used to demonstrate oligodendrocytes. Fibroblastic and endothelial cells were characterized by their distinctive staining patterns with antifibronectin and antimyosin. In cultures grown in 20% serum, neurites elongated and glia migrated directly onto the substrate rapidly. After several days the neurites were primarily on top of the glia. By six days a number of granule cells had migrated onto the glial mat amid a dense meshwork of neurites. These cells could be identified by their position relative to the pyramidal cell layer in the explant and their size and shape under phase contrast and after silver impregnation. The great majority of the cells were astrocytes although patches of fibroblasts or endothelial cells, and occasional oligodendrocytes were seen. In older cultures pyramidal neurons could be recognized in the outgrowth after silver impregnation.

Synapses were seen in the outgrowth by the fifth day in culture, and rapidly increased in number. The earliest synapses were symmetric with few vescicles, but within a few days many of the synapses had pronounced postsynaptic densities and accumulations of vesicles. Cultures were also grown in serum free media (Bottenstein & Sato, PNAS 76: 514, 1979). In serum free cultures non-neuronal cell proliferation and migration into the outgrowth was markedly suppressed. The extent and rate of neurite outgrowth during the first week appeared similar to that achieved in the presence of serum, but a denser neuritic network grew directly on the substrate without serum. In these cultures non-neuronal outgrowth was never very extensive and did not overtake the neurite outgrowth. These cultures will be of use in studying the factors regulating differentiation synaptogenesis and plasticity in hippocampal neurons. (Supported by NIMH grant no. MH 19691 and NIH grant no. NS 08597.)

192.1 SYNAPTIC PLASTICITIES AT AN IDENTIFIED SYNAPSE IN APLYSIA ABDOMINAL GANGLION CAN BE CHARACTERIZED USING THE SPONTANEOUS FIRING OF THE PRESYNAPTIC NEURON. P.B. Guthrie & S.H. Barondes. Dept. of Neurosciences and Psychiatry, UCSD, La Jolla, CA 92093, and Dept. of Psychiatry, VAMC, San Diego, CA 92161.

Neuron RC1, monitored by its postsynaptic potentials in R15 (synapse RC1-R15), has been shown to be spontaneously active in an isolated Aplysia central nervous system preparation (Woodson & Schlapfer, Br.Res. 173:225-242, 1979). Since the RC1-R15 EPSP has been shown to exhibit pronounced plasticities (history-dependent amplitude variations) upon stimulation of the right connective, we wished to determine whether the frequency of the spontaneous bursting activity of RC1 elicited significant amplitude variations of this type.

We initially tested the manner in which these plasticities might be expressed at RC1-R15 in the isolated abdominal ganglion by choosing a stimulation pattern resembling the spontaneous firing pattern of RC1. Trains of stimuli (20-100 stimuli) at a given frequency (1/sec-5/sec) were separated by intervals of variable duration. Data collection was begun after 10 minutes of stimulation. Plots of the amplitude of the first RC1-R15 EPSP following the interval versus the interval duration show three phases corresponding to 1) short term facilitation, 2) early (rising phase) post-tetanic potentiation (PTP) and 3) late (falling phase) PTP. The magnitude of the amplitude variations representing the different plasticities varied as a function of the train frequency.

The amplitude of the spontaneous RC1-R15 EPSP in the isolated central nervous system preparation, plotted as a function of the preceeding interval, showed an identical complex curve. This suggests that the instantaneous frequency of RC1 is a major factor in determining the EPSP amplitude. To test this, we recorded the temporal pattern of RC1 and used this pattern to stimulate RC1-R15 in the same preparation. A one-to-one comparison between the spontaneous RC1-R15 amplitudes initially observed with the pattern and the stimulated EPSP amplitudes induced by artificial stimulation of the right connective with this same pattern showed a high correlation over the entire frequency range of RC1. This result also provides very strong evidence for the presynaptic nature of these synaptic plasticities.

This method of analysis of the spontaneous RC1-EPSPs has also been used to verify quantitative differences in PTP amplitudes observed at several different RC1-synapses upon right connective stimulation.

Supported by the Veterans Administration Medical Research Program.

192.2 POSTSYNAPTIC MODULATION OF SYNAPTIC EFFICIENCY BY A FAST, TRANSIENT OUTWARD CURRENT. Lawrence Salkoff* (SPON: W.S. CAIN). Dept. of Biology, Yale Univ., Box 6666, New Haven, Ct. 06511.

Changes in synaptic efficiency are usually associated with presynaptic changes involving the release of neurotransmitter substances. However, an exception is reported here that shows plasticity in synaptic efficiency due to a postsynaptic change in membrane excitability. In the dorsal longitudinal flight muscles of Drosophila depolarizing electrical activity lowers the voltage and current thresholds for the spiking response (Salkoff & Wyman, submitted). Thus, EPSPs which are below spike threshold prior to muscle membrane electrical activity may be above threshold following membrane electrical activity. This is illustrated in the accompanying figure where nerve stimulation applied at 2 Hz evoked 8 EPSPs of equal amplitude, shown superimposed in the figure. The first seven EPSPs produced identical subthreshold responses. 200 ms prior to the 8th sweep a priming pulse was delivered to the muscle through an intracellular electrode (the priming pulse, not shown, was 50 ms in duration and of sufficient current to elicit several spikes). The final EPSP, although no larger than the previous 7, then elicited the spike shown in the figure. The mechanism responsible for the membrane excitability increase involves the depression of an inhibitory, fast, transient outward current, the Drosophila A-current, which is similar to the molluscan A-current first analyzed by Conner & Stevens (1971, J. Physiol. 213: 21-53). Voltage clamp analysis has shown that the Drosophila A-current is suppressed by a prior depolarizing voltage step more positive than -55 mv. Suppression of the current persists for up to 1.5s following a depolarizing voltage step.

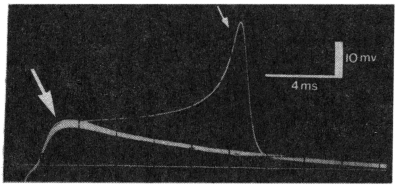

Figure Legend

large arrow: 8 consecutive EPSPs

small arrow: spike elicited by 8th EPSP following a priming pulse.

The effect of prior membrane activity on synaptic efficiency was also demonstrated entirely by nerve evoked responses. A single EPSP was below spike threshold, but a pair of EPSPs would summate to cause a muscle spike. This single spike sufficiently inactivated the A-current so that the next EPSP did elicit a spike. SUPPORTED BY USPHS NS07314 to R.J. WYMAN.

192.3 REPETITIVE NERVE FIRING IN DROSOPHILA MUTANTS: THE ROLE OF SPATIAL AND GENETIC INTERACTIONS. B. Ganetzky* and C. F. Wu. Dept. of Genetics, Univ. of Wisconsin, Madison, Wis. 53706 and Dept. of Zoology, Univ. of Iowa, Iowa City, Iowa 52242.

Shaker (Sh) mutants exhibit leg-shaking behavior under ether anesthesia and prolonged ejps at the larval neuromuscular junction (Jan et al., Proc. Roy. Soc. Lond. B 198:87, 1977). Abnormal repetitive firing of motor axons is also observed in Sh larvae. The behavioral and physiological phenotypes of Sh are suppressed by nap^{ts} (no action potential, temperature-sensitive), a mutation that decreases nerve excitability. A subcritical dose (15-25nM) of tetrodotoxin (TTX) coordinately reduces repetitive firing and ejp duration of Sh mutants in a manner similar to that of nap^{ts}. However, other evidence implicates the axon terminal in the generation of multiple nerve spikes: (1) A nerve severed near the terminal shows no repetitive firing. (2) After blocking the axonal Na spike with a high dose of TTX (>50nM) prolonged transmitter release can still be evoked by a strong electrotonic stimulus. (3) Repetitive firing is reversibly blocked when the presynaptic Ca current is blocked in 0[Ca^{2+}] saline or by 5mM Co^{2+}. (4) Simultaneous recording at two points along the nerve indicate that the extra spikes travel antidromically from the terminal. A positive feedback model involving the axon and the terminal is proposed. We suggest that the Sh terminal is abnormally excitable and capable of developing a presynaptic Ca action potential. The presynaptic Ca current serves as a source of depolarization that triggers additional axonal Na spikes, which in turn further depolarize the terminal or help maintain the depolarization. Interrupting the feedback cycle by reducing excitability at either the terminal or the axon inhibits the generation of repetitive nerve firing and prolonged ejps.

Repetitive nerve firing is also caused by a bang-sensitive (bas^{MW1}) mutation. The mechanism is not yet clear but it differs from Sh in that the terminal apparently plays a lesser role. The behavioral and physiological defects of bas^{MW1} are also suppressed by nap^{ts}.

192.4 LONG-LASTING HOMOSYNAPTIC AND HETEROSYNAPTIC POST-ACTIVATION POTENTIATION IN THE HIPPOCAMPUS. John M. Sarvey. Dept. of Pharmacology, Uniformed Services University of the Health Sciences, Bethesda, MD 20014.

Following repetitive electrical stimulation of a monosynaptic input to pyramidal cells of either field CA1 or CA3 in hippocampus, a long-lasting potentiation of the excitatory response to single stimuli to that input has been found by several laboratories. Those groups recording from CA1 report that the potentiation is homosynaptic, i.e., restricted to the response to the repetitively stimulated input (Andersen et al. Nature 266:736, 1977; Lynch et al. Nature 266:737, 1977), while those recording from CA3 report that the potentiation is heterosynaptic, i.e., response to a second, unstimulated input is also potentiated (Yamamoto & Chujo. Exp. Neurol. 58:242, 1978; Misgeld et al. Exp. Brain Res. 37:217, 1979). It is difficult to decide whether the contrasting findings are due to differences in methodology or in the two hippocampal fields.

In 300-400 µm thick hippocampal slices from guinea pigs population spikes could be extracellularly recorded from stratum pyramidale of CA1 in response to "single" (0.37 cps) rectangular current pulses to either stratum radiatum (Schaffer, Sch) or stratum oriens (OR) in CA1. Repetitive (20 or 50 cps for 10 s) stimulation of either OR or Sch resulted in potentiation of the orthodromic population spike. This potentiation, which was followed for 30 min to 3 hr, was homosynaptic (restricted to the repetitively stimulated input).

In contrast, repetitive stimulation of the dentate hilus (mossy fiber, mf) of fimbria resulted in potentiation of the orthodromic response in stratum pyramidale of CA3 to single stimuli to either stimulation site. Similarly, heterosynaptic potentiation in CA3 resulted when the stimulation sites were mf and Sch. Failure of a conditioning shock to the heterosynaptic input (e.g., Sch) to facilitate the response to a test shock 20 ms later to a second input (e.g., mf) compared with consistent homosynaptic facilitation (e.g., mf-mf) insured that two separate inputs were indeed being stimulated.

The finding of homosynaptic potentiation in CA1 and heterosynaptic potentiation in CA3 in the same laboratory suggests that there are intrinsic differences in these two fields of the hippocampus.

192.5 QUANTAL ANALYSIS IN FASCIA DENTATA GRANULE CELLS: B. L. McNaughton and C. A. Barnes. Institute of Neurophysiology, University of Oslo, Karl Johans Gate 47, Oslo 1, Norway.

Synaptic response variability was analysed in granule cells of the fascia dentata in vitro in order to determine the quantal characteristics of the EPSPs from afferent fibres in the molecular layer. Hippocampal slices were incubated at 34 ± 2°C in a medium containing (in mM): NaCl 124; $CaCl_2$ 2; KCl 2; KH_2PO_4 1.25; $MgSO_4$ 2; $NaHCO_3$ 26; glucose 10. Standard intracellular recording techniques were used. The cells used in this study had the following mean characteristics: RMP 69 ± 2 mV; R_{in} 41 ± 3 MΩ; action potential 58 ± 1 mV; EPSP at discharge threshold 24 ± 2 mV.

In 40 cells, the stimulus intensity was adjusted to give a very small EPSP (.7 ± .08 mV) and 500 responses were collected at a frequency of 0.5 Hz. Fifteen data sets showing drift of resting potential of more than ± 3 mV or non-stationarity in response amplitude were rejected from the analysis. Three types of analysis were carried out: 1) a fourier transform method was devised to detect the most significant periodicity in the EPSP amplitude frequency histograms; 2) the mean quantal content ($\bar{m}$) was calculated from the logarithm of the total number of trials divided by the number of apparent response failures; 3) $\bar{m}$ was also calculated from the ratio of the mean response amplitude ($\bar{V}$) squared divided by the amplitude variance (after subtraction of an estimate of the noise variance). The quantal size was estimated by $\bar{V}/\bar{m}$. The three methods gave similar results (quantal sizes of .08 mV, .26 mV, and .14 mV respectively). Large reductions in $\bar{V}$ brought about by elevated Mg^{++} (12 mM) or reduced Ca^{++} (0.8 mM) resulted in a significant increase rather than a decrease in apparent quantal size (estimated by method 3). This indicates that the EPSP variability was not due to conduction failures. Detailed analysis of the minimally detectable EPSPs at stimulus intensities bordering threshold suggest that the mean quantal content of the EPSP due to a single afferent fibre is close to 1. Analysis of the role of non-linear summation of unitary EPSPs at multiple synaptic sites is still in progress. At present, however, the lower and upper bounds on the number of synapses required to discharge the average granule cell can be set at about 150 and about 1000 respectively.

192.6 INTRACELLULAR RECORDING OF SYNAPTIC INTERACTIONS BETWEEN PYRAMIDAL CELL AND INTERNEURON PAIRS IN HIPPOCAMPAL BRAIN SLICES. W. D. Knowles and P. A. Schwartzkroin, Dept. Neurological Surg., University of Washington, Seattle, WA 98195.

Simultaneous intracellular recordings were made in vitro from pairs of neurons in longitudinal slices of guinea pig hippocampus. Special attention was given to synaptic interactions between CA1 pyramidal cells and interneurons (identified per Schwartzkroin and Mathers, 1978).

Slices of adult guinea pig hippocampus were cut 500 μ thick in the dorsal-ventral longitudinal plane, and maintained in 35° C. Ringer's solution. Intracellular recordings were made using 50-100 megohm, 4M K^+ citrate + .01 M KCl filled electrodes. Possible synaptic interactions were tested for by injecting depolarizing intracellular current pulses (.5 to 1 nA x 100 ms) to evoke spike trains in one cell while noting postsynaptic potentials in the second cell.

Synaptic interactions between CA1 pyramidal cells were rare, occurring in 13% of 101 pairs. Only hyperpolarizing postsynaptic potentials were seen. These hyperpolarizations were usually low amplitude (<5mV), slow, and smooth, and lasted for the duration of the spike train in the presynaptic cell. Occasionally individual IPSPs corresponding to each presynaptic spike could be detected. We did not observe any signs of electrotonic coupling. The same cell was penetrated with both electrodes more frequently than penetration of synaptically coupled cell pairs. Such double penetrations must be kept in mind when studying interactions.

Of more than 360 cells successfully penetrated, less than 6% were identified as interneurons. Simultaneous recordings were made from 19 different interneurons and 43 different pyramidal cells. Induced spike trains in the interneuron caused IPSPs in the pyramidal cell in 30% of the 43 pairs. These IPSPs were similar to the IPSPs seen in pyramidal cell pairs. Stimulation of the pyramidal cell caused EPSPs or spikes in the interneuron in 28% of the pairs. In 53% of the pairs, no interactions were seen.

These results provide the first direct confirmation of the hypothesis (Andersen, Eccles, and Løyning, 1964) that IPSPs may result from recurrent inhibition mediated by inhibitory interneurons. The magnitude of inhibitory interactions in our study, however, was surprisingly small considering that large IPSPs were produced in pyramidal cells by extracellular stimulation of afferent pathways.

192.7 SYNAPTIC TRANSMISSION: DEPENDENCE ON CALCIUM LEVELS IN HIPPOCAMPAL SLICE. G. Somjen and Raymond Dingledine. Dept. Physiol., Duke Univ., Durham, N.C. and Dept. Pharmacol., Univ. N. Carolina, Chapel Hill, N.C.

Measurements in the brain and spinal cord of interstitial calcium activity ($[Ca]_o$) with calcium-sensitive microelectrodes have demonstrated that changes in $[Ca]_o$ accompany epileptiform seizures, spreading depression and, to a smaller extent, repetitive stimulation of synaptic afferent systems. We have asked whether such changes in $[Ca]_o$ could influence local transmitter release. The question here is the sensitivity of synaptic transmission to small departures of $[Ca]_o$ from its resting level of 1.2mM. Rat hippocampal slices (350 μ thick) were perfused at 33-36°C in vitro with a solution of the following composition (in mM): NaCl 130, KCl 3, NaH_2PO_4 1.25, $NaHCO_3$ 24, $CaCl_2$ 1.2, $MgSO_4$ 1.2, glucose 10. A tungsten microcathode was inserted among the afferent fibers running in the stratum radiatum of the CA1 region, while a Ca-sensitive microelectrode was positioned nearby in the same layer and used to record both $[Ca]_o$ and extracellular focal potentials. Weak electrical stimuli evoked a typical two-component field potential, interpreted to reflect the presynaptic volley, and the excitatory postsynaptic current (the focal EPSP: Andersen et al., Brain Res., 144:11, 1978). By varying the stimulus intensity different numbers of presynaptic fibers were recruited, and input-output curves for the activated synapses could be constructed by plotting the size of the presynaptic fiber volley against the size of the focal EPSP. With moderate intensities of stimulation such input-output curves were linear, the slopes of which were taken as measures of the effectiveness of synaptic transfer.

Following a step change in [Ca] at the inflow valve, bathing fluid surrounding the slices equilibrated to the new level within 3-5 min, while the interior of the slices required 30-60 min for complete equilibration. During an imposed gradual decrease in $[Ca]_o$, from 1.2 to 0.5mM, the slope of the input-output transfer became progressively less steep. When $[Ca]_o$ was raised to 3mM the slope increased in a graded manner. A curvilinear relation was found between the normalized slope (the slope at 1.2mM $[Ca]_o$ being defined as 100%) and log $[Ca]_o$, the form of which suggests that synaptic transfer depends on the second power of $[Ca]_o$. For deviations from the "normal" 1.2mM level, a change of 0.1mM $[Ca]_o$ produced about 15% change in the slope of the input-output function. Under certain pathological conditions changes in $[Ca]_o$ are large enough for local synaptic transmission to be significantly affected.

192.8 TRANSMISSION AT THE Ia FIBER-MOTONEURON SYNAPSE IN THE CAT. T.C. Cope and L.M. Mendell. Duke Med. Ctr., Durham, N.C. 27710

We have previously demonstrated that EPSPs produced by the action of single group Ia fibers in α motoneurons fluctuate both in amplitude and latency from trial to trial. In the present work we have examined these fluctuations in greater detail. EPSPs were recorded intracellularly in motoneurons; in anesthetized preparations sweeps triggered by the group Ia impulse recorded in the dorsal rootlets were digitized and stored on tape at 20 μsec resolution. Latency of each EPSP was measured and EPSPs in each latency bin were summed on an averaging computer. We found a linear inverse relation between amplitude and latency. We also noted a systematic highly significant decrease in rise time (RT) for EPSPs as latency increases; the slope of this relationship averaged -1 μsec(RT)/μsec(latency). These results indicate that fluctuations in EPSP parameters are not due to activation of different portions of the soma-dendritic membrane by a distributed system of boutons given off by single Ia fibers since large, short latency EPSPs would be expected to exhibit the shortest rise times rather than the longest ones. These fluctuations are not correlated with changes in motoneuron membrane potential or motoneuron time constant, and so they probably represent variability in a presynaptic process. One possibility is invasion of different boutons in the ensemble from trial to trial, but the arrangement of boutons would have to be highly regular with respect to the Ia fiber axon and motoneuron soma at different synapses in order to give the uniform correlations which have been observed. Variability in the action potential from trial to trial due for example to fluctuations in terminal polarization (e.g. PAD) might be postulated to explain our results. However, any decrease in the amplitude and rate of rise of the terminal action potential causing a decrease in EPSP amplitude and an increase in latency would be expected to prolong EPSP rise time due to broadening of the action potential. The uniform correlations we have observed are best predicted by a model similar to that proposed for the neuromuscular junction (Barrett and Stevens, J. Physiol. 227:665, 1972). Arrival of the impulse at the terminal causes increased probability of release of transmitter. Release of a quantum at any time during the period of increased probability is independent of previous release. Therefore short latency EPSPs (i.e. first quantum released early) will tend to be the largest (i.e. most quanta released since period of release is longest) as well as having the slowest rise time (i.e. each increase of 1 μsec in period of release causes a 1 μsec increase in rise time). Our findings support the quantal hypothesis for synaptic transmission at this synapse. (Supported by NIH; NS08411; NS14899.)

192.9 PROPERTIES OF EPSP LATENCY DISTRIBUTIONS AT Ia FIBER-MOTONEURON SYNAPSES IN THE CAT. L.M. Mendell and T.C. Cope (Spon. S.G. Nelson). Duke Univ. Med. Ctr., Durham, N.C. 27710

Individual EPSPs produced in a motoneuron by the action of a single Ia fiber fluctuate in onset latency from trial to trial. Latency distributions at all synapses are unimodal but differ in variance (Collatos and Mendell, Neurosci. Abst. 5, 1979). We have analyzed 11 synapses whose EPSPs exhibited large amplitudes (178 μV<A<1090 μV) and brief rise times (140 μsec<RT<460 μsec); these differ not only in standard deviation ($\sigma=\sqrt{\text{variance}}$; 41 μsec<σ<116 μsec) but also in mean (μ; 281 μsec<μ<534 μsec) measured from arrival of the Ia impulse in the terminal region (i.e. from the terminal potential). A key finding is the linear correlation between μ and σ (r=0.81, n=11). The intercept (μ for σ=0) is 216 μsec. The slope is 2.66 yielding the relation $(216-\mu)/\sigma=-2.66$. Assuming normality (satisfied by most of these distributions), we conclude that the probability of an EPSP with latency < 216 μsec is small ($p<0.01$; i.e. $z=-2.66$); this latency is the same for each distribution. Our interpretation is that the expected minimum latency is similar at each of these synapses. The measured minimum latency fluctuated from synapse to synapse with a mean of 204±15 μsec (SEM); this was not correlated with μ. This variability arose from the difficulty in fixing the minimum latency accurately due to the relatively small number of EPSPs with short latency, as well as possible contributions from other active fibers synapsing on the motoneuron. Our estimate of minimum latency (216 μsec) is less than that obtained by Munson and Sypert (260 μsec - J. Physiol. 296:329, 1979) using averaged EPSPs whose onset always occur at a longer latency than the minimum measured from single trials. It follows that minimun synaptic delay (= synaptic latency − postsynaptic electrotonic delay) is about 45 μsec less than the 170 μsec estimated using averaged EPSPs (Munson and Sypert, ibid). We speculate that minimum synaptic delay is fixed at all synapses of this type, and that our finding of fixed minimum EPSP latency is a consequence of similar postsynaptic electrotonic delays for these very brief EPSPs. Synaptic efficacy is related to μ and σ since mean EPSP amplitude is inversely correlated with the square of the coefficient of variation ($C.V.=\sigma/\mu$) of the latency distribution ($p<0.05$). This may be explained by the finding (Kuno and Miyahara, J. Physiol. 204:405, 1969) that EPSP amplitude fluctuations are Poisson distributed (mean EPSP amplitude α quantal content α $1/C.V.^2$), and that EPSP amplitude and latency are linearly correlated at single synapses (Cope and Mendell, this volume). We propose that these synapses vary in kinetics of transmitter release, and that this is correlated with the average number of quanta released. (Supported by NIH-NS08411; NS14899.)

192.10 EFFECTS OF STIMULUS RATE ON POSTSYNAPTIC POPULATION POTENTIALS EVOKED BY IMPULSES IN SINGLE IA FIBERS. Hans-R. Lüscher, Paul Ruenzel* and Elwood Henneman. Dept. of Physiology, Harvard Medical School, Boston, MA 02115.

Evidence from studies on post-tetanic potentiation of EPSPs in motoneurons (Nature 282: 859, 1979) suggests that conduction in terminal arborizations of Ia fibers is influenced by the recent history of activation of the arborization. This has led us to investigate how the frequency of impulses in single Ia fibers influences the amplitude of the responses they evoke in motoneurons. To do so, we have measured changes in the amplitudes of postsynaptic population potentials (PSPPs), elicited by stimulating single Ia fibers electrically at different frequencies. The PSPPs were recorded from ventral roots perfused with isotonic sucrose, using a recently developed technique (J. Neurophysiol. 42: 1146, 1979). Input to the spinal cord was restricted to a single Ia fiber by dissecting the muscle nerve into branches and further into bundles for stimulation. All the dorsal roots on the left side were cut from L_5 to S_2, except for a filament containing the single Ia fiber. The PSPP measured at each frequency was an average of 256 sweeps. All but 1 of the 15 Ia fibers tested showed a relatively standard frequency response curve characterized by low frequency depression and high frequency facilitation. The lowest frequency used (1 Hz) was sufficient to produce a slight depression of PSPPs. With increasing frequency, a progressive depression of PSPP amplitude developed that was maximal at 2-5/sec. With further increases in frequency, PSPP amplitude increased to a maximum at 10-20/sec. It is likely that oscillations in the excitability of the membrane following action potentials modulate conduction through regions of low safety. Low frequency depression may be due to increases in branch point failure when successive action potentials coincide with phases of depressed membrane excitability following preceding impulses. High frequency facilitation may be due to less branch point failure when successive action potentials coincide with the hyperexcitable period. The observation that PSPP amplitude is a function of stimulation frequency suggests that the architecture of the terminal arborization together with the impulse pattern conducted through it play decisive roles in determining the total synaptic action of Ia impulses. Perhaps most important of all is the conclusion that the information from the periphery, carried to the terminal arborization and coded as a pulse train, can itself modulate the coupling between cells.

192.11 SYNAPTIC EFFICACY DEPENDS ON MOTOR UNIT SIZE IN NORMAL FROG NEUROMUSCULAR JUNCTIONS. Alan D. Grinnell and Albert A. Herrera. Jerry Lewis Neuromuscular Research Center, UCLA, Los Angeles, CA. 90024.

Neuromuscular junctions of the frog sartorius often exhibit low safety factors, some eliciting only subthreshold EPPs on single stimulation (Grinnell & Herrera, J. Physiol. in press). We have shown that when 1/2 of the muscle is removed, so that the motor axons reinnervate a reduced number of muscle fibers, they form stronger synapses, releasing an average 4.2X more transmitter per unit length of terminal (Herrera & Grinnell, Soc. for Neurosci. Abs., 1979). Reinnervated whole muscles do not show this enhancement. This suggests that a reduction in the number of terminals a motoneuron must maintain makes the remaining terminals stronger.

The enhanced transmitter release in muscles with reduced motor unit size might also suggest that, in normal muscles, junctions belonging to the largest motor units would show lowest safety factor, and vice versa. We have examined this hypothesis by measurement of tensions elicited by stimulation of single motor units, obtained by dissection of the sciatic nerve in nerve-muscle preparations from Rana pipiens. We find that the opposite obtains: the largest motor units have synapses of uniformly high safety factor, all suprathreshold to a single stimulus, with no change in twitch tension to changes in external Ca^{++} concentration between 3.0 and 1.0mM in the Ringer (normal = 1.8 mM). Progressively smaller motor units show smaller and smaller safety factors and an increasing proportion of subthreshold junctions. The twitch tensions of small motor units increase in size in 3 mM Ca^{++} Ringer, and drop sharply with reduction of Ca^{++} to 1.0 mM. The smallest motor units (approximately 5-10 mg twitch tension in the frogs we used) showed a tetanus/twitch ratio of 50-100, compared with a ratio of approximately 2 for motor units of more than 300-400 mg twitch tension. Visual inspection of contraction reinforces the conclusion that axons forming the smallest motor units innervate up to 50X as many fibers as they can drive with a single stimulus. This implies that there are many more subthreshold junctions in the sartorius than have been recognized to date. It seems probable that most of these subthreshold synapses constitute polyneuronal inputs to junctions innervated by other, suprathreshold, inputs. The subthreshold components may be so small that they are undetectable by the usual physiological techniques of assessing polyneuronal innervation. (Supported by USPHS grant NS06232, an MDA grant, and an NIH postdoctoral fellowship to A.H.)

192.12 PRESYNAPTIC EFFECTS OF γ-AMINOBUTYRIC ACID ON INTRASPINAL SINGLE CUTANEOUS AFFERENT C- AND Aδ-FIBERS. M. Randić, K. Semba and K. Murase*. Dept. Vet. Physiol., Iowa State Univ., Ames, IA 50011.

A high density of GAD-positive terminals is found in the superficial parts of the dorsal horn, the area where primary afferent fibers are known to terminate. Furthermore, recent observations on the distribution and synaptic relationships of the GAD-positive terminals within laminae II and III of the rat spinal cord (Barber et al., Brain Res., 141, 35-55, 1978) have provided additional support for the concept that GABA-containing terminals are involved in synaptic pathways which may influence excitability of primary afferents terminating in this region. While GABA is known to enhance excitability of the terminals of large A-fibers, its action on the excitability of C- and Aδ-fibers was not previously investigated.

In cats either spinalized or anesthetized with pentobarbital, small filaments of the sural nerve were prepared for recording, and thresholds for the antidromically-evoked nerve impulses of single afferent fibers were measured during intraspinal stimulation (Aδ-fibers: 1.6-8 μA; C-fibers: 4-15 μA) with a fine platinum microelectrode positioned within laminae I-III of the dorsal horn. GABA (0.5 M, pH 4.5), bicuculline hydrochloride (5 mM, pH 3-5), and piretanide (13.8 mM, pH 7.3) were iontophoretically ejected through glass micropipettes glued to a stimulating electrode (intertip distance <15 μm). Bicuculline was also administered intravenously (1 mg/kg).

The responses of C- and Aδ-fibers to GABA (50-100 nA) were not uniform: both threshold decrease and increase were observed. In the majority of C-fibers tested, GABA decreased threshold in a reversible and dose-dependent manner (range: 66-95% of control), although in some fibers, electrical excitability at the threshold value was decreased (105-139%). In Aδ-fibers, both elevation (n=7) and reduction (n=5) in threshold was produced by GABA. In some of C- and Aδ-fibers, bicuculline and piretanide reversibly suppressed the GABA-produced decrease in threshold.

The complex actions of iontophoretically applied GABA on the electrical excitability of intraspinal cutaneous afferent C- and Aδ-fibers observed in our experiments may reflect the complexity of the GABA synaptic relationships recently demonstrated in the superficial parts of the dorsal horn. Our results provide a direct pharmacological evidence that GABA is capable of modifying the electrical excitability of cutaneous afferent C- and Aδ-fibers.

192.13 RECRUITMENT OF POSTGANGLIONIC NEURONS BY BURST PATTERNING OF PREGANGLIONIC INPUT IN THE CAT STELLATE GANGLION. R.I. Birks, W. Laskey* and C. Polosa*. Physiology Department, McGill Univ., Montreal, Canada H3G 1Y6.

Burst patterning of the preganglionic neural input to the perfused cat superior cervical ganglion (SCG) has been shown to increase acetylcholine (ACh) output up to 3 times that found in response to stimulation with equally spaced pulses at the same mean frequency as the patterns (Birks, R.I., J. Physiol. 295, 51-52P, 1979). It has now been found that patterns of pulses that increase ACh stores and ACh output in the SCG are equally effective in increasing the efficacy of synaptic transmission in the cat stellate ganglion in situ.

Stimulation of the preganglionic thoracic sympathetic trunk or portions of it (between rami T4 and T5) with 0.5s trains at 40/s every 10s increased the area of the postganglionic compound action potential (CAP) recorded from the inferior cardiac nerve. Stimulation with equally spaced pulses at 2/s did not increase the CAP. In five experiments using 40/s trains, the mean increase in CAP response to patterned stimulation was 258% the control CAP before patterning. This recruitment of the neuronal pool was as great as the maximum post-tetanic potentiation of the CAP response, indicating saturation of the pool. The increase in CAP was 200% in 6 trials using a train frequency of 20/s in the patterns, and 160% in 4 trials with a train frequency of 10/s. The pool was not saturated by the patterned stimulation in these tests at reduced train frequency. The greater proportion of the increase in CAP occurred within 1 min of the start of stimulation with a smaller increase occurring over 4-9 min of further stimulation.

The time-course and magnitude of the increase in postganglionic CAP are similar to the time-course and magnitude of the increase in ACh output in SCG found earlier. These similarities, and the fact that burst patterning at a mean frequency of only 2/s can recruit into the discharge zone the entire available neuronal pool, confirm and reinforce the hypothesis (Birks, R.I., J. Physiol. 280, 559-570, 1978) that burst patterning of preganglionic input is a major mechanism of modulation of the transmission process in sympathetic ganglia.

192.14 THE EFFECTS OF CALCIUM AND MAGNESIUM ON QUANTAL CONTENT AND PROBABILITY OF RELEASE. George J. Blake* and Kenneth L. Dretchen. Dept. of Pharmacology, Schools of Medicine & Dentistry, Georgetown University, Washington, D.C. 20007.

The effects of limited Ca^{++} availability on quantal content (m) and probability of release (p) were studied on the rat hemidiaphragm "cut muscle" preparation. Miniature end plate potentials (MEPPS) and end plate potentials (EPPS) were recorded using standard techniques, and m was determined by the direct method (EPP/MEPP) at low frequency (0.1 Hz). The normal bathing medium contained 2 mM Ca^{++} and 1 mM Mg^{++}. Release was binomial, p ranged from 0.7 to 0.99 and was not significantly affected by stimulation rate. The highest values for m were obtained at low stimulus frequency (0.1 Hz); as stimulation rate increased m was depressed. High frequency (150 Hz, 1 sec.) stimulation produced a biphasic effect - an initial facilitation followed by depression of EPP amplitude to a "plateau" with m = 72% ± 4 of the first EPP. Decreasing the Ca^{++} concentration to 1 mM decreased m throughout the range of stimulus frequencies used, but p did not change. Elevation of Mg^{++} to 2 mM had no significant effect alone, but in combination with decreased Ca^{++} (to 1 mM) there was a decrease in m, n, and p, but release remained binomial. The extent of depression of these parameters was found to be dependent on the rate of stimulation. The effect of this treatment on m was the reverse of control: m measured at 0.1 Hz was depressed to 30% of control, and increased to 47% of control at 150 Hz. In addition, high frequency stimulation produced EPP's that were initially depressed and increased to 153% ± 15 of the first EPP. Although p measured at 0.1 and 2 Hz was significantly depressed to 55% of control, the difference was no longer significant when measured at 150 Hz. MEPP amplitude, frequency, rate of rise and duration were unaltered by these treatments. These results show that under conditions of depressed m, quantal release remains binomial. The depression in m, n and p produced by 2 mM Mg^{++}/1mM Ca^{++} treatment can be overcome by high frequency stimulation.

Supported in part by NSF grant BNS 78-26849.

192.15 FURTHER OBSERVATIONS ON CHANGES IN EXTRACELLULAR a_K AND a_{Ca} EVOKED IN RAT HIPPOCAMPUS BY REPETITIVE ACTIVATION. M.E. Morris, K. Krnjević, R.J. Reiffenstein* and N. Ropert*. Anaesthesia Research & Physiology Depts., McGill University, Montreal, Canada.

We have previously reported that in rats under urethane, repetitive stimulation of the fimbria or entorhinal cortex can lead to marked changes in hippocampal a_K and a_{Ca} (Krnjević et al., Can. J. Physiol. Pharmacol. 58: May 1980). At low frequencies of stimulation (< 3/s), only small increases in a_K are detectable, but there is no change in a_{Ca}. At higher frequencies, when firing in bursts is generated - and especially if electrographic seizures are manifested by desynchronized firing and after-discharges - the rise in a_K becomes very large (to 9-12 mM), and it is initially accompanied by a major fall in a_{Ca} (from 1.5 to 1.0-0.5 mM). For both ions, the maximal changes are recorded at the superficial pyramidal layer (where fimbrial stimulation elicits the largest positive field); but a sharp fall in a_{Ca} is evident only at this level, whereas a substantial rise in a_K is seen over a wide range of depth (> 1 mm).

More recent experiments have confirmed these findings during both urethane and ketamine anaesthesia; the principal difference seen with ketamine was that unusually low intensities of fimbrial stimulation were adequate to evoke population spikes, seizure discharges and corresponding large changes in ions. Moreover, systematic measurements in the CA1 and CA3 regions, combined with marking of critical points of recording by local release of small amounts of pontamine blue, showed no major difference in the pattern of depth distribution, frequency sensitivity, etc. of changes in a_K and a_{Ca}. In view of the probable existence of a cholinergic (septo-hippocampal) input, a possibly serious source of error in our measurement of a_K is that the "classical" ion-selective microelectrodes (prepared with the Corning liquid-ion-exchanger) are even more sensitive to ACh^+ than to K^+; therefore, similar recordings were made using valinomycin microelectrodes (Oehme and Simon, Analyt.Chim.Acta. 86:21,1976) which are much more sensitive to K^+ than to ACh^+, though having a slightly slower response time. The results were essentially indistinguishable from those obtained with "classical" a_K electrodes, and so confirm the identity of the signals previously ascribed to a_K. Finally, by varying the intensity of repetitive fimbrial or entorhinal stimulation, we have obtained further evidence of a close correlation between the appearance of population spikes and the sudden large increments in a_K or falls in a_{Ca}. This reinforces the conclusion that, in contrast to the situation in the spinal cord and the dorsal column nuclei, in the hippocampus changes in extracellular a_K and a_{Ca} are generated mainly by post-synaptic neuronal firing.

Supported by the Canadian Medical Research Council.

192.16 PROPERTIES OF POTASSIUM CHANNELS IN SYNAPTOSOMES MEASURED WITH ^{86}Rb. M. P. Blaustein, R.K. Ickowicz* and H. Rasgado-Flores*. Dept. of Physiol., Univ. of Maryland, School of Med., Baltimore, MD. 21201

Potassium channels play an important role in the modulation of neurotransmitter release from presynaptic nerve terminals. To gain new insight into the physiology of K permeability in presynaptic terminals, we investigated some properties of ^{86}Rb efflux from presynaptic terminals (synaptosomes) from rat forebrain. Synaptosomes, isolated by the method of Krueger et al. (J. Membrane Biol. 50:287, 1979), were loaded with ^{86}Rb, a K analogue known to pass through voltage-sensitive K channels (Hille, J. Gen. Physiol. 61:669, 1973). When ^{86}Rb was added to standard physiological salt solution (with 5 mM K and 145 mM Na), the tracer accumulation was ouabain-sensitive (i.e. Na-K pump mediated). Tracer uptake rose to a steady level, equivalent to ~400 μmoles K/gm synaptosome protein, with a half-time of about 5 min at 30°C.

The ^{86}Rb-loaded synaptosome suspensions were diluted 40-fold into "efflux solutions" of desired composition; these solutions often had reduced Na concentrations, with some Na replaced isosmotically by K or choline. Following incubations of 5 to 60 sec. at 30°C, the suspensions were rapidly filtered on glass fiber filters (Whatman GF/C) and washed with three 4 ml aliquots of tracer-free ice-cold physiological saline containing 25 mM TEA (tetraethylammonium). The washed filters were analyzed for ^{86}Rb content by liquid scintillation spectroscopy; a reduction in ^{86}Rb counts on the filters, with increasing time of incubation or promoted by special incubation conditions, was taken as a measure of Rb efflux.

The rate coefficient for Rb efflux, from ^{86}Rb-loaded terminals, into control (5 mM K) solutions was 0.03-0.1 min^{-1}. The Rb efflux rate coefficient increased with increasing $[K]_o$, to ~0.4 min^{-1} at 90 mM $[K]_o$ and ~0.6 min^{-1} at 150 mM $[K]_o$. Rb efflux was not increased when external Na was replaced by choline at constant $[K]_o$. The fraction of the Rb efflux promoted by K-rich media was almost completely blocked by 25 mM TEA and by 1.25-2.5 mM 4-aminopyridine, two agents known to block K channels in excitable cells. Phencyclidine (100 μM), which is also known to block K channels (Albuquerque et al., Proc. Natl. Acad. Sci. USA, 77:1224, 1980), reduced the K-stimulated Rb efflux by about 50%. These data indicate that tracer flux methods can be used to study some of the physiological and pharmacological properties of K channels in mammalian presynaptic nerve terminals in vitro. 192.18 DEPLETION OF SUBSTANCE P IN A SYNAPTIC VESICLE FRACTION DERIVED FROM VERATRIDINE-DEPOLARIZED SYNAPTOSOMES. E. Floor and S.E. Leeman. Dept. Physiol., Harvard Medical School, Boston, MA 02115

Synaptic vesicles containing a peptide neurotransmitter, substance P (SP), were partially purified and evidence that at least some are involved in transmitter release was obtained. Synaptosomes prepared from rat brainstem by homogenization in 0.32M sucrose, differential centrifugation and banding on a linear Ficoll/sucrose density gradient were lysed by osmotic shock, centrifuged to remove debris, and the resulting crude vesicle supernate fractionated according to particle size on a glass bead column of average pore size 290nm. Acid extractable, radioimmunoassayable SP eluted in a major peak of material slightly larger than ^{14}C-labelled bacteriophage P22 (diameter about 60nm). This peak probably represents the large (100nm) SP-reactive synaptic vesicles seen by immunohistochemistry. SP-like immunoreactivity from whole rat brain was shown to be identical to synthetic SP by reverse-phase HPLC. In the peak fractions from the glass bead column SP was enriched 5 to 10-fold (per mg protein) over the initial homogenate. Vesicular SP in the crude vesicle supernate was not attacked by endogenous proteases at 0^{o} or 37^{o} although added, synthetic SP was degraded at both temperatures.

If the vesicle population identified above were active in transmitter release, strong depolarization of synaptosomes might be expected to reduce its content of SP. Veratridine (VA) has been shown to depolarize rat brain synaptosomes and to induce a tetrodotoxin(TTX)-sensitive, calcium-dependent release of transmitters. Synaptosomes were placed at $37^{o}C$ in a physiological buffer (Schenker et al., Nature 264: 790, 1976) and bubbled gently with O_2 for 4 min. Parallel batches were then oxygenated an additional 5 min under various conditions, lysed, and the crude vesicle supernate run on the glass bead column. Recoveries of SP in the vesicle peak after treatments with VA (75 µM) or TTX (1 µM) were as follows (percent of control ± SEM): VA, 73 ± 3% (n=5); TTX + VA, 109 ± 4% (n=4); and VA in calcium-free buffer, 96 ± 7% (n=3). The mean recoveries of protein under each of the three experimental conditions in synaptosomes after $37^{o}C$ incubation and in the crude vesicle supernate after lysis were within 4% of control values. Recoveries of vesicular SP were normalized with controls in each experiment on the basis of these protein recoveries. These results show that veratridine induces a substantial TTX-sensitive, calcium-dependent depletion of SP in the vesicle fraction and suggest that part of the readily releasable pool of SP in synaptosomes is vesicular.

192.19 ACETYLCHOLINE SYNTHESIS FROM [^{14}C]-GLUCOSE AND [^{3}H]-CHOLINE IN SYNAPTOSOMES FOLLOWING HIGH-AFFINITY CHOLINE CARRIER INHIBITION BY CHOLINE MUSTARD AZIRIDINIUM ION. B. Jane Rylett and E. Howard Colhoun*. Dept. Pharmacology, University of Western Ontario, London, Canada, N6A 5C1.

In our laboratory, the nitrogen mustard analogue of choline, choline mustard aziridinium ion (ChM Az), has been shown to be a potent and irreversible inhibitor of both high- and low-affinity choline transport into rat forebrain synaptosomes. Although not a selective blocker of the high-affinity choline uptake, this choline analogue shows a greater potency with respect to the sodium-dependent, high-affinity choline carriers in synaptosomes. In addition, synaptosomes incubated with ChM Az show a decrease in intrasynaptosomal choline acetyltransferase activity which paralleled the time-dependent alkylation of sodium-dependent, high-affinity choline carriers by the nitrogen mustard compound. In the present study, the ability of ChM Az-treated synaptosomes to synthesize acetylcholine (ACh) from either [6-^{14}C]-glucose or [^{3}H-N-Me]-choline was investigated to obtain more information about the sources of choline for the synthesis of ACh, and the contribution which choline supplied by the high-affinity choline carrier and choline present in the nerve terminal cytoplasm make in the biosynthesis of the neurotransmitter. Synaptosomes incubated with 1 µM [^{3}H]-choline at 37°C for 7 min showed 50% acetylation of the accumulated radioactive precursor, while those exposed to 8.2 µM (60.5 µCi/µmol) [^{14}C]-glucose at 37°C for 1 hr incorporated the [^{14}C] label into a quaternary compound with an R_f the same as ACh. Treatment of synaptosomes with 50 µM ChM Az resulted in 80% decrease in the total transport of [^{3}H]-choline into synaptosomes (high-affinity transport was completely blocked) and blocked [^{3}H]-ACh formation. The same concentration of ChM Az, following a 10 min exposure of synaptosomes to the nitrogen mustard analogue, gave a 30% decrease in the synthesis of [^{14}C]-ACh from [^{14}C]-acetylCoenzyme A stores formed in synaptosomes incubated with [^{14}C]-glucose. The results indicate that although choline transported on the high-affinity choline carrier contributed to the available choline pool for the synthesis of ACh, the transmitter may be formed also from endogenous choline in the nerve terminal. Inhibition of the high-affinity choline carrier along with inhibition of choline acetyltransferase decreased [^{14}C]-ACh synthesis which suggests either blockade of [^{14}C]-ACh formation from cytoplasmic choline at the level of choline acetyltransferase, or inhibition of unmeasureable high-affinity uptake of non-isotopic choline released from synaptosomes into the incubation medium by phospholipid degradation. Would similar results be obtained with a stimulated nerve-muscle preparation? Supported by National Research Council of Canada.

192.20 INVESTIGATION OF THE RELATIONSHIPS BETWEEN CYTOPLASMIC AND MEMBRANE ASSOCIATED ACETYLCHOLINE IN SYNAPTOSOMES. G.E. Duncan*, M.J. Clark* and P. Rowell. Dept. of Pharmacology and Toxicology, Univ. of Louisville Sch. of Med., Louisville, KY 40292.

We have investigated the time course of accumulation, the effects of varying external choline (Ch) concentration, and the effects of ions on the subsynaptosomal distribution of acetylcholine (ACh) in rat cerebral cortical synaptosomes. The ^{3}H-ACh synthesized from ^{3}H-Ch was found to be located in the cytoplasmic fraction and in membrane of hypotonically shocked synaptosomes ("H-band fraction," Whittaker, Prog. Brain Res. 31, 211, 1969) as determined by sucrose density centrifugation. No ^{3}H-ACh was associated with monodisperse synaptic vesicles. The time course of accumulation of ^{3}H-ACh associated with the synaptosomal membranes paralleled that of cytoplasmic ^{3}H-ACh as determined by hypotonic shock in distilled water. The membrane-bound ^{3}H-ACh also paralleled the cytoplasmic ^{3}H-ACh after incubating synaptosomes in varying ^{3}H-Ch concentrations. When synaptosomes were disrupted in hypotonic solutions containing 62mM Na^{+}, there was a 2-fold increase in the membrane-associated ^{3}H-ACh compared to synaptosomes disrupted in 62mM K^{+}. These hypotonic solutions were essentially as effective as distilled water in releasing the intrasynaptosomal contents. The "shocking" solution containing 62mM Na^{+} resulted in a 3-fold increase in membrane-associated ^{3}H-ACh compared to synaptosomes disrupted in distilled water.

This finding and other preliminary results indicate that disrupting nerve terminals in distilled water (a standard procedure used in subcellular distribution studies of ACh) may lead to a gross underestimation of the amount of ACh associated with nerve terminal membranes and an over estimation of the amount of ACh in the cytoplasm.

192.21 ACETYLCHOLINE AND CHOLINE LEVELS OF RAT TISSUE AND THE EFFECT OF β-BUNGAROTOXIN. M.W. Newton*, C.B. Gundersen and D.J. Jenden. Dept. of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024

The presynaptic neurotoxin, β-bungarotoxin (βtx), causes a threefold increase in acetylcholine (ACh) in the rat diaphragm (Gundersen et al., Brain Res. 182:486, 1980). We have studied the effect of βtx on ACh and Ch content of other tissues. For peripheral tissues βtx (5 µg i.p.) was injected in male rats (130-150 g). Rats were decapitated after 1.5 hr and each tissue excised. For brain regions, rats were cannulated and allowed to recover for 2 days. βtx (1 µg in 5 µl) or saline (5 µl) was injected intraventricularly. After 105 min rat brains were fixed by microwave irradiation (5 kW for 2.1 s). ACh and Ch were extracted using 15% 1 N aqueous formic acid in acetone and assayed using GCMS (Freeman et al., J. Neurochem. 24:729, 1975). Results were as follows:

	ACh ± S.E.		Ch ± S.E.	
	Control	Treated	Control	Treated
Units:nmol/gm wt wgt				
Str	64.7 ± 4.1	84.4 ± 6.2*	22.5 ± 2.0	46.0 ± 3.7**
Hip	23.4 ± 1.8	33.0 ± 2.4**	21.4 ± 3.4	42.6 ± 3.0**
Ctx	22.7 ± 3.2	24.1 ± 1.5	17.6 ± 1.0	39.0 ± 2.9**
Dia	0.91± 0.2	3.79± 0.2**	85.3 ± 4.7	71.8 ± 7.7

Str=striatum; Hip=hippocampus; Ctx=cortex; Dia=diaphragm; Hrt=heart atria; Ile=ileum; Tem=temporalis muscle; Scg=superior cervical ganglion; Adr=adrenal. N = between 4 and 13.

Results indicate the most marked increases occur in diaphragm ACh and brain Ch content. We conclude that the effect of βtx on ACh and Ch levels is consistent in direction but variable in degree among tissues. (Supported by USPHS grant MH-17691.)

192.22 DIVERSE EFFECTS OF β-BUNGAROTOXIN ON ACETYLCHOLINE METABOLISM IN MAMMALIAN PREPARATIONS IN VITRO. C.B. Gundersen and D.J. Jenden, Department of Pharmacology, UCLA School of Medicine, Los Angeles, CA 90024

The neurotoxic phospholipase A_2 β-bungarotoxin (β-Btx) causes up to a threefold increase of diaphragm acetylcholine (ACh) content (Gundersen et al., Brain Res. 182:486,1980). To characterize the mechanism of this effect we have used a GCMS assay for ACh and choline (Ch) to study the action of β-Btx on ACh turnover in P_2 fraction, brain minces and diaphragm of rat, and in longitudinal strips of guinea pig ileum. In P_2 fractions β-Btx causes a dose-dependent stimulation of the appearance of endogenous Ch in the medium. Using 0, 5 or 10 min preincubations followed by a 4 min incubation with $[^2H_4]$Ch (2 µM), β-Btx (1.25 µg/ml) causes a 40-60% increase of $[^2H_0]$Ch in the medium. We observed no inhibitory effect of β-Btx on the uptake and acetylation of $[^2H_4]$Ch or on the pellet content of $[^2H_0]$ACh and $[^2H_0]$Ch. These results contrast with those of Sen & Cooper (J. Neurochem. 30:1369,1979), who reported a significant inhibition by β-Btx of $[^3H]$Ch uptake in synaptosomes. Our data indicate that the apparent inhibition by β-Btx of Ch transport observed by Sen & Cooper may have resulted from a dilution of $[^3H]$Ch specific activity by the release of endogenous Ch. This Ch "releasing" effect of β-Btx is not seen in Ca^{++}-free solutions. Certain non-neurotoxic phospholipases A_2 and high K^+ media cause smaller increases of medium Ch (5-20% relative to control) while gramicidin D (2 µg/ml) and dinitrophenol (0.125 mM) have no significant effect. Increased "release" of Ch is not observed in diaphragm or ileum preparations treated with β-Btx (1.4 µg/ml). However, after prolonged incubation (2 hr) with toxin (1 µg/ml) a substantial rise of medium Ch is seen in experiments using brain minces. From these results we suggest that the effect of β-Btx to raise medium Ch may be an indirect action associated with the phospholipase activity of the toxin. While brief exposure to β-Btx (0.14 or 1.4 µg/ml for 30 min) raises the ACh content of diaphragm, sustained (3 hr) treatment first increases, then reduces the ACh content to a level only slightly above control. This decline of diaphragm ACh is accompanied by a significant increase of ACh efflux. β-Btx (1-2 µg/ml) does not significantly increase the ACh content of P_2 fractions, brain minces or ileum preparations. However, long term treatment of brain minces with β-Btx causes a massive outpouring of ACh and a decline of the ACh content to approximately 20% of control. The findings in these experiments are consistent with the postulate that the effects of β-Btx on ACh metabolism are highly dependent on the tissue used and the dose and time of exposure to toxin. (Supported by USPHS grant MH-17691.)

192.23 INDUCIBILITY OF MYOTONIA IN NEONATAL RATS. J. W. Gerst*, F. C. Garb* and R. A. Brumback* (SPON: W. Beatty). Zool. Dept., North Dakota St. Univ. and Neurol. Ser., V. A. Med. Ctr., Fargo, ND 58102.

Anthracene-9-carboxylic acid (9-AC, 9-Anthroic acid) is a potent inhibitor of membrane chloride conductance (G_{Cl}) and induces transient myotonic behavior in adult rat muscle. 9-AC (60 mg/kg, ip) was injected into 5-7, 10-12 and 28-30 day old Wistar/Furth rats. Electromyography (EMG) was performed on anesthetized rats 1-2 hours after 9-AC dosing. EMG of hind leg muscle was compared in uninjected, solvent injected and 9-AC injected neonates. The grading scheme was: 0 -- insertional irritability, individual motor unit activity clearly discernible (normal neonatal response); 1 -- insertional irritability with bursts of high frequency discharges obscuring individual motor unit activity; 2 -- high frequency discharges and short, waxing-and-waning (myotonic) discharges during needle insertion and/or needle movement; 3 -- sustained myotonic discharges during needle insertion and/or needle movement; 4 -- persistent myotonic discharges, either spontaneous or easily provoked by needle insertion, needle movement or muscle percussion. Neonates, 5-7 days old, EMG grade 0.9±0.14(6) (±SEM), and 10-12 days old, EMG grade 1.3±0.21(6), failed to demonstrate 9-AC induced, EMG myotonia. Furthermore, the neonates exhibited no clinical signs of myotonia. Young rats, 28-30 days old, developed EMG myotonia, EMG grade 3.0±0.06(6), and all showed obvious muscle stiffness within 3-5 minutes after 9-AC dosing.

The failure of neonates to develop myotonia in response to 9-AC injection might indicate that 9-AC does not block G_{Cl} in neonatal muscle. However, an alternative explanation is that the incomplete T-tubular system development in neonatal rat muscle may not support an adequate accumulation of potassium ions necessary for the generation of depolarizing after-potentials and myotonic spike-discharges. The threshold potential for the activation of sodium conductance in neonatal muscle may be more positive than in adult muscle; therefore, larger depolarizing after-potentials would be required to elicit the myotonic discharges in neonatal muscle (Bryant, S. H., Ann. N. Y. Acad. Sci., 317:314, 1979). Intracellular microelectrode studies on 5-12 day old neonate rats are in progress.

193.1 THE IONIC BASIS OF RESTING, RECEPTOR AND ACTION POTENTIALS IN THE CILIATE, STENTOR COERULEUS. D.C. Wood, Psychobiology Program, University of Pittsburgh, Pittsburgh, PA 15260.

The ciliate protozoan, Stentor coeruleus, produces an all-or-none contraction in response to suprathreshold mechanical and electrical stimuli. Mechanical stimuli elicit graded receptor potentials. Mechanoreceptor potentials of sufficient magnitude trigger all-or-none action potentials and contractions. The ionic basis of these mechanoreceptor and action potentials was investigated in these studies by varying the external concentration of K^+, Ca^{++}, Na^+, Mg^{++} and Cl^-.

The resting potential is a curvilinear function of $[K^+]_0$ in the range of 0.1-8mM. Dependence on extracellular $[Ca^{++}]$ was also observed over the concentration range of 0.04-10mM. Changes in extracellular $[Mg^{++}]$, $[Na^+]$ and $[Cl^-]$ produced little effect on the resting potential. These data are well fit by an equation derived with the same assumptions as the Goldman equation but in which I_{Na^+} is replaced by $I_{Ca^{++}}$ and allowance is made for the double valence of Ca^{++}. The best fit parameters in this equation are: $[K^+]_i$ = 13.1mM, $[Ca^{++}]_i$ = 0mM, $[Cl^-]_i$ = 9.9mM, P_{Ca}/P_K = 0.066 and P_{Cl}/P_K = 0.072. These intracellular concentrations are in good agreement with the values of 12.5 and 9.4mM found for $[K^+]_i$ and $[Cl^-]_i$ respectively by flame photometry. At low (<2mM) $[K^+]_0$ P_K is reduced significantly below the values observed at higher $[K^+]_0$.

As in Paramecium the peak of the action potential is most affected by variations of $[Ca^{++}]_0$ but the slope of this relation is only 12.5mV/10 x change in $[Ca^{++}]_0$. Increasing $[Cl^-]_0$ concentration makes the peak of the action potential less positive and suggest that Cl^- as well as Ca^{++} carries current during the generation of the action potential. The variations of the action potential peak are well described by the Goldman model if the previous $[K^+]_i$, $[Ca^{++}]_i$ and $[Cl^-]_i$ concentrations are assumed and P_{Ca}/P_K = 7.9 and P_{Cl}/P_K = 1.0 at the peak of the action potential.

Mechanical stimuli elicit a brief (<40m sec) inward current which was studied by voltage clamping. The reversal potential of this mechanoreceptor current is most dependent on $[Ca^{++}]_0$ but the slope of this relation is again less than 1/2 that predicted by the Nernst relation. As with the action potential increasing $[Cl^-]_0$ makes this reversal potential less positive. The data are described by the Goldman model if P_{Ca}/P_K = 18.1 and P_{Cl}/P_K = 1.74.

Both the current which generates the action potential and that which generates the receptor potential are carried largely by Ca^{++} with a lesser involvement of Cl^-. Both currents are largely blocked by 2mM Co Cl_2 and 0.1mM La Cl_3. However the channels for these 2 currents are different since a) the voltage dependence of the 2 sets of channels is different and b) d-tubocurarine blocks mechanoreceptor currents but does not affect action potentials.

193.2 THE CELLULAR ORGANIZATION OF SEGMENTAL GANGLIA. Kate Skinner. Dept. of Zoology, University of California, Davis, CA 95616.

The arrangement of neurons into tracts and synaptic neuropils is being investigated in the fourth abdominal ganglion of the crayfish, Procambarus clarkii. The ganglion consists of a ventral layer of neuronal somas, several cells thick, and a ganglion "core" of neuropils. The neuropils can be distinguished from one another on the basis of density of stain and size of the component fibers. They form landmark structures within the ganglion which can be repeatedly recognized from animal to animal.

The largest volume of neuropil is occupied by the four layers of longitudinal through-tracts which alternate with the three layers of cross-ganglion commissural tracts. The two dorsal layers of through-tracts carry the largest fibers, including the giant fibers, and have the largest area in cross-section. The more ventral tracts carry smaller fibers and are more variable in route through the ganglion. The most dorsal commissure is likewise the largest, capping the entire neuropil, while the more ventral ones are divided into anterior and posterior branches and are more variable in route. These through-tracts and commissural pathways can be used to describe the routes through the ganglion of the major identified neurons.

In the ventral half of the ganglion core is a large, U-shaped synaptic neuropil arranged horizontally with the arms of the U directed anteriorly and slightly ventrally. This synaptic neuropil is a dense and distinctly dark-staining structure which can be seen in section and in the living, trans-illuminated ganglion. It is composed of small (10-30 micron), even-staining clumps which appear at the electron microscope level to be synaptic glomeruli. There are substructures within the U-shaped neuropil at three locations, which consist of horizontal rings or wreaths of glomeruli. One of these is at the midline at the level of the second peripheral roots and the other two are in the "arms" of the U at the level of the first peripheral roots. The synaptic neuropil at the lateral edges of the ganglion, between the first and second roots, appears lighter in the light microscope and is composed of larger axonal profiles (2-10 microns), which frequently contain dense core vesicles.

For light microscopy, ganglia were fixed in glutaraldehyde and osmium tetroxide, block-stained in ethyl gallate solution, and embedded in soft plastic. For electron microscopy, ethyl gallate was omitted and the selected thick sections were re-embedded for thin sectioning of specific regions of neuropil.

193.3 THE MEDIAL GIANT FIBER NEURON: MORPHOLOGY, ANATOMY, PHYSIOLOGY T. Viancour, Rice U., Biology, Houston, TX 77001. Abbreviations: Al=Antennule, A2=Antennal, c.=contralateral, i.=ipsilateral, MGFN=Medial Giant Fiber Neuron, np=neuropile.

Results from intracellular injection of Lucifer-Yellow dye: The MGFN has three major 2nd order branches terminating within the cerebral ganglion of crayfish. The parolfactory branch arborizes to the 5th order within the i. parolfactory np. The Al branch courses ventrad through the c. parolfactory np to the entrance of the Al nerve; it sends off a few 'insignificant' 3rd order branches, and its distal termination is illdefined and amorphous, appearing to invade a bundle of large axons from the Al nerve. The A2 branch terminates along the rostral margin of the A2 lobe. Three 3rd order branches of the initial segment terminate within the i. parolfactory lobe, and another terminates in the i. optic np. Other 3rd and higher order branches are variable in position and occurrence from preparation to preparation. The MGFN dye-couples, with a high probability, to its contralateral homolog and, with a lower probability, to one ipsilateral and one contralateral optic tract fiber. Dye coupled neurons contact the MGFN as it decussates between the initial segment and parolfactory neurites ipsilaterally and the Al, A2 and axon neurites contralaterally. Adaxonal sheath glia also dye-couple to the MGFN axon permitting an estimation of 19,000 such glia per MGFN axon.

Al and A2 motor neurons backfilled with cobalt terminate in close apposition to the MGFN axon on the dorsal surface of the circumesophogeal connective at the base of the brain.

Intracellular recordings made at the decussation: Depolarizing PSPs result from Al, A2, tegumental and visual stimulation ipsilaterally and contralaterally. Antidromic spikes invade the decussation decrementally, and coupling potentials from spikes evoked in the contralateral MGFN have the same time course as the antidromic decremented spike. The coupling potential amplitude is 0.6 times that of the decremented antidromic spike.

The MGFN axon has a length constant of 4.4 mm, a time constant of 2.3 ms, input impedance of 3.7×10^4 ohms, membrane resistance of 2×10^3 ohm·cm^2, core resistance of 52 ohm·cm and a membrane capacitance of 1.1 μf/cm^2. Similar determinations are being attempted for the passive neurites, and presentation of an electro-morphological model of the MGFN is anticipated.

[Portions of this work were conducted in collaboration with R. Glantz, Rice Univ., and G. Bittner and M. Ballinger, Univ. of Texas, Austin]

193.4 EFFECTS OF ENVIRONMENTAL AND ACCLIMATION TEMPERATURE ON LONG TERM FACILITATION IN TWO CRAYFISH SPECIES. J. Roger Jacobs and Harold L. Atwood. Dept. Zoology, University of Toronto, Ontario, Canada, M5S 1A1.

Previous studies on long term facilitation (LTF) at the crustacean neuromuscular synapse have done much to clarify the presynaptic processes involved, and the conditions favouring LTF development, but little attention has been directed towards determining the ability of the intact animal to generate and exploit LTF. In the experiments reported here, it was established that LTF can develop in normal crayfish, and that LTF can be exploited to compensate for changes in neuromuscular performance brought on by sudden temperature changes.

Experiments were performed by stimulating the common excitor motoneuron innervating the 'opener' and 'stretcher' muscles in vivo and in vitro, and recording changes in the amplitude of the myogram of the stretcher muscle. The frequency of spontaneous firing in this motoneuron is suppressed at temperatures colder than that at which the crayfish is acclimated. These low temperatures do not greatly affect short term facilitation, but LTF develops to higher levels. Depression interferes only at extremely cold temperatures, or during long periods of stimulation.

After acclimation to colder temperatures, the temperature range over which LTF is produced is lowered. This adjustment is more pronounced in a northern crayfish species (Orconectes virilis) which must be active during cold periods, than in a more southern species (Procambarus clarkii), which is under less compulsion to be active during cold spells.

Tension development was also studied during periods of LTF growth. Tonically active muscles such as the stretcher appear to be capable of developing increasing tension during long periods of activation, but the degree of facilitation in tension growth during decay of LTF is highly variable. Most especially at cold temperatures, postsynaptic changes have greater influence than LTF on tension development.

193.5 IONIC DEPENDENCE OF RAPID PICROTOXIN-SENSITIVE AND SLOW PICROTOXIN-RESISTANT INHIBITORY POSTSYNAPTIC POTENTIALS IN THE LOBSTER STOMATOGASTRIC GANGLION. J. Eisen and E. Marder. Biology Dept., Brandeis University, Waltham, MA. 02254.

Inhibitory Post-Synaptic Potentials (IPSPs) are usually due to increases in Cl^- or K^+ conductance. In many preparations rapid IPSPs are mediated by Cl^-, and slow IPSPs by K^+. Both glutamate (glu) and acetylcholine (ACh) elicit increases in K^+ conductance on stomatogastric ganglion (STG) neurons, and are likely to be STG inhibitory transmitters. The 2 PD neurons and the AB neuron of the STG are electrically coupled, show simultaneous membrane potential oscillations, and make similar chemical synaptic connections in the STG. Combined IPSPs from the PD and AB cells were recorded in LP, VD, or PY cells impaled with 2 microelectrodes, while simultaneously monitering both AB and PD membrane potentials intracellularly. This compound IPSP showed rapid rise-time (7-15 msec) IPSPs which corresponded 1-to-1 with AB action potentials, superimposed upon a slow component. Both rapid and slow components of the IPSP recorded in LP, VD and 1 class of PY cells showed clear reversal potentials at 20-25 mV hyperpolarized from rest, a value typical of the reversal potential of K^+ dependent iontophoretic responses in these cells. In $2x[K^+]$ saline, E_{IPSP} was shifted by 15-19 mV, as expected for an increase in K^+ conductance. Extensive hyperpolarization with KAc or KCl electrodes had no measurable effect on E_{IPSP}, although E_{Cl^-} is easily shifted by such manipulations. Thus, it appears that both the fast and slow components of these IPSPs are mediated by an increase in K^+ conductance. 10^{-6} M picrotoxin (PTX) blocks the fast component of these IPSPs, leaving the slow IPSP. PD-AB IPSPs recorded in a second class of PY cells were complex. They showed fast components similar in all respects to the fast IPSPs described above. The slow component, however, was hyperpolarizing at all levels of membrane potential from rest to -120 mV. 10^{-6} M PTX abolished the fast IPSP, leaving the slow IPSP. A portion of the slow IPSP appeared to be sensitive to changes in external $[K^+]$. That portion resistant to changes in external $[K^+]$ may be due to a conductance decrease. These 2 classes of PY cells are likely the PE and PL classes defined by Hartline et. al. (1979 Neurosci. Ab. 5:248). The PD cells make cholinergic neuromuscular junctions, and the PTX-resistant IPSP may be due to PD-released ACh. PTX blocks glu elicited increases in K^+ conductance, and rapid IPSPs correlated with AB action potentials may be due to synaptically liberated glu. Glu is likely to be the neuromuscular transmitter used by the LP neuron. LP-PD and LP-AB IPSPs were similar to the rapid, PTX-sensitive IPSPs discussed above, and thus are likely to be glu-mediated. Support: McKnight Found. Scholars Award and NSF BNS 78-15399.

193.6 EFFECTS OF TEMPERATURE ON FACILITATION AT CRAB NEUROMUSCULAR JUNCTIONS. H.L.Atwood and P.J.Stephens. Dept. of Zoology, Univ. of Toronto, Toronto, Ontario M5S 1A1, Canada.

The stretcher muscle in the crab limb is innervated by a single excitor (E) axon. Excitatory junctional potentials (ejp's) recorded from stretcher fibers have been categorised with respect to amplitude and facilitation. Small ejp's facilitate well at high frequencies whereas large amplitude ejp's show poor facilitation (Atwood and Bittner, J. Neurophysiol. 34, 1971). The present paper reports some effects of temperature on the amplitude and facilitation of ejp's recorded from stretcher muscle fibers of crabs (Pachygrapsus) acclimated to 12°C.

In most stretcher fibers the ejp amplitude decreased as temperature was increased from 8 to 23°C. Facilitation measurements using pairs of pulses applied to the E axon at short (25 ms) intervals revealed a decline in facilitation from 8 to 10°C, a near uniform value up to 16°C, and an increase in facilitation from 17 to 23°C.

Frequency-response curves were constructed by making facilitation measurements using pairs of pulses with intervals between 10 ms and 2 s. In fibers with small ejp's, facilitation was high at short intervals and decayed exponentially with increased time interval. There was a semi-log relationship between facilitation and pulse interval, and two linear components were discerned. The initial component exhibited a more rapid rate of decay than the second. The pulse interval at which the two components intersected decreased with temperature.

In fibers with large amplitude ejp's, pairs of pulses at short intervals revealed that the second ejp was smaller than the first. Extracellular recordings of synaptic potentials showed that this anti-facilitation was due to a decrease in synaptic output. An exponential decay of anti-facilitation was observed with increased time interval. At warm temperatures the anti-facilitation observed at short intervals was followed by facilitation at longer intervals. The degree of facilitation increased with temperature. Temperature increases also produced changes in the rates of facilitation decay and changes in the pulse interval value at which the two components intersected. In some fibers that exhibited poor facilitation at low temperatures, changes in their facilitation properties at high temperatures resulted in their conversion to small ejp, highly facilitating fibers.

193.7 THE EFFECT OF TEMPERATURE ON THE MINIATURE EXCITATORY JUNCTION POTENTIALS AT THE NEUROMUSCULAR JUNCTION OF THE DROSOPHILA MUTANT, SHIBIRE^{ts1}. J. H. Koenig and Kazuo Ikeda, Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

The junction potentials of the dorsal longitudinal flight muscle (DLM) of the Drosophila mutant, shibire^{ts1} (shi), have been shown to progressively diminish as the temperature is raised above 27° C, until they almost completely disappear at 30° C (Ikeda, K. et al, Nature 259: 489-491, 1976). It has also been shown that synaptic vesicles at the nerve terminals of the DLM of this mutant are common at 18° C, but are almost completely absent at 30° C (Ikeda, K. & Saito, K., Neurosci. 5: 1448, 1979). The effect of raising the temperature on the miniature excitatory junction potentials (m.e.j.p.s) in the DLM of shi was observed and compared to that of the wild-type controls. In shi flies, temperatures above 26° C induce centrally originating nervous activity to the DLM. In order to observe the effect of temperature on the m.e.j.p.s independently of the effect of previous nervous activity, the posterior dorsal mesothoracic nerve (PDMN) which innervates the DLM was cut in some flies.

In both the wild-type flies and the shi flies with the PDMN cut, the m.e.j.p.s, which ranged in amplitude from about 2 mV to under 100 μV, increased drastically in frequency as the temperature was raised from 18 to 30° C. No qualitative difference in the frequency or amplitude of the m.e.j.p.s was observed between the wild-type and shi flies at 30° C, the temperature at which the evoked junction potential and the synaptic vesicles have almost completely disappeared in shi. However, in shi flies in which nervous activity to the DLM occurred as the temperature was raised (PDMN uncut), the frequency of the m.e.j.p.s decreased to almost zero by 30° C. The amplitude of the m.e.j.p.s at 30° C did not appear to be affected.

The results suggest that the occurrence of m.e.j.p.s is not dependent on the presence of synaptic vesicles in the nerve terminal. However, a relationship between the occurrence of the m.e.j.p.s and previous activity in the nerve terminal is demonstrated. Supported by USPHS NIH grant NS-07442.

193.8 IDENTIFIED ISOLATED APLYSIA NEURONS CULTURED IN VITRO. D. Dagan* and I.B. Levitan, Friedrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

Events occurring on the somatic membrane of Aplysia neurons can be dissociated from synaptic events occurring in the complex neuropile by intracellular recordings from isolated neurons in tissue culture. Utilizing a variety of enzymes and several methods to induce attachment of cells to a growth substrate, the following conditions were found most favorable for culturing: Incubation of ganglia in 1% neutral protease (Strumwasser et al., Neurosc.Abstr.4,207,1978) for 15 hrs at 15°C followed by 3 hrs at 21°C. Ganglia are then desheathed and identified somata are gently separated by mechanical manipulation. The isolated neurons are transferred to either chick plasma (GIBCO) clotted with 300 U/ml thrombin (Hoffmann La Roche), or to a 2% polymerized methyl cellulose solution (DOW). Single neurons and clusters are then cultured at 20°C in an Aplysia salt solution supplemented with vitamins, amino acids, hormones and fetal calf serum. Neurons extend long processes either in 3 dimensions in the plasma clot or on the surface of acid washed glass cover slips, within 5 hours of plating. Growth rates studied by time lapse cinematography range from 4 to 40 μ/hr. Growth of individual branches of one neuron are independent, and fast retraction (70 μ/hr) of single processes observed. Somata are seen to pivot around an attachment point of a growth cone in cases of monopolar cells, indicating that the somata themselves are not attached.

Intracellular recordings utilizing voltage clamp techniques show normal input resistances and spiking activity in many of the neurons cultured for up to three weeks. We are studying the conditions necessary for synapse formation in vitro utilizing these cultures.

193.9 NEURONAL CIRCADIAN OSCILLATOR: RHYTHM IN PROTEIN SYNTHESIS IN THE EYE OF APLYSIA. D.P. Lotshaw* and J.W. Jacklet. Dept. of Biol. Sci. and Neurobiology Res. Ctr., SUNY Albany, Albany, N.Y. 12222.

The isolated eye of Aplysia exhibits a circadian oscillation in the frequency of spontaneous compound action potentials (CAP) recorded from the optic nerve. Under free-running conditions the rapid increase in CAP frequency anticipates the subjective dawn (circadian time 0 or CT 0) and later declines to a low frequency corresponding to the subjective night. Pulse applications of protein synthesis inhibitors, puromycin and anisomycin, induce phase-dependent phase shifts in this rhythm (Rothman and Strumwasser, J. Gen. Physiol., 68:359-384; Jacklet, Science, 198:69-71), and inactive derivatives of anisomycin do not (Jacklet, J. Expt. Biol., 83:3342) suggesting that protein synthesis may be involved in the underlying circadian clock. When maintained in culture medium under free-running conditions, the isolated eye exhibits a circadian oscillation in total protein synthesis as measured by ^{3}H-leucine incorporation into TCA insoluble material during 1.5 hr pulses applied at various times during the CAP rhythm. Minimal incorporation occurs following the peak CAP rate and remains constant until the CAP rate sharply declines. Incorporation then increases throughout the subjective night reaching a maximum during the rising phase of CAP activity and then declines rapidly to the minimum level. Comparison of the phase response curve (PRC) of anisomycin with the synthesis levels indicates that inhibition of protein synthesis during the decrease in protein synthesis results in phase advances. Inhibition of synthesis during the subjective night produces increasingly large delays corresponding to the increasing rate of synthesis. Repeating the PRC to 6 hr pulses of puromycin gave results similar to those of Rothman and Strumwasser. The transition from delays to advances coincides with that produced by anisomycin, occurring at the time which the CAP frequency increases to half its maximum (CT 0). The maximum delay of 8 to 9 hrs is produced when a pulse is applied shortly before the transition from delays to advances. Advances of 4 to 5 hrs were produced by pulses applied after CT 0. While the transition point in the PRC's of puromycin and anisomycin are very similar, anisomycin produces larger delays earlier in the subjective night than puromycin, 8 hr and 1 hr respectively, when applied around CT 12. This difference may be related to a more efficient inhibition of protein synthesis produced by the concentration of anisomycin used as compared to puromycin. These data suggest that the circadian clock in the eye of Aplysia has a continual requirement for protein synthesis except for the period between maximum CAP frequency and the transition to a rapidly decreasing CAP frequency. 193.10 EFFECTS OF BACLOFEN AT SYNAPSE RC1-R15 OF APLYSIA CALIFORNICA ON SYNAPTIC DEPRESSION, FREQUENCY FACILITATION AND PTP. J.P. Tremblay and É. Philippe*. Lab. de neurobiologie, Dépt. d'Anatomie, U. Laval, G1K 7P4.

Baclofen [-(4-chlorophenyl)- - aminobutyric acid or lioresal] is currently used to alleviate spasticity. Because of its structural ressemblance to GABA it was initially postulated that baclofen produces its effects by activating the GABA receptor (Pierau et al., Exper. Neurol., 48, 343, 1976). More recently Curtis et al. (Brain Res., 70, 493, 1974) and Davis and Watkins (Brain Res., 70, 501, 1974) have suggested that the effect of baclofen might derive from an interaction with catecholamine receptors. Cholinergic EPSPs can be recorded in cell R15 of Aplysia californica after minimal stimulation of the right pleurovisceral connective. The synapse producing this EPSP has been called RC1-R15. Since GABA, serotonin and dopamine affect the synaptic transmission of RC1-R15, we expected that baclofen would also modify it and that its mechanism of action could be determined by using blockers of GABA, dopamine and serotonin. Perfusion of baclofen (3×10^{-5}M or 5×10^{-5}M) reduces the size of all EPSPs produced by a train of 100 stimuli at 1.5Hz. Baclofen also reduces the amount of synaptic depression observed during the first few EPSPs of that train, the depression being quantified by the ratio of the first EPSP of the train to the second EPSP. Baclofen increases the amount of facilitation observed during such a train, facilitation being quantified by the ratio of the hundreth EPSP to the first EPSP. Finally baclofen reduces the posttetanic potentiation observed for an EPSP produced 30 sec after the end of a train. The PTP is quantified by the ratio of the size that EPSP to the size of the hundreth EPSP of the train. These effects are similar to those produced by GABA, serotonin and dopamine on this model. The effects of baclofen are not antagonized by bicuculline and picrotoxin (two GABA antagonists). However its effects are partially blocked by SQ-10,631 (antagonist of serotonin) and butaclamol (antagonist of dopamine). To establish if baclofen produces its action by liberating the amines from some nerve ending or by direct interaction with aminergic receptors located on the presynaptic terminal of synapse RC1-R15, Aplysia were treated with reserpine to deplete the aminergic pools. Following a two days treatment with reserpine, baclofen failed to produce any effect suggesting that it acts by liberating dopamine and serotonin. However in these preparations treated with reserpine, GABA still produce its normal effects. This result suggest that baclofen produces its effects by liberating amines from synaptic terminals located near RC1-R15 synapse. These results also indicate that the mecanisms of action of baclofen and of GABA on the synaptic transmission of RC1-R15 are different.

194.1 PARALLEL UNIT RECORDING IN VISUAL CORTEX. Michael Kuperstein
Dept. Psychol., M.I.T., Cambridge, Ma. 02139

With the development of a new multichannel microelectrode, simultaneous unit recordings can be made from areas of the brain accessible within 2 mm of the surface. The electrode named PRONG (parallel recording of neural groups)has 24 independent recording sites. They are spaced at 85 um intervals along the edge of the PRONG's needle shaped tip. The fixed sites are arranged in one of two ways for a given electrode: with either all sites along one edge spanning 2 mm or a 2 X 12 array along both edges spanning 135 um X 1 mm. The PRONG is fabricated in 4 patterned layers using photolithography. A 17 um thick molybdenum foil is the substrate and layers of photoresist, gold and photoresist are applied and patterned in succession. The gold layer is patterned into recording sites, leads and connector pads, while the photoresist insulates the gold layer from the substrate and the brain leaving the recording sites exposed. The area of each site is 120 um^2 and each site is plated with platinum black. For implantation the PRONG is clamped into a connector and fixed to a microdrive. The input capacitance is 20-30 pf, the shunt capacitance is 3-4 pf and the cross channel capacitance is .6 pf.

Unit recordings with the PRONG in cat visual cortex show two features: single channels pick up neural activity similar to single microelectrodes and visually evoked responses recorded by single channels show the classical receptive field specificities. Below are examples of simultaneous histograms from 6 channels correlated to moving light bars of different orientations. These results suggest that the PRONG is a practical experimental tool which might be productive in analyzing local circuitry in visual cortex and other brain areas. 194.2 THE NUMBER OF NEURONS, GLIAL CELLS AND SYNAPSES IN THE STRIATE CORTEX OF MACAQUE MONKEY: A STEREOLOGICAL ANALYSIS. J. O'Kusky* and M. Colonnier. Lab. de neurobiologie, Pavillon Notre-Dame, 2075 av. de Vitré. Québec. Qué. G1J 5B3.

The diameter of the nuclei of neurons and glial cells was measured in individual laminae of macaque visual cortex in toluidine blue, 1.0 um sections using a semi-automatic image analyzer. Their numerical density was determined by using the method of size-frequency distribution (Weibel '69, Int. Rev. Cytol: 26,266). Under each mm^2 of surface there is an average of about 330,000 neurons, each lamina having its own characteristic density confirming the visual impression which underlies the classical description of laminae and sublaminae. The number of glial cells within the same volume of tissue is of the order of 119,000, giving a glia-neuron ratio of 0.36. This ratio is considerably less than that found in whale cortex and thus supports the hypothesis that the glia-neuron index does not increase with phylogenetic development but rather with brain size (Hawkins and Olszewski '57, Science: 126,76). The surface of the striate cortex was reconstructed from frozen Nissl sections cut in the frontal plane. The sum for both hemispheres is about 1200 mm^2. There are thus about 4.0×10^8 neurons and 1.4×10^8 glial cells in the total striate cortex.

The numerical density of synapses, determined by measuring the length of synaptic membranes and treating them according to the formula for disks as in Mayhew '79 (J. Anat: 129,95), is estimated at approximately 6.0×10^8 under each mm^2 of cortical surface. There are thus about 7.2×10^{11} synapses in the sum of right and left striate areas. From these combined figures, a monkey striate neuron receives on average 1800 synapses.

Our data on individual laminae show that there are 9.3×10^7 neurons and 1.0×10^{11} synapses in layer IVC, the main recipient of the geniculate input. From the literature, the number of thalamocortical terminals in that lamina is most reasonably estimated at 10 to 25% of the total number of synapses, giving $1.0 - 2.5 \times 10^{10}$ synapses. If they contacted only neurons in that lamina, each neuron would receive on average from 100 to 270 geniculocortical synapses. Taking into account the apical dendrites of underlying pyramidal cells and the dendrites of all cells in the immediately adjoining sublaminae, our figures show that the terminals might contact at most 2.0×10^8 cells for an average of 50 to 125 contacts per neuron.

194.3 VISUALLY RESPONSIVE UNITS IN STRIATE CORTEX OF BLIND MONKEYS. Richard K. Nakamura, Robert Desimone*, Stanley J. Schein, and Mortimer Mishkin, NIMH & NEI, Bethesda, MD 20205.

We have previously reported that chronic blindness can be produced in monkeys by a large cortical removal that preserves all areas known to be necessary for visual discrimination learning (Neurosci. Abs. 5:800, 1979). The large lesion spared the visual cortex (striate, prestriate, and inferior temporal) but included all other cortical areas. The lesion was placed in only one hemisphere, the other hemisphere having been left intact but visually deafferented by optic tract section and forebrain commissurotomy.

To investigate the basis of the blindness we have begun single-unit recordings in the blind animals. Striate cortex was studied in five monkeys prepared as above to produce chronic blindness, except that the optic tract was left intact in two of the animals to provide control hemispheres. The recordings were made while the monkeys were anesthetized with nitrous oxide and immobilized with pancuronium bromide. Implanted wells and head holders were used to minimize possible sources of pressure or pain.

We isolated 244 units from the hemispheres made 'blind' by the ablation, and 83 units from the 'seeing' intact hemispheres. Of the units from the blind hemispheres, 53% were moderately or highly responsive visually as contrasted with 95% of those from the seeing hemispheres. The loss of visual responsiveness was related to a consistent histological finding of inadvertant damage to optic radiations representing primarily the lower visual field, in that there was a strong positive correlation between a cell's visual responsiveness and the vertical position of its receptive field. For example, at more than 5^o below the horizontal meridian, only 12% of the units were moderately or highly responsive, whereas at more than 5^o above the horizontal meridian, 71% of the units were moderately or highly responsive.

There was no difference between the blind and seeing hemispheres either in the proportion of responsive cells with oriented receptive fields (69% and 68%, respectively) or in the proportion of oriented cells with complex-type receptive fields (71% and 63%, respectively).

We conclude that 1) although many units respond poorly or not at all in the striate cortex of the blind hemispheres, there appear to be enough moderately or highly responsive units to support vision, particularly in the upper fields; 2) moreover, visual information is not only reaching striate cortex but is being processed there as indicated by the normal proportions of cells with oriented and with complex-type receptive fields; 3) the loss of visual processing or disconnection of the efferent visual pathway responsible for the blindness must be occurring at some point beyond striate cortex.

194.4 ROLE OF VESTIBULAR INPUT IN VISUAL CELL SPECIFICITY. S. Reinis, R.H. Lahue* Jr., J. P. Landolt and K. E. Money* Dept. Psychol., Univ. of Waterloo, Waterloo, Ont. N2L 3G1 and DCIEM, Downsview, Ont., Canada.

Receptive field characteristics of complex cells in area 18 of the visual cortex were examined in cats as a function of head position. Properties of cells after 30^o head tilt to the right or to the left were compared with those obtained in a horizontal head position. Of 25 cells, almost all exhibited changes in receptive field size and two thirds exhibited changes in relative receptive field position in the visual field after head tilt. In one third of the cells changes in the orientation of the major axis of the receptive field corresponded to the degree of head tilt, in the remaining cells the change in orientation either exceeded or fell short of the degree of head tilt. Directional preferences for stimulus movement also altered in some cells following head tilt. Spontaneous firing of the studied cells depended on the position of the head as well. Intravenous injection of deuterium oxide changed the receptive field size in all studied cells, and increased substantially the rate of their spontaneous firing. In contrast to the previous literature, a rather complex visual-vestibular interaction was demonstrated.

194.5 NEURONAL PROPERTIES IN AREA 19 OF THE CAT. G.A. Orban, J. Duysens and H.W. van der Glas*. Laboratorium voor Neuro- en Psychofysiologie, Katholieke Universiteit te Leuven, Campus Gasthuisberg, B-3000 Leuven, Belgium.

Single unit recordings were made in area 19 of anesthetized and paralyzed cats. Shifts in receptive field (RF) position and histological reconstruction allowed us to attribute neurons to area 19. Eccentricities between 5 and 40° were explored. RF organization and orientation selectivity were assessed with hand-held stimuli. Direction selectivity and velocity sensitivity were evaluated using computer-driven stimuli according to the multihistogram technique. 75% of the area 19 neurons were end stopped to various degrees. About two-thirds of the cells could be fitted in the A, B, C, S scheme (Kennedy, H. and Orban, G.A., J. Physiol., 298:24-25P, 1980) since they responded to light slits, bars and edges of optimal length. The remaining cells responded only to bright or dark rectangles (patterns which are wider than their length).

The velocity-response curves of area 19 neurons were chiefly of two types : neurons responding over a wide range of velocities, including slow ones (broad band type : 50%) and neurons responding better to fast movements (high pass type : 30%). The response level of the neurons was low. Most of the cells were not direction selective or only direction asymmetric.

Compared to area 18 neurons of similar eccentricities, areas 19 neurons show more end stopping, less direction selectivity, lower response levels and stronger responses to slowly moving stimuli. These differences marked a clear functional separation between areas 18 and 19 in penetrations crossing the 18-19 border.

194.6 SOME CONNECTIONS OF STRIATE CORTEX (AREA 17) IN THE GREY SQUIRREL. C. G. Cusick*, T. P. Pons*, and J. H. Kaas. Depts. of Psychology and Anatomy, Vanderbilt Univ., Nashville, TN 37240

The squirrel is a good experimental animal for studies of visual connections because its visual system is well-developed with architectonically distinct subdivisions at both cortical and subcortical levels. Efferent and afferent connections were investigated by injecting horseradish peroxidase (HRP) or HRP conjugated to wheat germ agglutinin (WGA-HRP) into striate cortex in six grey squirrels. Standard histochemical procedures (diaminobenzidine, benzidine dihydrochloride, and tetramethyl benzidine reactions) were used to reveal retrogradely labeled cell bodies and anterogradely labeled terminal fields of axons. In some of the cases, connections were also revealed with autoradiographic methods after combined injections of ^{3}H-proline and HRP. Subcortical targets of Area 17 projections included the dorsal lateral geniculate nucleus, the rostro-medial pulvinar, the ventral lateral geniculate nucleus, the reticular nucleus of the thalamus, the pretectum, pontine nuclei, and the superficial layers of the superior colliculus. The connections to at least the dorsal lateral geniculate nucleus and the superior colliculus were homotopic. The locations and concentrations of labeled cells in the thalamus indicated that most neurons in the dorsal lateral geniculate nucleus, and a few of the cells in the pulvinar project to striate cortex. Ipsilateral cortical connections included homotopic and reciprocal connections with Area 18 (V-II). Zones of reciprocal connections were also observed in cortex lateral to Area 18. Finally, in some of the cases with injection sites confined to Area 17, labeled cells were also found in cortex anteromedial to Area 17 in "limbic" cortex. In all cortical regions projecting to Area 17, labeled cells were found in both supragranular and infragranular layers. Efferent projections of Area 17 terminated in both infragranular and supragranular layers. Overall, the connections of striate cortex of the squirrel are similar to the patterns observed in more commonly studied mammals. However, species differences do appear to exist. Area 17 projections in monkeys, for example, include the superior pulvinar and two divisions of the inferior pulvinar. Projections in squirrels were observed in only one division of the pulvinar complex.

194.7 CONNECTIONS OF THE DORSOLATERAL VISUAL AREA (DL) OF EXTRASTRIATE VISUAL CORTEX OF THE OWL MONKEY (AOTUS TRIVIRGATUS). R. E. Weller* and J. H. Kaas, Depts. of Psychology and Anatomy, Vanderbilt Univ., Nashville, TN 37240

Electrophysiological mapping methods have been used to subdivide extrastriate cortex of owl monkeys into a number of separate representations of the visual hemifield (Allman and Kaas, Sci., 191: 572, 1976). These include the second visual area, V II, the Dorsomedial Visual Area (DM), the Medial Visual Area (M), the Dorsointermediate Visual Area (DI), the Middle Temporal Visual Area (MT), and the Dorsolateral Visual Area (DL). To date, connections of many of the identified extrastriate visual areas have been described. A puzzle has been that none of these areas provide input to the large region of visually responsive inferior temporal cortex (IT), while in macaque monkeys, part of extrastriate cortex has been found to project to IT. Our present ongoing investigations of the connections of DL in the owl monkey lead to the conclusion that the major source of visual input to the IT region is DL. In these studies horseradish peroxidase (HRP) or HRP conjugated wheat germ agglutinin, and/or ^{3}H-proline was injected into DL of one hemisphere of seven owl monkeys. Since DL is not architectonically distinct, the injection sites were defined by location relative to the clear architectonic borders of Areas 17 and MT, and the estimated width of Area 18. All injection sites were judged to be in DL, but some involvement of Areas 18 and MT occurred in all but two cases. The results indicate a major projection from the region of DL to IT. This projection is not the result of involvement of Areas 18 or MT, since they do not project to IT. Other connections of DL are less certain because they are similar to those of adjoining visual areas, but injections of ^{3}H-proline judged to be confined to DL in two owl monkeys produced label in ipsilateral MT, V II, and the frontal lobe. Callosal connections of DL were with DL and IT cortex. The projection of DL to IT cortex may account for a major feature of the responsiveness of neurons in IT, since most neurons in both visual areas have receptive fields including central vision.

194.8 AREAL BOUNDARIES AND TOPOGRAPHIC ORGANIZATION OF THE VENTRAL POSTERIOR AREA (VP) OF THE MACAQUE MONKEY. W. T. Newsome, J. H. R. Maunsell and D. C. Van Essen. Div of Biology, California Institute of Technology, Pasadena, CA, 91125

In a previous report (Van Essen, et al., Neurosci. Abst.,1979) a marked asymmetry was found in the projections of striate cortex in the macaque monkey. Whereas dorsal striate cortex projects to three cortical targets - V2, V3 and the Middle Temporal area (MT) - ventral striate cortex projects only to V2 and MT. We have studied the cortex adjacent to the ventral half of V2 and have found that it contains a well defined visual area which we have called the Ventral Posterior area (VP) because of its apparent homology with VP in New World primates (Newsome and Allman, J. Comp. Neurol., in press). VP has a long, narrow shape (25-30 mm by 2-3 mm) and contains a topographic representation of only the upper half of the visual field. Electrophysiological mapping experiments have shown that VP shares a common representation of the horizontal meridian with V2 along its posterior boundary, whereas its anterior boundary is formed by a representation of the superior vertical meridian. Thus the representation of the upper visual quadrant in VP forms a mirror image to that of ventral V2, much as the representation of the lower visual quadrant in V3 forms a mirror image to that of dorsal V2. However, because of the difference in connections with V1, and also a difference in myeloarchitecture, it seems most reasonable to regard VP as a visual area distinct from V3. The representation of the upper visual quadrant in VP emphasizes the center of gaze to about the same degree as is found for V1 and V2. A narrow band of callosal inputs coincides precisely with the vertical meridian representation along the anterior boundary of VP and thus serves as an effective guide in locating VP. ^{3}H-proline injections into ventral V2 have shown that VP can be independently defined by a topographically organized projection which it receives from V2. Occasionally V2 injections give rise to multiple sites of transported label in VP, suggesting that the topographic organization of VP is not always simple. Focal HRP injections in V2 demonstrate a reciprocal projection from VP to V2.

194.9 THE SPATIAL ORGANIZATION OF CONNECTIONS BETWEEN V1 AND V2 IN THE MACAQUE: PATCHY AND NON-PATCHY PROJECTIONS. J. H. R. Maunsell, W. T. Newsome and D. C. Van Essen. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Several recent reports have demonstrated an unexpected complexity in the organization of projections from V1 to V2 in primates, in that discrete injections of labeled amino acids in V1 often reveal a patchy pattern of terminations in V2. We have analyzed the interconnections of V1 and V2 in the macaque in greater detail using ^{3}H-proline as an anterograde tracer and horseradish peroxidase (HRP) as both an anterograde and retrograde tracer. Projections from V1 to V2 originate from cells in layers II, IVb, and, to a lesser extent, III and IVa; they terminate in all layers of V2, but predominantly in layer IV. Projections from V2 to V1 originate from cells in layers II, III, V and VI and terminate mainly in layers I, II, IVb, and V.

Focal tracer injections in V1 (1-2 mm in extent for proline, 0.1-0.3 mm in extent for HRP) resulted in anterograde labeling over a variable extent in V2, ranging from 2-4 mm in width, and 3-8 mm in length. In most cases (10 of 12) the projection was distinctly patchy, with a center-center spacing between patches of 1-3 mm. Cells in V2 labeled by retrograde transport were largely coextensive with the region of anterograde projections, but the two distributions were not identical.

Markedly different results were obtained following HRP injections in V2. In all 7 cases the projections from V1 originated in a roughly circular zone 3-4 mm in diameter, with most cells situated in a central core 1.5-2 mm across. Within this central region cells were usually distributed relatively uniformly, but in one case the pattern was clearly patchy, with a center-center spacing of 0.75-1 mm between patches. The distributions of anterograde and retrograde labeling were very similar. These observations are consistent with the notion that V2 contains a "repetitive" representation in which most points in the visual field are represented at multiple, distinct loci within V2.

The internal connections of V1 and V2 revealed by HRP injections differ markedly in their spatial and laminar distribution. In V1 layers II and III are densely labeled, but only within 1-3 mm of the injection site, deeper layers are labeled more sparsely but over a greater extent (up to 10 mm in layer VI). In V2 the interconnections are more irregular and extensive, with distinct patches of anterograde and retrograde labeling up to 5 mm from the injection site.

194.10 SPECTRAL PROPERTIES OF CELLS IN THE PRESTRIATE CORTEX OF MONKEY. S.J. Schein, R.T. Marrocco and F.M. de Monasterio*. Clinical Branch, National Eye Institute, NIH, Bethesda, Maryland 20205.

Recent studies of monkey prestriate cortex have reported an abundance of both color-opponent and color-biased cells in an area termed V4. The mechanisms underlying color-opponency and biasing in this broadly defined area are not well understood. We report here preliminary findings on the spectral properties and the distribution of cell types encountered in this area.

Extracellular recordings were made from anesthetized (N_2O) and paralyzed rhesus and cynomolgus monkeys. We made horizontal penetrations into the anterior bank of the lunate sulcus, the posterior bank of the superior temporal sulcus, and points in between. Penetrations were confined to the region within 10 mm of the tip of the inferior occipital sulcus. Averaged responses to moving and flashing stimuli were obtained on neutral and chromatic backgrounds photopically matched; the narrow-band test stimuli were equal-quantum or photopically matched.

Of 152 cells, 21% were visually unresponsive. The remaining cells were classed as color-opponent (CO, 3%), color-biased (CB, 19%), and non-color-coded (NC, 57%). Two varieties of CO cells were observed. Whereas both showed excitation to the onset of some wavelengths and opposite excitation to the offset of others, one variety also showed typical spectrally-opponent inhibition. CO cells were of the "red-green" or "magenta-green" opponent type. CB cells were strongly excited by some lights and weakly or not at all by others, including white. Most were red-biased while a few were blue- or magenta-biased; so far, no green-biased cells have been encountered. They do not have concealed color-opponency since an (inhibitory) opponent response was not disclosed by neutral or chromatic backgrounds. NC cells had roughly equal responses to photopically-matched lights on neutral backgrounds, and selective chromatic adaptation did not disclose a color-opponent response. The spectral sensitivity of CO and CB cells was not unusually narrow-band but comparable to that observed at more peripheral centers. All cells had spatially-delimited receptive fields (typically smaller than 4-5° on the side) within the central 10° of the visual field: many were orientation-biased or directionally-biased. CO and CB cells were found adjacent to NC and visually-unresponsive cells of the same penetration. Also, any given penetration produced a mixture of cell types.

Our results do not lend support to the notion that the area termed V4 is primarily devoted to color processing. Rather, they suggest that V4 may be functionally heterogenous, subserving luminance, movement and orientation, as well as color information.

194.11 QUANTIFICATION OF COLOR VISION ABNORMALITIES. D. B. Reingold*, F. C. Chu*, R. D. Gunkel*, and D.G. Cogan*. Nat. Eye Institute, National Institutes of Health, Bethesda, MD 20205.

Recently we described a method for evaluating color vision, based on outlining the portion of a chromaticity diagram perceived as colorless, or neutral. Enlargement of this "neutral area" towards a particular color indicates some difficulty in detecting that color.

Colors of various hues and saturation are presented sequentially to each eye, and the chromagram, or outline of the neutral area, is mapped. We digitize the data, and curve fit the C.I.E. x,y coordinates of each threshold point using a least squares technique. The parameters describing these curves are derived for each subject or group of subjects. We have obtained normal values for these curves, and applied the method to the study of acquired color vision defects.

194.12 COLOR DISCRIMINATION BY GROUND SQUIRRELS: VARIATION WITH STIMULUS SIZE. Earl Kicliter. Lab. of Neurobiology and Dept. of Anatomy, Univ. of Puerto Rico Sch. of Med., San Juan, PR 00901

An aspect of color vision which has received little attention in animal psychophysics is the relation between spectral and spatial properties of a color stimulus. These relation(s) may reveal some organizing principles of both spatial and color vision since it appears that these two stimulus dimensions are processed together cortically. As a first step I have investigated the color discrimination of ground squirrels (Spermophilus tridecemlineatus) as a function of stimulus size. The color discrimination test employed (Kicliter and Loop, Vision Res. 16: 951-956, 1976) is based on pseudoisochromacy and contains internal controls against the subjects' use of brightness cues. Three ground squirrels were trained on the color discrimination task in a darkened two-choice visual discrimination apparatus with the stimuli located approximately 2.0 cm from the animal. The stimuli for original training measured 6.5 X 5.0 cm and subtended approximately 70°of visual angle. After training to criterion performance the animals were tested on the same color discrimination at both 6 and 12 cm viewing distances with targets measuring 10 X 10 mm to 0.35 mm diameter. A staircase method was employed and animals were tested for 200-300 trials with each of the different sized targets. The target size necessary for 80% correct discrimination subtended from 0.2 - 1.0°for these three subjects. Each subject had similar thresholds at 6 and 12 cm viewing distances. I also determined spectral sensitivity over the range 450 - 640 nm for each subject under dimly light-adapted conditions (background intensity approximately 5 cd/m^2). For the spectral sensitivity measures the 70°stimulus was used. Goodness of target size discrimination was directly related to spectral sensitivity and inversely related to number of trials required for criterion performance on initial learning of the pseudoisochromatic color problem. That is, the animal most sensitive in the spectral sensitivity test had the smallest threshold for target size. This animal required 700 trials to criterion versus 1000 and 1100 for the other two subjects.

Supported by NIH grant NS-07464. Contribution no. 94 of the Laboratory of Neurobiology.

194.13 RESPONSES OF INFERIOR TEMPORAL NEURONS TO COMPLEX VISUAL STIMULI. R. Desimone*, T.D. Albright*, C.G. Gross and C. Bruce. Dept. Psychology, Princeton Univ., Princeton, N.J. 08544

The inferior temporal visual area (IT) of primates is known to play an important role in visual perception and memory. We have shown that, unlike neurons in striate or prestriate cortex, IT neurons have very large, bilateral receptive fields which include the center of gaze. In the present study we found that most IT neurons are selective for complex stimulus features rather than the size, orientation, color, or direction of movement of simple slits or edges. The recordings were made in the middle part of IT in immobilized macaques, anesthetized with nitrous oxide. We studied each unit with bars, slits, edges, shadows, and a set of fifteen complex three-dimensional objects and transformations of these objects. The transformations included photographs and slides of different sizes and orientations, scrambled photographs, high contrast cutouts, and modified versions of the objects themselves.

Two-thirds of the units responded strongly and consistently enough to be studied. Of these, most responded selectively to one or a small subset of the three-dimensional objects. Thirty-five percent were selective for an object, but responded weakly to slits and edges. When tested with modified representations of the object, such as scrambled photographs, these units did not appear selective for the object per se, but rather appeared selective for such properties as the object's texture, shape, size, or color. Ten percent of the units were selective for one object, but responded equally well to a slit or edge which shared a common property such as size, color, or orientation. About fifteen percent of the units responded best to an object, but we were unable to discover any simple stimulus feature which could explain their response. These included units which responded best to faces, hands, or body shapes. Thirty-five percent of the units were classified as non-selective, since they did not respond selectively to any of the objects or the bars; however, they sometimes responded better to each of the objects than to a bar, slit, or edge.

194.14 ELECTROCORTICAL EVIDENCE FOR A TEMPORAL LOBE VISUAL FUNCTION IN MAN. Richard A. Roemer, Charles Shagass*, and William Nixon*. Eastern Pennsylvania Psychiatric Institute and Temple University Health Sciences Center, Philadelphia PA 19129.

We studied patterns of functional linkage between different brain areas by means of an electroencephalographic (EEG) measure, the "cortical coupling" index (Callaway and Harris, Science, 183, 873, 1974). Evidence is presented for systematic changes of cortical coupling patterns associated with simple changes in visual activity. EEG records from 12 scalp leads were obtained in 80 paid volunteers. Two and one half minutes of EEG recordings were made while subjects sat in a dark room with their eyes closed and then while fixating on a central point embedded in a stationary checkerboard pattern of low luminance (1.2 ft L.).

The work of Callaway and colleagues has suggested that patterns of functional relationships between different brain areas may be revealed by the cortical coupling relationships. This index, derived from information processing theory, calculates the extent to which activity in different "channels" (or in our case, different scalp areas) may be related. From a computational point of view, the coupling measure is more economical than other procedures, such as cross-correlation or coherence analyses, that could be used to evaluate such brain relationships.

Marked differences in patterns of cortical coupling were observed between the eyes closed and open conditions; these differences were primarily related to the lead pairs which included temporal scalp areas. Summary results of visual activity include: (1) increased temporal-occipital coupling both within and between hemispheres; (2) reduced coupling between frontal-central and temporal-central areas; and (3) increased interhemispheric coupling between homologous brain areas.

These findings are compatible with the visual functions in the temporal lobe which have been observed in primates and subprimates.

197.1 THE ORGANIZATION OF AXONS IN THE OPTIC TRACT OF THE CAT. F. Torrealba*, C.A. Mason, E.H. Polley and R.W. Guillery. Dept. Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL, 60637.

Previous reports, that there is at least a rough visuotopic order in the arrangement of axons in the optic tract, have been confirmed by making small retinal photocoagulation lesions and by localized injections of ^{3}H proline into the retina. Axons from the two eyes are ordered in the tract so that in a frontal section the upper contralateral hemifield is represented dorsolaterally, the lower field ventromedially, central areas dorsomedially, and peripheral areas ventrolaterally. A segregation of fiber diameter classes previously described (e.g., Bishop, P.O. et al., J. Physiol., 121: 415-432, 1953) has also been confirmed. In a 1µm coronal section one sees the coarsest fibers confined to the ventrolateral half of the tract, where they are mingled with many much finer axons. In the dorsomedial parts of the tract the axons are predominantly intermediate in size, mingled with few fine fibers. Cutting or radioactively labelling all of the axons in one optic nerve shows that whereas crossed and uncrossed axons are mingled in most of the tract, there is a small dorsomedial crescent that is made up of crossed axons only.

Our first interpretation, that this "monocular crescent" of the tract might represent the monocular crescent of the visual field, is disproved by the fact that the axons in the crescent are relatively fine, and by lesions of the relevant part of the nasal retina, which produce coarse and fine degeneration in the ventral but not the dorsal parts of the tract. A second possibility is that this monocular component of the tract represents crossed axons arising in the temporal retina. Lesions limited to the temporal retina do produce degeneration in the contralateral tract, but the degenerating axons are not seen in the monocular crescent of the tract if the lesions are clear of the area centralis. Many of the fibers in the crescent appear to arise from the region of the area centralis. The particular population of ganglion cells giving rise to these crossed axons that are not accompanied by any visuotopically matching uncrossed axons remains to be defined.

197.2 TWO KINDS OF TOPOGRAPHIC PROJECTION IN THE CHICK VISUAL SYSTEM. D. Ehrlich* and R.F. Mark* (SPON: M.J. MUSTARI). Department of Behavioural Biol., R.S.B.S., ANU, Canberra, Australia.

In vertebrates the primary visual projections to the optic tectum are retinotopically organised so that the axons of ganglion cells from adjacent points on the retina terminate beside one another in the brain. Scholes (Nature 278: 620-624, 1979) has shown that in the cichlid fish the arrangement of axons travelling in the optic nerve also preserves the neighbourly relations of ganglion cells over most of the retina but the mapping of the polar coordinates of the retina is transformed into a Cartesian mapping in the nerve. Fibers from cells on either side of the position of the choroidal fissure take diverging pathways across the retina and add on to opposite sides of the nerve at the optic nerve head, becoming separated in the nerve even though their parent ganglion cells are close together in the ventral retina. The reformation of a map on polar coordinates is seen as a reordering of fiber bundles to reunite the separated fascicles just as the optic nerve enters the optic tectum.

By the use of small lesions made through the full thickness of the retina with a laser and staining degenerating nerve terminals, we have mapped the central projections of the optic nerve in chickens. Lesions placed near the optic nerve head axotomise a sector of ganglion cells radiating out from the lesion to the peripheral retina. There appear to be two kinds of topographic projection, exemplified by those to the optic tectum and to the ventral lateral geniculate of the thalamus. The projection to the tectum is retinotopically organised, showing radial patterns of degenerating terminals over the surface corresponding to the radial sectors of axotomised retinal ganglion cells. The projection to the ventral geniculate is Cartesian in that radial lesions of the retina produce side-by-side rostro-caudal slabs of terminal degeneration. Retinal sectors on either side of the pecten, the position of the choroidal fissure, are represented at opposite sides of the nucleus just as they are represented at opposite sides of the optic nerve in the cichlid fish. The projection to the tectum, representing retinotopic order over the whole field, is likely to subserve spatial aspects of vision. That to the ventral lateral geniculate, which appears to follow the nearest neighbour relations in the retina and the developmental constraints of the position of the choroidal fissure, may reflect the packing of fibers in the optic nerve. It may have no spatial significance since it does not undergo the re-transformation required to transmit faithfully the geometry of the retina and visual field.

197.3 CENTRAL MORPHOLOGY OF PHYSIOLOGICALLY CHARACTERIZED AXONS FROM SINGLE RETINAL GANGLION CELLS IN THE CAT. Douglas B. Bowling* and Charles R. Michael. Dept. of Physiology, Yale Univ. Sch. of Med., New Haven, CT 06510.

Since the axons of retinal ganglion cells are the sole channels carrying information from the eye, the organization of their branches and terminations is of fundamental importance in visual processing. To examine the central projections of single optic-tract fibers we have impaled the axons themselves, near their sites of termination, and injected them iontophoretically with the marker enzyme horseradish peroxidase. This method has revealed the thalamic and midbrain ramifications of single physiologically characterized axons. The axons we have studied were Y-like in that they had high conduction velocities and nonlinear spatial summation in their receptive fields. Individual axons sent collaterals to three nuclei: the LGNd, the MIN, and the SC. In each nucleus the axons' collaterals formed arborizations with different and characteristic patterns: converging to single loci in the LGNd, diffuse and radiating in the SC, and spread out in thin, bowl-shaped laminae in the MIN. In the geniculate the single axons from the contralateral eye terminated in more than one lamina (A, C, and C_2) while ipsilateral afferents terminated in only a single lamina (A_1). In lamina A and A_1 the synaptic terminals were distributed in broad-based columns that spanned the thickness of the laminae. In the planes of the laminae, the distributions of the terminals were basically circular with a constant lateral spread of 300-400 µm. In the MIN the bowl-shaped terminal distributions were also about 300-400 µm across but were oriented perpendicularly to the retinotopic map. Their lateral spread was about 50 µm. In the SC the terminals were grouped into irregular patches which were distributed as an ellipse (1 x 2 mm) with its major axis oriented approximately medio-laterally. In the geniculate complex single axons often had two or more long branches which traveled by different paths to converge on the same retinotopic location. It would be interesting to know what functional significance, metabolic constraint, or mode of development these multiple and somewhat indirect pathways may reflect. Supported by NIH Grant EY00568 and NIH Training Grant NS07102-03.

197.4 MORPHOLOGY AND CENTRAL PROJECTIONS OF DIFFERENT TYPES OF RETINAL GANGLION CELLS IN CAT AND OLD-WORLD MONKEY (M. FASCICULARIS). A. G. Leventhal, R. W. Rodieck, B. Dreher . Dept. of Ophthalmology, University of Washington, Seattle WA 98195.

Labeled ganglion cells were studied in whole-mount retinas of animals that received electrophoretic injections of horseradish peroxidase (HRP) in various regions of the brain. The histochemical procedures used allowed the cell bodies, axons and dendritic fields of many of the labeled cells to be visualized.

In the cat, the morphological types we have labeled include the previously recognized types: alpha, beta, gamma and at least three other distinct types. Alpha cells project to laminae A, A_1 and C complex of the dorsal lateral geniculate nucleus (LGNd), superior colliculus (SC) and pretectal complex (PC). Beta cells project to laminae A, A_1 and C complex of the LGNd and to PC. Gamma cells project to the SC, PC and ventral LGN. Other types project to the C complex of LGNd, retinal recipient zone of pulvinar complex, ventral LGN, SC and PC.

The A laminae of the cat LGNd are reported to receive retinal afferents only from the functional types Y and X; our findings show that they receive retinal afferents only from the morphological types alpha and beta, thus lending further support to a correspondence between these functional and morphological types.

In the monkey, injections were made into the parvocellular and magnocellular laminae of the LGN and into SC and PC. At least six morphological types have been observed. Three of these have been termed A cells, B cells and C cells. A cells have large somas, coarse axons and large, distinctive dendritic fields. B cells have small to medium size somas, fine to medium gauge axons and small, distinctive dendritic fields. C cells have small to medium size somas, fine axons and large, distinctive dendritic fields. Some of the remaining types have dendritic fields that are much larger than those of A or B cells and somas as large as those of A cells. The morphology of some if not all types varies gradually with distance from the fovea. Characteristics that vary include soma size, dendritic field size, thickness of dendrites and number of dendrites. For example, B cells in the foveal region are typical midget ganglion cells, while B cells in the far periphery have larger somas, larger dendritic fields and more than one principal dendrite. In all parts of the retina, however, adjacent B cells closely resemble each other.

The magnocellular laminae receive their major retinal inputs from A cells while the parvocellular laminae receive their major inputs from B cells. SC receives inputs from C cells and some A cells. Other types of ganglion cells also project to the LGN and SC. PC receives retinal inputs from C cells, A cells and other cell types.

A cells project to the magnocellular laminae, which reportedly contain only relay cells with Y-like properties; B cells project to the parvocellular laminae, which reportedly contain only relay cells with X-like properties. Thus, A and B cells presumably have Y-like and X-like properties, respectively.

Although A and B cells in the monkey differ morphologically from alpha and beta cells in the cat, the relative differences between the different cell types in the two species parallel each other. 197.5 FUNCTIONAL ORGANIZATION OF THE TREE SHREW LATERAL GENICULATE NUCLEUS. Janet Conway, Peter H. Schiller and Lisa Misler, Dept. Psychology, MIT, Cambridge, MA 02139

The tree shrew (Tupaia glis) has a dorsal lateral geniculate with six well-defined layers. Ipsilateral retinal fibers terminate in the most medial layer (layer 1) and in layer 5 and contralateral fibers project to layers 2, 3, 4, and 6. Unlike other primate and prosimian species, there are no striking differences in the size of cells in the different laminae of the tree shrew LGD.

Tree shrews weighing 130-240 grams were paralyzed with a continuous infusion of Pavulon, artificially respirated with a 70/30% mixture of NO2 and O2, and catheterized to prevent urinary retension. A maxillary clamp fixed the head and allowed for unrestricted vision during recording. Visual stimuli generated by an optic system were back-projected onto a hemisphere positioned around the head. Horizontal electrode penetrations were made through a burr hole. Small lesions (3 microamp for 3 sec.) were made during penetrations to identify recording sites. In some experiments HRP injections (.5 microliter) were made in different locations in Area 17. Separate brains were processed for cresyl violet, Merker silver nissl, acetylcholinesterase activity, Golgi Kopsch, and TMB neurohistochemistry.

Our neurophysiological results revealed a pattern of activity which was quite consistent from animal to animal. Y type cells with transient response properties were found only in layer 6, adjacent to the optic tract. Some of these cells discharged to both stimulus onset and offset. In the remainder of the LGD all cells appeared X like, with sustained response properties. Layers were specific in that cells in each lamina gave either only ON or only OFF responses. We found three OFF layers and one ON layer for the contralateral eye and one OFF layer and one ON layer for the ipsilateral eye. The cells in layers 1 and 5, the ipsilateral layers, had their receptive fields limited to an area near the vertical meridian. In the anterior LGD, layer 1 was not present and layer 5 is present, as our histology shows, only in the dorsal part of the nucleus. (This work was supported by NSF grant #BNS 76-82543 and NIH grant 5 ROI EY00676).

197.6 PROPERTIES OF X AND Y CELLS IN THE LATERAL GENICULATE NUCLEUS OF THE MACAQUE MONKEY. R. Shapley* and E.Kaplan* (SPON: J.GORDON) Rockefeller University, New York, N.Y. 10021.

Visual cells in the lateral geniculate nucleus (LGN) of macaques may be classified as X or Y on the basis of linearity of spatial summation, as in the cat LGN. The four parvocellular layers of the macaque LGN are composed, with rare exceptions, only of X cells. These parvocellular X cells are of three main types: 1) color-opponent cells with an obvious neutral point near 580 μm. 2) non-opponent cells. 3) "Blue" cells which receive excitation from short wavelengths and inhibition from long wavelengths. The "Blue" cells are much less sensitive to grating patterns than any of the other parvocellular X cells, and their spatial resolution is also much less. In the magnocellular laminae there are X cells and Y cells. The monkey Y cells are very similar to cat Y cells; their responses at the modulation frequency (of contrast reversal or drift) have poor spatial resolution, while their frequency-doubled responses to contrast reversal have a spatial resolution comparable to that of X cells. Almost all monkey X cells (parvo- and magnocellular) showed less spatial tuning than their feline analogues, indicating less center-surround spatial antagonism in the monkey at the level of the LGN.

197.7 MORPHOLOGY OF PHYSIOLOGICALLY IDENTIFIED NEURONS IN THE C LAMINAE OF THE CAT'S LATERAL GENICULATE NUCLEUS. L.R. Stanford*, Michael J. Friedlander, and S. Murray Sherman. Dept. of Neurobiology and Behavior, State Univ. of New York at Stony Brook, Stony Brook, NY 11794.

Single unit recordings from neurons in the C laminae of the cat's lateral geniculate nucleus allowed us to classify a number of these cells as W-cells. Both X- and Y-cells have also been recorded in these deeper laminae of the LGN. A neuron was considered to be a W-cell if the following criteria were met: 1) the latency of the postsynaptic response to optic chiasm stimulation was greater than 3 msec. and 2) a "sluggish" response occurred with visual stimulation. All of the neurons meeting the above criteria (and therefore classified here as W-cells) have been encountered in the C laminae of the lateral geniculate nucleus.

The receptive fields of some of the W-cells found thus far have had antagonistic center-surround organization. When tested with a counterphased sine wave grating these cells display linear properties similar to those seen in geniculate X-cells. The responses of W-cells to this stimulus differed from X-cells in their marked preference for low spatial frequencies. Other W-cells responded only to slowly moving stimuli; some of these cells were directionally selective. Motion sensitive W-cells did not respond to a counterphased grating for contrasts up to 0.6.

After determining that a neuron, by our criteria, was classifiable as a W-cell, we impaled and iontophoretically injected the cell with HRP. The W-cells successfully injected and recovered thus far have had small to medium sized perikarya (150 to 250 μm^2). The dendrites of these W-cells are fine and relatively appendage-free (although occasionally spines and small clusters of grape-like appendages are seen). These W-cell dendrites are oriented primarily parallel to the laminar borders of the LGN and therefore perpendicular to the projection lines through the nucleus. The axons of the injected W-cells can be traced into the optic radiation. Guillery[1] has described cells in the C laminae of the cat LGN that have small to medium-sized cell bodies and dendritic arborizations parallel to the plane of lamination. It thus appears that Guillery's Class 4 cells may be equivalent to geniculate W-cells. Experiments are now in progress to test this hypothesis and to further describe the morphological characteristics of physiologically identified W-cells. Most C laminae Y-cells have morphology similar to those in the A laminae[2], although occasional unusual morphological variants were seen. To date, no C laminae X-cells have been recovered.

197.8 SYNAPTIC MORPHOLOGY OF X- AND Y-CELLS IN THE CAT'S DORSAL LATERAL GENICULATE NUCLEUS. James R. Wilson, Michael J. Friedlander and S. Murray Sherman. Dept. of Anatomical Sciences and Dept. of Neurobiology and Behavior. SUNY at Stony Brook, NY 11794. (SPON: J. Cabot).

Neurons in laminae A and A1 of the cat's dorsal lateral geniculate nucleus were recorded extracellularly and classified as X- or Y-cells by previously used criteria including latency to optic chiasm stimulation, response to gratings, and receptive field size. These neurons were subsequently impaled, intracellularly re-identified, and then injected with horseradish peroxidase. The brain was perfused, vibratomed, reacted with diaminobenzidine, and embedded in Epon 812 between plastic slides. Each injected neuron was morphologically identified and drawn prior to final trimming and thin sectioning. The thin sections were stained and then examined under the electron microscope. To date, only one X-cell and one Y-cell have been ultrastructurally analyzed. The X-cell and Y-cell each had retinal terminals (RLP profiles) which formed synapses close to the cell soma, either on spines or large dendrites; on more distal and smaller dendrites were synaptic terminals which were probably from cortex (RSD profiles). However, a qualitative assessment of these neurons indicates that the X-cell had a larger number of flattened-vesicle terminals (F profiles) associated with the area of RLP terminals and a lesser number of RSD terminals making synapses onto its peripheral dendrites compared with the Y-cell. Also, collaterals from the X-cell and another Y-cell (which is still under analysis) gave rise to terminals which were small to medium size, contained round vesicles, and made asymmetrical synapses which were usually onto large, proximal dendrites. We are continuing our analysis of geniculate X- and Y-cells, but our present sample suggests that these two physiological cell types have different synaptic morphology.

(This research supported by USPHS EY 03038.)

197.9 LAMINAR DIFFERENCES IN RECEPTIVE-FIELD PROPERTIES OF LATERAL GENICULATE NEURONS IN A PROSIMIAN PRIMATE (GALAGO CRASSICAUDATUS). T.T. Norton and V.A. Casagrande. Dept. of Physiological Optics, Sch. of Optometry/The Medical Center, Univ. of Alabama in Birmingham, Birmingham, AL 35294 and Depts. of Anatomy and Psychology, Vanderbilt University, Nashville, TN 37232.

Several recent studies have suggested a correlation between the size of retinal ganglion cells (i.e., small, medium and large) and functional subdivisions into W, X and Y cells respectively. Moreover, recent studies in monkey lateral geniculate nucleus (LGN) have shown that X cells occur in the parvocellular layers and Y cells occur in the magnocellular layers. The object of the present investigation was to assess the degree of correlation between LGN receptive-field properties and soma size in Galago, a primate which shows a unique laminar segregation into pairs of layers containing small, medium and large cells. LGN units were studied in paralyzed Galagos anesthetized with nitrous oxide. Our main finding is that there are basic laminar differences in unit properties in Galago LGN. However, these differences are not identical to those reported for other primates. Specifically, we find the following: neurons recorded in the magnocellular layers (1 and 2) have short latency responses to optic chiasm shock (OX latency), short latency responses to antidromic activation, relatively large receptive-field center diameters and respond transiently to visual stimuli. These findings are consistent with previous reports suggesting that the magnocellular layers in primates contain Y cells. However, when these units were studied with a variety of other measures, including rapidly moving stimuli, spatio-temporal maps to flashing spots and a bipartite field, their variable response profiles suggested that the magnocellular layers may contain a mixture of X and Y cells. In contrast, similar tests of units within the medium-size layers (3 and 6) indicate that most of these cells belong to a homogeneous population with X-like properties. Finally, units in the small-cell layers (4 and 5) typically show very long OX latencies but have heterogeneous response properties. Some of these units resemble X and Y cells, while others exhibit properties not typically associated with the primate LGN, such as direction selectivity, and still others were not driven by any of the visual stimuli we presented. In each of the six LGN layers, both ON-center and OFF-center units were found intermixed. Taken together, our results suggest that cell size segregation in the Galago LGN, as in other primates, reflects differences in laminar function. Supported by grants EY02909, EY01778 and 1 K07-EY00061.

197.10 DEVELOPMENT OF NEURONAL RESPONSE PROPERTIES IN THE CAT LATERAL GENICULATE NUCLEUS DURING MONOCULAR LID SUTURE. Stuart C. Mangel*, James R. Wilson, and S. Murray Sherman. Dept. of Physiology, Univ. of Virginia, Charlottesville, VA 22908

Following neonate monocular lid-suture, previous physiological recordings in the adult cat's dorsal lateral geniculate nucleus (LGNd) have revealed two findings. Fewer Y-cells are encountered in deprived as compared to nondeprived laminae and deprived X-cells exhibit lower spatial acuity on average than nondeprived X-cells. We further studied the development of these effects by examining neuronal responses in the LGNd at 8, 12, 16, 24, and 50-60 weeks of age.

Conventional single unit, extracellular recording was limited to laminae A and A1. The eyes were refracted and covered with contact lenses having 3 mm artificial pupils. Each cell was classified using standard tests, including latency to optic chiasm stimulation, linearity of spatial summation and response to a large, fast-moving disk of opposite contrast to the receptive field center. After hand-plotting, further visual stimuli were generated on an oscilloscope and consisted of counterphased, sine-wave gratings with a mean luminance of 33 cd/m^2 and contrast from 0 to 0.6.

Within the central 10° of visual field no significant difference in spatial acuity between nondeprived and deprived X-cells was observed until 24 weeks of age. In addition, at 24 weeks of age, X-cell spatial acuity was significantly reduced in deprived lamina A1 whereas mean spatial acuity in deprived lamina A and in the nondeprived lamina A were indistinguishable. However, a spatial acuity deficit was observable in both deprived A laminae in cats 13 months of age.

The average X-cell latency to optic chiasm stimulation was greater in deprived laminae than in the nondeprived laminae at all ages studied. Y-cell latency, however, appeared to be unaffected by deprivation.

At eight weeks of age, the proportion of Y-cells encountered in the A laminae was approximately 30 percent in both nondeprived and deprived laminae. However, by twelve weeks, Y-cell proportions are significantly lower in deprived laminae. No obvious differences in the development of this effect were observed between layers A and A1.

These data indicate that following neonate monocular lid-suture the onset of the deprivation effect on Y-cells precedes the spatial acuity effect on X-cells by approximately two to three months. In addition, a spatial acuity deficit of X-cells is observed at an earlier age in deprived lamina A1 as compared to deprived lamina A.

97.11 ABNORMALITIES OF TEMPORAL RETINA IN SIAMESE CATS. M.H. Rowe, D. Murakami and M.A. Sesma. Dept. Psychol., Univ. Calif., Riverside 92521

Ganglion cell axons arising in temporal retina of the siamese cat have an anomalous pattern of decussation at the optic chiasm, resulting in a substantial reorganization of the central visual pathways. We have compared the soma size and axonal conduction velocity of ganglion cells in temporal and nasal retina in both siamese and normal cats in an effort to identify some of the factors which might underlie these abnormalities.

In normal cats, X-cells in temporal and nasal retina identified following injections of HRP into LGN laminae A_1 and A, respectively, differ markedly in soma size: temporal X-cells are larger ($\bar{x}$ = 21μm) than nasal X-cells ($\bar{x}$ = 18 μm), and Y-cells also show a tendency to be larger in temporal retina ($\bar{x}$ = 32.1 μm) than in nasal retina ($\bar{x}$ = 30.5 μm). Similarly, in field potentials recorded at the optic disc in response to optic chiasm stimulation, the amplitude of the t_2 component is larger for temporal retinal axons than for nasal retinal axons, and the latency of this component is shorter in temporal retina, suggesting that the axons as well as the somas of temporal X-cells are larger than those of nasal X-cells.

In the siamese cat medium sized cells projecting to lamina A from nasal retina average 1μm smaller than either the medium sized cells in temporal retina which project to the normal (ipsilateral) segment of A_1 or those that project to the abnormal (contralateral) segments of A_1. In field potentials recorded at the optic disc in response to stimulation of the optic chiasm or optic tracts, the amplitude of the t_2 component relative to the t_1 component is noticeably reduced, and the reduction seems more pronounced among ipsilaterally projecting axons. Consistent with earlier findings, both the HRP and field potential analyses indicate that very few large cells in temporal retina project to the normal segment of A_1. Many of these results have also been seen in white, non-siamese cats in which retinal pigment is largely absent.

198.1 LONG-TERM, COMPLEX FIXED ACTION PATTERNS PERSIST IN THE ISOLATED UNSTIMULATED VENTRAL NERVE CORD OF LIMULUS. Winsor H. Watson III Zoology Department, Univ. of New Hampshire, Durham, NH 03824.

The gill appendages of Limulus are utilized for several different activities, all of which commonly occur in long-term patterns. The most common pattern observed consists of 1 minute bouts of gill cleaning, alternating with 1 minute periods of ventilation. Isolated, unstimulated abdominal nerve cords of Limulus display patterns of motor output characteristic of rhythmic gill ventilation and of gill cleaning, and these also occur as organized long-term patterns.

In the intact animal there are two different mirror-image arrangements of the gill-plates during cleaning. Both are also expressed by the isolated CNS and occur with the same rough alternation as in intact animals. The cardioinhibition associated with gill cleaning also appears to be part of the endogenous central motor program generated by the isolated CNS. Similar patterns of cardioregulatory nerve discharge are observed in both instances. Thus, all the patterns of gill-plate movement and the associated changes in heart rate observed in intact animals, except those involving swimming, have underlying motor programs that are expressed by isolated nerve cords in the absence of stimulation or of sensory feedback.

198.2 MODIFICATION OF SENSORY EVOKED BEHAVIORAL AND NEURAL RESPONSES DURING DIFFERENT BEHAVIORAL STATES IN APLYSIA. Behrus Jahan-Parwar, Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545, USA.

Chemical cues from food (seaweed) arouse Aplysia and elicit locomotor and feeding behaviors (Am. Zool., 1972). Chemical cues from an egg-laying Aplysia and/or an egg mass also attract Aplysia and elicit aggregation, mating and/or egg-laying in this hermaphroditic organism (The Physiologist, 1976). In the presence of both food and sex attractants Aplysia displays a behavioral choice which appears to depend on its behavioral state. In the egg-laying state the food induced motor responses are suppressed. These responses are also suppressed in functional males if they are actively engaged in mating but not in their female partners. As a result, the food aroused mating females frequently end up carrying their male partners to the food site. These observations suggest a hierarchical organization of chemosensory evoked behaviors in Aplysia. A behavioral choice in the presence of different ethologically significant chemosensory stimuli suggests altered sensitivity to stimuli eliciting lower order behaviors during higher order behavioral states. Behavioral state-dependent response modification is not restricted to chemosensory responses. In a food arousned Aplysia, mechanosensory responses are also modified. Tactile stimulation of a tentacle elicits a withdrawal reflex in the unaroused state (96%, N=200) and a characteristic orienting reflex in the food aroused state (92%, N=200). Tactile response modification following food stimulation can also be obtained at the level of the 4th order neurons (4° Ns) along the activated neural pathways (Comp. Biochem. Physiol., 1980). Before stimulating with food chemicals, tactile stimulation of a tentacle produces a two component inhibitory response in the 4° Ns, but after food sensory stimulation which strongly activates the 4° Ns, an identical tactile stimulation results in an excitatory (spiking) response. Preliminary data suggest that interaction of an electrogenic pump (Comp. Biochem. Physiol., 1979) and the two component tactile synaptic input may be partially responsible for the motivational state-dependent modification of sensory integration in the 4° Ns. The firing of the 4° Ns in food aroused Aplysia may be significant because these cells appear to be motor neurons mediating foot movement (J. Neurophysiol., 1978). They also appear to make synaptic connections with many other neurons which also appear to have motor functions (Brain Res. Bull., 1979) and thus may be capable of coordinating the body movements required for orienting. These data suggest that behavioral and neural responses to a particular sensory stimulus obtained during one behavioral state can be altered during another behavioral state. Since a single sensory stimulation can rapidly alter the behavioral state of an organism, the interpretation of the neural responses to the commonly used random or repetitive sensory stimulations may be complicated unless the behavior or some other indication of the total organismic response to these stimuli is monitored. (Supported by grants: NS 12483, NS 14388 and BNS 77-24174)

198.3 MECHANICS AND COORDINATION OF FEEDING AND REJECTION IN PLEUROBRANCHAEA. R.P. Croll and W.J. Davis, Thimann Labs, Univ. of Calif. at Santa Cruz, Santa Cruz, CA 95064

The buccal mass of Pleurobranchaea is capable of producing two distinct cyclic behaviours. One of these, i.e. feeding, can be elicited by presentation of food homogenates to the rhinophores, tentacles or oral veil. The other behaviour, rejection of inappropriate substances from the buccal cavity, can be reliably elicited either by injecting alcohol or detergent, or by introducing a non-palatable object, such as a string, into the mouth. Although both behaviours have previously been reported (Davis and Mpitsos, 1973; MacLellan, 1978, 1979) no detailed descriptions of the muscular coordination or mechanics have appeared.

Cinemagraphic analysis of buccal movements in unrestrained, whole animals and electromyograms from exposed buccal masses reveal that a systematic difference in muscular activity underlies these two behaviours. For instance, during feeding the circumferential buccal muscle 5 (Davis and Mpitsos, 1973) contracts vigorously during retraction of the radula, thus insuring a firm hold on the food. Muscle 4, which everts the radula, then fires briefly in antiphase with muscle 5. During rejection muscle 5 is silenced during retraction of the radula. Activity in muscle 4, on the other hand, is greatly enhanced and serves to expel inappropriate substances from the mouth. Although changes in the activity patterns of these two muscles are the most dramatic, the activity in certain other muscles is also slightly inhibited or enhanced during either of the two behaviours. However, phase relationships between active muscles are preserved. This suggests that the same neural oscillatory network is responsible for both types of movements and that excitation or suppression of specific elements in the network underlies the differences in the motor patterns.

198.4 PERISTALTIC SWALLOWING IN NAVANAX: FUNCTIONAL ORGANIZATION OF CIRCUMFERENTIAL MUSCLE AND MOTOR UNITS. M.S. Cappell, D. C. Spray, D. H. Hall and M.V.L. Bennett. Division of Cellular Neurobiology, Dept. Neuroscience. A. Einstein Col. Medicine, Bronx, New York 10461.

Cinematographic analysis of feeding by a dissected animal with a window through the body wall (Susswein et al., Soc. Neurosci. Abstr. 5: 262, 1979) shows that Navanax can swallow small prey by a peristaltic wave of circumferential constriction of the pharynx from anterior to posterior. Several features of the circumferential muscle and motoneuron organization appear important in the generation of peristalsis: Pharyngeal circumferential muscle consists of discrete bands which are highly consistent in total number and pharynx position. Circumferential bands are regionally specialized and are classifiable into anterior and posterior sphincters with three intervening groups dorsolaterally and four intervening groups ventrally based on differences in size and shape. Borders between band groups are generally distinct, with a consistent number of bands per group. Motor fields were mapped in terms of identified bands, by four techniques (Cappell et al., Soc. Neurosci. Abstr. 5: 243, 1979). The borders of specific circumferential motor fields coincide with the borders of specific muscle band groups. Although most motoneurons innervate a single band group; a few innervate several adjacent band groups. No motorneurons innervated parts of adjacent band groups. Circumferential motoneuron fields exhibit little variability between animals. Most circumferential motorneurons innervate exclusively dorsolaterally or ventrally while others innervate both regions, permitting independent or coordinated activity. The consistency and correspondence of motor fields and muscle band arrangements should permit precision in the generation of peristalsis and facilitate progress in its cellular analysis. MSC is supported by NIH grant 5T 32GM7288.

198.5 ARE SUBGENUAL ORGANS "EARS" FOR HISSING COCKROACHES? Margaret C. Nelson, Sect. Neurobiol.& Behav., Cornell Univ., Ithaca, NY

Male Madagascar cockroaches (Gromphadorhina portentosa) produce sound signals in the form of amplitude-modulated hisses. The presence of females elicits stereotyped courtship hissing; receptive females respond with stereotyped receptive behavior that may lead to copulation (Nelson and Fraser, Soc.Neurosci.Abs.3, '77). This receptive behavior depends on auditory signals, but the basis for sound reception has been unknown (Nelson & Fraser, Behav. Ecol.& Sociobiol. in press; Nelson, Soc.Neurosci.Abs.5,'79). I now report that the tibial subgenual organs of all 6 legs may be responsible for detection of auditory signals in G. portentosa.

The subgenual organ (SGO) of cockroaches typically consists of a distal organ, an accessory organ, and a subgenual organ proper. In G. portentosa the SGO contains 40-50 chordotonal sensilla (as compared to 15-20 in Periplaneta, which does not produce sounds). It is part of a tibial sensory complex that includes campaniform sensilla, spines, and hairs from the proximal tibia; the axons of all these run in the tibial sensory nerve, N5r8. The fibers from this branch of N5 enter each thoracic ganglion to form several sets of bifurcating projections in cobalt backfills.

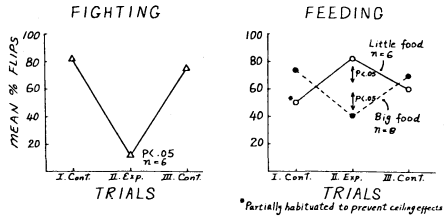
Involvement of the SGO in detection of acoustic signals was studied by recording from *1)* auditory interneurons in the thoracic connectives, and *2)* primary afferents in N5r8.
*1)*Several interneurons in the thoracic nerve cord (TNC) are driven by acoustic stimuli in the 3-7 kHz range (Nelson, Soc.Neurosci. Abs.5,'79); their activity was used to assay the contribution of various sensory fields to auditory reception. The only part of the body found to have input to these cells was the tibia: removal of a single tibia from any leg decreased activity recorded from the TCN upstream and abolished activity when the relevant thoracic ganglion had been isolated from the rest of the CNS and the opposite leg. Localized lesions at the level of the SGO sparing the tibial branches of N5r8 reduced or abolished the response, while localized lesions of the tibia distal to this region had no effect. Injection of μl amounts of vaseline into the bloodspace at the "knee" of the tibia also abolished the response.
2) Primary afferents sensitive to acoustic stimuli could be detected in N5r8 in the femur. These afferents showed essentially the same frequency range as the interneurons described above. Local destruction of the SGO sparing the other tibial branches of N5r8 greatly reduced the response; destruction of the campaniform sensilla had no effect on the auditory response.

These experiments thus strongly support the hypothesis that the SGO's mediate sound reception in G. portentosa.

198.6 ADAPTIVE CONTROL OF ESCAPE BEHAVIOR DURING FEEDING AND FIGHTING IN CRAYFISH. K. Bellman* and F.B. Krasne, Dept. Psychol., UCLA, Los Angeles, CA. 90024.

All nervous systems must be organized to cope adaptively with conflicting demands presented by the environment; the relative simplicity of nerve circuitry in invertebrates invites attack on the mechanisms involved in the resolution of such conflict. As a prelude to such investigation we have studied the effects of engagement in fighting and feeding on crayfish escape behavior.

Tail-flip escape responsiveness was evaluated by gradually approaching and touching crayfish with a fish net (an "escape trial") that on other occasions was used to capture them.* All testing was in groups of 3 successive escape trials: on the first and third, which served as controls, the net was presented alone; on the second it was presented while the animal was feeding or fighting with a conspecific. When escape was tested during fighting, tailflip probability was severely depressed; this held whether or not the animals' claws were locked together. Without such suppression of escape, animals would be unable to engage in sustained fighting. When escape was tested during feeding, the result depended on food size. Feeding on large pieces of food that could not readily be moved depressed probability of escape; but feeding on small bits of food enhanced it,** and when the animals flipped they carried the food with them. This makes adaptive sense. But it is a more complex result than might have been anticipated for crayfish, and it tends to rule out simple control schemes in which activity of feeding circuitry automatically and uniformly inhibits — or facilitates — escape mediating circuitry. Supported by NIMH NRSA MHO 7836 & NIH NS 8108.



*This sort of stimulus typically evokes non-giant mediated tailflips; experiments on giant-mediated responses are in progress.

**Facilitation of escape by possession of food in the presence of conspecifics was previously discovered by G. Hagiwara and J. Wine (in prep).

198.7 HETEROGENEITY OF THE EFFECT OF TEMPERATURE ON IDENTIFIED GRASSHOPPER NEURONS. Thomas W. Abrams and Keir G. Pearson. Dept. Physiology, Univ. of Alberta, Edmonton, Alberta, Canada.

Like many poikilotherms, grasshoppers show an increase in their level of locomotory activity at warmer body temperatures. We have tried to identify the changes in neuronal properties which are responsible for the increased behavioral activity.

We have investigated the effects of temperature on a number of interneurons and motoneurons in the thoracic CNS, including neurons involved in jumping behavior. Cells were penetrated with microelectrodes and measurements were made while the temperature was varied from 14°-35° C. We find that two groups of opposing effects combine to determine how the activity of central neurons changes with temperature; the relative importance of these different effects varies amongst neurons causing different cells to have different temperature sensitivities.

All interneurons and motoneurons tested showed a slight increase in voltage threshold (relative to V_{rest}) with warming, and a marked increase in threshold for injected currents. Thus the fact that warm animals are behaviorally more active is not due to a reduction in the threshold of the central neurons producing the behavior.

In contrast, the effect of temperature on repetitive firing properties was heterogeneous amongst the neurons studied. Generally there was a tendency towards a steepening of frequency-current (f-I) curves at higher temperatures; with sufficient current the initial firing rate is faster in warm neurons. However, the extent of the change in the f-I curve slope varied greatly; at least one flexor motoneuron showed almost no change in firing rate with temperature. Furthermore, in an auditory interneuron, the G neuron, there was greater adaptation during injected current pulses at higher temperatures; after the initial spikes, G fired more slowly when warm.

The combined effects of temperature on threshold, on the f-I relationship and on adaptation tend to cause the G neuron to be less responsive to injected currents when warm. Yet G's responsiveness to white noise stimuli increases with temperature. This is due to increased input from auditory receptors. The responsiveness of these afferents was extremely temperature sensitive, more so than any of the central neurons. This was also true of a tibia proprioceptor. We suggest that increased firing in sensory afferents may be the main factor responsible for increased behavioral activity in warm animals.

198.8 CORRELATION OF STRUCTURE AND FUNCTION OF DENDRITES IN IDENTIFIED MULTIMODAL INTERNEURONS IN THE CRAYFISH BRAIN. R.M. Glantz, M. Kirk and T. Viancour. Dept. Biology, Rice University, Houston Tx 77001.

Approximately 100 interneurons in the crayfish brain have been impaled with microelectrodes containing the fluorescent dye Lucifer-Yellow. Sensory receptive fields were mapped, and monosynaptic and polysynaptic inputs were distinguished by electrical shocks to the afferent roots. Each cell was dye filled and the dendritic morphology examined in whole mounts of the brain. The results have allowed us to uniquely identify 9 different interneurons by their sensory fields, the location of the soma, axon and principal neurite and the distribution of their dendrites. In addition to the identified cells, 45 additional neurons have each been dye filled and characterized physiologically on a single occassion. The data were analyzed to determine if the presence of a dendrite in a sensory neuropile of the brain was a sufficient or necessary condition to predict the functional (modality) and or synaptic input to the cell.

The results suggest that certain limited, functional inferences can be drawn on the basis of the dendritic geometry of a multimodal interneuron. If an interneuron projects a dendrite to a hemineuromere of the brain (left or right half of the proto-, deuto- or tritocerebrum) it will receive functional input (in 95% of our observations) from a sensory root to that hemineuromere. Most of these inputs (86%), will at least contain a monosynaptic, primary afferent component. If an interneuron does not project a dendrite into a hemineuromere, then 90% of the time it will not derive monosynaptic input from the corresponding sensory roots. The preponderance (83%) of the exceptional instances are associated with the contralateral antennal nerve. Cobalt backfills of the antennal nerve reveal groups of primary afferents which project outside of the ipsilateral tritocerebrum (Viancour, In Preparation). If a neuron does not project a dendritic branch to the protocerebrum it will not exhibit visual input. For other polysynaptic inputs the dendritic location is neither a necessary nor a sufficient predictor of input.

The results imply that the organization of the sensory neuropiles of the brain is quite simple and that both the modality and synaptic input of multimodal interneurons is essentially predictable from the distribution of interneuronal dendrites. (Supported by N.S.F. Grant No. BNS 7910335)

199.1 A SIGNIFICANT CORRELATION BETWEEN SIZE OF CANARY BRAIN NUCLEI CONTROLLING SONG AND SIZE OF SONG REPERTOIRE. F. Nottebohm, Rockefeller University, New York, N.Y. 10021.

Male canaries learn to sing by reference to auditory information (Marler and Waser, 1977; Waser and Marler, 1977). Two telencephalic nuclei, hyperstriatum ventrale, pars caudale (HVc) and nucleus robustus archistriatalis (RA) have been shown to be the two highest stations of the efferent song control pathway. Effects on song of unilateral destruction of HVc and RA suggest that the left HVc and RA are dominant for song control (Nottebohm, Stokes and Leonard, 1976; Nottebohm, 1977). The purpose of the present study was to search for possible correlations between the size of HVc and RA and the size of the song repertoire. A second intent was to look for right-left size differences in these nuclei in adult males, in hopes of discovering a clue to the functional differences between the two sides.

Twenty-five 1-3 year-old male canaries of the Rockefeller University closebred Waserschlager strain were used. They had all been exposed to other birds in our canary colony and had breeding experience. They were sacrificed after their song repertoire was recorded. These birds were perfused with 10% formalin in .9% saline. Their brain and testis were then removed. The testis were weighed. The brains were stored for a week in the perfusing solution, then transferred to 30% sucrose in 10% formalin until they sunk. At this time the brains were weighed, then embedded in gelatin-albumin. Frozen sections were cut at 50 μ, 50 μ and 25 μ intervals; one series of 50 μ sections was mounted and stained with cresyl violet. A microprojector was used to draw the total area of sections through HVc and RA, permitting a reconstruction of the volume of these nuclei.

Song repertoires ranged from 23 to 47 different syllable types per bird, with a mean of 31.6 (S.D.=6.4). There were no significant age differences in size of syllable repertoire or in size of HVc and RA. Syllable repertoire showed no significant correlation with brain weight (r=.135), testis weight (r=.042) or volume of nucleus rotundus (r=.087), a thalamic nucleus not involved in vocal control. The size of the syllable repertoire did correlate significantly with total (right plus left) HVc volume (r=.449, $P < .02$) and total RA volume (r+.380, $P < .05$). There was no significant difference between the volume of the right and left sides of HVc and RA.

The vocal control pathways of the songbird brain consist of well defined nuclei. The learned behavior they control is easily quantifiable. Clearly there is no one-to-one relation between the size of a nucleus and that of the song repertoire. But even after this caveat, this material seems well suited for establishing whether the amount of brain space available for a learned skill and the amount of learned skill are related. The answer is YES.

199.2 MEDULLARY NUCLEI FOR VOCAL CONTROL IN PARAKEETS. K.R. Manogue* and F. Nottebohm (SPON: T.J. DeVoogd). Rockefeller U., N.Y.10021.

In parrots, order Psittaciformes, the proximal tracheosyringeal (ts) branch of each hypoglossus nerve courses alongside the trachea to reach a common anastomosis on the midline. This anastomosis gives rise distally to two nerves, each of which innervates the muscles of one syringeal half. Section of either right (R) or left (L) ts nerve proximal to the anastomosis results in only minor and temporary changes in vocal patterning. Section of either R or L ts nerve distal to the anastomosis results in gross, long lasting vocal deficits. Thus parrots, unlike canaries and other oscine songbirds, show no hypoglossal dominance for song control, and both syringeal halves are equally important for vocal patterning. In addition, parrot phonation is thought to involve the larynx and tongue (Nottebohm, 1976). The absence in parrots of neural or muscular asymmetries in the peripheral control of phonation is similar to the human condition. We would like to know whether any asymmetries occur centrally. As a first step we here describe in parakeets, Melopsittacus undulatus, medullary motor nuclei presumed to partake in vocal control. These nuclei were identified by placement of horseradish peroxidase crystals on the proximal end of cut nerves supplying the motor innervation of the syrinx, larynx, or tongue, and sacrificing the birds 24-48 hrs later.

We reacted 50μ frozen sections of the fixed brains with the chromogens tetramethylbenzidine and diaminobenzidine, and obtained the following results. 1) The rostral pole of each hypoglossal nucleus (nXIIling) innervates the tongue via the lingualis branch of the hypoglossal nerve; each lingualis nerve was composed of axons from the ipsilateral nXIIling only. 2) The much larger caudal portion of each hypoglossal nucleus (nXIIts) innervates the syringeal muscles via the ts branch of the hypoglossal nerve. Proximal to their anastomosis, R and L ts nerves are composed of axons from ipsilateral nXIIts motorneurons only. Distal to the anastomosis both the R and L ts nerves contain axons arising from both R and L nXIIts. Thus, motorneurons in each, R or L, nXIIts project bilaterally to the muscles of the syrinx. 3) A distinct crescent of motorneurons arching ventrolaterally to nXII innervates the larynx; each laryngeal nerve is supplied by ipsilateral motorneurons only.

What comes as a surprise in this initial set of observations is that muscles on each right or left syringeal half receive bilateral medullary control. We also know that each nXIIts receives bilateral input from telencephalic and mesencephalic vocal control nuclei (see companion abstract by Paton, Manogue and Nottebohm). The significance of such bilateral projections remains unclear.

199.3 TELENCEPHALIC EFFERENT PATHWAYS FOR VOCAL CONTROL IN PARAKEETS. J.A. Paton, K.R. Manogue*, and F. Nottebohm. Rockefeller University, New York, N.Y. 10021.

Vocal learning in birds has evolved independently at least three times, in oscine songbirds, in hummingbirds, and in parrots and their allies, order Psittaciformes. Has the brain of these three orders of birds arrived at a similar solution for this task? We used a combination of retrograde anatomical techniques and antidromic electrical stimulation to map neural pathways connecting the telencephalon to motor neurons innervating the syrinx (vocal organ) of parakeets, Melopsittacus undulatus. We found that this pathway contains nuclei homologous to those already identified in songbirds (Nottebohm et al., 1976), but with bilateral rather than unilateral connections.

The motor nucleus of the syrinx (nXIIts) was located by electrically stimulating the tracheosyringeal nerve (ts) and searching for evoked potentials in the brainstem. Horseradish peroxidase (HRP) or HRP conjugated with wheat germ agglutinin was then iontophoresed into one side of the motor nucleus. After 24 to 48 hrs the animal was sacrificed and perfused with a 2.5% glutaraldehyde fixative. The brain was removed and sunk in a solution of 30% sucrose in fixative and embedded in gelatin-albumin, to be cut frozen into 50u sections. The sections were reacted using either the tetramethyl benzidine or diamino benzidine methods.

Well defined unilateral injections in nXIIts led to bilateral labelling of cells in two regions: 1) an area dorsomedial to the auditory nucleus of the tectum, probably corresponding to pars dorsalis medialis of nucleus intercollicularis in songbirds; 2) an area of large, loosely packed cells in the archistriatum, probably corresponding to nucleus robustus archistriatalis (RA) in songbirds. In an earlier experiment lesion of this putative RA in parakeets caused bilateral anterograde degeneration of fibers and terminals in nXIIts (D.B.Kelley and F.Nottebohm, unpub. obs.).

The afferents to RA were labelled by extending the previous paradigm one step. The nXIIts motor nucleus was located as before. The recording electrode in nXIIts was then used to stimulate RA antidromically while another electrode was advanced through the telencephalon. When the putative RA was found, judging from evoked potentials, HRP or HRP-WGA was injected. This procedure was then used to identify inputs to this nucleus.

The bilateral projection of RA to nXIIts raises interesting questions since each nXIIts, in turn, projects to the ipsi- and contralateral syringeal muscles (see abstract by Manogue and Nottebohm).

199.4 INTERHEMISPHERIC PROJECTIONS OF TEMPORAL LOBE CORTICAL AREAS IN THE RHESUS MONKEY. S. Demeter and G.W. Van Hoesen, Depts. of Neurol. and Anat., Univ. of Iowa, Iowa City, IA 52242.

The origins of axons which form the interhemispheric commissures of the primate have been delineated by others with retrograde tracing methods. With the exception of the sensorimotor cortices, less precise information is available about the trajectories of commissural axons and the topography of their terminations. Moreover, current knowledge is based largely on ablation-degeneration methods.

Therefore, we studied this problem in 14 rhesus monkeys (Macaca mulatta) using autoradiographic and horseradish peroxidase (HRP) tracing methods. Solutions of either tritium labeled amino acids (leucine, lysine and proline) or 20% HRP were injected into the various cytoarchitectural fields of the temporal lobe (Bonin and Bailey areas TE, TF, TG and TH and Brodmann areas 28 and 35). Autoradiographic cases were processed by standard methods following seven-day survivals. HRP cases were processed by the Mesulam tetramethylbenzidine procedure following two-day survivals. Injection sites and retrograde and anterograde labeling were assessed with brightfield and darkfield microscopy.

All areas studied gave rise to axons that crossed in the anterior commissure and/or hippocampal commissure (psalterium). Three cortical tiers were recognized in this regard. Cortices in close relation to the hippocampus such as area 28 were interconnected exclusively through the hippocampal commissure while cortices in more distant relation to it such as areas TG and TE were interconnected exclusively through the anterior commissure. Intermediately related cortices such as area TF were interconnected through both commissures.

Topographically, three categories of terminal labeling were recognized. Homotopic terminals were observed contralateral to all areas studied. Non-homotopic terminals contiguous with the homotopic terminals and within the same cytoarchitectural field were observed in most cases. Non-homotopic terminals in different cytoarchitectural fields were observed in some cases. All non-homotopic projections were mirrored by more prominent projections to the corresponding, ipsilateral areas.

HRP retrograde tracing studies provided support for these observations. Labeled neurons were observed in the contralateral homotopic area, in contiguous, non-homotopic areas within the same cytoarchitectural field and in non-homotopic areas in different cytoarchitectural fields.

The parahippocampal cortices, in particular, projected to and received afferents from widespread cortical areas of the contralateral hemisphere.

199.5 BEHAVIORAL AND BIOCHEMICAL ASYMMETRIES IN THE RAT FOLLOWING UNILATERAL CORTICAL SUCTION LESIONS. G.D. Pearlson. Dept. of Psychiatry & Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

Previous research has demonstrated asymmetries in both behavioral and biochemical response to ischemic lesions in the rat cerebral hemisphere, (Science 205: 707, 1979). Because this method is difficult to execute and vascular lesions are by their nature variable, we used suction lesions in a series of experiments in an effort to produce technically easier lesions with higher comparability.

Suction lesions were made in either the right or left cerebral hemisphere of male Sprague-Dawley rats of the same age in the lateral fronto-parietal cortex just anterior to the middle cerebral artery and above the rhinal fissure. The site chosen was located approximately 1.15 to 1.20cm ant.to ear bar zero. Marked spontaneous hyperactivity, as measured by total daily revolutions of an exercise wheel, occurred in 14 right-hemisphere lesioned animals, which was still present at the time of sacrifice 30 days postoperatively. NE depletion to approximately 65% of preoperative values in both ipsilateral and contralateral locus coeruleus and cerebral cortex was demonstrable by HPLC with electrochemical detection. By contrast, 16 left hemisphere operated animals showed neither behavioral nor biochemical differences from sham-operated controls. There were no significant differences in food or water intake between groups. Comparability of right and left-sided hemispheric lesions was demonstrated by histological examination of stained frozen or paraffin-embedded sections as well as by lesion volume assessment on a stereomicroscope equipped with horizontal and vertical vernier scales.

199.6 BRAIN ASYMMETRIES IN 2-DEOXY-D-GLUCOSE UPTAKE DURING POSTNATAL DEVELOPMENT OF THE RAT. D.A. Ross, S.D. Glick and R.C. Meibach., Dept. Pharmacol., Mt. Sinai Sch. of Med. of CUNY, New York, N.Y. 10029

A modification (Meibach et al., Brain Res., in press) of the 2-deoxy-D-glucose (DG) technique (Sokoloff, L. et al., J. Neurochem., 28:897-916, 1977) was used to investigate the postnatal ontogeny of functional brain development in the Sprague-Dawley rat. Different asymmetries in [^{3}H]-DG uptake in various micro-dissected brain regions were present at different ages and are listed in table 1. All asymmetries were significant at $p < .05$ using the Chi-Square test.

Days	Structure	Asymmetry
0-5	Hippocampus	R > L
	Brain Stem (Medulla/Pons)	L > R
0-15	Diencephalon	R > L
6-30	Cortex	L > R
31-60	Brain Stem	L > R
	Caudate Nucleus	R > L

In addition to these left-right asymmetries, we also looked for changes in [^{14}C]-DG activity within specific subanatomical fields of the hippocampus using radioautography. At birth the dentate gyrus had the highest activity. By day 5 the dentate activity decreased and that of CA 1 increased to render it the most active hippocampal subfield. Although the caudate asymmetry was associated with changes in circling behavior, the precise relationships between most of these findings and behavior remain elusive. However, the data do suggest that the two sides of the brain develop at differential rates.
(Supported by NS 14812 & DA 70082).

Session

199.7 ASYMMETRICAL DOSE-RESPONSE CURVES FOLLOWING UNILATERAL INTRACORTICAL 6-HYDROXYDOPAMINE INJECTIONS R.G. Robinson, T.G. Stitt*. Dept. of Psychiatry and Behavioral Science, Johns Hopkins University School of Medicine. Baltimore, Maryland 21205.

Following surgical ligation of the right middle cerebral artery in the rat, spontaneous hyperactivity occurs during the first 20 postoperative days and norepinephrine (NE) concentrations in the non-injured as well as injured areas of the cortex and in the locus coeruleus are depleted by about 30% to 50%. (Brain Res. 181:202, 1980). Left middle cerebral artery ligation, on the other hand, does not lead to an alteration in either the animals spontaneous activity or brain catecholamine concentrations (Science 205:707, 1979; Brain Res. 188:63, 1980).

Microinjections of the neurotoxin 6-hydroxydopamine (6-HDA) were made into either the right or left cerebral hemispheres of rats to determine what role injury to catecholamine containing terminals might play in the behavioral and biochemical asymmetries previously reported. 6-HDA (2µg/ul plus ascorbic acid 1mg/ml) was injected 1mm below the surface of the brain at a rate of 0.5µl/min in the area adjacent to the middle cerebral artery about where ligations were made. The dose-response curves for the right and left hemispheres are markedly different ($F., 55=126, p < .001$) with doses as small as 1µg (N=8) or as high as 6µg (N=12) producing hyperactivity which continued throughout the 30 day postoperative period. Left hemispheric injections did not produce any hyperactivity until the dose reached 6µg (N=7) when the animals mean activity was about 130% of control values. Analysis of norepinephrine concentrations using the high pressure liquid chromatography with electrochemical detection revealed that 6-HDA depleted NE concentrations in both the ipsilateral cortex and ipsilateral and contralateral locus coeruleus by about 30% to 50%. The 6µg dose of 6-HDA which caused hyperactivity when injected into the left hemisphere was the only dose which caused contralateral (right) hemispheric depletion of NE. The hyperactivity resulting from left hemispheric injection thus may be the result of right hemispheric mechanisms.

Since injections into either hemisphere cause ipsilateral depletions of NE but only right hemispheric injections cause hyperactivity, these data suggest that the asymmetrical neural pathways which lead to hyperactivity are postsynaptic to the cortical noradrenergic terminals.

199.8 THE DEVELOPMENT OF CIRCLING BEHAVIOR AND ROTATORY BIASES IN SHAKER-1 MUTANT MICE. John M. Cooke, Department of Anatomy, University of Massachusetts Medical School, Worcester, MA 01605.

Shaker-1 mutant mice have been shown to exhibit stable patterns of circling behavior as adults (Cooke and Wolf, Soc. Neurosci. Abstr. 5, 1979). Both the rate of circling and bias for a particular direction of rotation were very reproducible in repeated tests of the same animal. In the present study, thirty-eight shaker-1 mice (15 females, 23 males) were observed for three minute test periods, three times a week, from the third to the ninth postnatal week in order to determine the time of onset of circling behavior as well as the time when rotatory biases were expressed.

Circling behavior was arbitrarily considered to be established when a particular mouse circled at a rate of at least 10 rotations per minute during two consecutive test periods. The transition from not circling to circling was typically quite abrupt and usually occurred within a period of one week. Among 15 females, nine had begun to circle by postnatal day 28, and all 15 were circling by day 43. In contrast, only seven of 23 males had begun to circle by day 28, and five were still not circling as late as day 50. The ability of each mouse to hear and to swim was also tested, and, in general, there was no clear correlation between the time when a particular mouse began to circle and the time when the same mouse showed behavioral evidence of inner ear disease.

Observation of numerous adult shaker-1 mice had previously indicated that the rotatory biases of adults were maintained, in most cases, over the lifetime of the individual. Twenty-five of the 38 mice in the initial part of this developmental study were also tested as adults. Seven of the 25 adults showed a bias for circling in a preferred direction that was greater than 3:1, that is, the ratio of the total number of circles in the preferred direction to the total number of circles in the non-preferred direction was greater than 3:1. Even as early as the first week of testing after the initiation of circling activity, five of these seven had displayed biases that were similar in magnitude and in the same direction as their adult rotatory biases. Likewise, shaker-1 mice which showed weak rotatory biases as adults tended to show little or no bias during initial periods of circling activity. These preliminary observations suggest that the mechanism underlying the behavioral asymmetry of shaker-1 mice may be established quite early, perhaps even before circling behavior is actually expressed.

200.1 A LONG-LASTING BEHAVIORAL CHANGE IN THE NUDIBRANCH MOLLUSC AEOLIDIA PAPILLOSA. M.B. Boyle*, L.B. Cohen, L.G. Harris* and K.P. Irons*. Dept. of Physiology, Yale University School of Medicine, New Haven, CT, 06510, and Dept. of Zoology, University of New Hampshire, Durham, N.H., 03824.

We have attempted to repeat in the nudibranch, A. papillosa, a behavioral paradigm previously used in the prosobranch Urosalpinx cinerea (Wood, Malacologia 6, 267, 1968) and in the pulmonate, Achatina fulica (Croll and Chase, Behav. Biol. 19, 261, 1977). This paradigm, which has been called injestive conditioning, consists of feeding the animal only one food and testing for changes in orientation to food orders in an olfactometer. Aeolidia were collected from the coast of Massachusetts and New Hampshire where they prey on the anemone, Metridium senile. The Aeolidia were divided into two groups, one fed only Metridium and the other only Anthopleura elegantissima (clonal), an anemone obtained from the California coast and never before eaten by the Aeolidia. The two groups were then compared using a simple olfactometer consisting of a rectangular box 31 cm x 6 cm with two inlets at one end, and a 18 cm long, vertical partition dividing the box at the inlet end. The sea water coming into one inlet had passed through a container of Metridium; that coming through the other inlet had passed through a container of Anthopleura. In several trials with 8 to 12 animals in each group, animals which were fed Anthopleura showed a significant ($p < 0.02$, one-tailed t test) preference for the side of the olfactometer receiving Anthopleura odor when compared with animals which were fed Metridium. This effect was observed 24 hours after the last previous meal. There was, however, variability of unknown origin; in other trials the differences between groups were not significant although the direction of the change in preference was always the same.

Compared to the two snails, the Aeolidia nervous system may be more amenable to investigation of the physiological basis of such behavior changes. We hope that our experiment can be improved to the point that the change in behavior can be demonstrated in each animal.

200.2 OPERANT CONDITIONING OF CLAW POSTURE IN THE CRAYFISH. W. Stern-Tomlinson, S.B. Ellis*, and G.L. Gerstein. Depts. of Physiology and Biology, U. of Pa., Philadelphia, PA 19104

Procambarus clarkii were given an electric shock train to the tail in order to reinforce the maintenance of the dactyl within a selected position range. This study differs in method from a previous one (Stafstrom and Gerstein, Br. Res., 134: 185, 1977), because the shock is now removed from the body part being conditioned; therefore, behavioral changes cannot be due to antidromic stimulation of the claw neuromuscular system. The present experiments were done to determine the feasibility and design of future neurophysiological investigations of conditioned claw behavior.

Measurements of dactyl position were made for both claws, although only one (E) was effective in controlling the shock. In principle, the noneffective claw (N) could serve as a naive control, and neurophysiological data pertaining to its behavior could then be used as a point of departure in assessing the determinants of conditioned behavior in the E claw. Our findings were as follows:

1. The E claw spends a significantly greater proportion of time in the position zone affording safety from shock than it did before training.
2. The conditioned behavior is usually maintained for a minimum of 30 minutes to an hour.
3. Animals can learn to open the claw from a more closed posture, or to close the claw from a more open posture, indicating the plasticity of the behavior. Therefore, the behavior is unlikely to be a reflex response to shock which, in such a case, would drive ascending central neurons directly or through tail receptors. Such behavior would be more stereotyped.
4. The behavior of the N claw is not random; it is consistently related to the behavior of the E claw. Therefore, it cannot be used as a naive control.

200.3 First- and Second-Order Associative Learning in the Terrestial Mollusc, Limax maximus. Chris Sahley, Alan Gelperin & Jerry W. Rudy*. Departments of Biology and Psychology, Princeton Univ., Princeton, New Jersey, 08544.

Olfaction plays an important role in the localization and selection of food in many molluscs, including Limax. Potato (P) and carrot (C) odors normally signal the availability of preferred food sources and slugs readily locomote toward these odors. We present evidence that the signal value of these odors can be modified through first- and second-order conditioning such that slugs no longer approach the formerly highly attractive food odors.

In a two-phased Pavlovian conditioning paradigm, experimental slugs, Group SOC, were exposed first to pairings of carrot odor and quinidine sulfate, a bitter tasting plant extract (Phase 1) and in Phase 2 were exposed to paired presentations of carrot and potato odors. Slugs in two additional groups controlled for the Phase 1 and Phase 2 pairing operations. Slugs in Group U/P received unpaired (U) presentations of carrot and quinidine in Phase 1 and paired (P) presentations of carrot and potato in Phase 2. Slugs in Group P/U received paired presentations of carrot and quinidine in Phase 1 but unpaired presentations of carrot and potato odor in Phase 2.

First-order conditioning was demonstrated by the result that the slugs in the two groups that received Phase 1 carrot-quinidine pairings (SOC and P/U) displayed a reduced preference for carrot odor in comparison to slugs in Group U/P that experienced unpaired presentations of carrot and quinidine. Second-order conditioning was demonstrated by the result that slugs in Group SOC (that received both Phase 1 C-Q and Phase 2 P-C pairings) displayed a reduced potato-odor preference in comparison to slugs in Groups P/U and U/P. These observations not only suggest that the slug is capable of associative learning, they also suggest that associative learning processes may play an important role in regulating the food selection of slugs in their natural environment. Thus with behavioral procedures that allow a clear definition of the variables that influence associative learning by the intact slug, and with an in vitro preparation that is amenable to cellular analysis, we hope to make progress in understanding the synaptic interactions that underly associative learning.

200.4 REWARD LEARNING IN DROSOPHILA MELANOGASTER. B.L. Tempel* and W.G. Quinn*. (SPON: R.W. Cholewiak). Dept. of Biology, Princeton University, Princeton, N.J. 08544.

The fruit fly, Drosophila melanogaster, can learn to avoid specific odors, colors, or body postures if they are presented with aversive reinforcers such as electric shock, mechanical vibration, or bitter quinine powder. We report here a new training procedure, using positive reinforcement, in which hungry flies learn to choose a specific odorant that was previously presented in association with a sucrose solution. After being starved 18-20 hrs, a population of hungry flies are run alternately towards two odorants, 3-octanol and 4-methyl-cyclohexanol, in 17 x 100 mm test tubes. In one of the odorant tubes they are given the opportunity to feed on a localized solution of 1.0 M sucrose. The flies' odor preference is then tested in a T-maze, with each of the two chemical odorants in one arm. Usually about 2/3 of the flies run toward the sucrose-associated odor, while 1/3 of the population runs toward the control odorant. This learning performance found with sucrose reward is comparable to that found with electric shock reinforcement. However, memory persists much longer after reward training.

The positive nature of the sugar reinforcements is seen most clearly when the flies encounter only one odor during training and choose between that odor and air at testing. The odorant alone is slightly aversive; however, after pairing the odor with sucrose, trained flies will choose that odor over air. Exposure to sucrose does not itself change the flies' natural aversion to an odorant unless it is presented simultanously with the odor.

For reward learning to occur, the reward solution must be delicious but not necessarily nutritious: flies will choose odorants associated with fucose, which is tasty but not metabolizable by the flies.

Three single gene mutants selected on the basis of their failure to learn negatively reinforced tasks have been tested in this sucrose reward paradigm. We find that one mutant (cabbage) fails both testing procedures while two others (dunce and rutabaga) show some learning on the sucrose reward task.

200.5 PAVLOVIAN CONDITIONING IN PLEUROBRANCHAEA: DISCRIMINATIVE RESPONSES AND ELECTROPHYSIOLOGICAL CORRELATES. G. J. Mpitsos, C. S. Cohan*and A. D. McClellan*. Dept. of Anatomy, Case Western Reserve Univ., Cleveland, OH 44106.

Previous work on Pleurobranchaea has dealt primarily with operant food aversion training in which a squid stimulus (Ssq) was paired with electrical shocks (ES) (Mpitsos, Collins and McClellan, Science, 199: 497, 1978). Using a Pavlovian paradigm, we have trained these marine molluscs to cease feeding and to withdraw from another palatable stimulus prepared by boiling a commonly available beer to 0.1 volume and then diluting it to various concentrations (Sbr) as described for Ssq. In "discriminative test" experiments, animals were tested for feeding and withdrawal thresholds to Ssq and Sbr before and after training but were given only the Sbr and ES during training. Experimental animals (E's) were given only 5 trials spaced 2 hrs. apart of 60 sec. of Sbr with an overlapping ES during the last 50 sec.; concurrently run control animals (C's) were given the same amount of stimulation and handling but Sbr was unpaired from ES by 1 hr. Before training, all animals exhibited equal feeding thresholds and did not withdraw from the Ssq or Sbr, which, by definition, indicated that they did not discriminate between Ssq and Sbr. After training, the E's withdrew from and had greatly suppressed feeding behavior to Sbr but not to Ssq; C's were little changed from pretraining and were significantly different from E's. Similar associational response differences that persisted for several weeks after training were obtained from animals that were given the above E and C procedures together in a discriminative conditioning paradigm. Moreover, suspended and semi-intact preparations that had been dissected and attached with electrodes to muscles and nerves exhibited conditioned discriminations similar to those obtained from them before dissection. About 30% of the preparations that had ingested the CS^- (Ssq) not only withdrew and ceased feeding when the CS^+ (Sbr) was coapplied, but they also regurgitated or rejected the ingested CS^-. Despite the fact that obviously different behavioral responses were observed, the underlying motor programs recorded electrically were indistinguishable, except for the active phase of regurgitation as reported for untrained animals (A. D. McClellan, Soc. for Neurosci., 1978 and 1979). Along with feeding, regurgitation and rejection, the mouth, jaws and radula of Pleurobranchaea are also used cyclically in at least two other behaviors: defensive bite and self and inter-animal gill grooming. Thus, unless there are criteria for one behavior to distinguish it from all other motor programs produced by the same appendages, it is presently impossible to establish unambiguously in Pleurobranchaea, or other animals, the neurophysiology of conditioned or unconditioned responses without using preparations in which a vigil can be kept on the behavior itself. (NSF BNS 76-8123)

200.6 DEFENSIVE CLASSICAL CONDITIONING IN APLYSIA: EVIDENCE FOR CONDITIONED FEAR IN AN INVERTEBRATE. E.T. Walters,* T.J. Carew and E.R.Kandel. (SPON: R. Ambron). Div. of Neurobiol. & Behavior, Depts. Physiol. & Psychiat., P & S, Columbia Univ., N.Y. State Psychiatric Inst., New York, N.Y. 10032.

Aversive associative learning has recently been demonstrated in a number of simple invertebrates. In mammals aversive conditioning is thought to produce conditioned fear (McAllister and McAllister, 1971). This raises the question: to what degree do the effects of aversive conditioning in invertebrates resemble conditioned fear in higher animals? We have begun to examine this question in Aplysia californica, a gastropod mollusc. We have previously shown that Aplysia can form a classically conditioned association between a chemosensory conditioned stimulus (CS, shrimp extract) and an aversive unconditioned stimulus (US, electric shock to the head). The associative learning is expressed as a powerful facilitation of escape locomotion by the CS (Walters et al., 1979, PNAS, 76). One prediction of a conditioned fear hypothesis is that the fear-inducing CS should modulate additional behaviors in a motivationally consistent pattern: defensive behaviors should be enhanced while appetitive behaviors should be suppressed or unaffected (Konorski, 1967). To test this prediction we have examined whether the CS, after conditioning, can enhance four different defensive responses varying in complexity: escape locomotion (a complex fixed action pattern), inking (an all-or-none fixed act), and siphon and head withdrawal (two graded reflex acts).

In each experiment two groups of animals (8 to 15 animals per group) were trained: one with the CS and US temporally paired, the other with the CS and US explicitly unpaired. Twenty-four hours after training each group was tested using a blind procedure. Siphon withdrawal and escape locomotion were triggered by tail shock and were examined simultaneously in the same animals. Inking was triggered by noxious shock to the body wall. Head withdrawal was elicited by application of the CS to the head in a "split-foot" preparation (Hening et al., 1979, Brain Res: 179). We found that, in the presence of the CS, each of the four defensive responses was significantly facilitated in paired compared to unpaired animals ($p < .005$ in each case). We are presently examining whether the CS can inhibit appetitive responses such as feeding, in addition to facilitating defensive responses.

Our results show that, after aversive classical conditioning, the CS acquires the ability to facilitate four distinct defensive responses ranging from simple withdrawal reflexes to complex motor programs. The fact that several response systems are modulated by the CS in a motivationally consistent pattern supports the hypothesis that some invertebrates, such as Aplysia, can learn a form of conditioned fear functionally similar to that exhibited by vertebrates.

200.7 DEFENSIVE CLASSICAL CONDITIONING IN APLYSIA: FUNCTIONALLY DISTINCT MOTOR SYSTEMS SHOW DIFFERENT NEUROPHYSIOLOGICAL CORRELATES. T.J. Carew, E.T. Walters,* and E.R. Kandel. Div. of Neurobiol. & Behavior, Depts. Physiol. & Psychiat., P & S, Columbia Univ., and N.Y. State Psychiatric Inst., New York, N.Y. 10032.

Aplysia can learn to associate a chemical conditioned stimulus (CS, shrimp extract) with an aversive unconditioned stimulus (US, electrical shock to the head). After pairing with the US, the CS becomes capable of facilitating a number of defensive behaviors: escape locomotion, inking, siphon withdrawal and head withdrawal. These findings have led us to propose that Aplysia may exhibit a form of conditioned fear (Walters et al., 1979, PNAS, 76; Neurosci. Abstr., 1980).

As a first step towards a cellular analysis of associative learning we have searched for neuronal correlates of conditioning. All animals first received either paired or specifically unpaired (control) training. We then examined (blind) three separate motor systems: escape locomotion, inking, and siphon withdrawal, using a modified "split-foot" preparation (Hening et al., 1979, Brain Res: 179) for recording intracellularly from motor neurons during behavioral testing. To study escape locomotion we applied the CS to the head and then shocked the tail. In the presence of the CS, paired animals (N=10) showed significantly greater numbers of steps and significantly more action potential bursts in pedal motor neurons than unpaired animals (N=10; $p < .01$ and $p < .025$, respectively). To study inking and siphon withdrawal we first applied a test stimulus to the tail. The CS was then applied to the head and a second test stimulus was delivered. In the presence of the CS paired animals (N=8) showed significant facilitation of the amplitude and duration of complex EPSPs elicited by the test stimuli in both ink and siphon motor neurons compared to unpaired animals (N=9; $p < .005$ in each case).

These results demonstrate that neuronal correlates of associative learning are different in functionally distinct motor systems in Aplysia. In the locomotor system, where the learned behavior is expressed as an increase in a recurrent motor sequence, the CS enhances the output of the central program, leading to an increase in the number of spike bursts in the motor neurons. By contrast, in the inking and siphon withdrawal systems, where the learning is expressed as a decrease in threshold or an increase in response amplitude, the CS enhances afferent synaptic input directly onto the motor neurons.

Examining the effects of learning in the identified motor cells of several different behavioral systems is useful for two reasons: first, it may allow us to select from a number of different behaviors the simplest monosynaptic test system for examining the mechanisms by which a motor response is modulated by associative learning. Second, it may simplify the search for neurons that are causally related to the associative learning.

200.8 SUPPRESSION OF THE GILL WITHDRAWAL REFLEX OF APLYSIA BY ARGININE VASOTOCIN. J.A. Thornhill, Ken Lukowiak*, K.E. Cooper and W.L. Veale. Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

Over the last year we found that arginine vasopressin (AVP), in picomole concentrations, caused a marked reduction in the amplitude of the gill withdrawal reflex (GWR) in Aplysia evoked by tactile stimulation of the siphon. In addition, AVP caused the rate of habituation of the reflex to be significantly increased. Finally, AVP caused a reduction in the excitatory input to central gill motor neurons (CGMN's) evoked by siphon stimulation. Recently, our laboratory has shown (Fed. Proc. 39; 1743, 1980) that a related neurohypophyseal peptide, arginine vasotocin (AVT), is present in the nervous system of Aplysia, being most concentrated in the pleural ganglia. Thus, the present experiments were designed to determine if exogenously applied AVT affected the GWR and the neuronal activity evoked by siphon stimulation in a similar manner as AVP.

The preparation consisted of the siphon, mantle, gill and abdominal ganglion (PVG) of Aplysia californica. The branchial, ctenidial and siphon nerves were left intact, all other nerves were severed. The PVG was isolated in a leak-proof chamber from the rest of the preparation so that AVT could be infused directly over the PVG. The GWR was evoked by tactile stimulation (1g) of the siphon with the 'Tapper'. An infusion of AVT (10^{-12}M) for 15 min over the PVG caused a marked and significant decrease in the amplitude of the GWR and increased the rate of reflex habituation. In addition, AVT caused a decrease in the number of action potentials evoked in the CGMN's by the siphon stimulus. The suppressive effects of AVT were completely reversible following washout with artificial seawater and a 3 h rest. AVT did not affect the passive membrane properties of the CGMN's. It is thought that AVT brings about its effects by increasing the activity of neurons which pre-synaptically 'gate' the input from sensory neurons to the CGMN's and which also results in increased CNS suppressive output to the PNS in the gill which ultimately mediates gill reflex behaviours.

200.9 THE EFFECTS OF VASOTOCIN ON ABDOMINAL GANGLION NEURONS IN APLYSIA ARE NOT MEDIATED BY THE NEUROSECRETORY BAG CELLS. J.P. Edstrom*, K. Lukowiak*, J.A. Thornhill (SPON: K.E. Cooper).
Division of Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

Previous reports in the literature have described how bag cell activity and exogenously applied bag cell extract are able to inhibit the pacemaker cells L_3-L_6 in the abdominal ganglion of Aplysia for long periods of time while the same procedures increase the activity of another pacemaker, R_{15} (Mayeri et al., 1979, Sci., 204, 417).

Several recent series of experiments in this laboratory have investigated the effects of the peptides vasotocin and vasopressin on Aplysia neurons. These experiments have demonstrated the presence of significant concentrations of vasotocin in the Aplysia central nervous system and that the peptides exert a prolonged suppressive influence on the gill withdrawal reflex and inhibit pacemakers L_3-L_6 while exciting R_{15} (1980, in press). Because the hormone synthesized and released by the bag cells has been identified (Chiu et al., 1979, PNAS, 76, 6656) and is known to be neither vasotocin nor vasopressin, the similarity of the actions of vasotocin and bag cell activity on the identified pacemaker cells suggested the possibility that the effects of vasotocin and vasopressin on the pacemaker cells was an indirect one caused by activation of the bag cells. This was tested by simultaneously observing the activity of identified abdominal ganglion pacemaker and bag cells before, during and after bathing the ganglion in artificial sea water containing between 10^{-6} and 10^{-12}M/ℓ of either vasopressin or vasotocin. Standard intracellular techniques were used to record from the cells L_3-L_6, R_{15} and bag cells. The artificial sea water was maintained between 16 and 18 degrees Celsius and had a pH between 7.7 and 7.9. At no time was either vasopressin or vasotocin observed to activate the normally quiescent bag cell population. Subsequent stimulation of the right connective nerve could usually activate the bag cells. This resulted in a prolonged inhibition of the L pacemakers and activation of R_{15} and showed that the lack of response of the bag cells to either vasopressin or vasotocin was not due to an inability of the bag cells to fire. At the same time vasopressin and vasotocin had their normal effects on cells L_3-L_6 and R_{15}. Although a direct action of vasotocin and vasopressin on the pacemaker cells has not yet been proved, these results do indicate that the effects of vasotocin and vasopressin are not mediated by bag cells.

Supported by the MRC of Canada.

200.10 BIOCHEMICAL CORRELATES OF A LONG-TERM ASSOCIATIVE BEHAVIORAL MODIFICATION IN HERMISSENDA: CHANGES IN THE LEVELS OF SPECIFIC PHOSPHOPROTEIN BANDS FOLLOWING A CONDITIONING PROCEDURE. J.T. Neary, T. Crow and D.L. Alkon. Lab. of Biophysics, NINCDS, NIH, Marine Biological Laboratory, Woods Hole, MA 02543.

A conditioning procedure consisting of the temporal association of light and rotation produces a long-term modification of photopositive behavior in the nudibranch mollusk, Hermissenda crassicornis (Crow, T. and Alkon, D., 1978, Science 201:1239). Cellular neurophysiological changes in B photoreceptors (persistent depolarization and increased input resistance) following training were correlated with the modification of photopositive behavior (Crow, T., and Alkon, D., 1980, Science, in press). In an effort to investigate biochemical correlates of the behavioral modification, we have examined protein phosphorylation in the eyes of animals from trained, unpaired, random, and normal control groups. Following three days of behavioral training, the circumesophageal nervous systems were dissected from trained animals and control groups and incubated separately in artificial sea water containing 0.625 mCi ^{32}Pi/ml for 2 hr at 15°C. Eyes were then dissected from the nervous systems on a cooling plate and dissolved in lysis solution. Total ^{32}Pi incorporation into proteins was determined by TCA precipitation. No significant differences were detected in total protein phosphorylation levels (paired $\bar{X}$=10,500 $\pm$ 4910 cpm/eye; random $\bar{X}$=10,900 $\pm$ 5410 cpm/eye; unpaired $\bar{X}$=9560 $\pm$ 3320 cpm/eye). Aliquots of the eyes were subjected to one-dimensional SDS-polyacrylamide gel electrophoresis, and autoradiograms of the gels were analyzed by densitometry. Seven phosphoprotein bands were detected in the eyes from all animals. In paired vs. control groups, there were no significant differences in five of the phosphoprotein bands. However, significant overall differences between paired and control groups ($p<.01$) were found for bands with approx. MW of 23,000 and 20,000 daltons. Post-hoc comparisons revealed that the paired group was significantly different from both the random and unpaired control groups ($p<0.01$) while the controls were not different from each other. One phosphoprotein band (approx. MW=23,000) was increased 49% in paired as compared to random controls. The second phosphoprotein band (approx. MW=20,000) was increased 56% in paired as compared to random controls. The changes in the two phosphoprotein bands, as mediated perhaps by protein kinases and/or phosphatases, may be related to the increase in input resistance in type B photoreceptors observed in trained animals and to the increase in the long-lasting depolarization in type B photoreceptors observed in isolated nervous systems following pairing. In summary, the data presented here indicate that the phosphorylation of specific proteins in the eyes is correlated with the acquisition of an associative behavioral modification in Hermissenda.

201.1 SPINAL MODULATION OF THE ACOUSTIC STARTLE RESPONSE: THE ROLE OF NOREPINEPHRINE, SEROTONIN, AND DOPAMINE. D.I. Astrachan* and M. Davis. Dept. of Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06508

The acoustic startle reflex is being used increasingly as a model system to study how different neurotransmitters modulate reactivity to sensory stimuli. Systemic administration of serotonin (5-HT), norepinephrine (NE), or dopamine (DA) agonists increase acoustic startle amplitude. Acoustic startle involves a brainstem-spinal cord reflex arc. Anatomical studies indicate that spinal motor neurons receive dense 5-HT and NE inputs. Single unit recording studies indicate that 5-HT and NE facilitates excitation of motor neurons produced by afferent stimulation. Behavioral studies indicate that 5-HT or NE facilitates spinal reflexes in spinal or decerebrate animals. It is thus possible that excitatory effects on startle produced by systemic administration of 5-HT or NE agonists result from a direct action in the spinal cord.

To test this rats were implanted with catheters in the lumbar enlargement of the spinal cord (Yaksh & Rudy, Physiol. Behav., 1976, 17, 1031-1036). After recovery they were presented with startle-eliciting noise bursts before and after infusion of different compounds onto the spinal cord (intrathecally).

Intrathecal administration of 5-HT increased acoustic startle. This effect was potentiated and prolonged by intraperitoneal (ip.) administration of pargyline. The 5-HT agonist 5-methoxy-N,N-dimethyltryptamine (5-MeODMT) also markedly increased startle. Effects of 5-HT or 5-MeODMT were blocked by ip. administration of the 5-HT antagonists cinanserin or cyproheptadine but not the NE antagonist WB-4101. Intrathecal administration of NE or the α_1-agonist phenylephrine also increased startle amplitude. These effects were completely blocked by the α_1-antagonist WB-4101 given ip., but not by cyproheptadine. In contrast, intrathecal infusion of a wide range of doses of the β-agonist isoproterenol, or the DA agonist apomorphine did not alter startle. Intrathecal infusion of d-amphetamine markedly increased acoustic startle. This effect was completely blocked by ip. administration of WB-4101, but not by cyproheptadine, propranolol, or haloperidol.

The results indicate that excitatory effects of systemically administered 5-HT and NE agonists on startle may be mediated partially or even entirely by the spinal cord. On the other hand, excitatory DA agonist effects must involve supraspinal systems. More generally, this study demonstrates the importance of the spinal cord as a potential target for mediating drug-effects on behavior since, in fact, most behaviors used in psychopharmacology ultimately involve spinal output.

201.2 EFFECTS OF LOCUS COERULEUS LESIONS ON SELF-STIMULATION BEHAVIOR IN RATS-REVERSIBILITY BY MORPHINE ADMINISTRATION. A. Tempel, S.S. Steiner, D. Ocheret*, C. Pavlides* and S. Berman*. Behavioral Physiology Lab., Dept. Psych., The City College of New York, New York, N.Y. 10031.

It has been shown that an important relationship exists between central nervous system mechanisms of reward and drugs of abuse, the nature of which were explored in the following study.

Nine rats were stereotaxically implanted with 2 pairs of bipolar stainless steel electrodes aimed at one of the following combinations: fields of forel (ff) and crus cerebri (cc); medial forebrain bundle (mfb) and ff; mfb and cc. Stimulation consisted of biphasic rectangular pulse-pairs. Each bipolar electrode was used in a monopolar fashion. Animals received 7 days saline (0.9%), 1 day naloxone(1mg/kg), 7 days saline, 7 days morphine (2.5mg/kg), 1 day morphine + naloxone and 6 days post-drug saline. Subjects were then given d- and l- isomers of amphetamine alternated in an ABBA series, followed by 7 days saline. All doses were 1mg/kg, injected s.c. 40 min. before the beginning of the ICSS session. Acute locus coeruleus lesions (LC) were then made unilaterally in all animals. Following the lesion, animals were run for 21 days of saline to allow for complete fiber degeneration and neuroheumoral depletion. ICSS drug paradigms post-lesion were identical to the pre-lesion paradigm.

Prior to lesion, animals showing a large facilitation in ICSS response rates during morphine administration, also showed a large increase in ICSS rates to the d- but not the l- isomer of amphetamine. Animals showing no response to morphine administration, had ICSS rates that were equally enhanced by both isomers of amphetamine.

Post-lesion saline rates were depressed in animals where the lesion included areas of the LC proper, ventral LC and/or subcoeruleus area. These animals maintained their response facilitations under morphine administration, which were naloxone reversible.

Animals, in which the LC was spared, showed no alterations in saline ICSS rates post-lesion and maintained their response facilitation under morphine administration.

These data indicate that lesions in the area of the LC produce marked decreases in ICSS behavior which are reversible by morphine administration.

201.3 ENDOGENOUS OPIOIDS AND MOTIVATION: AVERSIVE PROPERTIES OF NALOXONE IN DRUG-NAIVE RATS. D. van der Kooy, R.F. Mucha* and M. O'Shaughnessy*. Depts. of Anatomy and Pharmacology, Univ. of Toronto, and Addiction Research Foundation of Ontario, Toronto, Canada M5S 1A8.

We have previously reported that rats prefer environments in which they receive intravenous or intracranial morphine compared to environments in which they receive corresponding saline treatment (Soc. Neurosci. Abstr. 1979, 5, 657). In the course of investigating the pharmacological blockade of this place preference effect, it was found that naloxone alone (in drug-naive rats) produced a place aversion.

A detailed analysis of naloxone-induced place aversion is now reported. Male Wistar rats were placed in one of two separate environments: a black box with a black plexiglas floor or a similar white box with a sawdust floor. They received naloxone injections on daily 30 min trials for 4 days in one box. Similar saline training trials were also given each day in the other box. On day 5 rats were tested by providing simultaneous access to both training environments for 15 min and measuring the amount of time spent in each environment. Naloxone produced aversions, for the environment in which it was administered, over a wide range of intravenous doses (0.1, 0.5, 2.0 and 45.0 mg/kg).

At the lower doses naloxone injections during training did not produce any gross behavioral changes except for a possible small decrease in locomotor activity, but the 45.0 mg/kg dose produced behavioural convulsions during training and an especially strong aversion on the test day. The naloxone aversion was stereospecific, as 0.5 mg/kg (+)-naloxone failed to produce place conditioning. In morphine dependent rats (subcutaneous 75 mg morphine base pellet 3 days prior to training), potent naloxone aversions were seen at .004 and .025 mg/kg doses. This suggests that morphine dependence may simply be an exaggeration of a process present in drug naive animals.

In an attempt to see if the naloxone aversion could be mediated by receptors in the brain, naloxone training was carried out with 10 µg injected into the lateral ventricle. No aversion was seen with ventricular injections, however a total of 10 µg of naloxone injected bilaterally into the central nucleus of the amygdala did produce a clear aversion. This site has recently been shown to be particularly sensitive to naloxone induction of withdrawal in morphine dependent rats (Lagowska et al., Neurosci. Letter 1978, 8, 241). Bilateral morphine injections (10 µg total) into the central nucleus of the amygdala produced only small, relatively insensitive place preferences. These results suggest that decreasing activity in endogenous opioid systems may induce changes in reward, and further that other effects of naloxone (eg. in feeding) may be secondary to the motivational consequences.

201.4 SEROTONERGIC AND DOPAMINERGIC MEDIATION OF THE DISCRIMINATIVE STIMULUS PROPERTIES OF LISURIDE. Francis J. White and James B. Appel. Behavioral Pharmacology Lab., Dept. Psych., University of South Carolina, Columbia, S.C., 29208, USA.

Lisuride hydrogen maleate (LHM) is a semi-synthetic ergot derivative, structurally similar to LSD, which has many of the biochemical, physiological and behavioral effects of this potent hallucinogen. However, LHM is reportedly not hallucinogenic in man (Somerville and Herrmann, Headache, 18, 75-79, 1978) and is used clinically in the treatment of migraine as well as endocrine disorders. This study investigates the discriminative stimulus properties of LHM in order to elucidate its mechanism of action in vivo and to compare this mechanism with that of LSD in identical behavioral situations.

Male albino rats were trained to discriminate LHM (.08 mg/kg) from saline in a two-lever, water-reinforced drug discrimination task. Following acquisition of this discrimination, the rats were divided into three groups (n=13/group) which were then exposed to a 'fading' procedure in which the training dose of LHM was either increased gradually, decreased gradually or remained the same. By using this procedure, the three groups were trained to discriminate a relatively wide range of doses of LHM (.02 mg/kg, .08 mg/kg, .32 mg/kg) at high levels of accuracy (>95%). Substitution tests with various novel compounds, conducted under extinction conditions, revealed that LSD (.01-.64 mg/kg), and the dopamine (DA) agonist, apomorphine, (.25-4.0 mg/kg), produced significant LHM-lever responding which depended on both the dose of the test drug and the dose of the training drug (LHM). The serotonin (5-HT) agonists quipazine and 5-methoxydimethyltryptamine produced intermediate results. Both the DA antagonist, haloperidol, and the 5-HT antagonist, methiothepin, were capable of reducing (blocking) the LHM cue; the amount of reduction depended on both the dose of the antagonist and the training dose of LHM.

These results indicate that the LHM cue, unlike the LSD cue (Kuhn et al. Neuropharmacology, 17, 257-263, 1978), is mediated by interactions with both DA and 5-HT systems. They also support the hypothesis that transfer and antagonism results in drug discrimination studies depend, to some extent, on the dose used to establish the discrimination.

201.5 MULTIPLE DA RECEPTORS AND HETEROGENEITY OF APOMORPHINE RESPONSES DURING SIX MONTHS NEUROLEPTIC ADMINISTRATION. John L. Waddington and Stephen J. Gamble. (SPON: A. Taylor). Div. of Psychiatry, MRC Clinical Research Centre, Harrow, Middlesex HA1 3UJ, U.K.

The concepts that the prolonged antipsychotic action of neuroleptic drugs might be mediated via cerebral DA receptor blockade and that neuroleptic-induced DA receptor supersensitivity may be a pathophysiological substrate of tardive dyskinesia show some superficial inconsistencies. We describe here behavioural sequelae of six months administration of phenothiazine neuroleptics.

Rats were treated with fluphenazine or trifluoperazine (FPZ and TPZ, 1.7 and 3.8 mg/kg/day in drinking water). After six months responses to low (0.15 mg/kg) and high (1.0 mg/kg) doses of apomorphine (APOM) were assessed while neuroleptic administration continued and compared with controls.

Low intensity features induced by 0.15 mg/kg APOM were attenuated after either neuroleptic. The more intense stereotypy induced by 1.0 mg/kg APOM was modified in a complex manner. After FPZ continuous sniffing was attenuated while locomotion was greatly enhanced. After TPZ continuous sniffing was attenuated and occurred with some locomotion, while 60% of TPZ animals also showed gnawing. Thus some aspects of APOM stereotypy were enduringly antagonised while others were facilitated during protracted phenothiazine administration.

Chronic neuroleptic treatment may differentially influence heterogeneous classes of DA receptor that mediate distinct DA-dependent behaviours.

We are grateful to E.R. Squibb Ltd., U.K., for facilitating this study.

201.6 EFFECTS OF SEROTONIN ANTAGONISTS ON PUNISHED AND UNPUNISHED RESPONDING IN RATS. Paul C. Mele* and Marjorie A. Caplan. Dept. of Psychol., Adelphi Univ., Garden City, N.Y. 11530

Drugs that deplete or antagonize serotonin (5HT) increase rates of schedule-controlled operant behavior that have been suppressed by electric-shock punishment. Many of these drugs have been shown to increase unpunished responding as well. It is difficult to determine whether these drugs selectively increase punished or unpunished responding, however, since in most studies punished and unpunished responding were maintained by different schedules of reinforcement and at different control rates of responding; these factors are determinants of drug effects on schedule-controlled behavior (McMillan, Fed. Proc., 1975, 34:1870). The present study therefore, sought to determine whether or not some anti-5HT agents selectively increase punishment-suppressed responding when these factors are controlled for.

The structurally distinct 5HT antagonists methysergide (ME) and cinanserin (CN) were tested in rats responding on a multiple schedule of milk reinforcement. The multiple schedule was composed of two fixed-interval 2-minute components; each component was signalled by a distinctive exteroceptive stimulus. Responding in one component was suppressed by foot-shock delivered after every fifth response (a fixed-ratio 5 punishment schedule). The sympathomimetic amine d-amphetamine (AM) and the benzodiazepine chlordiazepoxide (CD) were administered as reference drugs as their differential effects on punished and unpunished responding are well documented. ME (3-17mg/kg) and CD (5-20mg/kg) increased overall rates of punished responding while producing smaller increases in unpunished responding. CN increased punished responding at 32 or 64mg/kg but not at 8 or 16mg/kg; unpunished responding was not consistently altered by any dose of CN. AM (0.5-1.5mg/kg) produced dose-dependent decreases in both punished and unpunished responding. Since overall rates of punished responding ranged from one-half to one-fifth of unpunished rates, comparisons were made between drug-induced alterations in punished and unpunished rates from within the fixed-intervals, i.e. local rate comparisons. When local rates of punished and unpunished responding were similar, ME and CN generally increased these rates to comparable degrees. CD frequently increased punished responding more than comparable local rates of unpunished responding. AM primarily decreased local rates of punished responding while unpunished responding was increased or decreased less than punished responding. Thus, CD and AM selectively altered punished vs unpunished responding while ME and CN did not. These results do not support the notion of a serotonergic inhibitory system which specifically mediates punishment-induced response suppression. They do suggest a more general behavioral inhibitory system mediated by serotonin.

201.7 BEHAVIORAL EFFECTS OF PARAQUAT. W. Brock and J. Dougherty (R. Yokel), University of Kentucky and Veterans Administration Medical Center, Lexington, Ky.

There is evidence to suggest that the accumulation of paraquat in the body can become a toxicological problem. Because the symptoms associated with paraquat poisoning in humans include CNS changes, the effects of oral paraquat on two types of behavior were studied in two groups of Wistar rats. Paraquat dichloride was administered for 7 days in the drinking water in the home cages via graduated drinking tubes at concentrations of .07, .19, .38 and .77 mg/ml. The rats were exposed to each paraquat concentration 23 hr per day for seven days. The concentrations were administered in ascending order, with 3-10 days of water only access between 7-day exposure periods. Two behavioral procedures were used to evaluate the compound: non-cued single spatial alternation (SSA) and a fixed-ratio (FR-60) schedule. Both procedures were conducted in daily 1-hr sessions in operant chambers, required a lever press response, and utilized 45 mg sucrose pellets as reinforcers. In the SSA task, two retractable levers were presented to the rat on a discrete trial basis. Reinforcers were delivered only when alternation of responses between levers occurred on successive trials. Each daily session consisted of 100 trials, and each trial was terminated after a response, or 30 sec, whichever came first. A 10-sec inter-trial interval was programmed to occur between trials. Accuracy and speed of responding (latency) were measured. It was found that in 5 of 6 rats an average of 10-30 mg/kg/day paraquat over 7 days decreased accuracy 5-25% and increased latency 140-700% over pre-drug baseline performance levels. Significant behavioral effects persisted for 3-7 days following removal of the paraquat source. In the free operant FR 60 study, mean doses of 15-30 mg/kg/day over the 7-day exposure period in three rats resulted in a response rate decrease of 10-45%. Response rates gradually returned to baseline levels within 4-8 days after removal of paraquat from the water. Results from these studies indicate that paraquat reversibly decreases the speed of responding in discrete trial and free operant situations, and impairs the accuracy of choice behavior necessary for successfully meeting environmental contingencies.

203.1 CERVICAL SPINAL CORD POTENTIALS ELICITED BY NERVE STIMULATION. A.M. Sherwood, E.M. Sedgwick* and W.B. McKay*. Dept. of Clinical Neurophysiology, The Institute for Rehabilitation and Research, Houston, TX 77030.

A cervical somatosensory evoked potential can be recorded in man from surface electrodes placed over the 7th cervical vertebra and the suprasternal notch following median nerve stimulation at the wrist, at motor threshold. Epidural electrodes placed over the posterior midline of the cervical spinal cord were also successful in recording responses to median nerve stimulation, although with more complex morphology. (The electrodes were temporarily implanted, with distal leads externalized, as a part of the evaluation of the effectiveness of spinal cord stimulation on the patient's impaired motor control.) Responses were differentially amplified 25,000 times using a Teca AA6 MKIII amplifier, and averaged over 128 stimulus repetitions using a HP 1000 minicomputer system with a Preston 500 KHz analog to digital converter.

The responses appeared with a latency of 8 ms, a duration of 15 ms, and a peak amplitude of 10 to 30 microvolts. The early portion of the response consisted of multispike activity with a short refractory period superimposed on a slow wave background, while the latter portion consisted of only a longer duration, monophasic potential, with a longer refractory period. This waveform was recorded in three patients with electrodes at high cervical levels, above the 6th vertebra radiologically. In these patients, we were unable to elicit recordable potentials in the epidural electrodes in response to bilateral tibial nerve stimulation at the popliteal fossae.

However, recording from epidural electrodes at T1-T3 in another patient, stimulation of the tibial nerve at an amplitude sufficient to induce an H-reflex in the triceps surae muscle resulted in a response which consisted of a mono- or biphasic pulse of 1 microvolt amplitude, with a latency of 18 ms, and a duration of 3 ms. With the electrodes in this position, however, we were unable to record responses to median nerve stimulation.

These responses were compared to those made from surface electrodes, and from epidural records over the lumbar spine. The comparison showed the dependence of the large potentials upon the localized anatomy. These responses were found to be of nerve root and spinal cord origin. In contrast, the tibial responses recorded over the high thoracic spinal cord were of ascending fiber origin.

203.2 EFFECTS OF COMPRESSION AND ISCHEMIA ON ASCENDING AND DESCENDING SPINAL CORD CONDUCTION M.H.Bennett, Department of Neurological Surgery, University of Pittsburgh Medical School, Pittsburgh, PA 15261

Somatosensory evoked potentials (SEP's) have been used to monitor spinal cord function during various neurosurgical and orthopaedic surgical procedures. Since SEP's provide no information on descending long tract function, their limitations as an operative monitoring technique must be critically evaluated.

In cats ascending and descending spinal cord activity was recorded above and below the lesion sites in response to sciatic nerve and motor cortex stimulation. Potentials were measureed during the application of graded dorsal or ventral compression or following multilevel bilateral radicular artery coagulation until a conduction block occurred. SEP's and ascending activity were also measured during the production of the conduction block.

Data will be presented to show the relative decrements in ascending and descending long tract conduction produced by each type of lesion during the establishment and recovery of the conduction block. The degree of decrement of ascending and decending activity was highly dependent upon the site of compression. However, in no case was only one system affected by the compression. Ischemia equally affected both systems. SEP amplitude was approximately proportional to ascending activity amplitude. From these observations it was concluded that, although possible, it is unlikely that acute cord ischemia or compression would produce descending system deficits without detectable SEP changes. It was concluded that SEP monitoring has considerable merit as an operative monitor of spinal cord function.

203.3 A PRELIMINARY REPORT ON THE EFFECTS OF BARBITURATE COMA ON MULTIMODALITY EVOKED POTENTIALS (MEPS) IN PATIENTS FOLLOWING SEVERE HEAD INJURY. P. G. Newlon*, R. P. Greenberg and D. P. Becker. Div. of Neurosurgery, Med. Coll. of Va., Richmond, VA., 23298.

Pentobarbital (PB) has been advocated as a means of controlling intracranial pressure in patients with severe head injury. But therapeutic PB coma prevents adequate evaluation of brain function since information about a patient's neurological condition cannot be easily ascertained. We report preliminary results assessing brain function by means of multimodality evoked potentials (MEPs), i.e. visual (VER) and somatosensory (SER) cortical and somatosensory (SBSR) and auditory (ABSR) brainstem responses recorded from 13 PB treated (mean serum level 20.5 ug/ml) and 6 control severe head injury patients otherwise receiving equivalent treatments. MEP studies were obtained in treated patients and controls in the acute period following head injury (mean day 2.3) and after PB therapy was discontinued (mean day 14.9). Comparisons of evoked potential waveforms were made between treatment and nontreatment time periods in both patient groups.

All PB treated patients demonstrated an increased latency (1-3 msec) in all components of the SER and SBSR, seen as early as the Erbs Point potential - but returned to normal latency when PB was discontinued. No such change in latency was exhibited by controls. The amplitude of the P15-N20 complex in PB treated patients was not affected although SER later waves were markedly reduced in amplitude compared to controls. There were no significant amplitude or latency differences in ABSR's of PB treated patients or in the control group. The amplitudes of VER's in the PB treated group were markedly reduced and returned to control level after PB was withdrawn, but latency variability in these patients was similar to that seen in the control group.

The latency increases in the SER and SBSR may well be due to the effects of PB coma on body temperature and hence peripheral conduction velocity rather than as a result of a direct effect of PB. Mean core temperatures for the PB and control groups were 96.8 and 100.4 F. respectively. The reduced amplitude seen in cortical responses is due to depressant effects of the drug. These results demonstrate that while PB coma alters evoked potentials recorded in head injury patients, it is still possible to monitor brain function with them. Cortical activity is present, though diminished in amplitude and brainstem responses show little change except for slight shifts in latency which may be attributable to slowed peripheral conduction. Hence, as long as these effects are known and considered, assessment of neuroelectric activity in PB treated head injury patients remains a valuable technique with which to evaluate brain function. 203.4 NEURAL GENERATORS OF BRAINSTEM AUDITORY EVOKED RESPONSES. PART I: LESION STUDIES. R.H. Britt and G.T. Rossi. Div. Neurosurg. R155, Stanford Med School, Stanford, CA 94305 and Palo Alto Veterans Hospital, Palo Alto, CA 94304.

In a series of 70 pentobarbital anesthetized cats, the neural generators of click brainstem auditory evoked responses (BAERs) were studied by discrete lesions (44 animals) and gross electrode recordings (32 animals) in the nuclei and tracts of the ascending auditory pathway. Ten per second clicks were presented monaurally, filtered (150Hz-3 or 8kHz) and averaged from differential recordings between vertex and mastoid electrodes. Cochlear microphonic, N1 and N2 responses were recorded bilaterally from round window electrodes. Lesions were made either by visual aspiration, transection using a scalpel, or by stereotaxic radiofrequency thermocoagulation and verified histologically.

Five waves (I-V) were routinely recorded in this preparation. Wave I matched the latency of N1 and remained after complete aspiration of the cochlear nucleus (CN). The configuration of wave I elongated with complete CN lesions. If the CN were surgically isolated all but waves I and II disappeared. Wave II assumed an elongated configuration. Wave III was most affected by large lesions of either superior olivary complex (SOC). If the lesion was contralateral to the stimulus, the residual activity of wave III shifted to a shorter latency and merged with the latter part of wave II. Wave IV was still present but diminished in amplitude. If the lesion was in the ipsilateral SOC, all except waves I and II disappeared. Wave IV had its most significant reduction in amplitude with large bilateral lesions of the lateral lemnisci (LL) near the dorsal nucleus. Wave V could be significantly reduced by complete aspiration of the contralateral inferior colliculus (IC). A similar effect on wave V was seen with a sagittal midline transection of the brainstem extending from the commissure of the IC to the caudal medulla. The residual wave V was eliminated by a complete lesion of the ipsilateral IC. The effects of midline lesions on waves III and IV were similar to those seen with large lesions of the contralateral SOC.

These lesion studies suggest that wave I of the BAER arises at a site proximal to the cochlear nucleus, most likely activity in the eighth nerve. Wave II remained with CN isolation and disappeared with CN aspiration, suggesting that the ipsilateral CN is the principal neural generator of wave II. Waves III and IV have bilateral generators. Lesions of either SOC complex effected the greatest reduction of wave III. Wave IV was the most difficult to selectively effect with lesions, but the greatest reduction in amplitude occurred with large lesions of the rostral LL bilaterally. The studies suggest that wave V arises primarily in the contralateral IC. (Studies supported by VA RAG/Merit Review and NIH (NS 15860) Grants and the Neurosurgery Research Fund)

203.5 NEURAL GENERATORS OF BRAINSTEM AUDITORY EVOKED RESPONSES. PART II: ELECTRODE RECORDING STUDIES. G.T. Rossi and R.H. Britt. Div. of Neurosurgery R155, Stanford Med. Sch., Stanford, CA 94305 and Palo Alto Veterans Hospital, Palo Alto, CA 94304.

In a series of 32 pentobarbital anesthetized cats, gross electrode recordings to click stimuli were made in the nuclei and tracts of the ascending auditory pathway. With bipolar electrodes a biphasic waveform was recorded when the electrode was centered within a neural generator. On either side of the neural generator, a monophasic peak of the same latency was recorded, however, a reversal of polarity occurred when the electrode crossed from a site proximal to the generator to a site distal. Unipolar recordings were referenced to the same vertex electrode used to record the BAER and had a positive polarity with amplitudes best correlated with the biphasic responses recorded with the bipolar electrodes. The details of stimulus presentation and BAER recordings are given in the companion abstract. Electrode tracts and positions were histologically verified.

Recordings from cochlear nucleus (CN) showed activity comparable with wave II. The dorsal CN contributed little when compared with the high amplitude of activity recorded from the ventral CN. Recordings from the midline trapezoid body (TB) showed activity that extended from the latter part of wave II through wave III. Recordings from either superior olivary complex (SOC) demonstrated high amplitudes of activity corresponding to wave III. Wave IV activity was maximally seen in the rostral lateral lemnisci (LL) bilaterally, but was also seen caudally down to the SOC and rostrally to the inferior colliculus (IC). Activity comparable with wave III, although maximally present in the SOC, was also seen in TB recordings and rostrally in the LL and, finally, to a minor extent, in the superficial aspect of the inferior IC. Activity with a latency of wave V was first recorded at the level of the inferior colliculus; with the majority of activity arising from the IC contralateral to the stimulus.

These studies support the concept of multiple neural generators for most of the component waves of the click evoked BAER. We have divided the neural generators into "primary" and "secondary" based on their relative contribution to each component wave: Wave I: primary - 8th nerve; Wave II: primary - CN, secondary - TB; Wave III: primary - SOC bilaterally and TB, secondary - LL and IC; Wave IV: primary - LL bilaterally, secondary - SOC and IC bilaterally and Wave V: primary - contralateral IC, secondary - ipsilateral IC.

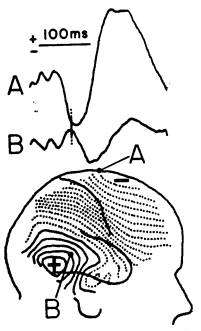
203.6 SCALP DISTRIBUTION OF HUMAN AUDITORY EVOKED POTENTIALS: A REASSESSMENT. C.C. Wood* and J.R. Wolpaw (SPON: T. Allison). VA Medical Center, West Haven, CT 06516 and Armed Forces Radiobiol. Res. Inst., Bethesda, MD 20014

Inferences about the origin of human auditory evoked potentials (AEPs) have depended heavily on their scalp distribution. Vaughan and Ritter (EEG J., 28:360, 1970) reported that the auditory vertex potential (VP), a prominent negative-positive sequence with latencies of 80-100 and 160-200 msec, reversed in polarity across the Sylvian fissure. They concluded that this distribution was consistent with a dipole source for the entire VP located in the supratemporal plane in or near primary auditory cortex. Kooi et al. (EEG J., 31:166, 1971) suggested that the apparent polarity reversal was an artifact of VP activity at the nose reference used by Vaughan and Ritter, since no reversal occurred with a chest reference. Later work has supported the Kooi et al. interpretation using even more distant noncephalic references (Picton et al., Multidisci. Perspect. in ERP Research, 1978). Wolpaw and Penry (EEG J., 39:609, 1975) reported that additional potentials occur at temporal scalp locations during the latency range of the VP.

AEPs to a monaural or binaural click (50 dB SL, 3.2 sec isi) were recorded simultaneously from 20-channel arrays over the right hemisphere in 11 adults (ages 15-49). Other electrodes were located on the nose, ear, mastoid process, knee, ankle, and at 3-cm intervals down the neck. All were referred to a balanced thorax electrode; AEPs based on other references were derived by computer subtraction. The results indicate: (1) VP-like activity is present in recordings between the nose and noncephalic locations in some but not all subjects. (2) With a noncephalic reference, polarity reversals between temporal and fronto-central scalp occur at a number of latencies, including the region of the VP negativity (see fig., which is based on grand average AEPs from all 11 subjects). However, the reversal during the VP is better characterized as the summation of potentials from several sources than as a reversal due to a single dipole source. (Note the focal temporal distribution of the 80-msec positive peak.) (3) The ear and the mastoid process, both widely used as references in AEP recordings, are significantly active relative to noncephalic references.



203.7 FAST AND SLOW COMPONENTS OF THE HUMAN AUDITORY BRAINSTEM RESPONSES. O. Özdamar* (SPON: Y. Geinisman). Siegel Institute, Michael Reese Hospital, Chicago, Illinois 60616.

Human auditory brainstem response (ABR) consists of a series of fairly regular peaks and valleys (Jewett waves) superimposed upon a broad response. These two responses, designated fast and slow components, have energy concentrations in the high and the low frequencies respectively. Recent studies (Davis and Hirsh, 1980; Huang, 1980) suggest that these components originate from different anatomical structures with different electrophysiological mechanisms. The objective of this study is to explore the characteristics of these components in normal subjects and in neurological patients.

A method of differentiating fast and slow components of the ABR is to utilize different filter bandwidths. In this study wide-band ABRs, which include both the fast and the slow components, were recorded with filter settings at 3-2000 Hz. Fast ABRs were recorded using 100-2000 Hz filter bandwidths. The slow component was isolated by subtracting the fast ABR from the wide-band ABR. To expedite recording time, simultaneous two channel recordings with different bandwidths were used in most recordings. Click stimuli were used in all the recordings.

In normals, slow responses are characterized by a vertex positive wave, occasionally followed by a negative wave of smaller amplitude. The vertex positive wave begins 4-5 msec post-stimulus onset and has a peak latency of 5-7 msec. Latencies of fast responses conform to previously published norms.

This study shows that slow and fast responses may be independently affected in neurological patients. In demyelinating diseases such as multiple sclerosis, the later components of the fast ABR can be small and fused. However, the slow component often is not, or less, affected by the disease. Generally the slow response is prolonged, diminished in amplitude or absent only at advanced stages of the disease. Data from neurological patients support the hypothesis that fast and slow components of the ABR are generated by different physiological mechanisms.

203.8 MAGNETIC AUDITORY EVOKED FIELDS: INTERHEMISPHERIC ASYMMETRY. M. Reite, J.T. Zimmerman* and J.E. Zimmerman*. Univ. of Colo. Med. Center, Denver, CO 80262 and Nat. Bureau of Standards, Boulder, CO 80302.

We recorded magnetic auditory evoked fields (AEF) from 10 normal adult human subjects using binaural and monaural stimulation. The magnetic sensor was a 2" diameter 2-D first derivative SQUID gradiometer. Subjects were recorded in an aluminum shielded room. The magnetic sensor was placed about 1 cm from the scalp centered over a point thought to approximately overlie the primary auditory cortex (approximately 1/3 of the distance from T_3 to C_3 or T_4 to C_4).

Stimuli were irregularly spaced 0.1 msec clicks with a modal inter-stimulus interval of 700 msec (range 500-1500). Sound was conducted to the ears by a system of plastic tubing. The magnetoencephalogram (MEG) was amplified, filtered with a 0.1-30 Hz bandpass, and averaged for 500 msec following 128 stimuli.

AEFs exhibited considerable interindividual variability. There was additionally some evidence of intraindividual phase reversals across time. Within an individual, recording from the same location and during a single recording session, responses were very similar. These responses were used for amplitude analysis. The amplitude of the largest magnetic responses occuring within the first 400 msec were measured for bilateral, contralateral, and ipsilateral stimulation.

Recording from the right hemisphere, 8 of 10 subjects exhibited larger amplitude AEFs to contralateral stimulation, with contralateral responses being 134$\pm$ 37% of ipsilateral responses. Using all data (several subjects were recorded more than once), mean contralateral response amplitudes from the right hemisphere were 176$\pm$ 39 femptotesla (fT) peak-to-peak; mean ipsilateral response amplitude was 134 $\pm$ 33 fT. Recording from the left hemisphere, 7 of 7 subjects had higher amplitude contralateral AEF amplitudes, with contralateral responses being 147$\pm$ 52% of ipsilateral response amplitudes. Using all data, mean left hemisphere contralateral response amplitude was 187$\pm$ 47 fT; mean ipsilateral response amplitude 129$\pm$ 43 fT. Contralateral and bilateral responses were similar in amplitude, with contralateral being of slightly greater magnitude over the left hemisphere.

These findings suggest that cortical current dipoles produced by contralateral auditory stimulation are of greater magnitude than those resulting from ipsilateral stimulation. They are compatible with the anatomical evidence that a majority of centripetal auditory input is crossed. The similar magnitude AEFs to bilateral and contralateral stimulation suggests the relationship is not simply linear. (Supported by Office of Naval Research Contract No. N00014-79-C-0383).

203.9 LUMINANCE-DEPENDENT PATTERN VEP DELAY IN HUMAN DEMYELINATING DISEASE. J. Camisa, I. Bodis-Wollner, and L. Mylin*. Department of Neurology, Mt. Sinai School of Medicine, New York, N.Y. 10029

VEP measurements are widely used in the diagnosis of MS. In humans, increased latency is commonly attributed to impaired conduction due to demyelinization in the optic nerve. However, VEP latency is not an absolute measure: parameters of the visual stimulus do affect whether or not an abnormality is found. The existence of spatial frequency and orientationally selective abnormalities in MS have been studied by psychophysical (Regan, et al., 1980) and electrophysiological (Camisa, et al., 1979) methods. Now we report the effects of pattern luminance on VEP in MS.

Visual evoked potential latencies were measured for each eye of 42 patients. Observers viewed a 2.3 c/d checkerboard pattern (4^{o} visual angle) reversing at a rate of 1 Hz. For each patient, latencies were recorded at two mean luminance levels--1.7 log ft lamberts and .7 log ft lambert--at the identical pattern contrast (90%). The patients' latencies at each luminance level were compared to the normal (15 control observers) bivariate distribution of right eye/left eye latencies. Of the 42 patients, 23 (55%) were categorized as abnormal in the high luminance condition, and 31 (74%) of the patients were classified as abnormal for the low luminance condition. This difference was significant ($p < .05$). Comparing the amplitude and the "width" of the P-100 "component" revealed no systematic differences between the two luminance conditions, either for patients who had abnormal latencies at both or only at the low luminance level.

We conclude that luminance is an important parameter in studying conduction velocity with VEP methods. Since an enhanced abnormality at low luminance does not appear to be accompanied by either VEP amplitude reduction or waveshape broadening, the data do not so far suggest either 1) less synchrony in multiple pathways or 2) a reduction in the number of pathways responding as explanations of the luminance-specific conduction defect in MS.

203.10 SPATIO-TEMPORAL ANALYSIS OF THE HUMAN VISUAL EVOKED RESPONSE. E. Sutter. Smith-Kettlewell Inst. of Visual Sciences, San Francisco, California 94115.

Some of the factors which can cause variations of the visual evoked response with retinal stimulus position are known. They are: gradients in retinal receptor populations, gradients in receptive field properties, cortical magnification factor and gross cortical anatomy. A spatio-temporal analysis thus provides important information on these anatomical and physiological factors. Some of the data presented here were recorded with very high spatial resolution. Surprisingly, they contain features which cannot be explained on the basis of these factors alone.

A technique using spatio-temporal white noise stimuli has been employed for a simultaneous local investigation of extended retinal areas. Results from two sets of experiments are presented:

1. large area (10°), low resolution (50').
2. small area (1.5°), high resolution (3').

In both experiments, remarkable differences were found between luminance and edge response, the edge response showing a much less uniform spatial distribution. The high resolution recording showed extremely localized features extending less than 10' of arc. To determine their physiological significance, it will be necessary to study their dependence on stimulus orientation and electrode position.

204.1 TRANSIENT CATECHOLAMINERGIC CELLS IN MOUSE EMBRYONIC PANCREAS COEXIST WITH CELLS PRODUCING GLUCAGON. G. Teitelman, T.H. Joh and D.J. Reis, Laboratory of Neurobiology, Dept. of Neurology, Cornell Univ. Med. College, New York, NY 10021.

In the embryonic rat, cells containing catecholamine (CA) biosynthetic enzymes tyrosine hydroxylase (TH) and dopamine-B-hydroxylase (DBH) appear in several sites which in the adult do not contain adrenergic neuronal perikarya. Such transient CA cells are found, among other locations, in the gut of rat embryos before midgestation (Teitelman et al., PNAS 76:509, 1979). The fate of this transient population of cells is not known: they may transform into cells which synthesize other substances, possibly peptides. To test this hypothesis, we sought to determine: (a) whether a transient population of catecholaminergic (CA) cells can be detected in the embryonic pancreas; and, if so, (b) whether the presence of the CA cells overlap in time with those containing glucagon; and (c) if the CA cells are localized within the glucagon islets.

Mouse embryos at different gestational ages were processed for immunocytochemical localization of TH, L-dopa decarboxylase (DDC), DBH, and glucagon according to the PAP technique.

Cells containing TH were found in the dorsal pancreatic anlage only between days 11 and 12 of development (E11-E12). Between 12 to 25 stained cells were present in each section throughout the pancreatic primordia. These cells lack neurite-like processes and are found either dispersed or in clumps. The intensity of the PAP reaction was typically lower than that of sympathetic ganglia cells present in the same section at different sites. While cells containing immunoreactive DBH were also found in the gut, no DBH was detected in cells of the embryonic pancreas although some of them did contain DDC. Therefore, these cells are probably dopaminergic. Sections were also stained for glucagon to determine whether cells containing pancreatic peptides were localized in the same regions as the TH cells. Cells containing glucagon were found in the pancreas at E12 and their distribution and number were similar to that of the TH cells. However, while cells containing TH disappear at E12, those containing glucagon persisted throughout life. When sections were sequentially incubated with both antibodies, cells containing TH were found within the glucagon islets.

We conclude: (a) that the embryonic mouse pancreas contains a population of cells transiently expressing TH and DDC but not DBH and (b) that the TH cells coexist in time and space with glucagon producing cells. These findings suggest an intimate developmental and functional interrelationship between neural and pancreatic tissue.

204.2 DEVELOPMENTAL ASPECTS OF SEROTONIN N-ACETYLTRANSFERASE STIMULATION AND TRYPTOPHAN METABOLISM IN PINEAL MONOLAYER CULTURE. V. Rowe, J. Parr*, and V. Steinberg*. University of Kansas Medical Center, Kansas City, Kansas 66103, and Veterans Administration Medical Center, Kansas City, Missouri 64128.

We have previously shown that pineal cells derived from neonatal rat pineal glands can be maintained in monolayer culture for extended periods. Further studies on the adrenergic pharmacology of these cultures show that stimulation of serotonin N-acetyltransferase (NAT, E.C. 2.3.1.5.) activity is mediated by receptors having both α-and β-adrenergic properties. In addition, concentration response curves for NAT stimulation suggest that α-adrenergic properties increase as the cells age and develop in culture. Furthermore, L-propranolol, a β-adrenergic antagonist, exhibits partial agonist characteristics in these cultures. Finally, rat serum was found to stimulate synthesis of metatonin, 5-methoxyindole acetic acid, 5-methoxytryptophol, N-acetylserotonin, and 5-hydroxytryptophol.

204.3 FACTORS AFFECTING THE DEVELOPMENT OF PINEAL β-ADRENERGIC RECEPTORS IN CULTURE. M. Blair Clark* and Benjamin Weiss, Dept. of Pharmacol. Medical College of Pennsylvania, Philadelphia, Penna. 19129.

Previous studies have shown a marked developmental increase in the density of β-adrenergic receptors in rat pineal gland. The present experiments were designed to determine if β-adrenergic receptors continue to develop in an in vitro preparation and whether exogenously administered catecholamines can influence their development. Timed pregnant Sprague-Dawley rats were kept under an alternating 12 hr light-dark cycle for at least one week prior to parturition. Dispersed cell cultures of pinealocytes were prepared by a modification of the method of Buda and Klein (Endocrinol. 103:1483, 1978). Cells were placed in plastic 60 mm culture dishes at a density of 2-3 x 10^6 cells/dish in a supplemented Dulbeccos Modified Eagles Medium. Whole pineal glands were cultured on stainless steel grids in plastic organ culture dishes in a modified BGJ_b Fitton-Jackson medium. The β-adrenergic antagonist ^{3}H-dihydroalprenolol (DHA) was used to quantitate β-receptors in sonicates prepared from cells or whole glands. The density of β-adrenergic receptors (Bmax) of dispersed pinealocytes prepared from 2-day-old rats increased about 2-fold after 24 hr in culture. There was no appreciable change in the dissociation constant for DHA binding (Kd). After 16 days in culture, these cells exhibited a 10-fold increase in both the Kd and Bmax for DHA binding, suggesting that long term culture causes qualitative as well as quantitative changes in DHA binding sites. Cultured whole pineal glands removed from 2-day-old rats also showed an increase in DHA binding following 24 hr or 48 hr in culture. In fact, the increase in DHA binding was quantitatively greater in culture than that seen developmentally in vivo. Whole pineal glands removed and cultured from adult rats also exhibited an increase in DHA binding. These results suggest a type of adrenergic denervation supersensitivity of β-receptors caused by the removal of catecholamine input. To examine this possibility we exposed whole pineal glands to l-isoproterenol (10 μM)during a 48 hr culture period. This treatment completely blocked the rise in DHA binding. In summary, these experiments show for the first time an increase in pineal β-adrenergic receptors in vitro. This increase apparently is genetically predetermined but can be modified by the degree of sympathetic input. This in vitro system may provide a useful model for studying further the neural and hormonal factors that modulate the development of β-adrenergic receptors. Supported by USPHS Grants NS13768 and NS16242 and NS07061.

204.4 LONG TERM CHANGES IN DOPAMINE REGULATION OF PROLACTIN SECRETION IN OFFSPRING FOLLOWING MATERNAL TREATMENT WITH HALOPERIDOL. N.R. Plach, G. Jawahir,* L.J. Grota, J.A. Seggie and M.P. Rathbone. Neuroscience Dept., McMaster Univ., Hamilton, Ontario, L8N 3Z5.

Dopamine (DA) neurons of the tuberoinfundibular system exert a tonic inhibitory influence on pituitary prolactin (PRL) secretion. This inhibitory influence can be blocked by DA antagonists such as haloperidol. We investigated whether administration of haloperidol during the prenatal period when tuberoinfundibular neurons are first developing would lead to long term changes in DA regulation of PRL secretion in offspring. Pregnant Wistar rats received daily injections of haloperidol (1.2 mg/kg SC) during the last trimester. At birth, both control (CON) and haloperidol (HAL) litters were fostered to untreated dams. Except for weighing and visual inspection once per week, the pups were left undisturbed until weaning on day 21 when they were sexed and housed in groups of 6. On postnatal day 25, half of the HAL and half of the CON offspring received an acute injection of haloperidol (0.3 mg/kg SC). The other half of each group received a control injection of vehicle. One hour later, trunk blood was collected. The results showed that serum PRL levels in response to vehicle injections were the same in both the prenatal HAL and CON groups. The rise in serum PRL levels of animals receiving the haloperidol challenge, however, was significantly less in the case of prenatal HAL offspring as compared to CON offspring.

One interpretation of these results is that the pituitaries of offspring who received prenatal haloperidol treatment developed supersensitivity to DA inhibition. In order to test this possibility, we investigated the direct effect of DA on PRL secretion in isolated pituitary incubation experiments. The anterior pituitaries from 25 day old animals, treated prenatally as in the previous experiment, were bisected and preincubated for 1 hour in aerated Medium 199 at 37°C. One of each pair of hemipituitaries was then transferred into fresh medium containing DA, the other into control medium (no DA). Following a 3-hour incubation period, the amount of PRL released in each sample was assayed and dose-response curves for HAL and CON pituitary PRL secretion were compared. The results of these experiments indicated that the pituitaries of offspring treated prenatally with HAL were more sensitive to inhibition by DA than that of CONs. From these data we conclude that maternal treatment with haloperidol can produce long term supersensitivity to DA inhibitory effects on PRL secretion in the pituitaries of offspring.

204.5 DEVELOPMENT OF SEX DIFFERENCES IN STRIATAL DOPAMINE RELEASE in vitro. Jill B. Becker and V.D. Ramirez. Neural and Behavioral Biology Program and Dept. of Physiology and Biophysics, Univ. of Ill., Urbana, Ill. 61801.

In earlier experiments, we have reported sex differences in the amphetamine (AMPH)-stimulated release of dopamine (DA) from rat striatal tissue in vitro. In striatal tissue from adult females, the release of DA by AMPH stimulation is altered by the in vivo presence or absence of gonadal steroids. In contrast, the AMPH-stimulated DA release from striatal tissue obtained from adult males is not affected by hormonal manipulations.

The present experiments were conducted to investigate the development of these sex differences. Employing an in vitro perifusion system, we examined the effect of AMPH on DA release from striatal tissue of male and female rats: 1) pre-pubertally; 2) in adults which had received hormonal treatments neonatally that are known to alter the pattern of gonadotropin release; and 3) in the adult rat, following post-pubertal ovariectomy (OVX) or castration (CAST).

There were no sex differences in DA release at 4, 19 or 31 days of age. AMPH stimulated significant DA release from striatal tissue at all ages, regardless of the sex of the donor. Striatal tissue from feminized males (CAST at day 2, tested as adults) and control males (CAST at day 15, tested as adults) showed significant AMPH-stimulated DA release. Striatal tissue obtained from both androgenized females (500 µg testosterone propionate day 2, OVX day 15, tested as adults) and control females (OVX day 15, tested as adults) also showed significant AMPH-stimulated DA release. In contrast, with striatal tissue from females OVX as adults, there was a dramatic decremant in the release of DA in response to AMPH stimulation. In adult OVX females, there was attenuation of AMPH-stimulated DA release at 4, 11, or 45 days following OVX. However, the effect of CAST in adult males did not differ from its effect in young male rats. 45 days after CAST, there is significant AMPH-stimulated release of DA from striatal tissue.

These experiments confirm our previous report of a sex difference in striatal DA release in response to AMPH stimulation. We conclude that this sex difference in AMPH-stimulated DA release from the striatum is not found pre-pubertally and is not a function of the organizational effects of neonatal androgen exposure. Our results suggest that there are specific ovarian events which occur later in development, perhaps in association with puberty, which directly or indirectly induce changes in the striatal DA response to AMPH stimulation in female rats.
(RIAS GRANT NSF-SER 76-18255)

204.6 CHLORPROMAZINE ELEVATED PROLACTIN SECRETION IN PREPUBERTAL MALE RATS. C. Hoops* (SPON: S. Rosner). Dept. of Anatomy, Thomas Jefferson University, Phila., Penna. 19107.

Since hypothalamic dopamine acting on the pituitary prolactin cell is viewed as the principle regulatory inhibitor of prolactin secretion and chlorpromazine (CPZ) is thought a dopamine receptor blocker, administration of CPZ to rats normally causes increased prolactin secretion indicated by elevated serum prolactin concentrations. The purpose of this study was to determine whether such a response to chlorpromazine would occur in prepubertal male rats thus indicating prolactin cell secretory capacity and the presence at this stage of a dopaminergic inhibitory apparatus.

Prepubertal male Long Evans rats each received a total of 5 mg/200 g body weight in equally divided doses given in daily intraperitoneal injections over a period of time and were sacrificed on the last day of injection, at 16 or 25 days of age. (Control group animals received injections of PBS.) Serum prolactin concentrations in the chlorpromazine treated rats were significantly ($P < 0.005$-0.010) higher (22 to 55 ng/ml) than those in the control rats (≤2.5 to 16 ng/ml). Examination by electron microscopy of pituitary prolactin (mammotrophic) cells from 25 day old animals suggested morphological development (i.e. increased granule formation, cell hypertrophy) of these cells in the CPZ treated animals, presumably a result of increased secretory activity in these cells during the CPZ treatment period.

It is inferred from this work that a neural dopaminergic mechanism effecting inhibition of prolactin secretion is present at prepuberty, that a dopaminergic receptor is normally operative at this developmental stage on pituitary prolactin cells, and that the prolactin cell is capable of increased secretory activity. It remains to be determined to what extent the dopamine inhibition has matured, when the onset of neural regulation of prolactin secretion begins, and what events of neuron maturation attend the maturation of dopaminergic inhibition of prolactin secretion during the perinatal and prepubertal periods.

204.7 CERVICALLY-STIMULATED PROLACTIN RELEASE IN THE FEMALE RAT: MODULATION BY NEONATAL STEROID TREATMENTS. L.C. Krey* and F. Kamel*, (SPON: L.-M. Kow). The Rockefeller University, New York NY 10021.

In the female rat, cervical stimulation induces a pattern of prolactin release characterized by nocturnal and diurnal surges. These surges are necessary for pregnancy. In the present study, we report that neonatal exposure to testosterone or estrogen blocks cervically-stimulated prolactin release in the mature rat.

Neonatal female rats were implanted with Silastic capsules filled with 1,4,6-androstatriene-3,17-dione (ATD, day 2-10); testosterone (T, day 3-10); 20% testosterone (LoT; day 3-10: T + ATD; or LoT + ATD. Additional females were injected with 10µg estradiol benzoate on day 3. At 60-70 days of age, the rats were castrated. At 1800 the following evening, they were subjected to cervical stimulation with a glass rod. Groups of rats were rapidly decapitated at 3-hour intervals beginning at 30 hours following stimulation. Serum prolactin and corticosterone levels were measured by radioimmunoassay.

Rats treated with ATD or LoT + ATD had ovaries filled with corpora lutea. In response to cervical stimulation, they displayed nocturnal (0300) and diurnal (1800) prolactin surges. In contrast, rats in the other treatment groups had polyfollicular ovaries and displayed a constant pattern of prolactin secretion with no evidence of nocturnal or diurnal surges. However, the diurnal pattern of corticosterone secretion was comparable in all treatment groups.

These results indicate that neonatal exposure to testosterone will influence the organization of the brain circuits mediating cervically-stimulated prolactin release as well as those regulating preovulatory gonadotropin secretion. The findings that estrogen mimics testosterone action while the aromatase inhibitor ATD blocks testosterone action suggest that the organizational influences of androgens on these neuroendocrine circuits depend on the intraneuronal conversion of androgen to estrogen and the subsequent uptake of this steroid by estrogen receptor systems.

204.8 ONTOGENY OF PITUITARY THYROTROPIN-RELEASING HORMONE RECEPTOR IN THE RAT. C. Prasad and A. Banerji* (SPON: D.G. Kline). Section of Endocrinology, Department of Medicine, LSU Medical Center, New Orleans, LA. 70112

Pituitary thyrotropin (TSH) responsiveness to exogenous thyrotropin-releasing hormone (TRH) is significantly greater in neonatal than in adult rats (Prog. Endocr. Soc. Ann. Mtg. Abs. #179, 1976). This exaggerated TSH response to TRH has been explained partly by a marked inability of L-triiodothyronine (T_3) to suppress this response in young, but not adult rats. However, since in the adult there is a close correlation between the TRH-receptor density and TSH response to TRH, we postulated that the exaggerated response in the young may be due to an increase in the number of pituitary TRH-receptors.

The present study was undertaken to determine if there is any change in pituitary TRH-receptor concentration during the first two weeks of postnatal development in male and female Sprague-Dawley rats and to compare this to adult animals. The measurement of TRH-receptor number was performed as described elsewhere (Endocrinology 100: 1496, 1977) except that the homogenization buffer also contained 250 mM sucrose. The binding of ^{3}H-TRH to pituitary membranes was very low in one day old male rats (< 10 fmole TRH bound/mg protein) but increased linearly with time to a maximum at day 4 (168 fmole TRH bound/mg protein). It then declined steadily to an undetectable level by day 12. The female rats followed a similar pattern except that the maximum binding was observed at day 7 (186 fmole TRH bound/mg protein) and the decline in binding was much slower. At almost all ages studied, females possessed higher number of TRH receptors than males. The following table shows for the first time that the neonatal pituitary has significantly higher numbers of TRH-receptor than the adult.

Age	fmole TRH bound/mg protein	
	Male	Female
4-7 Days	115.0 ± 25.5(4)	164.7 ± 14.1(4)
Adult	37.0 ± 5.8(10)	58.9 ± 7.7(10)

We conclude that the availability of TRH-receptors could be an additional regulatory step in the action of TRH on the pituitary gland and the exaggerated TSH response to TRH in the neonatal pituitary may be a function of an age dependent increase in TRH-receptor density.

205.1 SELECTIVE ISCHEMIC DAMAGE TO STRIATAL GABAergic NEURONS
A.J. Francis* and William Pulsinelli* (Spon. T.E. Duffy)
Dept. Neurol., Cornell Univ. Med. Coll., New York, NY 10021

Sensitivity to ischemic damage differs markedly among neuronal populations. There are no accepted chemical or physiological explanations for this phenomenon. We reported striatal GAD (glutamic acid decarboxylase) activity was depleted (54±6% of control) at 5-8 days following 40 min of ischemia in rats, while striatal CAT (choline acetyltransferase) was stable. This suggested selective damage to striatal GABAergic neurons (Neurol 30 431). The present study determined if damage to striatal GABAergic neurons affects striatal GABA binding or GAD activity of substantia nigra (SN). Striatal GABA binding should increase in response to GABAergic denervation and GAD activity in SN should be depleted by damage to striatonigral GABAergic neurons. Transient forebrain ischemia was induced for 30 or 40 min in Wistar rats by reversible occlusion of the common carotid arteries 24 hr after cauterization of the vertebral arteries (Stroke 10 267). In this model, blood flow to striatum is 1% of control, but brainstem is partially perfused (27-35%). Neuronal damage to striatum is severe and reproducible, while brainstem neurons including those of SN are histologically normal. GAD activity was estimated by trapping CO_2 enzymatically released from L-(1-^{14}C)-glutamic acid. ^{3}H-GABA binding was modified from Campochiaro et al. In preliminary studies, GAD activity in SN was measured at 2-6 days following 30 (N=2) or 40 (N=8) min of ischemia. Activity was 78.7±2.5% and 67.4±6.4% of control respectively. This suggests depletion of GAD from SN occurs by striatonigral denervation, since the SN neurons were histologically normal. Striatal GABA binding was studied (at 5 nM) following 40 min of ischemia:

Post-isch. survival	^{3}H-GABA bound(%control±SEM)	N
6 hrs	133 ± 8	4
1 day	175 ± 27	4
3 days	427 ± 24	5

Kinetic studies of ^{3}H-GABA binding are in progress. Increased GABA binding to striatum after ischemia may represent denervation supersensitivity, similar to that reported in kainic acid lesions which also deplete striatal GAD (Campochiaro et al. Brain Res 136 501). Both depletion of GAD activity from SN and enhanced striatal GABA binding after ischemia are consistent with selective ischemic damage to striatal GABAergic neurons.

Supported by 1-T32-NS-0741

205.2 IRON DEFICIENCY AND THE DOPAMINE RECEPTOR IN THE CAUDATE IN THE RAT. R. Ashkenazi, D. Ben Shachar* and M.B.H. Youdim*.
Department of Pharmacology, Technion, Haifa, Israel.

Behavioral and biochemical studies have demonstrated that iron deficiency in rats inhibits both 5-HT and DA mediated behaviors, but has no effect on either presynaptic synthesis of monoamines or monoamine catebolizing enzyme activity (Youdim et al., Neuropharmacol., 19:259, 1980). 21 days old rats were made iron deficient by feeding them on semi-synthetic diet low in iron, while their control received the same diet with iron supplement. After one week on the diet it was found that the behavioral response to apomorphine (2 mg/kg i.p) was decreased. The iron deficient group was anemic as was judged from the hemoglobin as serum iron values. At the same time, ^{3}H-haloperidol binding in the caudate of the iron deficient group was about 50% of that of control. When iron deficient rats (4 weeks on iron deficient diet) were put on control diet for 2 weeks it was found that only hemoglobin levels returned to normal values. The behavioral response to apomorphine, the serum iron, the non-hem iron in the brain and the ^{3}H-haloperidol binding in the caudate remained low. The decrease in the DA receptor caused by iron deficiency may explain the inhibition of the DA mediated behavior. Our results also indicate that the iron deficiency and not anemia per se may play an important role on receptor function and the response to drug treatment.

205.3 CHANGES IN CENTRAL EPINEPHRINE AND β-ADRENERGIC RECEPTORS ELICITED BY ANTIDEPRESSANTS AND α_2-ADRENERGIC BLOCKERS.
M. Goldstein, K. Ueta*, M. Saito* and J.Y. Lew*, New York Univ. Med. Cntr., Dept. of Psychiatry, Neurochemistry Lab., New York, N. Y. 10016

The findings that the PNMT inhibitor SKF 64139 is a potent α_2-adrenergic blocker (M. Goldstein, M. Saito, J. Y. Lew, P. Hieble and R. G. Pendelton, Eur. J. of Pharmacol., in press) prompted us to investigate its effects alone or in combination with desmethylimipramine (DMI) on central epinephrine (E) levels and on the binding characteristics of β-adrenergic receptors. Sprague-Dawley rats were treated with SKF 64139, DMI, or with a combination of both drugs. Sixteen hours after termination of treatment the catecholamine levels were determined in the hypothalmus, and the specific binding of ^{125}I-Iodohydroxybenzylpindolol (IHYP) was measured in cerebral cortical membranes. Treatment with SKF 64139 for three days (once a day 25 mg/Kg, i.p.) resulted in a small reduction of E (10-15% and in a small reduction of the specific binding of IHYP (5-10%). Treatment with DMI (10 mg/Kg, i.p. once a day) resulted in a small reduction of E (10-15%) and in a small reduction of the specific binding of IHYP (10-15%). The combined treatment of SKF 64139 with DMI resulted in a greater decrease of E levels (35-40%) and in a greater decrease of the specific binding of IHYP (25-30%) than the treatment with each drug separately. The combined treatment with SKF 64139 and DMI decreases the B_{max} to a much greater extent than treatment with DMI alone. (B_{max} controls: 50, DMI treated: 42, SKF 64139 + DMI; 35, f moles/mg protein). These results suggest that decrease in central E levels may contribute in some brain regions to the subsensitivity of β-adrenergic receptors elicited by antidepressants (AD). Thus, central E may be involved in the pathology of affective disorders. Furthermore, treatment with α_2-adrenergic antagonists in combination with AD may be of therapeutic value in affective disorders.

205.4 HYPERSENSITIVITY OF RATS WITH CHRONIC CEREBELLAR LESIONS TO ABNORMAL BEHAVIORS INDUCED BY APOMORPHINE. Vernice Jackson, Judy Glassgold*, Carl Miller*, and Stuart R. Snider.*
Dept. Neurology, College of Physicians & Surgeons, Columbia Univ., N.Y.,N.Y. 10032.

Radiographic, surgical and pathologic evidence for anterior cerebellar atrophy in approximately 40% of patients with schizophrenia was recently presented by Weinberger et al. and Heath et al. A possible link between the cerebellum and schizophrenia is provided by reports from other investigators of a pathway from cerebellum to ventral tegmental dopamine (DA) neurons; abnormal function of DA systems is postulated in the "dopamine hypothesis" of schizophrenia. The present study was initiated to determine whether limited cerebellar lesions would result in abnormalities of DA-mediated behavior.

Groups of control rats (n=16) or rats with anterior cerebellar lesions (n=32) were tested with intraperitoneal apomorphine in open trials at 1, 2, 3 and 8 weeks after surgery. Motor behavior was recorded on a 0 to +4 scale. At most testing intervals, abnormal oral behaviors (stereotyped licking, biting, carrying or eating feces) were more severe and frequent in the lesioned than the control animals. Aggressiveness, irritability and locomotor hyperactivity were increased at all intervals compared to controls while apomorphine-induced grooming was less frequent. Stereotyped limb movements and sympathetic signs were equally frequent.

These results indicate that chronic anterior cerebellar lesions result in abnormal behavioral sensitivity to the DA agonist, apomorphine. They support the possibility of a role of the cerebellum in DA-influenced abnormal behavior in human psychosis.

205.5 DDT-INDUCED MYOCLONUS AND CEREBELLAR BENZODIAZEPINE RECEPTOR BINDING. Eunyong Chung Hwang and Melvin H. Van Woert*. Depts. of Neurology and Pharmacology, Mt. Sinai Sch. of Med., New York, N.Y. 10029.

Certain types of stimulus-sensitive arrhythmic myoclonus in patients are particularly responsive to therapy with benzodiazepine derivatives as well as serotonin precursors such as L-5-hydroxytryptophan. Intragastric administration of the insecticide p,p'-DDT (200-600 mg/kg) to rodents produces an animal model of stimulus sensitive myoclonus which also can be reduced by treatment with benzodiazepines and serotonin agonists.

Paul and Skolnick (Science 202:892, 1978) reported that pentylenetetrazol- and electroshock-induced seizures produced an increase in benzodiazepine receptor binding in rat cerebral cortex. Since myoclonus may be a type of seizure, the effect of p,p'-DDT (600 mg/kg) on specific (^{3}H)-flunitrazepam binding to washed membranes from rat brain cerebellum, cortex and remaining areas of the brain was examined. (^{3}H)-flunitrazepam binding was increased only in the cerebellum of DDT-treated rats. The increase in cerebellar (^{3}H) flunitrazepam binding is gradual, being significantly higher 2 hours after DDT administration (when mild myoclonus starts), reaching a maximum elevation at 3.5 hours and remaining elevated at 5 hours (during maximum intensity of myoclonus). Scatchard plot analysis revealed that 3.5 hours after DDT, the total number of cerebellar binding sites (B max) was 140 pmoles/g tissue weight which is a 13% increase from controls (124 pmoles/g). The K_D was not affected by DDT treatment (4.00 and 3.85 nM for control and DDT, respectively).

Although the mechanisms by which DDT rapidly increases the number of cerebellar benzodiazepine binding sites is not known, the close correlation of these biochemical changes with the myoclonic movements suggests that the major pathophysiological changes in DDT-myoclonus and the antimyoclonic action of clonazepam may be localized in the cerebellum. Furthermore, the site of antimyoclonic action of benzodiazepines may be distinct from their anticonvulsant action. (Supported by USPHS grants NS 12341, NS 05802 and NS 71631).

205.6 EFFECTS OF PURKINJE CELL DEGENERATION ON THE NORADRENERGIC PROJECTION TO MOUSE CEREBELLAR CORTEX. S. Roffler-Tarlov and M. J. Zigmond. Dept. of Neuroscience, Children's Hosp. Med. Ctr., Boston, MA 02115 & Dept. of Biol. Sciences, Univ. of Pittsburgh, Pittsburgh, PA 15260.

Purkinje Cell Degeneration (pcd) is a mouse mutant in which all cerebellar Purkinje cells die between 20 and 40 days of age (Mullen et al., P.N.A.S. 73, 1976, 208-212). Purkinje cells are thought to be the principal targets for the plexus of noradrenergic axons within cerebellar cortex which originate in locus coeruleus. Thus, pcd offers the opportunity to examine the impact of loss of target cells on noradrenergic neurons. We report here the results of measurements of transmitter stores and of activity of the rate limiting biosynthetic enzyme, tyrosine hydroxylose (TH), in 9 pairs of pcd mutant mice and control littermates aged 2 to 6 months. Samples were homogenized in 50mM Tris-HCl buffer, pH 6.0. One aliquot was taken for analysis of NE content using a radioenzymatic assay involving methylation of NE by ^{3}H-S-adenysl methionine and COMT (Saller & Zigmond, Life Sci. 23, 1978, 1117). A second aliquot was used to determine the activity of TH by the hydroxylation of 75μM ^{14}C-carboxyl labelled tyrosine in the presence of 3mM 6MPH$_4$, followed by conversion of the product to $^{14}Co_2$ in the presence of excess dopa decarboxylase (Kapatos & Zigmond, Brain Res. 170, 1979, 299).

We observed a significant and permanent increase in NE content of mutant cerebellar cortex, an area which was reduced to 52% of control weight. The NE content had increased significantly whether expressed per gram tissue (314±25% control) or per cerebellar cortex (164±11% control). In contrast, TH activity increased slightly on a per weight basis (128±7 percent but was reduced when expressed per area (68±5% control) resulting in a large decrease in the ratio of TH activity to NE content (42±3% control). The NE content of hippocampus (a region believed innervated by the same locus coeruleus cells but with no known cell loss) was increased in some but not all cases: the average value was 131±14% control whereas TH activity was unaltered.

These results show that the noradrenergic projection to cerebellar cortex is maintained despite the loss of its principal target cells. They also indicate that compensatory adjustments take place leading to a decrease of TH activity. Such changes are not seen in hippocampus, another terminal field of the same cell group. It is possible that in the absence of the principal targets, NE afferents are less active resulting in a selective accumulation of transmitter stores and a decline in the availability of biosynthetic enzyme in these terminals.

205.7 DECREASED STRIATAL AND NIGRAL SUBSTANCE P LEVELS IN HUNTINGTON'S DISEASE. S.H. Buck*, T.F. Burks, H.I. Yamamura, E.D. Bird*, M. Rossor*, and M.R. Brown. (SPON: R.P. Gruener). Dept. Pharmacol., UAHSC, Tucson, AZ 85724; MRC Neurochem. Pharmacol. Unit, Cambridge, England CB2 2QD; Peptide Biology Lab, Salk Institute, La Jolla, CA 92037.

The undecapeptide, substance P (SP), is found in discrete regions and nerve tracts in the brains of laboratory animals. The substantia nigra contains the highest levels of SP in brain and lesion studies indicate that most of the nigral SP originates from a striatonigral neuronal pathway. SP is also found in human brains with a regional distribution similar to that in animals (Duffy et al., Neuropharmacol. 14, 615, 1975). It has been reported that in brains from humans with Huntington's disease (HD), in which there is marked atrophy of basal ganglia, there is moderate reduction of SP content that is limited to globus pallidus and nigra (Gale et al., J. Neurochem. 30, 633, 1978).

We have re-investigated alterations in SP levels in HD using a radioimmunoassay for SP. Rabbit anti-SP serum was used which showed cross-reactivity of 1% with physalaemin and 0.01% with eledoisin. Using ^{125}I-tyr^8-SP as tracer, sensitivity was about 10 fmol SP. Tissues were extracted 2X with cold 2M acetic acid; extraction efficiency was 90.3 ± 1.1% (n=6) as determined using labeled tracer. Assay of varying dilutions of samples (control and HD) produced curves that were parallel to the standard curve.

SP Immunoreactivity - pmol/g wet weight ± s.e.m. (n)

	Controls	HD	↓	P
Cortex (BA 32)	5.74 ± 0.60(10)	5.70 ± 0.92(10)	0.0%	NS

S. nigra -				
p. compacta	267.16 ± 48.07(5)	83.91 ± 20.64(5)	68.6%	<.005
p. reticulata	866.34 ± 100.82(5)	66.12 ± 9.33(5)	92.4%	<.0005
Thalamus	1.42 ± 0.31(8)	1.86 ± 1.21(7)	+31.0%	NS
Hypothalamus	64.15 ± 12.04(10)	60.69 ± 12.29(10)	5.4%	NS

Our results confirm the relative distribution of SP in normal human brain. Highest levels are in basal ganglia and nigral p. reticulata contains 3 - 4 times more than p. compacta. In HD, there are reductions in SP that are limited to basal ganglia. In caudate, SP was undetectable in 6/10 HD and 0/10 control brains. These data indicate that in HD there is depletion of SP throughout basal ganglia and that in some areas this depletion is nearly total. This is the first time that evidence has been presented that the reduction in SP levels in HD also occurs in the neostriatum.

205.8 DOPAMINE RECEPTORS IN SCHIZOPHRENIC HUMAN BRAINS: DIFFERENTIAL CHANGES. Tyrone Lee and Philip Seeman. Department of Pharmacology, University of Toronto, Toronto, Canada M5S 1A8.

Abnormal dopamine receptors have been demonstrated in schizophrenic human brains using ^{3}H-haloperidol or ^{3}H-spiperone to label the post-synaptic receptors (Lee et al., Nature 274:897, 1978 and Am. J. Psychiatry 137:191, 1980). Such abnormalities were indicated by elevation of ^{3}H-neuroleptic binding in dopamine-rich regions of the schizophrenic brain: caudate nucleus, putamen and nucleus accumbens. In order to determine whether the enhancement in binding was due to a change in receptor affinity (K_D in nanomoles/liter) or receptor density (B_{max} in femtomoles/mg protein), Scatchard analysis was carried out in postmortem normal and schizophrenic brains. Post-synaptic dopamine receptors (D-2 receptor sites) in the caudate and putamen were labeled by ^{3}H-spiperone while the high-affinity presynaptic dopamine receptors (D-3 receptor sites) were labeled by ^{3}H-dopamine. N represents the number of brains assayed. The results are as follows:

^{3}H-SPIPERONE BINDING (D-2 RECEPTORS)				
	NORMAL		SCHIZOPHRENIC	
	CAUDATE	PUTAMEN	CAUDATE	PUTAMEN
B_{max}	115±14	128±13	198±24**	191±23*
K_D	0.39±.06	0.31±.03	0.39±.05	0.51±.09
N	15	17	16	13

*$P < 0.05$; **$P < 0.001$.

^{3}H-DOPAMINE BINDING (D-3 RECEPTORS)				
	NORMAL		SCHIZOPHRENIC	
	CAUDATE	PUTAMEN	CAUDATE	PUTAMEN
B_{max}	46.9±5.4	53.9±3.9	38.4±6.7	50.5±4.2
K_D	1.16±.22	2.04±.51	0.62±.08	1.23±.13
N	8	11	5	6

Dopaminergic hyperactivity in schizophrenia could result from too few pre-synaptic dopamine receptors or too many post-synaptic dopamine receptors. The present results indicate that the density of the presynaptic D-3 sites is normal, but that the density of the post-synaptic D-2 receptors is increased.

206.1 QUANTAL ASPECTS OF SYNAPTIC TRANSMISSION IN THE LAMPREY SPINAL CORD. M. E. Selzer. Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

In giant interneurons of adult sea lamprey (Petromyzon marinus) spontaneously occurring depolarizing potentials with amplitudes in the 0.1-1 mV range persisted in tetrodotoxin (TTX), which blocks all known action potentials in the lamprey. Interval histograms of TTX resistant potentials deviated slightly from the negative exponential density function expected for a random process because of under-representation of very short intervals. Amplitude histograms showed a skewed distribution with under-representation of small potentials. Both of these findings are most likely secondary to bias in signal detection due to noise. The mean amplitude of TTX resistant potentials (approx. 0.5 mV) increased during intracellular passage of hyperpolarizing current and decreased with depolarizing current. Therefore they are probably "miniature" EPSPs. Spontaneous hyperpolarizing potentials were also observed, but the vast majority were eliminated in TTX.

Attempts were made to estimate mean quantal content (m) and quantal voltage (q) at synapses between presynaptic Muller axons and postsynaptic lateral cells. At six synapses, activated at 2-5 second intervals, mean steady state EPSP amplitude ($\bar{V}$) was 1.90 mV (range 0.81-3.15). m was calculated from long series of EPSPs using a correction for noise by the formula $m = \frac{\bar{V}^2}{SD^2 - RMS^2}$ where SD^2 = variance and RMS = root mean square of noise (generally .05-.10 mV). m averaged 43 quanta (range 11-114) and q averaged 75 μV (range 18-210). These calculations assume a Poisson behavior of quanta, including a low probability of release. There was no consistent change in q when $\bar{V}$ was decreased by reducing Ca^{++}. For example at one synapse $\bar{V}$ was 1.2, 2.3 nd 3.1 mV at bath (Ca^{++}) of 0.5, 1.0 and 2.6 mM respectively. Corresponding qs were 47, 46 and 49 μV. When pairs of impulses were initiated in the presynaptic axon, facilitation was seen at interstimulus intervals shorter than 50-75 msec, while synaptic depression was seen at longer intervals. Thus a large number of $\bar{V}$s was obtained by varying interstimulus intervals in different series of paired EPSPs. Once again, q was constant, suggesting a low probability of release.

The data presented above suggest that true mEPSPs occur in the lamprey spinal cord and that the statistical behavior of EPSPs at an identified synapse is Poisson in nature, suggesting a quantal mode of transmission.

206.2 "SPONTANEOUS" QUANTAL RELEASE OF TRANSMITTER ABSENT IN VIVO. A.R.Blight and W.Precht*. Max-Planck Institute for Brain Research, Frankfurt/M 71, Federal Republic of Germany.

Spontaneous release of transmitter at rates up to several quanta per second is generally accepted as a normal property of synaptic terminals though the few recordings of such release in intact animals do not exclude the possibility that it was promoted by mechanical damage. Recording intracellularly from lumbar motoneurons of the in situ spinal cord of curarised frogs (R.temporaria) we noticed that spontaneous activity, previously shown to be partly quantal release in isolated cord (J.Physiol.Lond.168,389), was usually absent, of very low frequency, or clearly generated by action potentials in presynaptic neurons. Cutting the thoracic spinal cord (a procedure intrinsic to the isolated preparation) increased the incidence of spontaneous potentials.

Further analysis was made with the neuromuscular junction of m.extensor digitorum longus IV of intact, anaesthetised or spinalised fogs. First, random microelectrode penetrations were made over the middle third of the muscle length (exposed under mineral oil), each cell held 1-3 min. The peroneal nerve was cut in one leg of each frog 1-24 hr before recording and the presence of miniature potentials (MEPPs) compared in the muscle with intact and that with cut innervation. Of 257 penetrations in 8 lesioned muscles MEPPs could be recorded in 52, compared with 6 in 257 penetrations from intact muscles. 5 of 8 intact muscles showed no MEPPs (in 158 penetrations). Secondly, recordings were made from muscles with innervation vitally stained by methylene blue. 57 penetrations close to stained innervation in 10 intact muscles produced one fibre with MEPPs; 83 penetrations in 12 muscles with cut peroneal nerve showed 31 with MEPPs.

Finally, the presence of effectively "silent" endplates in phasic muscles fibres of the frog was confirmed by recording up to 10 min from muscle fibres with no spontaneous potentials, then superfusing with hypertonic saline, causing release of MEPPs. This was also done by cutting the peroneal nerve under TTX saline while recording from single muscle fibres, to demonstrate directly the effect of presynaptic lesions in producing "spontaneous" discharge. We conclude that most if not all cases of quantal release we have recorded in vivo were due to mechanical damage. It remains to be determined whether spontaneous release is totally absent at the normal junction or occurs at rates which are orders of magnitude less than those found in isolated preparations.

206.3 POST-TETANIC POTENTIATION OF EPSPS IN MOTONEURONS OF DIFFERENT SIZE: FURTHER EVIDENCE REGARDING PRESYNAPTIC MECHANISM. Elwood Henneman, Paul Ruenzel* and Hans-R. Lüscher. Dept. of Physiology, Harvard Medical School, Boston, MA 02115.

Stimulation of muscle nerves with single shocks that set up maximal volleys in their Ia fibers evokes aggregate EPSPs in their motoneurons, which are large in small cells and small in large cells. Recently we showed (Nature 282: 859, 1979) that a 500/sec conditioning tetanus applied to the nerve for 10 sec caused post-tetanic potentiation (PTP) of these aggregate EPSPs that was greatest in large cells and least in small cells. These results suggested 1) that Ia impulses normally invade the relatively simple terminal ramifications of fibers going to small motoneurons more completely than the extensive arborizations on large cells and 2) that hyperpolarization of Ia fibers during PTP, with consequent increases in the amplitude and duration of their impulses, presumably facilitates invasion of Ia terminals, leading to activation of more synaptic endings and that this effect is greater for large cells which normally have more uninvaded terminals.

To determine precisely how potentiation of EPSPs in large and small motoneurons depends on duration of tetani, 500/sec conditioning shocks were applied for 2, 4, 8, 16 and 32 sec. Percent potentiation increased with prolongation of tetani, but no ceiling in PTP was reached, even with 32 sec stimulation. When duration of tetanus was plotted against % potentiation on a semilogarithmic scale, a strikingly linear relationship was apparent. The slope of this relationship was greatest for large cells and least for small cells. Sensitivity to duration of tetanus was clearly greatest in the biggest motoneurons.

Since temperature is known to influence conduction at branch points, control and potentiated responses were studied at 34° to 41°C. Postsynaptic population potentials (PSPPs) elicited by electrical stimulation of single Ia fibers were recorded from ventral roots by the sucrose gap technique (J. Neurophysiol. 42: 1146, 1979). Amplitude of control PSPPs was linearly related to temperature ($p < 0.001$). There was a clear, but non-linear, correlation between early potentiation of PSPPs and temperature. The results are consistent with the view that lower temperature and PTP both facilitate conduction at presynaptic branch points where conduction failures occur.

These findings add further evidence that invasion of Ia terminals is generally more complete in the terminal arborizations on small cells because they have fewer branch points.

206.4 TWO DIFFERENT MECHANISMS FOR CALCIUM CURRENT MODULATION UNDERLY HABITUATION AND SENSITIZATION IN APLYSIA. M. Klein* and E. R. Kandel, Div. of Neurobiology & Behavior, P & S, Columbia University, New York, N. Y. 10032.

The gill-withdrawal reflex of Aplysia undergoes habituation and sensitization. Each of these has been shown to result from alterations in transmitter release from sensory neuron terminals (Castellucci & Kandel, 1974, 1976), and both are associated with changes in the Ca^{++} influx of the presynaptic terminal (Klein and Kandel, 1978, 1980). To analyze the mechanisms underlying the modulation of the Ca^{++} current we voltage clamped the sensory neurons and caused them to release transmitter with brief depolarizing pulses. To unmask the Ca^{++} current, we blocked the Na^+ and K^+ currents. Repeated depolarization steps simulating habituation caused a parallel decline in the presynaptic Ca^{++} inward current and in the postsynaptic potential, while application of serotonin, the presumed facilitating transmitter, had no effect. In the presence of K^+ currents, however, serotonin reduced the outward currents and enhanced the inward currents. In another set of experiments, Cs^+ ions were substituted for intracellular K^+ using the antibiotic nystatin. Serotonin again had no effect on the membrane current as long as K^+ was absent. When K^+ was injected into the cell, however, serotonin reduced the partially restored K^+ current. These results imply that homosynaptic depression results from a direct action on the Ca^{++} channel, while presynaptic facilitation results from an indirect action on the Ca^{++} current due to an increase in duration of the action potential secondary to a decrease in the repolarizing K^+ current.

In order to determine whether the small increases in action potential duration seen in normal solutions after heterosynaptic stimulation were adequate to increase transmitter release, we studied the sensory neuron output as a function of the duration of voltage-clamp depolarizations. We found that small increases in step duration caused large increases in the amplitude of the postsynaptic potentials. Because it prolongs the Ca^{++} current, the increase in duration of the action potentials might in turn cause a change in the shape of the PSP. When the shape of the postsynaptic potentials was analyzed we found that the time-to-peak did not change during habituation, but was prolonged after sensitizing stimulation. This finding also supports the hypothesis that habituation affects the Ca^{++} channel directly and is independent of the K^+ currents which determine the configuration of the action potential, while sensitization modulates the Ca^{++} current indirectly by depressing the K^+ current and increasing the duration of the action potential. Thus, although both habituation and sensitization involve a common site of synaptic plasticity, the presynaptic Ca^{++} current, modulation is direct in habituation and indirect in sensitization.

206.5 SPECIFIC IONIC CURRENTS UNDERLYING POST-TETANIC POTENTIATION IN APLYSIA. Robert Kretz,* Eli Shapiro,* Eric R. Kandel (SPON: M. Jacob). P & S, Columbia University, New York, N. Y. 10032.

Four types of synaptic plasticity have been analyzed in Aplysia and shown to be due to a modulation of the calcium current of the presynaptic terminal: homosynaptic depression, presynaptic facilitation and inhibition, and membrane potential-dependent modulation of transmitter release (Klein and Kandel, 1978; Shapiro, Castellucci and Kandel, 1980a;b). We have now begun a voltage-clamp analysis of a fifth type of plasticity, post-tetanic potentiation (PTP) using the synapses made by cholinergic cell L10. Firing L10 at .2 Hz in an unclamped state elicits stable PSPs in the follower cell. After a tetanus of 100 spikes at 4 Hz, follower cell PSPs are potentiated about 200% for 5-10 min. During the tetanus the spike of L10 increases in duration, but returns to control levels in less than 2 min. after the tetanus. Tetanic stimulation also hyperpolarizes L10 by 5-10 mV. This lasts for 5-10 min, and correlates well with the duration of PTP.

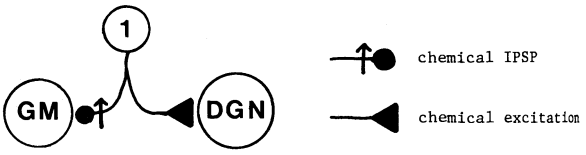
We next voltage clamped cell L10 in TTX solutions. Depolarizing test pulses (50 msec) from -40 to 0 mV at .2 Hz elicit stable PSPs. A tetanus of 100 test pulses at 4 Hz caused PTP of about 200% lasting 5-10 min. Three changes in ionic currents were observed: 1) Inactivation of the delayed voltage-dependent K^+ current. This current rapidly returns to control levels after the tetanus and correlates well with the time-course of spike-broadening. 2) Partial inactivation of the transient Ca^{++} current (measured during pharmacological blockage of the K^+ currents with TEA^+ and 4-AP). This current also returns rapidly to control levels after tetanus. 3) Activation of a slow non-voltage dependent outward current. This persists for 5-10 min after the tetanus and parallels the potentiation of the PSP and hyperpolarization of cell L10 in unclamped cells. This outward current was blocked by Co^{++} and by replacement of Ca^{++} by Ba^{++}, suggesting that the current is a Ca^{++}-dependent K^+ current. In other molluscan cells the amplitude of the Ca^{++}-dependent K^+ current has been shown to be proportional to the intracellular concentration of Ca^{++} (Eckert and Tillotson, 1978).

Our data suggest that repeated activation of L10 during the tetanus increases the intracellular Ca^{++} concentration. This in turn activates a Ca^{++}-dependent K^+ current and also causes increased transmitter release. These experiments support the idea (Rahamimoff, 1968) that a residual Ca^{++} mechanism contributes to PTP and indicate that intracellular Ca^{++} metabolism can affect synaptic transmission in Aplysia. Since L10 also undergoes modulations of the Ca^{++} current in response to presynaptic inhibition and membrane potential-dependent control of transmitter release, both Ca^{++} current modulation and changes in intracellular Ca^{++} concentration seem capable of contributing to different types of synaptic modifiability in the same set of synapses.

206.6 GRADED TRANSMISSION AND PULSATILE TRANSMISSION FROM ONE NEURON TO TWO DIFFERENT POSTSYNAPTIC NEURONS. B. Mulloney and D.H. Edwards, Jr. Zoology, University of California, Davis, CA 95616.

One neuron that has overshooting action potentials causes discrete, classical IPSPs in some of its follower cells, yet causes smoothly graded chemical excitation of another follower in the same ganglion. This chemical excitation shows no evidence of pulsatile secretion of transmitter synchronous with impulses in the presynaptic neuron.

The presynaptic neuron is Interneuron 1, in the stomatogastric ganglion of Panulirus (Selverston and Mulloney, 1974). This neuron is a spontaneous pacer that fires regularly at 5-10 Hz when the neural circuit of which it is part is not generating periodic bursts of impulses. Interneuron 1 makes seven synapses in the ganglion: six are inhibitory and one excitatory. We have studied transmission at two of these synapses:



Impulses in Interneuron 1 cause discrete, constant-latency IPSPs in GM. These IPSPs facilitate as the impulse frequency of Interneuron 1 increases. Interneuron 1 excites DGN, but no discrete EPSPs that follow presynaptic impulses can be recorded either from the soma or from the integrative segment of DGN. At its average membrane potential (-60 mv ± 5 mv), Int 1 excites DGN continuously. Small hyperpolarizations of Int 1, that slow its spontaneous firing, cause graded hyperpolarizations of DGN. Longer hyperpolarizations of Interneuron 1 cause no further response in DGN.

Both synapses are blocked by elevated extracellular Mg^{++} concentrations and augmented by elevated extracellular Ca^{++} concentrations. We have looked for evidence of an electrical synapse between DGN and Interneuron 1 by passing current into each neuron while recording the membrane potentials of both neurons; we have found no evidence of electrical synapses between these neurons.

The evidence in hand shows that different synapses made by the same neuron can have postsynaptic effects with very different temporal characteristics. Whether these differences arise from differences in the presynaptic release mechanisms or from differences in the postsynaptic membranes is under investigation.

Supported by US PHS Grant NS 12295.

206.7 EXTRACELLULAR POTASSIUM ACTIVITY AND AXON EXCITABILITY IN PERIPHERAL NERVES OF CRAYFISH AND RAT. D.O. Smith. Department of Physiology, University of Wisconsin, Madison, WI 53706.

Using K^+-selective microelectrodes, changes in extracellular levels of K^+, Δa_K, were measured during repetitive stimulation of the excitor axon of the opener muscle of the crayfish walking leg and the phrenic nerve innervating the rat diaphragm muscle. Double-barreled electrodes were used with which action potentials and Δa_K were recorded; the distance of the tip from the nerve was measured with a reticle in the microscope eyepiece.

In crayfish, levels of Δa_K in the periaxonal space rose within 5s to about 0.86 mM during stimulation at 50 impulses/s; this maximum was maintained at a steady value in most preparations although it declined in some during continual stimulation. Conduction failure occurred in several preparations after at least 90s of stimulation; levels of Δa_K were not abnormally high in these cases, suggesting that increased $[K^+]$ extracellularly may not have been directly responsible for the blockage. The diffusion coefficient for K^+ through the extracellular space was estimated to be 2×10^{-6} cm^2/s; treatment of the preparation with 0.1% collagenase increased this to 2×10^{-5} cm^2/s, which is quite close to the value observed in aqueous solution. Also, the magnitude of Δa_K was lowered significantly after treatment with collagenase. Soaking the preparation for 30 min in 1 mM ouabain resulted in maximum values of Δa_K which increased by a factor of 1.34; ouabain also eliminated any decay in Δa_K during continued axon stimulation.

In a related series of experiments, Δa_K was measured in the end-plate region of the phrenic nerve-diaphragm neuromuscular junction of young (9 mos) and aged (26 mos) rats. The results were qualitatively similar to those observed in crayfish. At 50 impulses/s, Δa_K rose within 5s to 0.5 mM; the diffusion coefficient was 6×10^{-6} cm^2/s. In aged rats, these values were 0.6 mM and 1×10^{-6} cm^2/s, respectively. After soaking the tissue for 1 hr in 0.1% collagenase, the diffusion coefficient rose to 3×10^{-5} cm^2/s in the young animals and 4×10^{-5} cm^2/s in the old rats.

It is concluded that K^+ accumulates extracellularly during axon stimulation due mainly to restricted diffusion through the collagenous components of the extracellular space. In crayfish, the magnitude of this accumulation is limited by reduced flux of K^+ per action potential and continuous activity by the Na^+-K^+ pump. It is also concluded that conduction failure in these preparations may not be a direct consequence of extracellular K^+ accumulation but that it may be the result of indirect intracellular mechanisms related to altered ionic activities. Supported by NIH grants NS13600, AG01572, and NS00380 (R.C.D.A.) and the Alfred P. Sloan Foundation.

206.8 THE IMPORTANCE OF Ca^{++} IN THE POTASSIUM STIMULATED NEURONAL RELEASE OF ^{14}C-SEROTONIN FROM THE CEREBRAL GANGLIA OF MYTILUS EDULIS: PHARMACOLOGICAL EFFECTS OF Ba^{++}, Mg^{++}, Co^{++} and La^{+++}. J. Brogan*, G.B. Stefano, E.J. Catapane. Dept. Natural Science. Medgar Evers College, C.U.N.Y., Brooklyn, New York 11225.

The potassium stimulated neuronal release of ^{14}C serotonin in the cerebral ganglion of the bivalve mollusc Mytilus edulis was examined to determine the influence of various ions on this process. The normal artificial sea water (ASW) used in these experiments contained 423mM Na^+, 9.0mM K^+, 9.3mM Ca^{++}, 48.4mM Mg^{++}, 26.0mM SO_4^{--} and 496mM Cl^-. When Ca^{++} free ASW was used isomolarity was maintained by substituting sorbital for Ca^{++}. When Mg^{++}, Co^{++}, Ba^{++}, La^{+++} or additional Ca^{++} were added as chloride, NaCl was lowered accordingly. The cerebral ganglia were placed in a 2 ml chamber with a constant superfusion of 0.2 ml/min. Aliquots (0.1 ml) of the superfusion solution were collected and counted for radioactivity every 5 min. The ganglia prior to being placed in the perfusion chamber were incubated in ASW containing ^{14}C-serotonin (1×10^{-6}M, specific activity 57 mCi/mM) for 30 min. The study demonstrated the following; (1) calcium was required for serotonin release, (2) neuronal release occured in tissue placed immediately in Ca^{++} free medium but not in tissue which was maintained in a Ca^{++} free medium for one hour, (3) high concentrations of Ca^{++} (27.9mM) prevented release, (4) the chelator, EDTA (400 uM) prevented release. Addition of Ba^{++} restored release in a Ca^{++} free medium. Mg^{++} (100mM), Co^{++} (60mM) and La^{+++} (5mM) when added to ASW inhibited serotonin release. This work was supported in part by Grant 1 S06 RR 08171-01 from DRR and N.I.M.H. and by Grant 1-T32GM07641 from the MARC Program of NIGMS.

206.9 PRESYNAPTIC EFFECTS OF ANTICHOLINESTERASES. David F. Wilson, Department of Zoology, Oxford, Ohio 45056

The influence of inhibiting acetylcholinesterase on neuromuscular transmission was reexamined in the cut-muscle preparation of the rat diaphragm (Wilson, Am J. Physiol. 237:C31-C37, 1979). Intracellular recording techniques were used to monitor end-plate potentials (EPPs) and miniature end-plate potentials (MEPPs). The preparations were examined in control saline and in the presence of an acetylcholinesterase inhibitor (neostigmine or eserine). In the presence of neostigmine ($5x10^{-8}$ to $1x10^{-6}$ g/ml) quantal release was unaffected by low frequency stimulation (2/sec). At a frequency of 10/sec or higher, a gradual buildup of endplate depolarization occurred and the EPP amplitudes declined. The decrease in EPP amplitude can only be partially explained by the maintained decrease in membrane voltage (2-8 mV). Desensitization appears unlikely since MEPPs can be observed between EPPs during maintained stimulation and desensitization has a relatively slow time course (several seconds) while the EPP decline occurs rapidly. Saturation of the receptors cannot explain the EPP decline since the EPP depolarization is not close to the reversal potential. The conclusion that quantal release is inhibited during moderate and high frequencies in the presence of neostigmine or eserine is supported by the observation that the acetylcholine output of this preparation (Straughan, Brit. J. Pharmacol. 15:417-424, 1960) closely parallels the quantal release data. The magnitude of quantal release inhibition by the anticholinesterases is dosage dependent.

It is postulated that the presynaptic acetylcholine receptors may serve to limit the amount of transmitter released by the motoneuron and function in a negative feed-back pathway. Under in vivo conditions, nerve impulses in a myasthenic patient may reach frequencies up to 50/sec. The present results can explain why high doses of anticholinesterase treatment can have deleterious effects on neuromuscular transmission. In moderate or high doses the net result will be small EPP's during a tetanus; failure to maintain tension in a muscle. The critical level of anticholinesterase treatment that is beneficial to myasthenic patients may be the dosage that prolongs the time course of the EPP while permitting removal of the acetylcholine before onset of the next motor nerve impulse.

206.10 RELEASE AND TURNOVER OF ACETYLCHOLINESTERASE IN RAT DIAPHRAGM S. Brimijoin and J. Carter*. Dept. of Pharmacology, Mayo Medical School, Rochester MN 55901.

Our recent work suggests that a significant fraction of the acetylcholinesterase (AChE) in nerve-muscle preparations is subject to spontaneous release. In a systematic study of this process, phrenic nerve-hemidiaphragms were removed from rats exsanguinated by perfusion with 0.9% NaCl and were incubated in vitro at 37° in 1.5 ml of oxygenated HEPES buffered salt solution containing glucose and albumin. After 3 h, baths were collected and tissues were homogenized in detergent-containing buffer for assay of AChE. Normal hemidiaphragms released enzyme activity at the rate of 30 U (μmol ester hydrolyzed/h) per h; over a 24 h period this would correspond to 12% of the total AChE activity of the tissue. The rate of release was not affected by supplementing the bathing medium with insulin and leucine or with pepstatin (10^{-5} M); release was increased, however, in muscles that had been denervated by transection of the phrenic nerve 1 to 7 days earlier. Ultracentrifugation of samples on 5-20% sucrose density gradients showed that released AChE was mainly of the 10S form although the muscles contained significant amounts of 16S and 4S enzyme in addition. The rate of spontaneous release was much greater than that of arrival of enzyme at the neuromuscular junction by rapid axonal transport along the phrenic nerve (estimated at 3.1 U/h from the rate of accumulation of AChE activity against a ligature applied for 24h in vivo). We concluded that most of the released enzyme originated in the muscle. In order to compare the rate of release with that of turnover in the muscle, rats were treated with the protein synthesis inhibitor cycloheximide, 20 mg/kg, sc, and the fall of AChE activity in the diaphragms was measured. The half-life derived from this experiment was 32 h and the daily turnover was calculated as 2200 U per hemidiaphragm. Approximately 1/3 of this turnover can thus be accounted for by spontaneous release. However, further sucrose density gradient experiments showed that only the 4S form of AChE was lost to a significant extent after cycloheximide treatment (estimated halflife 6h), whereas the turnover of 10S AChE was too slow to measure (half-life > 72h). If released enzyme is derived from 10S AChE in the muscle, therefore, then release may represent the sole fate of this slowly turning-over form. (Supported by Mayo Foundation and by NIH grant NS11855).

207.1 CODING OF SPECIES-SPECIFIC SIGNALS IN MORMYRID ELECTRIC FISH: I. FREQUENCY CHARACTERISTICS. A.H. Bass and C.D. Hopkins, Dept. of Ecology and Behavioral Biology, University of Minnesota, Minneapolis, Minnesota 55455.

During a recent trip to the Ivindo River district of Gabon, West Africa, we examined some response characteristics of Knollenorgans - the putative social communication receptors of mormyrids. Realizing the wide diversity in waveform and spectra of the Electric Organ Discharge (EOD) of these fishes (Hopkins, Behav. Ecol. Sociobiol., '80) we hypothesized a comparable divergence in the frequency response characteristics of their Knollenorgans.

Detailed information was gathered for five local fishes with distinct EOD's: Brienomyrus brachystius triphasic (BBTP; peak power of EOD spectrum -PPW- at 0.7 kHz), Brienomyrus brachystius long biphasic (BBLB; PPW at 0.5 kHz), Marcusenius paucisquamatus (MP; PPW at 2.5 kHz), Petrocephalus sp. (PE; PPW at 4.0 kHz), and Stomatorhinus corneti (SC; PPW at 9.0 kHz). We recorded the spike activity of individual Knollenorgans; stimuli consisted of 100 msec tone bursts of sine waves. Three response paradigms characterized receptors: conventional tuning curves, response profiles of frequency vs. spike activity, and best frequencies (BF's) determined by visual and auditory inspection of spike activity. The positions of all receptors were mapped and together with the BF data, determined topographic variation in BF's of receptors. BF's range from 0.3-3.5 kHz for BBTP, 0.4-2.4 kHz, 1.1-5.7 kHz for MP, 2.0-6.5 kHz for PE, and 0.5-17.2 kHz for SC. BBTP, BBLB, and MP display bimodal distributions of receptor types: a low frequency population (median at 0.6, 0.8, and 1.5 kHz respective BBTP, BBLB, and MP) localized at opercular levels, and a high frequency population (median at 1.3, 1.8, and 4.0 kHz respective BBTP, BBLB, and MP) with a widespread rostral-caudal extent. PE has a unimodal distribution with the median at 4.0 kHz. SC has a trimodal distribution with medians at 1.0, 2.5 and 6.0 kHz; with no systematic topography.

In conclusion, there is: (1) wide overlap in the BF range for both sympatric and allopatric species, and (2) no strict correlation between BF range and the PPW for each species examined. We believe these filter characteristics are a "communication window". A more discrete mechanism must govern the recognition of species-typical EOD's.

207.2 CODING OF SPECIES-SPECIFIC SIGNALS IN MORMYRID ELECTRIC FISH: II. TEMPORAL CHARACTERISTICS. C.D. Hopkins & A.H. Bass. Dept. Ecol. & Behav. Biol.; Univ. Minnesota; Minneapolis, Minn. 55455.

1. African electric fish (Mormyridae) produce trains of electric pulses characterized by: the waveform (or the Electric Organ Discharge -- EOD) and by the repetition rate or pulse rhythm (RHY). EODs are usually species-specific stereotyped "signatures" while RHYs vary greatly with context and show broad overlap between species.

2. One species with sexually different EODs (Brienomyrus brachyistius TP.) has an electric calling song made from bursts of EODs called "rasps". Rasps are used to attract females during the breeding season. We quantified rasps produced by males during field playback of EODs in Gabon (W. Africa).

3. Males sing when presented with computer-synthesized tapes of their own female's EOD combined with their own female's RHYs. They tend to ignore tapes of male's EODs or EODs of other species -even if driven by the female's RHY. They sing in response to the female's EOD even when paired with another species' RHY or with a scrambled RHY. Thus EOD, not RHY is used by males for female recognition.

4. Males sometimes are confused and sing in response to the EODs of the wrong species, but only if that species is allopatric.

5. Males can discriminate EODs whose phase spectra differ but whose power spectra do not. Time-reversed EODs of females elicit half the number of rasps that normal EODs will; phase-shifting the EOD by 90^{0} renders it ineffective. These results suggests that EODs are recognized using phase- or temporal-cues.

6. Natural EODs are presented to Knollenorgan electroreceptors on the skin of the fish. Spike responses recorded external to the skin are phase-locked to the stimulus. Each different EOD presented evokes a unique temporal pattern of spikes; spike number varies from 2 to 5 per EOD. The EOD of female B. brachyistius TP is coded by two spikes separated by 0.4 msec.

7. A square wave stimulus, 0.4 msec in duration imitates the neural code of the female's EODs yet the stimulus waveforms are quite different.

8. Field playback of 0.4 msec square waves to males evokes singing.

207.3 NEURAL CORRELATES OF A NON-JAMMABLE ELECTROLOCATION SYSTEM. Joanne A. Matsubara. Scripps Institution of Oceanography, UCSD, La Jolla, Calif. 92093.

Weakly-electric fish perceive objects in their immediate surroundings by emitting electric signals and evaluating small distortions in these signals as they are bent around objects. The electrosensory system is sensitive to all such electrical signals: not only their self-imposed Electric Organ Discharges (EOD) but also the EODs emitted by other nearby fish of the same species. An individual's electrolocation system is therefore subject to jamming by the discharges emitted by its neighbors, and various behavioral modifications have evolved to minimize this interference. One of these behavioral strategies, the Jamming Avoidance Response (JAR) is possessed by all but one genus of wave-type electric fish. Sternopygus unlike the others has no JAR, yet can electrolocate even in the presence of electrical jamming signals.

Since Sternopygus differs so drastically from other fish, we predicted that these differences would be reflected in the way the central nervous system processes information regarding electrolocation. A comparative study between Sternopygus and Eigenmannia, a closely related gymnotiform with a JAR, was undertaken. Extracellular, single unit recordings from the posterior lateral line lobe (pLLL) will be discussed. The pLLL is the first central processing area for electroreceptive inputs and is organized in a somatotopic fashion. Some pLLL cells have electroreceptive fields on the body surface which can be mapped using a localized amplitude-modulated signal. Simple receptive fields are either excited (Class 1) or inhibited (Class 2) by an increase in EOD amplitude. Class 3 cells have more complex receptive fields, consisting of both an excitatory and an inhibitory area. Results show that Class 3 cells, so far found only in Sternopygus, are unique in that they are responsive to EOD amplitude modulation only if it occurs over a limited portion on the cell's receptive field. Hence, Class 3 cells respond to moving objects since moving objects produce localized distortions in the EOD. Class 3 cells, however, do not respond to jamming signals because they produce large-field amplitude modulations which stimulate entire receptive fields. This mechanism reminds us of certain visual receptive fields in the vertebrate retina which respond to local contrast but not to overall changes in illumination.

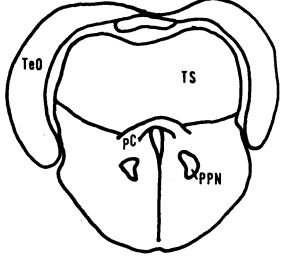
Hence, Sternopygus protects electrolocation not via a behavioral strategy but via central processing mechanisms which can be seen already at the first stage of central processing. This new mode of protection against jamming of the electrolocation system is similar to the lateral inhibitory mechanisms for contrast enhancement in the retina.

207.4 MISSING LINKS IN THE NEURONAL HARDWARE OF THE JAMMING AVOIDANCE RESPONSE (JAR) IN THE ELECTRIC FISH, EIGENMANIA. W. Heiligenberg, T. Finger, J. Matsubara, and C. Carr. Scripps Inst. of Oceanography, UCSD, San Diego, CA. and Univ. Colo. Med. Ctr.,Denver, CO.

The gymnotid fish, Eigenmania, emits a stable high frequency electric signal which the animal uses for electrolocation as well as social interactions. Eigenmania is able to shift the frequency of its electric organ discharge (EOD) in order to avoid interference from the EOD of a neighboring fish with a similar frequency. This jamming avoidance response (JAR) requires that the animal first sense a mixture of its own and its neighbor's EOD's, and then direct an appropriate shift in the frequency of discharge of the electric organ pacemaker nucleus in the medulla. An essential part of the sensory processing necessary for the JAR is performed in the second order electrosensory nucleus, the torus semicircularis (TS). We are studying pathways through which the TS or higher order electrosensory nuclei ultimately control the activity in the pacemaker nucleus.

Using either pressure or iontophoretic delivery methods, we injected small amounts (<20 nl) of HRP into the medullary pacemaker nucleus in six fish. After a 2-4 day survival period, the animals were perfused with 4% glutaraldehyde and processed for HRP by means of the Hanker, et al. method.

In 1 case, the HRP injection was entirely confined to the medullary pacemaker nucleus. In this case, retrograde label occurs only in a cluster of neurons, the prepacemaker nucleus (PPN) lying at the meso-diencephalic junction (see Figure). The PPN lies 300 µm lateral of the midline and about 500 µm ventral to the posterior commissure (PC). Axons leave the prepacemaker nucleus in a caudo-ventral direction and come to lie along the ventral margin of the brain in the rostral rhombencephalon. Just rostral to the level of the pacemaker nucleus, the fibers turn dorsally and medially to enter the pacemaker nucleus along the raphe.



In an attempt to further delineate the pathways involved in the JAR, we are now attempting to inject HRP into the area of the prepacemaker nucleus. We hope to be able to trace the pathway by which lateral line sensory input can influence the frequency of EOD.

207.5 2-DEOXYGLUCOSE IDENTIFICATION OF ELECTRORECEPTIVE PATHWAYS IN THE SOUTH AMERICAN WEAKLY ELECTRIC FISH, EIGENMANNIA. *Curtis L. Baker, Jr. and Catherine E. Carr.* Neurobiology Unit, Scripps Inst. Oceanography, U.C.S.D., La Jolla, CA 92093.

Electrolocation and the Jamming Avoidance Response (JAR) in weakly electric fish have been studied neurophysiologically as far as midbrain levels, while diencephalic and telencephalic electroreceptive pathways have only recently been explored.

The 2-deoxyglucose technique was used to map central electroreceptive areas in the gymnotiform, Eigenmannia virescens. Fish were curarized and injected intraperitoneally with 1 uCi ^{14}C-2-DG. A stimulus of two sine waves of slightly differing frequency, known to activate the JAR and affect electrolocation (Heiligenberg et al, 1978), were presented to the fish for an hour in a quiet, dark room.

Previous experiments demonstrated that the resolution of the Sokoloff et al(1977) 2-DG method was inadequate for studies on a brain of this size (3 mm length). We therefore adapted procedures used by T. Sejnowski (pers. comm.). The fish was perfused with saline and the brain placed overnight in cold anhydrous acetone (4°C). Xylene was substituted for the acetone, and the tissue processed for paraffin histology, modified to avoid contact with water. Sections were cut at 15 u and dry-mounted on albumin-coated slides. The slides were dewaxed, air-dried, and dipped in liquid emulsion (Kodak NTB-2). Slides were developed after 2-5 days.

Every region previously known to be electroreceptive was labelled: posterior lateral line lobe, lobus caudalis, eminentia granularis, n. praeeminentialis and torus semicircularis. Certain areas believed not to be electroreceptive were only slightly above background: torus longitudinalis, parts of the cerebellum and the reticular formation. In addition a number of unidentified diencephalic and telencephalic areas were also labelled.

We thank T. Sejnowski for his invaluable suggestions for alternative 2-DG procedures, and W. Heiligenberg for sponsorship. (Supported by NIMH grant PHSMH-2614904 and NSF grant BNS76-20761 to W.H.).

207.6 PRELIMINARY OBSERVATIONS ON THE NEURAL CONTROL OF SOUND PRODUCTION IN THE ATLANTIC CROAKER, Micropogon undulatus. L.S. Demski, E.J. Williams*, and J.G. Dulka*. School of Biological Sciences, Univ. of Kentucky, Lexington, KY 40506 and Gulf Coast Research Laboratory, Ocean Springs, MS 39564.

Croaking has been evoked by electrical stimulation of the brain in seven anesthetized croakers ranging in size from 11½ to 13 cm standard length. The fish were caught in a trawl in the Mississippi sound in July 1979. The techniques used were very similar to those used with toadfish (see Demski and Gerald, Anim. Behav. 20: 507). Due to an equipment failure, single pulses rather than biphasic square-wave pulse pairs were used. The anesthetic was a solution of 1 to 40,000 MS-222 in seawater. Frequencies of 10-100 Hz were used with currents up to 150 μA at a constant duration of 1 msec. *Thresholds ranged from 80 to 150* μA. Evoked responses occurred both during and at the termination of the stimulation (after-responses). Most responses sounded normal as compared to croaking evoked by gently squeezing anesthetized, unoperated fish. A total of 43 electrode tracts were run in a dorsoventral direction. Fourteen of 28 positive sites were marked and identified histologically. These sites were located on 13 tracts which were completely reconstructed. Five sites were in the area of the midbrain equivalent to the sonic midbrain area (SMA) of toadfish (see Demski and Gerald, Brain Behav. & Evol. 9: 41). Three sites were in the basal midbrain and their position suggests that a functional system may extend in ventral direction from the caudal part of the SMA into the reticular formation of the basal tegmentum. Six other sites were found in the ventrolateral medulla in positions analogous to many positive points in toadfish. These data compare quite well with the results of the toadfish studies and suggest that similar sonic mechanisms may exist in the two types of fishes studied. A group of croakers also received a series of brain transections in an attempt to determine grossly if the midbrain region from which sounds were evoked was critical for normal croaking. The animals were anesthetized in solutions of either 1 to 30,000 or 1 to 40,000 MS-222 and seawater and then tested for croaking in response to gentle squeezing. Fish that responded underwent brain transections (a sharpened spatula was used). Following this they were retested for croaking. Although the brains have not yet been examined histologically, it seemed apparent at the time of surgery that cuts through the rostral part of the midbrain had no striking effect on croaking, whereas cuts made in caudal midbrain near the cerebellum resulted in a loss of, or at least, a noticeable weakening in sound production. These preliminary observations are consistent with the idea of a SMA as defined from the stimulation studies.

207.7 THE MAUTHNER NEURON MEDIATES THE INITIAL STAGE OF A DIRECTIONAL AVOIDANCE RESPONSE IN GOLDFISH. Robert C. Eaton & William A. Lavender*. Dept. E.P.O. Biology, Univ. Colorado, Boulder, CO 80309

One of the most commonly observed behavior patterns in fish is the startle response to sudden and unexpected stimulation, as when an aquarium is bumped with the hand. Several lines of evidence support a hypothesis that this "fast-start" behavior is initiated by the Mauthner cells (M-cells), a single pair of large interneurons located in the hind-brain.

The typically observed fast-start pattern, the C-start, is biphasic. The initial stage is a brief, C-like, contraction of the body musculature on one side. The second stage is a highly variable, but strongly propulsive contraction on the side opposite the initial contraction. Because the first contraction lasts only 15-20 ms, it is usually apparent only after viewing high-speed cine films of the behavior. The major unresolved question is whether the M-cell initiates the first stage, the second, or possibly both.

To answer this, we filmed at 500 frames/sec, fast-start behavior in six goldfish, chronically implanted with single microelectrodes near one of the M-cells. This implantation procedure is based on that of Zottoli (J. Exp. Biol. 66:243, 1977), and the stimulus was a 74 gm ball dropped into the aquarium from above the fish. We found that the M-cell fires only once, 9.3 ms ±0.2 (±S.E., n=25) before the onset of stage 1 of the C-start. Neither M-cell appeared to directly activate the motoneurons initiating the second stage.

C-starts have been shown to occur in predator avoidance responses of goldfish, and an appealing hypothesis is that the M-cell system can mediate directional avoidance maneuvers that will carry the animal away from the predator. Our experiments confirm this for objects falling into the water and it is likely that the result can be extended to predatory strikes as well. We dropped the ball 18 times on the same side of the fish as the recorded M-cell soma, and in 15 trials (83%) the recorded M-cell fired, causing the fish to turn away from the side of the ball. The fish turned into the path of the ball in only 3 trials (17%).

The present experiments provide the first direct association between the M-cell action potential and a documented behavior pattern, occurring in freely-swimming animals. We demonstrate a precise time-locked correlation between the M-spike and the first stage of the C-start, and furthermore show that the M-cell system is activated so that the behavior is used for directional avoidance maneuvers.

207.8 MÜLLER AXON FIRING DURING MOVEMENTS IN LAMPREY. R.D. Clark and W.O. Wickelgren. Dept. of Physiology, Univ. of Colorado Medical School, Denver, Colorado 80262.

To obtain information about the role of lamprey giant reticulospinal cells (Müller cells) in motor behavior in this animal, intracellular recordings were made from the giant spinal axons of these cells during spontaneous and evoked writhing/swimming movements. Larval and adult lamprey were anesthetized briefly with MS-222 and a small region of spinal cord was exposed in the trunk. The underlying notochord was pinned in a saline-filled chamber at 5-8°C; the tail and head of the animal were lightly restrained as needed. Müller axons were identified by their depth in the cord and their characteristic resting and action potentials; identification was confirmed in several cases by dye injection. Movements in this nearly intact preparation were evoked by cutaneous stimulation of the sucker mouth and were monitored by a piezoelectric device in contact with the trunk. An attempt was made to sample from as many different Müller axons as possible; however, it is likely that in any single experiment an axon may have been penetrated more than once. Further, the precise timing of firing with respect to the onset of movement was not determined.

Of 47 Müller axon penetrations in adults, 21 (53%) fired a single spike or a burst in response to tactile stimulation of the sucker mouth; of these, 10 (21%) fired during spontaneous or evoked movements. The remainder (47%) were unresponsive even to stimulation which caused strong movements. In larval lamprey, 51 presumptive Müller axons were impaled. 32 (63%) fired once or a burst in response to sucker mouth stimulation; of these, 16 (31%) fired continually during spontaneous or evoked movement. 19 of 51 (37%) did not fire even during evoked strong movements. Identification of the particular Müller axons which fire during movement has not been made, except for one particularly active axon in larvae which has been tentatively identified as belonging to the anterior medullary cell body group (either B_2 or B_3) (cf. Rovainen, Physiol. Rev. 59, 1008, 1979).

Müller cells receive polysensory inputs and send outputs to spinal interneurons and motoneurons; further, stimulation of single Müller axons can evoke weak trunk and fin movements (Rovainen, ibid.). Thus it is somewhat surprising that many Müller axons were inactive during the movements studied here. This suggests that many Müller cells may have specialized motor functions not revealed by the present experimental conditions.

208.1 ANTAGONISM OF 5-HYDROXYTRYPTAMINE (5-HT) EXCITATORY EFFECTS ON SYMPATHETIC PREGANGLIONIC NEURONS (SPGN). K. Kadzielawa. University of Florida, College of Medicine, Dep. Pharmacol. Ther., Box J-267, Gainesville, Florida 32610.

The purpose of this study was to apply pharmacological analysis of the serotonin effects on SPGN , located in the thoracic segments of the spinal cord. These neurons are the main central sympathetic output station regulating heart rate and blood pressure.

Experiments were performed on cats anesthetized with a mixture of chloralose and urethane. SPGN (Th2-Th3) were identified with antidromic stimulation of the white rami of the stellate ganglion or the ramus to the Th3 intercostal nerve. The rate of the spontaneous firing of SPGN was analyzed. Serotonin (HCl-0.3 M, oxalate- 0.1 M, creat. sulf.-0.04 M; pH 3.5-4.5) and its antagonists: methysergide(maleate-0.01 M, pH 4.0) and cinnanserin (HCl -0.15 M, pH 4.5) were applied by means of microiontophoresis or with pressure ejection, from seven barrel micropipettes. 3-chloroimipramine (HCl-0.1 M, PH 4.0) was used as an inhibitor of 5-HT uptake.

The spontaneous activity of about 75 % of the 50 neurons tested was increased by 5-HT (40-80 nA) in proportion to the current applied and to the duration of ejection. Methysergide (60-80 nA) and cinnanserin (80-100 nA) attenuated or antagonized the excitatory effects of 5-HT, while chlorimipramine (40-60 nA) potentiated 5-HT action. When ejected for longer periods of time (5-10 min) 5-HT antagonists decreased the rate of firing of SPGN (inhibition of the endogenous 5-HT excitatory input ?).

These findings confirm the earlier report of DeGroat, W.C. and Ryall, R.W. (Exper. Brain Res., 1967, 3, 299-305) on the excitatory effects of 5-HT and indicate that this action of serotonin on SPGN can be blocked by specific 5-HT antagonists and that it is potentiated by an inhibitor of 5-HT uptake.

208.2 EVIDENCE FOR A TONIC GABAERGIC CONTROL OF SEROTONIN NEURONS IN THE MEDIAN RAPHE NUCLEUS OF RAT. C. M. Forchetti* and J. L. Meek* (SPON: E. Costa). Lab. Preclin. Pharmacol., NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

A method to determine which transmitters are secreted by neurons that innervate serotonin (5-HT) cell bodies is to inject into a raphe nucleus agonists and antagonists and then to measure 5-HT turnover in brain areas whose 5-HT innervation is by axons arising from these cell bodies. Iontophoretic studies of raphe nuclei have shown that GABA inhibits the activity of 5-HT neurons suggesting that 5-HT neurons contain GABA receptors on their cell bodies. We have examined whether the injection of GABA agonists and antagonists into the median raphe nucleus modifies the 5-HT turnover and/or the 5-hydroxyindoleacetic acid (5-HIAA) steady state level in the hippocampus of rats. This brain region receives its 5-HT innervation primarily from the median raphe nucleus. Since benzodiazepines amplify receptor responses to GABA we have studied the action of these drugs on hippocampal 5-HT turnover. The 5-HT turnover was estimated by measuring the rate of accumulation of 5-HIAA after probenecid (400 mg/kg i.p.); the 5-HIAA content was measured by High Pressure Liquid Chromatography (HPLC). The GABA agonist muscimol (100 ng) caused a 22% decrease in 5-HIAA content and reduced the 5-HIAA accumulation after probenecid by 30%. Subconvulsive doses of the GABA antagonists picrotoxin (2 µg) and bicuculline methiodide (4 µg) increased 5-HIAA steady state level by 47% and 33% respectively. Muscimol was able to almost completely block the effects of GABA antagonists and its action was potentiated by diazepam (5 mg/kg, i.p.). These results provide biochemical evidence of a tonic inhibition by GABA of 5-HT neuronal activity in the median raphe nucleus; this inhibitory effect is potentiated by a benzodiazepine.

208.3 EFFECTS OF IONTOPHORETICALLY APPLIED SEROTONIN ON MEMBRANE POTENTIAL, RESISTANCE, AND EXCITABILITY OF RAT FACIAL MOTONEURONS. C.P. VanderMaelen and G.K. Aghajanian. Depts. of Psychiatry and Pharmacology, Yale Univ. Sch. of Med., New Haven, CT 06508

Previous studies utilizing extracellular single unit recording techniques have found that microiontophoretic application of serotonin onto facial and spinal motoneurons results in a facilitation of excitatory inputs, but does not, by itself, cause these neurons to discharge (McCall & Aghajanian, Brain Res., 1979, 169, 11-27; White & Neuman, Brain Res., 1980, 188, 119-127). In an attempt to determine some of the underlying membrane mechanisms involved in this phenomenon we recorded intracellularly from rat facial motoneurons during extracellular microiontophoretic application of 5-HT, methysergide, or norepinephrine (NE).

Male albino rats were anesthetized with chloral hydrate (400 mg/kg, i.p.) and placed in a stereotaxic device. A hole was drilled in the skull to allow placement of the recording electrode assembly, and a cisternal drainage was performed. 5-barrel micropipettes were affixed with dental acrylic to intracellular glass microelectrodes. Recording electrodes were filled with 2 M KCl and had resistances of 15-25 MΩ. Iontophoretic barrels were filled with 5-HT creatine sulfate (0.04 M, pH 4.0), methysergide bimaleate (0.005 M, pH 4.0), l-norepinephrine bitartrate (0.1 M, pH 4.0), and NaCl (2 M or 4 M) for current balance. Sometimes the 5th iontophoretic barrel was filled with a solution of fast green for marking the recording location in the brain. Tip separations between recording and iontophoretic electrodes ranged from 25-60 µm. The facial nucleus was located by the presence of a characteristic antidromic field potential in response to stimulation of the zygomatic muscle branch of the facial nerve.

Iontophoretic application of 5-HT (25-60 nA for 30-120 sec) resulted in a slow depolarization of about 5 mV which remained subthreshold, accompanied by an increase in input resistance (measured by voltage displacement by a 1.0 nA hyperpolarizing pulse), and an increase in excitability (measured by responses to direct intracellular depolarizing pulses). NE also caused these same changes. Methysergide, a 5-HT receptor blocker, antagonized the effects of 5-HT but not NE, indicating that these actions of 5-HT are receptor mediated. We conclude that these membrane changes induced by 5-HT are responsible for the facilitation of excitatory inputs noted in previous extracellular studies, and underlie some of the major components of the excitatory behavioral "5-HT syndrome" seen in animals injected with 5-HT receptor agonists.

208.4 SEROTONERGIC MODULATION OF TRIGEMINO-FACIAL REFLEX ACTIVITY IN THE RHESUS MONKEY. D. S. Charney*, M. Davis and G. R. Heninger, Dept. of Psychiatry, Yale Univ., Sch. Med., New Haven, CT 06508.

Anatomical studies indicate that the facial motor nucleus receives a dense serotonin (5-HT) input, and single unit studies in rats have demonstrated that excitation of the facial motor nucleus is facilitated by 5-HT. The functional significance of these findings was investigated by determining the effects of 5-HT antagonists on shock-elicited trigemino-facial reflex activity. Reflex activity was elicited in 4 unanesthetized rhesus monkeys by delivering 0.5 msec constant current shocks through needle electrodes implanted over the left supraorbital branch of the trigeminal nerve. Stimulus intensity varied between 2 and 15 mAmps. Reflex activity was recorded from two subcutaneous needle electrodes placed over the ipsilateral orbicularis oculi muscle just below the pupil. Drugs or placebo were given with rapid intermittent infusions through a catheter placed in the superficial saphenous vein to determine cumulative dose-response effects over the 2 hour recording session. Total cumulative doses of the 5-HT antagonists were: cyproheptadine (1.5 mg/kg), methysergide (3 mg/kg) and cinanserin (9 mg/kg). Parametric variations of stimulus intensity and stimulation rate produced effects on the reflex that have previously been demonstrated in humans. Two reflex components were evoked; an early response (R_1) with a latency of approximately 7 msec and a later, more prolonged response (R_2) with a latency of 15-25 msec. Paired stimuli with interstimulus intervals between 100 and 350 msec led to an increased R_1, but a decreased R_2. The three structurally dissimilar 5-HT antagonists markedly reduced both components of the reflex in a dose-related fashion, in the absence of gross changes in behavior. The decrease in R_2 appeared at a lower cumulative dose of the 5-HT antagonist than the decrease in R_1. The data indicate that the serotonergic system exerts a chronic facilitatory effect on the trigemino-facial reflex in the unanesthetized monkey, probably via facilitation of inputs to the facial motor nucleus as shown in single unit recording studies in the rat. Changes in the activity of trigemino-facial reflex may be a clinically useful method for the investigation of serotonergic effects on sensitization of sensory motor systems in humans.

208.5 COMPARISON OF THE INTERACTION BETWEEN IONTOPHORETICALLY APPLIED GABA AND DIAZEPAM WITH SEROTONIN ON CEREBELLAR PURKINJE CELLS. Jean C. Strahlendorf, Howard K, Strahlendorf,† and Charles D. Barnes. Departments of Physiology and Pharmacology and Therapeutics,† Texas Tech University Health Sciences Center, Lubbock, Tx. 79430

Previous electrophysiologic studies from our laboratory have revealed that stimulation of the raphé nuclei (RN) inhibits spontaneous and evoked simple and complex spike activity of cerebellar Purkinje cells (PCs). Furthermore, RN conditioning stimulation, at current strengths subthreshold for inhibition of spontaneous PC activity, produced a marked augmentation of GABA mediated "off beam" inhibition. Preliminary findings have also revealed that iontophoretically applied serotonin (5-HT) at currents which are ineffective in changing ongoing PC activity potentiates the inhibition produced by concomitant iontophoretic pulses of GABA. Since recent neurochemical studies indicate an association between central nervous system GABA receptors and benzodiazepine receptors, we have compared the effects of 5-HT on GABA and diazepam (DIAZ) induced depression of spontaneous PC activity.

Experiments were performed on albino rats anesthetized with chloral hydrate or urethane. PCs located in the anterior and posterior vermis were recorded with conventional 5 or 7 barrel iontophoretic pipettes. Drug barrels were filled with 5-HT (0.05M, pH4.0), GABA (0.5M,pH4.5), DIAZ (0.05M,pH4.0), or sodium glutamate (0.2M,pH8,0). Recording and balance barrels contained 2M and 4M NACl respectively. Twenty to 30 second intermittent pulses of GABA or DIAZ were applied to PCs which resulted in a diminution of firing frequency during application. Following a control series, 5-HT was applied continuously at subthreshold currents while GABA or DIAZ continued to be pulsed. PCs showed a greater degree of inhibition to GABA and DIAZ in the presence of 5-HT; however, 5-HT potentiation of GABA actions (N=10 cells) exceeded that seen with DIAZ (N=8 cells). These studies support our previous contention that 5-HT may function as a neuromodulator or bias setter within cerebellar circuitry by influencing inhibitory processes. (Supported by the Tarbox Parkinson's Disease Institute of Texas Tech Univ. Health Sci. Ctr.)

208.6 NOREPINEPHRINE AND SYNAPTIC TRANSMISSION IN THE IN VITRO RAT HIPPOCAMPUS. Alan L. Mueller*, Barry J. Hoffer*, and Thomas V. Dunwiddie (SPON: Warren O. Wickelgren). Dept. of Pharmacology, Univ. of Colorado Health Sciences Center, Denver, CO 80262.

Adrenergic responses in the rat hippocampus were studied using evoked field potentials in CA1 of the in vitro hippocampal slice after stimulation of the Schaffer-commissural afferents. Superfusion of norepinephrine (NE) caused a weak and highly variable effect on population spike amplitude. This effect appeared to be dose-dependent, with lower doses generally producing weak excitations (approx. 30%) and higher doses more often producing inhibitions (0-40%); see Fig. 1. No effect on EPSP amplitude was seen. Application of isoproterenol (ISO), a β agonist, produced a much larger increase in population spike amplitude, up to 300%, with an EC_{50} of 270 nM. The β antagonists propranolol and timolol were able to completely block this effect of ISO. Clonidine, an α agonist, produced a dose-dependent inhibition of population spike amplitude, up to 50%, with an EC_{50} of approx. 2 uM. Phentolamine, an α antagonist, blocked this effect of clonidine while enhancing the effect of ISO. No change in EPSP amplitude was seen with either ISO or clonidine. Taken together, these results strongly suggest that NE acts at both α and β receptors to alter pyramidal cell excitability. We hypothesize that activation of β receptors leads to increased excitability while activation of α receptors leads to decreased excitability.

209.1 EFFECTS OF CONVULSANT BARBITURATES ON THE RELEASE OF ^{3}H-ACh FROM MOUSE HIPPOCAMPAL SLICES. J.R. Holtman, Jr.* and J.A. Richter, Depts. of Pharmacology and Psychiatry, Indiana Univ. School of Medicine, Indianapolis, IN 46223.

We have studied the actions of 5-(2-cyclohexylidene ethyl)-5-ethyl barbituric acid (CHEB) and (+) 1-methyl-5-phenyl-5-propyl barbituric acid (MPPB), both convulsant barbiturates, as well as (-) MPPB which possesses only depressant action in an effort to elucidate the mechanism of action of the convulsant barbiturates. The effects of these compounds on the release of preformed ^{3}H-ACH was studied in an in vitro superfusion system. In vivo studies were also performed for correlation with the in vitro results. The dose of CHEB causing convulsions in 50% of a population of mice was found to be 17 mg/kg. The brain level of CHEB at convulsion was then measured by radioimmunoassay in several brain regions of the same mice and did not differ significantly among regions (mean ± S.E.M., n=7):

Region	CHEB nmoles/gm
Cerebellum	14.8 ± 2.7
Cortex	14.0 ± 2.3
Midbrain	16.9 ± 2.7
Pons-Medulla	15.9 ± 2.6
Striatum	10.2 ± 1.0
Hippocampus	12.9 ± 2.3

CHEB brain levels in those mice not convulsing was lower in all regions. A concentration of 5.0×10^{-4}M CHEB was tested on the in vitro release of ^{3}H-ACh from mouse hippocampal slices. In preliminary exp eriments this concentration of CHEB was found to produce a near maximal drug-i nduced effect in mouse forebrain slices. Hippocampal slices were first loaded with ^{3}H-choline and then superfused at 0.25 ml/min with normal phosphate buffered medium for 30 min at which time a constant release of ^{3}H-ACh was observed. The slices were then superfused at the same rate for 60 min with medium containing 5.0×10^{-4}M CHEB or 50 mM K^+. This concentration of CHEB stimulated ^{3}H-ACh release to 166 ± 17% of resting release compared to 2213 ± 196% by the 50 mM K^+. The time courses for the releasing action of CHEB and K^+ were both similar with peak release occurring in the same fraction. After peak release, ^{3}H-ACh decreased in the remaining fractions collected to a point approximately the same as resting release. When (-) and (+) MPPB were tested in the same system neither isomer effected ^{3}H-ACh release. Further experiments will evaluate the dose dependency of the in vitro effects of these drugs as well as the Ca^{++} dependence and specificity of transmitter release by CHEB. (CHEB kindly supplied by Dr. H. Downes; MPPB isomers by Dr. J. Knabe).

209.2 ETHANOL POTENTIATES GABA-MEDIATED INHIBITION IN RAT HIPPOCAMPUS. J.N. Nestoros, K. Krnjević, R.J.Reiffenstein* & A.I. Shapovalov*. Anaesthesia Research and Physiology Depts., McGill University, Montreal, Canada H3G 1Y6.

Ethanol (ethyl alcohol) is the oldest antianxiety agent, and antianxiety drugs (benzodiazepines, barbiturates) are known to potentiate GABAergic neurotransmission. Furthermore, ethanol selectively augments only the GABA-evoked depolarization of primary afferent terminals in the amphibian spinal cord *in vitro* (Davidoff, Arch.Neurol.,28, 60, 1973) and the GABA-mediated inhibitions of feline cerebral cortical neurons *in vivo* (Nestoros, Science, in press). We have therefore studied in ketamine-anaesthetized rats the effects of intravenously administered ethanol on (1) the IPSPs and (2) the field potentials evoked in the CA1 and CA3 regions by stereotactic stimulation of the ipsilateral fimbria or entorhinal cortex.

Recording intracellularly with KCl electrodes we monitored continuously the neurons' membrane potential and input resistance at "rest" and during the IPSPs, by injecting with the help of a Linc 8 computer regularly repeated series of known current pulses through the recording electrode. Most often each pulse lasted 10 msec, it had a hyperpolarizing direction and 3 such sets of pulses were injected at intervals of 30 msec to measure the time course of the IPSPs. We found that ethanol consistently prolonged the time course of IPSP conductance increase independently of membrane potential changes. The prolongation of the IPSPs' time course occurred with doses as low as 8 mg/kg (the highest total dose used in these studies was 2,105 mg/kg). On the other hand, there was no clear change in the maximum of conductance increase at the peak of IPSPs.

With extracellular recording, the IPSPs evoked by low frequency (< 2 Hz) fimbrial stimulation generate a characteristic positive field response in the superficial pyramidal cell layer. Stimulation at higher frequencies rapidly leads to the appearance of single or multiple negative "population" spikes; and, if sufficiently prolonged, "seizure" activity is generated (desynchronized firing, after-discharges, followed by post-ictal depression). We found that intravenously administered ethanol (from 8 mg/kg) increased significantly the threshold (frequency of stimulation; time of stimulation) for the occurrence both of negative population spikes and seizure activity. Ethanol also antagonized the effects of picrotoxin (also given intravenously).

These findings further implicate GABAergic neurotransmission in the effects of ethanol on the CNS, and may have significance for both the etiology and treatment of alcoholism.

Supported by the Canadian Medical Research Council.

209.3 EFFECT OF SUBACUTE IN VIVO ETHANOL ADMINISTRATION ON ^{3}H-DIAZEPAM BINDING IN VITRO. R. L. Kochman, J. D. Hirsch, and G. A. Clay*. Dept. Biol. Res., G.D. Searle & Co., Chicago, IL 60680

The potentiation of the depressant effects of ethanol by benzodiazepines has been well documented clinically. The present study was designed to assess a possible interaction between ethanol and diazepam at the benzodiazepine receptor. Seven week-old male CD/CR rats (Charles River Breeding Laboratories, Wilmington, MA), weighing 185-230 grams and maintained on a Sustagen® (Mead Johnson Laboratories, Evansville, IN) liquid diet, were administered (p.o.) 2.5 grams/kg of 20% ethanol four times a day for 4.5 days. Control rats received 2.5 ml/kg of distilled water. Two hours after the last administration, all rats were decapitated. Crude mitochondrial pellets (P_2) from the whole brains with cervical spinal cords were prepared in 0.32M sucrose, osmotically shocked in deionized water, and frozen at -70°C. Saturation isotherms were determined using 0.5-40 nM ^{3}H-diazepam in the absence and presence of a 1000-fold greater concentration of unlabelled diazepam, 0.5-0.7 mg of homogenate protein from control or ethanol-treated rats, and 50mM tris·citrate (pH 7.4 at 0°C) in a total volume of 2 mls. for one hour at 0°C. The dissociation constants (K_D) for control (5.05±0.16 nM; n=8) and for ethanol-treated rats (5.30±0.27 nM; n=8) were not significantly different. However, ethanol treatment significantly lowered B_{max} values from 0.77±0.03 pmole/mg protein (control) to 0.68±0.02 pmole/mg protein (ethanol-treated)($p < .05$). These results suggest that the interaction between diazepam and ethanol may be mediated by a direct effect of ethanol at the benzodiazepine receptor.

209.4 DOSE-DEPENDENT EFFECTS OF ETHANOL ON THE EXCITABILITY OF IN VITRO CENTRAL MAMMALIAN NEURONS. P. Carlen, N. Gurevich, D. Durand, J.M. Wojtowicz and J.F. MacDonald. Playfair Neuroscience Unit, Addiction Research Foundation, University of Toronto, Toronto, Ontario, Canada, M5T 2S8.

The actions of ethanol, using conventional intracellular recording techniques, were examined on two preparations:
1) identified CA1 neurons of rat hippocampal slices (500 μm)
2) unidentified neurons of dissociated brain cultures derived from mouse foetuses and grown for a period of at least 4 weeks.

Ethanol was included in the perfusion medium of the hippocampal slices (20-200 mM) or applied by pressure microperfusion (10-200 mM) to single cultured neurons. Synaptic activity was assayed by stimulation of the stratum radiatum to evoke EPSPs and a subsequent long lasting IPSP (sometimes > 1 sec) in the case of slices, but was usually suppressed in cultures by elevating magnesium concentrations (10 mM $MgCl_2$).

Ethanol (20-50 mM) hyperpolarized and reduced the membrane resistance of CA1 neurons. Similarily cultured neurons were hyperpolarized by ethanol applications (10-100 mM) provided recording electrodes contained K Acetate (although most but not all cells, in either preparation, were responsive). Such responses were inverted to depolarizing responses when KCl electrodes were substituted (cultured neurons) and a correspondence of inversion potentials for ethanol and GABA responses indicated an increase in chloride permeability. Higher concentrations of ethanol (>150 mM) were significantly less effective in evoking this response in either preparation but were associated with a local anaesthetic action on spikes. After 10-15 minutes perfusion of ethanol (100 and 200 mM), CA1 cells occasionally demonstrated slow oscillations of membrane potential (3-8 sec period) and an increased frequency of presumed dendritic spikes. At all doses, an increase in the size of the stratum radiatum EPSP and IPSP were observed.

209.5 ETHANOL INDUCES A NEGATIVE SLOPE RESISTANCE REGION IN APLYSIA NEURONS. L. Silver*and S.N. Treistman (SPON: E. Thomas). Dept. of Biology, Bryn Mawr College, Bryn Mawr, PA 19010, and Worcester Foundation for Experimental Biology, Shrewsbury, MA. 01545.

Identified neurons from the buccal and abdominal ganglia of Aplysia californica were examined under voltage clamp to elucidate the effects of ethanol and other alcohols. As has been reported for a number of neural preparations, ethanol is capable of blocking the fast inward currents associated with the production of action potentials. However, at concentrations in which the action potential is only partially reduced, previously silent neurons were induced to generate "bursting pacemaker" discharges. This change in activity pattern was associated with a change in the quasi-steadystate current-voltage plot, characterized by the appearance of a negative slope resistance region (NSR). These events were very concentration-dependent, and in the silent cells studied, occurred at concentrations of 0.6M ethanol. At higher concentrations, the I-V plot became more linear, and membrane oscillations no longer occurred. The effects of ethanol were reversible with washing.

For comparison purposes, we examined the effects of 0.6M ethanol on cell R15, which exhibits a spontaneous bursting pattern and NSR. In this cell, 0.6M ethanol induced either extended bursts or beating activity, and reduced or abolished the NSR.

Ethanol is typically considered to be a membrane fluidizer. Our results suggest the possibility that the expression of NSR occurs in a relatively restricted fluidity range, and a normally bursting cell could be pushed out of this range by concentrations of ethanol which place silent cells into compliant range. The effects of ethanol were blocked by low temperature and decanol, which may act as membrane ordering agents.

Supported by NIH grant NS 15195-01

209.6 EFFECT OF ALCOHOL ON THE ELECTRICAL ACTIVITY OF CULTURED CNS NEURONS. D.L. Gruol. A.V. Davis Ctr. for Behav. Neurobiol., The Salk Inst., La Jolla, CA 92037.

The acute effects of ethyl alcohol (ETOH) on the activity of CNS neurons was tested using cultured fetal mouse spinal cord neurons as an in vitro model system and conventional electrophysiological techniques. ETOH was applied extracellularly by superfusion. Intracellular recordings were made from large (25 to 50 um) neurons which had been maintained in culture for 1 month or longer. Spontaneous depolarizing and/or hyperpolarizing potentials were observed in all spinal cord neurons studied (N=30). These potentials occurred singly or in burst discharges and were interpreted as presumptive excitatory and inhibitory synaptic potentials (EPSP's or IPSP's), respectively. Single or repetitive spikes were evoked by the spontaneous depolarizing potentials.

ETOH (30 to 500 mM) altered the pattern and frequency of the spontaneous activity of the cultured neurons. In neurons which showed a bursting discharge pattern, the lower ETOH concentrations (close to threshold for intoxicating blood levels) reduced the frequency of burst discharges and the number of synaptic potentials within each burst while the number of single potentials which occurred between burst discharges was increased. In neurons which did not show a bursting pattern, the frequency of the spontaneous potentials was reduced by ETOH treatment. These changes were not associated with a pronounced alteration in membrane potential, input resistance or depression of spike height in most neurons. At the higher ETOH concentrations tested, all spontaneous activity was suppressed and alterations in membrane potential and input resistance frequently occurred, the most consistent effect being an increase in membrane input resistance (10 to 30%). All ETOH effects were readily reversible.

In preliminary studies the response of the neurons to putative neurotransmitters was also evaluated in the presence and absence of ETOH in order to identify possible post synaptic effects of ETOH. ETOH (30 to 500 mM) reversibly potentiated the inhibitory GABA and glycine responses evoked by extracellular application of these amino acids via a glass micropipette. The excitatory glutamate response was unaltered or slightly depressed. The potentiation of the inhibitory responses could be partially explained by an increase in membrane input resistance produced by ETOH in these neurons.

These studies indicate that ETOH has multiple effects on the activity of cultured CNS neurons but the specificity and mechanisms underlying these effects remains to be elucidated. (Supported by Grant AA 03504.)

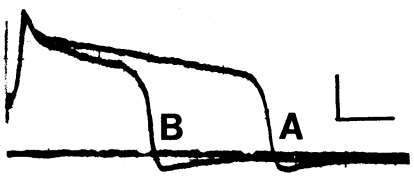
209.7 ALCOHOL DECREASES THE CALCIUM COMPONENT OF SENSORY NEURON ACTION POTENTIALS IN CULTURE. S. George Oakes* and R. S. Pozos (SPON: D. Forbes). Dept. of Physiology, Univ. of Minn.-Duluth, Sch. of Med., Duluth, MN 55812.

Ethanol has been reported to influence neurotransmitter levels (Hunt and Majchrowicz, J. Neurochem. 23:549, 1974) possibly by changes in release due to alterations of Ca^{2+} ion movement (Levett, Morini and Jack, Currents in Alcoholism, Vol. III, ed. Seixas, 1978). To investigate this possibility, electrophysiological measurements of sensory neurons exposed to ethanol were performed. Recently, Dunlap and Fischbach (Nature, 276(569), 837-839, 1978) have reported that increased extracellular Ca^{2+} accentuates the calcium component of DRG neurons producing an increased full width at half maximum amplitude (FWHM) action potential. The investigators feel that decreases in FWHM indicate decreased Ca^{2+} permeability in this model.

DRG were dissected from 17 day rat embryos, dissociated and maintained for 4-6 weeks. After 4 weeks recordings were made in a balanced salt solution containing 5.4 mM Ca^{2+} and 3.0 mM Ba^{2+}, which inactivates the K^+ conductance and passes through activated Ca channels. Ethanol was placed directly on the cell with a diffusion pipette. Control and post application recordings were recorded on an FM tape recorder and analyzed on a PDP-12 computer. Exposure to 0.2 gm% ethanol produced a marked decrease in the FWHM when compared to the control value (Fig. 1). The effect appears dose dependent since exposure to 0.5 gm% ethanol produced a much greater decrease in FWHM. The alteration was reversible within several minutes. Resting membrane potential and spike amplitude were unaffected by exposure to these levels of ethanol.

These data suggest ethanol in physiological dosages influences the calcium current in sensory neurons. Decreased calcium movement may account for changes in neurotransmitter release found with exposure to ethanol.

Figure 1 demonstrates (A) the FWHM before the application of ETOH and (B) the immediate effect on the FWHM of the application of .2 gm% ETOH (calibration: 20 mv and 10 ms).



Supported by a grant from the Minnesota Office of Alcohol and Other Drug Abuse Programming.

209.8 TOLERANCE TO ETHANOL-INDUCED CHANGES IN EVOKED POTENTIALS. Larry P. Gonzalez, Mitchell B. Friedman*and Boris Tabakoff. Department of Physiology and Biophysics, Univ. of Illinois Medical Center and the West Side V.A. Medical Center, Chicago, Il.

Acute administration of ethanol is known to alter the function of striatal dopaminergic neurons. While acute ethanol administration is believed to increase striatal dopamine release, such treatment produces an inhibition of acetylcholine in cortical and subcortical areas. In addition, an increase in hippocampal cholinergic receptors has been shown to accompany chronic ethanol administration. To further investigate the involvement of these neuronal systems in the mechanisms of action of ethanol, we have examined the acute effects of ethanol on evoked potentials in the caudate nucleus and in the hippocampus, both before and after chronic ethanol administration.

Averaged evoked potentials were recorded from the caudate nucleus in response to electrical stimulation of the substantia nigra and from the hippocampus in response to septal stimulation. Although the particular effects varied from subject to subject, the general effect of an acute injection of ethanol (1.5g/kg, 20% w/v, ip.) was a significant increase in the peak-to-peak amplitude of the early and late components of the evoked response of the caudate nucleus, and a decrease in these measures of the hippocampal evoked response. These results are consistent with the view that acute ethanol increases the activity of the nigrostriatal dopaminergic neurons but decreases the activity of cholinergic neurons terminating in the hippocampus.

Following this initial test of the acute effect of ethanol, the animals were maintained in an ethanol vapor chamber in which they were exposed to a low concentration of ethanol vapor (17.6 mg/l) for 12 hours per day following a total dose of 3.0g/kg. Evoked potentials were recorded before and after acute ethanol administration on every third day, 8 hours after the removal of ethanol vapor. The animals showed no signs of intoxication and ethanol was not detectable in the blood. After as little as 3-days of exposure to this regimen of ethanol administration, the effect of acute ip. ethanol on the evoked response was significantly reduced at both recording sites. At the same time, a reduction was observed in the effect of ethanol (total dose, 3.0 g/kg, ip.) on the righting reflex.

We interpret these results to indicate that alterations in the function of both dopaminergic nigrostriatal neurons and cholinergic septal-hippocampal neurons accompany the behavioral and physiological development of ethanol tolerance.

Supported by grants from PHS BRSG (79507), NIAAA (2696), NIDA (2024 and 1951), the state of Illinois DMH&DD (8083-13) and the Medical Research Service of the Veterans Administration.

209.9 EFFECT OF ETHANOL ON PROTEIN PHOSPHORYLATION IN HUMAN BLOOD PLATELET PROTEINS. Harish C. Pant* and Forrest F. Weight. Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, 12501 Washington Ave., Rockville MD 20852.

Incubation of intact human platelets with $^{32}PO_4$ reveals multiple phosphorylated proteins. Agents that induce the secretion of platelet granules (the platelet release reaction) cause an increase in the phosphorylation of specific platelet proteins. In the present study, we investigated in vitro, the effect of ethanol on protein phosphorylation in intact human platelets. Platelets were isolated by differential centrifugation from fresh EDTA-anticoagulated human blood and suspended in isotonic tris-buffered saline, pH 7.4. Aliquots of 100 µl of this suspension (approximately 10^8 platelets) were incubated with different concentrations of ethanol for 30 min. The phosphorylation reaction was initiated by adding 0.05 mCi of carrier free (^{32}P) P_i to each sample; the samples were incubated for 60 min at 37°C. The reaction was inhibited by adding 10% trichloroacetic acid. The phosphorylated proteins were analysed by sodium dodecylsulfate-polyacrylamide gel electrophoresis and liquid scintillation counting. The total amount of phosphorylated proteins was progressively decreased from 100% to 36% as the concentration of ethanol was increased from 0 to 500 mM. This decrease was found in all phosphorylated protein peaks. Thrombin induces the secretion of platelet granules. The application of thrombin (1 unit/ml) increased the phosphorylation of platelet proteins with molecular weights of 48,000-48,000 and 25,000-19,000 daltons. This increase in specific protein phosphorylation was not significantly affected by low concentrations of ethanol (5 to 250 mM). In addition, in thrombin treated platelets, these concentrations of ethanol did not significantly affect the other phosphorylated proteins. The results suggest that thrombin inhibits the effect of low concentrations of ethanol on protein phosphorylation in human platelets.

209.10 THE EFFECTS OF CHRONIC ALCOHOL CONSUMPTION ON THE LEVELS OF MONOAMINES IN DIFFERENT CNS REGIONS OF ALCOHOL-PREFERRING RATS. J.M. Murphy, W.J. McBride, L. Lumeng* and T.-K. Li*. Depts. of Psychaitry and Medicine, Inst. of Psychiatric Research, Indiana Univ. School of Medicine, Indianapolis, IN 46223.

The present study compared the regional levels of norepinephrine (NE), dopamine (DA), serotonin (5-HT) and 5-hydroxyindoleacetic acid (5-HIAA) in the CNS of rats selectively bred to prefer (P) or not prefer (NP) ethanol. The effects of chronic voluntary ethanol consumption on the CNS regional levels of these monoamines were also assessed in a group of P rats.

Two groups of adult males, one P (N=9) and one NP (N=9) group, were housed individually with ad lib food and water. A third group (N=9) of P rats (P-EtOH) was maintained in the same manner, except that free-choice ethanol (10% V/V) was available for 6-8 weeks. Rats in the three groups were killed by the near-freezing method (R. Takahashi & M.H. Aprison, J. Neurochem. 11: 887, 1964). The brains were dissected at -20°C into nine areas: cerebral cortex (CX), striatum (STR), septum (SEP), thalamus (TH), hypothalamus (HY), hippocampus (HIP), midbrain (MID), pons-medulla (PM), and cerebellum (CB). The tissue was frozen at -70°C until assayed by HPLC with electrochemical detection.

The most consistent finding was that the levels of 5-HT and 5-HIAA were 10-30% lower in the STR, TH and MID of the P animals than were found for the NP group. In addition, ethanol appeared to decrease the turnover of 5-HT in the SEP, HIP and HY regions as indicated by the 25-40% lower levels of 5-HIAA found in the P group relative to the P-EtOH animals. There were no significant differences in the levels of 5-HT or 5-HIAA in the CX, SEP, HY, PM or CB of the P compared to the NP group. CX NE levels of the P group (1.94 $\pm$ 0.13 nmol/g) were found to be higher than the NP group (1.46 $\pm$ 0.15 nmol/g), whereas NE content of the PM and CB was 15-20% lower for the P group ($P<0.05$). No significant differences were observed in DA levels for the P compared to the NP group or the P-EtOH compared to the P group.

The lower levels of 5-HT and 5-HIAA in several CNS regions of the alcohol preferring animals in comparison to the control NP group suggest a possible metabolic dysfunction or pathway deficiency in the serotonergic system of the P animals. The findings from the present study support the view of an involvement of serotonin in abnormal alcohol drinking behavior. (Supported in part by PHS Grant AA-03243 and MH 00203).

210.1 INTERACTIONS OF LIGANDS WITH MORPHINE AND ENKEPHALIN RECEPTORS ARE DIFFERENTIALLY AFFECTED BY SODIUM IONS AND GTP. E. Hazum*, P. Cuatrecasas*, A. Killian* and K.-J. Chang* (SPON: C.G. Lineberry). Dept. of Mol. Biol., Wellcome Research Laboratories, RTP, NC 27709.

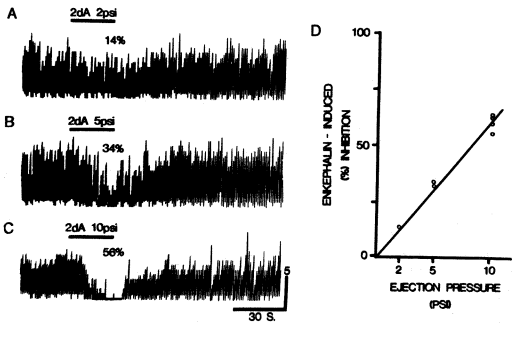
The effects of sodium ions (Na^+) and guanosine-5'-triphosphate (GTP) on morphine (μ) and enkephalin(δ) receptors were examined by using binding assays of [^{3}H]naloxone to rat brain membrane preparations and [^{3}H]diprenorphine to neuroblastoma cell membranes, respectively. The potencies of many opiate agonists and opioid peptides in competing with the binding of the labeled antagonist are reduced by Na^+ (100 mM) and GTP (0.1 mM). These effects are qualitatively similar for both subtypes of opiate receptors. However, quantitatively, the effects of Na^+ and GTP are much more profound for morphine receptor than for enkephalin receptors. Na^+ does not alter the affinity of opiate antagonists. GTP reduces the affinity of naloxone to morphine receptors by a factor of 2.5. Mg^{2+} (5 mM) increases the potencies of opiate agonists and enkephalins for both receptor sites. The combination of Na^+, GTP and Mg^{2+} further reduces the affinity of enkephalins and opiate agonists for enkephalin receptors and the affinity of Met- and Leu-enkephalin for morphine receptors. However, the combination of Na^+, GTP and Mg^{2+} partially restores the affinity of [D-Ala^2, Leu^5]- and [D-Ala^2, D-Leu^5]-enkephalin and morphine for the morphine receptors. These differential effects of cations and nucleotide further support the subtle differences between morphine and enkephalin receptors and indicate the complex interactions of cations and nucleotide with opiate receptors.

210.2 EVIDENCE FOR THE PRESENCE OF ENDOGENOUS FACTORS WHICH MODIFY NARCOTIC LIGAND BINDING CHARACTERISTICS. R.W. Barrett* and J.L. Vaught* (Spon: M.T. Spoerlein, Dept. Pharmacol., College of Pharmacy, Rutgers University) Piscataway, N.J. 08854.

We have recently reported the presence of non-opioid peptide factor(s) in the supernatents(S) of mouse brain homogenates which reduce the specific binding(SB) of ^{3}H-dihydromorphine (^{3}H-DHM) (The Pharmacologist, 1980). To further investigate the role of these factor(s) in drug-opioid receptor interactions, the ability of opiate ligands to inhibit the SB of ^{3}H-DHM was determined in the presence and absence of S. Membranes from pooled mouse brains, minus cerebellum(CB), were prepared by a single homogenization (unwashed membranes;UM) or by standard techniques (washed membranes;WM). In some experiments, S from the first centrifugation (49,000 xg;20 min) was used in place of fresh buffer to resuspend the final WM pellet. All binding assays were performed with 2.2nM ^{3}H-DHM±Levallorphan(37°C;20 min). Each experiment was repeated at least five times in independent membrane preps. The IC50's of naloxone (N) and morphine (M) in UM(4.0±0.1nM and 6.0±0.5nM; respec.)were significantly lower than those in WM(15.9±2.4nM and 12.2±1.3nM respec.). SB of ^{3}H-DHM,in the absence of any drugs, did not differ between UM and WM. When S was immediately removed from UM by centrifugation and the resulting pellet resuspended in fresh buffer, the N IC50 no longer differed from that of WM (11.6±1.1nM). Substitution of S for fresh buffer in the final resuspension of the WM pellet resulted in a significant reduction of the N IC50 to 6.1±1.9nM. Additionally, the SB of ^{3}H-DHM alone was reduced 54%. However, when S was dialyzed (12,000MW cut-off) before addition to WM, the N_2IC50 (10.4±1.8nM) no longer differed from WM, although the SB of ^{3}H-DHM alone was still reduced 42%. S similarly prepared from CB did not effect the N IC50 of WM (13.2±1.2nM) but decreased the SB of ^{3}H-DHM alone by 55%. These data indicate that in addition to factor(s) which reduce the SB of ^{3}H-DHM, S contains separate factor(s) which enhance the inhibitory potency of non-labelled opiates vs. ^{3}H-DHM. These results closely parallel those previously reported by Chau-Pham and Dewey (Life Sci.21: 1977). The fact that this new factor(s) is not present in S from CB suggests that it is not a preparative artifact and makes it more likely that this factor may play an important physiological role in drug-opioid receptor interactions (Supported in part by BRS Grant PHS RR 7058-14).

210.3 PHYSICAL AND PHYSIOLOGICAL CHARACTERISTICS OF MICROPRESSURE EJECTION OF DRUGS FROM MULTIBARRELED PIPETTES. B.J. Hoffer*, M.R. Palmer, S.M. Wuerthele. (SPON: S. Roper.) Department of Pharmacology, Univ. of Colorado, Denver, CO 80262.

The micropressure ejection technique was characterized in vivo as well as in vitro. Using a crystal clock controlled solenoid (Medical Systems Corp.) and fiber filled thinwall (1.5 mm O.D., 1.1 mm I.D.) multibarreled micropipettes, it could be demonstrated that volumes of radiolabelled drug released by this method increase linearly with increasing ejection pressure or time. This is reflected in vivo by graded inhibitions of cortical cell activity with increasing ejection pressures of enkephalin (2dA):



The linearity of this repsonse is independent of interejection time, suggesting that there is no warm-up phenomenon with the micropressure ejection technique. In vitro, interejection times do not affect the amount of 3H-sucrose released by micropressure ejection. The volume of drug released is highly reproducible. Likewise, responses of cerebellar Purkinje cells to repeated applications of norepinephrine or GABA are uniform over long periods of time. The variability in drug release between two barrels of a multibarreled pipette, or between two pipettes using this technique, is also considerably less than that observed with microiontophoresis. In addition to the linearity and reproducibility of micropressure ejection, these studies demonstrate that substances which are difficult to iontophorese, such as peptides, are readily applied by this method. Supported by USPHS Grants DA-07043 and ES-02011.

210.4 EFFECT OF INCREASING DOSES OF MICROIONTOPHORETICALLY INJECTED MORPHINE ON CAUDATE NEURONS IN NAIVE AND MORPHINE-DEPENDENT RATS. Avital Schurr, Benjamine M. Rigor*, Beng T. Ho and Nachum Dafny. Dept. Anesthesiol. and Dept. Neurobiol. and Anat., Univ. Texas Med. Sch., Houston, TX 77025

Experiments were performed on naive and morphine-dependent (using s.c. pellet implantation) Sprague-Dawley rats anesthetized with urethane (1.2g/kg). Unitary activity was recorded from caudate nucleus (CN) using glass multibarreled micropipettes. Barrels were filled with morphine (0.1M, pH 6.5), naloxone (0.1M, pH 6.5) and two with 4M NaCl for recording and current neutralization. Only those units which showed spontaneous activity and which remained stable over a period of at least 5 min were selected to be recorded and tested. Each unit was given 5 different doses of morphine (2,5,10,20,50 nA). Each injection lasted for 60 sec and was given simultaneously with the recording which continued for an additional 200 sec post-drug injection. A recovery period of 3 min was allowed between each morphine treatment. Naloxone was tested for its ability to reverse the effect induced by morphine, always after and at the same dose as the last morphine injection. Fifty units were recorded from naive animals in which 95% of these units changed their firing rate upon application of at least one of the morphine doses. The response of the CN units to morphine was found to be dose-dependent and could be divided into two classes: units which responded in a monophasic fashion (30%) either by increase or decrease in their discharge rate, and units whose response can be described as biphasic (70%) showing an increase in activity when low concentrations of morphine were injected and decreases in activity when high doses of the drug were applied, or vice versa. In morphine-dependent animals (n=20), two patterns of response were also observed, i.e. monophasic and biphasic. However, the percentage which responded to morphine in a monophasic manner increased from 30% to about 70%, while 30% of the units responded in a biphasic fashion. The neuronal population of the CN in morphine-dependent animals exhibited lower sensitivity to morphine (did not respond to the first two doses of the drug). In conclusion, the chronic morphine treatment changed the dose-response pattern in CN units, as compared to naive animals.

210.5 ENKEPHALIN'S EXCITATORY ACTION ON HIPPOCAMPAL NEURONS CANNOT BE EXPLAINED BY ATTENUATION OF RECURRENT INHIBITION. R. Dingledine
Dept. Pharmacol., Univ. N. Carolina, Chapel Hill, N.C. 27514.

When iontophoretically applied into the hippocampus, opiates increase the firing activity of pyramidal neurons. It has been proposed that this response is a disinhibitory phenomenon, being a consequence of inhibition of the tonic activity of inhibitory interneurons (Zieglgänsberger et al., Science, 205:415, 1979). In the present study this hypothesis was directly tested by examining the effect of D-ala^2,D-leu^5-enkephalin (ENK) on inhibitory and excitatory synaptic potentials in an in vitro rat hippocampal slice preparation. Intracellular recordings were made from CA1 pyramidal neurons identified by antidromic activation from the alveus. Stimulation through a microcathode inserted into the stratum radiatum activated the pyramidal cell population orthodromically via synapses made on their apical dendrites.

Bath application of ENK (500nM) enhanced the response to orthodromic stimulation, as manifested by an increase in the size and more prominently the duration of EPSPs. Extracellular field potential recordings showed a larger population spike for a given size field EPSP. These effects of ENK could be entirely reversed by naloxone (500nM). By focal iontophoresis it was shown that the soma and basal dendrite layers were the most sensitive to ENK, even though the test stimulus activated synapses on the apical dendrites. The enhanced orthodromic response was not due to an increased excitability of the pyramidal soma membrane, since membrane potential, input resistance, spike threshold and antidromic field potentials were all unchanged. The enkephalin effect did not appear to be caused by increased excitatory transmitter release or increased excitatory postsynaptic current, because in field potential studies the input-output relationship between the presynaptic fiber volley and the field EPSP remained unchanged. Finally, recurrent IPSP's, evoked by subthreshold electrical stimulation of the alveus, were not detectably reduced in size by ENK when in the same cell the orthodromic EPSP was enhanced.

On several occasions iontophoretic ejection of ENK into the st. pyramidale or st. oriens did affect the intensity of recurrent inhibition, which was monitored in these experiments by the reduction of an orthodromic population spike by a prior antidromic volley. Both potentiation and attenuation of recurrent inhibition were observed in different slices. Thus, although in certain circumstances a reduction of recurrent inhibition by ENK could be demonstrated, it is clear that this effect is not sufficient to explain the enhanced orthodromic responses produced by ENK. Supported by DA02360 and a Sloan Research Fellowship.

210.6 MORPHINE NON-SELECTIVELY DEPRESSES NOXIOUS AND NON-NOXIOUS INPUTS ONTO WIDE DYNAMIC RANGE NOCICEPTIVE NEURONS OF THE SPINAL CORD DORSAL HORN. F.J.Einspahr* and M.F.Piercey. (SPON: R.A. Lahti)
The Upjohn Company, CNS Research, Kalamazoo, MI 49001 .

Microelectrodes were used to record nerve impulses extracellularly from single dorsal horn neurons of unanesthetized, decerebrated, low spinal (L_1) cats. These cells were tested for their responses to noxious cutaneous heat (>45°C), intense cutaneous electrical stimulation, and non-noxious cutaneous air puff stimulation. Intravenous morphine (1-3 mg/kg) depressed the spontaneous activity of purely nociceptive dorsal horn neurons, as well as their evoked responses to cutaneous electrical and noxious heat stimulation. In wide dynamic range nociceptive neurons, morphine also depressed evoked responses to non-noxious air puff stimulation. Morphine was equally efficacious in depressing responses to the non-noxious, as it was to the noxious, stimulation and lowering the initial dose of morphine (0.3 mg/kg i.v.) failed to indicate a difference in threshold for either depression. All of the above effects of morphine were reversed by naloxone (0.3 mg/kg i.v.). Dorsal horn neurons which were purely non-nociceptive were not depressed by morphine in either spontaneous or non-noxious evoked activity. It is concluded that: (1) morphine has a spinal site of action in which both noxious and non-noxious sensory inputs to dorsal horn neurons are depressed, and (2) neurons receiving purely non-noxious sensory input are not depressed by morphine and may represent the only dorsal horn pathway transmitting innocuous sensations during morphine treatment.

210.7 EXCITATORY OR OPIATE-ANTAGONIST ACTION OF NALOXONE DEPENDING ON DOSE AND ROUTE OF ADMINISTRATION IN THE RAT. Y. F. Jacquet, Center for Neurochemistry, Rockland Research Institute, New York, NY 10035.

High or low naloxone doses were injected in rats either intraperitoneally (i.p.), intracerebroventricularly (i.c.v.) or into the CNS site, the periaqueductal gray (PAG) -- a site previously shown (Jacquet & Lajtha, Science 185:1055, 1974) to mediate many of morphine's actions. At low i.p. doses, naloxone antagonized morphine's depressant actions, while at high i.p. doses, naloxone resulted in sedation and immobility. A low i.c.v. or intra-PAG dose of naloxone antagonized the depressant actions of morphine, while a high i.c.v. or intra-PAG dose of naloxone resulted in a fearful hyper-reactivity, similar to the syndrome seen following a high dose of morphine administered i.c.v. or intra-PAG.

In the in vitro assay, the electrically-stimulated rat vas deferens, naloxone (1×10^{-4}M) added to the Krebs-Ringer bath resulted in excitation, and at the same time, blocked the inhibitory action of B-endorphin (1.4×10^{-7}M) added to the bath in its presence. The former excitatory action was non-stereospecific, occurring after both (-)- and (+)-naloxone, while the latter antagonist action was stereospecific, occurring only in the presence of (-)- but not (+)-naloxone.

These results and those of others show that naloxone effects are varied depending on dose. The opiate antagonist action was stereospecific, occurring only after (-)- but not (+)-naloxone (also, cf. Jacquet & Jimenez, Neurosci. Abs., 1979), while the excitatory action was non-stereospecific. These results support our previous proposal (Jacquet, Klee, Rice, Iijima & Minamikawa, Science 198:842, 1977) that opiate effects are mediated by two classes of receptors, one a stereospecific receptor that is antagonized by naloxone and mediates the inhibitory action of opiates, the other a non-stereospecific receptor that is not antagonized by naloxone and mediates the excitatory action. Naloxone at low doses antagonizes the former, while at high doses, exerts an agonist action at the latter. Precipitated abstinence following a high naloxone dose may be due in part to an unmasking of the excitatory action of opiates following selective naloxone blockade of the stereospecific inhibitory receptor, and in part due to an agonist action by naloxone (in addition to the agonist action of opiates) at the non-stereospecific excitatory receptor.

210.8 EFFECT OF MORPHINE ON EVOKED ACTIVITY OF THE HIPPOCAMPUS IN THE FREELY MOVING RAT. Mary Ann Linseman and William A. Corrigall.
Dept. Neurobiology, Addiction Research Foundation, Toronto, Ontario, M5S 2S1.

In previous work (Brain Res., 1980, in press) we have shown that morphine had a consistently stimulant effect on the field potential elicited in the CA_1 cell body layer of the hippocampus by stimulation of the stratum radiatum in the isolated transverse hippocampal slice of the rat. This was manifest as an increase in amplitude of the primary spike including a reduced threshold to stimulation, and a current- and dose-dependent appearance of a second and occasionally additional population spikes. Further analyses showed that both phenomena were probably due to a decrease in GABA-mediated inhibition induced by the morphine.

The present study was undertaken to determine if similar effects could be obtained in the intact, freely-moving animal when the drug was administered by a normal systemic route. Field potentials elicited in the ipsilateral and contralateral CA_1 by stimulation of the stratum radiatum, and in ipsilateral dentate and CA_1 by perforant path stimulation, were recorded prior to and following incremental doses of morphine (2, 6, and 15 mg/kg i.v.) and a subsequent infusion of 2 mg/kg naloxone. Both increases in the amplitude of the primary spike and secondary spikes were observed, frequently following 6 mg/kg, and reliably following 15 mg/kg. All effects were naloxone reversible. These effects were observed in the absence of any convulsive activity, electrophysiological or behavioral, and their occurrence was not consistently related to the presence of high amplitude activity in the simultaneously-recorded frontal cortical EEG.

We conclude that the isolated hippocampal slice is a valid model in this regard for the action of systemically-administered morphine on the hippocampus of the intact freely-moving rat.

210.9 PHYSIOLOGICAL EVIDENCE FOR OPIOID PATHWAYS IN GOLDFISH RETINA. M.B.A. Djamgoz* and W.K. Stell† Jules Stein Eye Inst., UCLA, Los Angeles, CA 90024; *Dept. Zool., Imperial College, London SW7 2BB, England; and †Univ. Calgary Fac. Med., Calgary, Canada T2N 1N4.

Recent studies have shown enkephalin-like immunoreactivity in amacrine cells (ACs), which may use enkephalin as a transmitter in the inner plexiform layer (IPL) (Brecha, N., et al., PNAS, 76: 3010, 1979). We investigated effects of externally applied opioid agonists and antagonists on the activity of ganglion cells (GCs), which are postsynaptic to ACs, and found pathways to all GCs to be specifically responsive to them.

Isolated goldfish retinas were placed receptors up in a chamber under moist 95% O_2 + 5% CO_2 gas at 22°C. GC spikes were recorded with tungsten microelectrodes. Light stimuli, a 1 mm diam. spot and a 1.2 mm i.d., 3.2 mm o.d. annulus, λ=650 or 500 nm, were presented alternately, 1 per 3 s for 0.7 s each. Responses were obtained at several light intensities. Chemicals in physiological saline were sprayed onto the retina through an atomizer system; different solutions could be applied in turn. Opioid agonists at estimated concentrations <1 μM in the IPL induce changes in GC activities.

GC center responses were defined as ON, OFF or ON-OFF to light. A chemical was then applied for a few seconds; after its effect reached a steady state the GC response was tested again. Exogenous D-Ala^2-Met^5-enkephalin (ENK) enhances light-evoked responses and more than doubles spontaneous activity of ON-center cells. In contrast, light-evoked responses and spontaneous activity of OFF-center cells are inhibited, following a transient excitatory period; sometimes their response is changed into ON-center. These effects are reversible; after application of minimum effective ENK concentrations, responses return to their original type in <5 min. In ON-OFF units, ENK either reverses the relative strengths of the two transient light responses or inhibits both of them. The actions of ENK on these 3 types of GCs are consistent with observations that the dendritic arborizations of enkephalin-containing goldfish ACs are multi- or bistratified in the IPL (Brecha, N., and Marshak, D., pers. comm.). Equimolar morphine mimics ENK but normal responses are not recovered in ≥ 20 min. Pre-treatment with a 100-fold molar excess of naloxone blocks the actions of ENK and morphine. After application of Co^{+2}, GCs generally fail to respond to ENK even at excessive concentrations. Physiological saline alone has no effect.

These observations show that opioid receptors are present in goldfish retina but probably not on GC dendrites. They suggest that enkephalinergic ACs synapse upon other ACs or bipolars presynaptic to GCs, rather then GCs directly. (Supported by Research to Prevent Blindness and NIH #EY 01190, EY 00331).

210.10 EFFECT OF ACUTE MORPHINE ADMINISTRATION ON CATECHOLAMINE LEVELS IN THE SUPERIOR CERVICAL GANGLION AND IRIS OF THE RAT PUP. T. G. Mattio* and M. L. Kirby. Dept. of Anatomy, Medical College of Georgia, Augusta, GA 30912.

The effect of morphine administration on catecholamines has been previously studied in monoaminergic brain nuclei. However, this approach has inherent problems in that these nuclei are heterogeneous, have complicated afferent and efferent connections, and are relatively inaccessible for experimental manipulation. In the present study we used the superior cervical ganglion (SCG) and iris of the rat pup to study the effects of acute morphine administration on tissue catecholamine stores. This system has many advantages over brain nuclei due to its relatively homogeneous cell population, well-defined afferent and efferent connections, and easy accessibility for experimental manipulation. Also the morphologic and biochemical development of SCG and iris has been well studied (Coughlin et al., Develop. Biol., 1978; Mytilineou and Black, Br. Res., 1978).

Sixteen day old rat pups were injected subcutaneously (s.c.) in the nuchal region with 10 mg/kg. of morphine in .2cc saline, a dose found to be analgetic by the formalin test (Dubuisson and Dennis, Pain, 1977). Control animals were injected with .2cc of saline. After 1 hour animals were anesthetized with nembutal intraperitoneally and the SCG and iridies were dissected, frozen, and stored in liquid nitrogen until assayed. Two ganglia and two iridies from the same animal were pooled for analysis. Tissue was assayed by using a radiometric assay that utilizes catechol-o-methyltransferase and S-adenosyl-L-(methyl-^{3}H) methionine (Kirby, Br. Res., 1978). Each sample was analyzed in duplicate and the catecholamine values were averaged. Appropriate internal standards and blanks were run with every assay. The sensitivity of the assay was 50pg.

Preliminary results show an increase in norepinephrine (NE) with unchanged dopamine and epinephrine levels in the iris and a slight increase in dopamine, norepinephrine, and epinephrine in the S.C.G. when expressed per mg wet weight. These data are consistent with results found in brain showing a decreased release of NE from neurons of the locus coeruleus after chronic morphine administration (Llorens et al., Nature, 1978). Whether this build up of catecholamines is due to increased synthesis, decreased release, or increased neuronal uptake is not known.

210.11 ALTERED MORPHINE SENSITIVITY FOLLOWING AMYGDALOID KINDLING IN C57BL/6J MICE. A. Mansour, R. Doyle, R. Katz & E.S. Valenstein; Depts. Psych., Neurosci. Lab. & Mental Health Res. Inst., Univ. Michigan, Ann Arbor, Mich. 48109.

Kindling refers to the progressive development of seizures by intermittent, electrical brain stimulation. This phenomenon has been reported to induce a "permanent" change, in that once kindled, a single stimulation will produce a generalized seizure even months after the last stimulation. Pilot experiments indicated that C57BL/6J mice show a marked increase in morphine sensitivity following amygdaloid kindling. The purpose of the present study was to extend these initial results and to examine whether the increase in opiate sensitivity was as "permanent" as the kindling phenomenon itself.

Thirty-five male C57BL/6J mice were implanted with chronic bipolar electrodes in the basolateral portion of the amygdala and divided into four groups. Nineteen animals were kindled to a criterion of 7 consecutive generalized clonic seizures and were subsequently tested with morphine (25mg/kg i.p.) at either 3 (N=9) or 28 days (N=10) following their last stimulation. The other sixteen animals were divided into two equal groups of handled controls.

A high percentage (89%) of kindled animals tested at 3 days exhibited generalized clonic seizures following morphine administration. The testing of kindled animals at 28 days is still in progress, but results indicate that they also exhibit a high percentage of clonic seizures. In contrast none of the control animals responded to morphine with behavioral seizures. Moreover, kindled animals tested at 3 or 28 days showed a greater increase in stereotyped running activity at 20, 40, 60, 80 and 100 minutes post injection compared to respective controls. The kindled mice also showed an exaggerated Straub tail response compared to controls.

These results clearly indicate that kindling produces a long lasting and perhaps permanent change in morphine sensitivity in C57BL/6J mice and suggest that the endogenous opiate system of animals may be altered by the kindling process.

210.12 SYSTEMIC MORPHINE BLOCKS THE EPILEPTIC EFFECTS INDUCED BY CENTRALLY ADMINISTERED MORPHINE. H. Frenk and G. Urca*. Depts of Psychology, and Pharmacology and Physiology, Tel-Aviv Univ., Ramat Aviv, Israel.

Intracerebroventricular (ICV) administration of both morphine and enkephalin produces marked neural and behavioral excitation as manifest by electrographic seizures accompanied by withdrawal-like phenomena such as wet dog shakes (Urca et al. Science, 1977; Frenk et al. Brain Res., 1978). On the other hand, systemic injections of opiates produce a predominantly inhibitory effect. Naloxone blocks both excitatory and inhibitory effects. We therefore sought to examine the question whether these effects are mediated via different, mutually antagonistic, opioid systems.

Male albino rats were prepared for chronic ICV injections and EEG recording. One week later animals were pretreated with 0, 5, 15, and 50 mg/kg of intraperitoneal morphine. Thirty min later morphine (200 μg) was injected ICV and cortical EEG and behavior monitored. Seven of 11 saline pretreated animals showed seizures whereas none were seen in the 7 animals pretreated with 50 mg/kg of morphine. Pretreatment with the lower doses of morphine had no significant effect on the occurrence of seizures. Administration of naloxone (1 mg/kg) 25 min following 50 mg/kg of morphine reversed its anti-epileptic effect such that all animals receiving ICV morphine 5 min after naloxone showed seizures.

An additional group of animals received either saline or 50 mg/kg of morphine intraperitoneally followed at 30 min by ICV leucine-enkephalin (50 μg). Morphine failed to block enkephalin seizures in any of the animals, however, it blocked the occurrence of wet dog shakes.

The ability of systemic morphine to block the epileptic effect of ICV morphine demonstrates the dual antagonistic action of opiates. The fact that both the anti- and pro-epileptic effects of morphine can be blocked by naloxone indicates that two different systems with different opiate receptor populations underly these phenomena. Indeed, the ability of morphine to block morphine- but not enkephalin-induced seizures lends further support to this suggestion.

210.13 ONTOLOGICAL DEVELOPMENT OF OPIATE RECEPTORS IN CHICK EMBRYONIC BRAIN. D. Ann Gibson* and Antonia Vernadakis*. (SPON: Norman Weiner). Departments of Pharmacology and Psychiatry, University of Colorado School of Medicine, Denver, CO 80262.

Infants born to mothers addicted to narcotic drugs exhibit a physiological dependence and develop symptoms of withdrawal during the postpartum period. Stereospecific opiate receptor binding sites have been demonstrated in animal and human brains, and narcotic analgesics are known to cross the placenta. Therefore, the time course for the appearance and binding affinities of the opiate receptors in the developing embryo may be relevant to identifying the periods in development when the nervous system is most sensitive to narcotics. We are studying opiate receptors in the embryonic chick brain at various stages of development (day 10 through hatching) in membrane preparations using the radioligand ^{3}H-etorphine. The competing ligands used to determine specific binding were naloxone, levorphanol and dextrorphan. With naloxone and levorphanol, ^{3}H-etorphine binding was blocked 40-60% and the specific binding was saturable; no reduction in ^{3}H-etorphine binding was observed with dextrorphan, suggesting the binding is stereospecific. Binding sites are present in homogenates of whole brain minus cerebellum as early as 10 days of gestation. Scatchard analysis showed dissociation constants (K_D's) are not significantly different from day 10 through hatching, but the number of binding sites increases during development. At the later stages of development (Days 20, 21 and hatching) several regions of the brain were examined: cerebral hemispheres, midbrain-diencephalon, and optic lobes. The K_D's were similar, although differences in the number of binding sites for the various regions were found. A high affinity site was detected in the cerebral hemispheres in Day 0 hatched chicks. We are presently determining whether a high affinity site is also present in the other regions of the chick brain and when during embryonic development it appears. (Supported by USPHS Research Grant 1 R01 DA 02131-01 from National Institute on Drug Abuse.)

210.14 EFFECTS OF CHRONIC MORPHINE, NALOXONE, AND STRESS ON PREWEANING OPIATE RECEPTOR ONTOGENY. M. T. Bardo, R. K. Bhatnagar, and G. F. Gebhart. Dept. of Pharmacol., Univ. of Iowa, Iowa City, IA 52242.

Evidence indicates that the normal ontogenetic proliferation in number of opiate receptors which occurs from birth to weaning in rats may be altered by various pharmacological and environmental factors. The present investigation assessed the ontogenetic proliferation of opiate receptors in various CNS regions of preweanling rats, and examined the influence of chronic morphine, naloxone, and footshock stress on opiate receptor ontogeny. Starting one day after birth, groups of male and female Sprague-Dawley rat pups were treated with either morphine sulfate (5 mg/kg, s.c.) for 21-22 days, naloxone hydrochloride (1 mg/kg, s.c.) for 23-24 days, or daily 30-min exposures to inescapable footshock (1 mA scrambled, 2 sec duration, presented on a variable interval 30 sec schedule). Shock treatment extended for either 7, 14, or 21 days after birth. Groups of litter-mate control pups were given either saline or exposure to the shock apparatus without shock. The animals were decapitated on the day following the last treatment day and the brains and spinal cords were removed and the brains regionally dissected into pons-medulla, midbrain, hypothalamus, striatum, and cortex. Opiate receptor assays were performed on homogenized tissue incubated with 1 nM ^{3}H-naloxone in the presence or absence of levallorphan (Coyle and Pert, Neuropharmacol., 15:141, 1976).

Morphine treatment for 21-22 consecutive days failed to alter stereospecific binding of 3H-naloxone, although both brain and body weights were significantly decreased by the morphine treatment. Naloxone treatment for 23-24 consective days significantly increased receptor binding in pons-medulla and hypothalamus (12% and 19% increase in fmol/mg wet weight, respectively). Nonsignificant increases in binding following naloxone treatment were obtained in midbrain (8%), striatum (5%), and cortex (11%); no change was observed in spinal cord. Shock treatment also tended to increase binding in all brain areas examined, except these trends were not statistically significant. Analyses of data from 7, 14, and 21 day-old control pups revealed marked regional differences in the ontogeny of binding capacity. While there was no change in binding in spinal cord from 7 to 21 days, age-related increases in binding were in pons-medulla (45%), midbrain (134%), hypothalamus (269%), striatum (698%), and cortex (900%). Supported by USPHS grants NS12121, NS12114 and MH15172.

210.15 SEX AND THE ENDOGENOUS OPIATES: NALOXONE REDUCES POST-COPULATORY BEHAVIOR IN FEMALE CATS. L.M. Johnson* (SPON: J. Roppolo). Department of Physiology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania 15261.

This experiment was designed as a test of the hypothesis (Stein & Belluzi, 1977) that endogenous opiates subserve a function in the regulation of satisfaction and reward behavior. The mating behavior of otherwise drug-naive cats was observed after intravenous administration of naloxone at two doses to determine whether the drug would alter the behavioral "after-reaction" that characterizes a female cat's highly stereotypical mating pattern. During mounting she normally displays lordosis, tail-deflection and treading of the hind paws. At ejaculation she emits a "mating cry", throws off the male and immediately proceeds to roll, pausing occasionally for genital licking. She is unreceptive to the male during most or all of this period.

Eight ovariectomized cats were given a 4 cm subcutaneous Silastic implant of crystalline estradiol-17β to induce behavioral estrus. Six of the animals had a chronically indwelling venous cannula and all were experienced at mating. A maximum of two matings were permitted on a given day, spaced one hour apart. On some days saline or no treatment was given. Naloxone was given either before a single mating or before the second mating, with the first mating serving as a control. After naloxone, no difference was observed in lordotic posture, tail-deflection or treading, nor in the duration and audibility of the mating cry. After control matings, rolling was continuous except for brief pauses to groom. Naloxone-treated cats often did not start rolling immediately after mating. When they did start, the rolling appeared normal for 7-30 seconds, but stopped abruptly or temporarily with the animal moving about or grooming and rolling only occasionally. The amount of time spent rolling was 379 ± 19 (SEM) seconds (n = 19) after non-treated or saline-treated matings; 77 ± 25 seconds (n = 7) after naloxone at 0.1 mg/kg given 10 minutes prior to entry of the male; and 102.5 ± 17 seconds (n = 4) after naloxone at 1 mg/kg given 2 minutes prior to entry of the male. The observations demonstrate a behavioral effect of naloxone in animals not exposed to exogenous opiates and support the hypothesis that affective behavior is mediated by endogenous opiates. (Supported by NIH Grant HD 12240).

211.1 MICROELECTROPHORESIS OF SUBSTITUTED OPIOID TETRAPEPTIDES - COMPARISON OF POTENCY AND DURATION OF ACTION. B. Lamishaw* and R. C. A. Frederickson. The Lilly Research Laboratories, Indianapolis, IN 46285.

This study was undertaken to examine the mechanisms of opioid peptide inactivation at putative enkephalinergic synapses. The natural enkephalins have been shown to be extremely labile to enzymatic degradation. Many modified analogues have been prepared which have protection from such degradation. The enkephalin structure (5AA's) was thought to be the minimal sequence with opioid activity but more recently it has become apparent that the tetrapeptide sequence (tyr-gly-gly-phe) is the minimally active sequence and extremely potent analogues of this structure have been prepared. The action of small opioid peptides applied microelectrophoretically to neurons in brain is terminated very rapidly, presumably due to synaptic inactivation mechanisms. We undertook the present experiments to examine the relative effects of N-terminal versus C-terminal modifications on this synaptic inactivation. Three tetrapeptides with the following structures were microelectrophoresed onto cells in rat frontal cerebral cortex: tyr-gly-gly-phe-NH_2, tyr-D-ala-gly-phe-NH_2, and tyr-D-ala-gly-(N-methyl)phe-NH_2. The peptides were dissolved in 0.05M NaCl at a concentration of 0.05M, pH 4, and were ejected as cations. The effects of tetrapeptides on spontaneous or glutamate-evoked neuronal firing were predominently inhibitory (70% of the cells tested), but excitatory (6%) and biphasic or other complex effects (14%) were observed. Approximately 10% of the cells were unaffected by tetrapeptide electrophoresis. Compared to the unsubstituted peptide, the substituted peptides were somewhat more potent at inhibiting neuronal firing and recovery from their effects was slower. However, there was little difference in the degree of inhibition or rate of recovery between the D-ala^2 analogue and the D-ala^2-4-N-methyl analogue. These results indicate that substitution of gly by D-ala in the second position affords greater protection from synaptic inactivation than substitution at the C-terminal phe residue. This suggests an important role for enzymatic attack at the N-terminus for the termination of synaptic action of the tetrapeptides.

211.2 THE USE OF HPLC COUPLED WITH RADIOIMMUNOASSAYS FOR DETECTING MULTIPLE SPECIES OF β-ENDORPHIN AND α-MSH. Y. Ueda*, H. L. Lin* and H. Akil. Mental Health Research Institute, Univ. of Mich., Ann Arbor, MI 48109.

While a great deal has become known about the structure and localization of the precursor of β-END/ACTH, pro-opiocortin and its products (β-LPH, β-END, ACTH, α-MSH), few studies have addressed the regulation or the normal physiological function of these products in brain. The difficulty lies in achieving highly specific yet sensitive measurements of these substances in various tissues. The problem is exacerbated by the existence of four different species of β-Endorphin (described by Smyth et al.): C, C', N Acetyl C and N Acetyl C', and the presence of at least two species of α-MSH-like substances: N-Acetyl ACTH 1-13 amide, and ACTH 1-13 amide (des-ac., α-MSH) (O'Donohue and Jacobowitz). While HPLC is capable of separating these species, the detection limits are below the amounts normally present in brain, blood or C.S.F. Radioimmunoassays, on the other hand, while highly sensitive, can cross-react with multiple species of peptides. We have therefore established a technique interfacing HPLC with a number of specific RIA's. A single run on a reverse phase column (Ultrasphere ODS, 5μm) separates the four species of β-END and the two forms of α-MSH from other known peptides, such as oxytocin, vasopressin, leucine and methionine enkephalin, or dynorphin 1-13. The peaks are collected and measured by highly sensitive radioimmunoassays. Changes in the concentrations of the peptides and their ratios can then be studied under various physiological states (eg. stress, pain) or after specific pharmacological manipulations.

211.3 REPEATED DOSES OF D-PHE^4-MET-ENKEPHALIN ALTER BLOOD CHEMISTRIES IN SQUIRREL MONKEYS. G. A. Olson, R. D. Olson, A. J. Kastin, R. H. Wolf*, G. M. Brown, and D. H. Coy*. Dept. of Psychology, Univ. of New Orleans, New Orleans, LA 70122

D-Phe^4-Met-enkephalin, an enkephalin analog with little or no opiate activity, was injected daily over five days in 10 squirrel monkeys (Saimiri sciureus). Half of the animals received a dose of 1.2 mg/kg while the others received 6.15 mg/kg. Behavioral observations and serum specimens were taken the day before the injections began as a baseline measure, the day after the injection series ended, and two weeks after the termination of injections to assess possible residual effects.

Blood samples were analyzed for levels of glucose, BUN, SGOT, SGPT, RBC, Hgb, PCV, WBC, differential, prolactin, and growth hormone. A mixed analysis of variance was performed on each measure and indicated significant changes in several of the tests over time. BUN levels decreased significantly over the injection series but rose again to pretreatment levels by the time of the follow-up measure. This was due primarily to two animals with very high levels at the start of the project who decreased to normal levels near 20 during the study but returned to the pre-treatment levels within two weeks after the termination of the peptide. RBC, Hgb, and PCV increased significantly after receiving the D-Phe^4-Met-enkephalin analog and had not returned to baseline at the time of the follow-up testing, suggesting that these measures might be extremely sensitive indices of the activity of peptides. WBC, prolactin, and growth hormone did not change reliably but the differential was altered as a result of treatment. SGOT also decreased over the injection period and reached a maximum decrease at the two week follow-up examination.

Several behavioral measures were taken to examine the effect of the non-narcotic enkephalin analog on gross motor performance. General activity, gait, posture, dowl grip, dowl bite, poke response (motor), poke response (vocalization), and visual tracking were all tested at each time base. Food intake and gross body weight were also monitored throughout the study on a daily basis. A mixed analysis of variance was performed on each of the behavioral measures but no statistically significant results were obtained for any of the tests, indicating that any effects of this peptide would be relatively subtle.

This study supports the position that opiate peptides have dissociative effects and that the non-narcotic effects may manifest themselves in a wide variety of test situations, both behavioral and biochemical. The data collected in this study indicate that D-Phe^4-Met-enkephalin had no deleterious effects on behavior or blood chemistry in squirrel monkeys, thus suggesting its suitability for potential clinical use.

211.4 EFFECTS OF SEROTONIN ANTAGONISTS ON HYPERTHERMIA INDUCED BY THE INTRACEREBRAL MICROINJECTION OF β-ENDORPHIN. G. E. Martin, C. B. Bacino and N. L. Papp. Merck Institute for Therapeutic Research, West Point, PA 19486.

The intracerebral microinjection of β-endorphin produces a long-lasting increase in the rat's rectal temperature (RT) which can be partially antagonized by the central serotonin (5-HT) antagonist methergoline (Martin, G. E. and Bacino, C. B. Eur. J. Pharmacol., 59: 227, 1979). These data led to the hypothesis that the β-endorphin induced increase in RT might be mediated by the activation of cerebral 5-HT receptors. To test this hypothesis, we examined the actions of methergoline and three additional antagonists of the central 5-HT receptor on the hyperthermia evoked by the intracerebral microinjection of β-endorphin.

In the preoptic/anterior hypothalamus region of each of 54 male rats, a single 24 ga TW injection guide was permanently implanted. β-Endorphin (2.5 μg), dissolved in 0.5 μl of CSF, was microinjected over a 30 sec interval 1 hour after pretreatment. The following drugs and dose levels (mg/kg i.p.) were used: methysergide (7.5,15); cinanserin (4.5,9); cyproheptadine (5); methergoline (1) and haloperidol (0.5). Haloperidol, an antagonist of central dopamine receptors, was used as a control. A counterbalanced design was used in which each rat was given two microinjections of β-endorphin separated by a 1-week interval. Half of the animals were first pretreated with the vehicle solution and half were given the antagonist. As a control for the direct action of the antagonists on RT, each was administered to rats not given a central microinjection. RT was determined by inserting a thermistor probe 6 cm into the unrestrained animal's rectum at selected time intervals. Baseline RT was determined for each rat by averaging the RT read 30 min and just before the pretreatment.

β-Endorphin produced a rise in the rat's RT when injected into the forebrain. However, neither methysergide (7.5,n=5; 15,n=8), nor cinanserin (4.5,n=5; 9.0,n=16), nor cyproheptadine (n=9) produced a marked reduction in this hyperthermia. Cyproheptadine did cause a significant reduction in the magnitude of the rise in RT, but also caused a significant drop in RT in control rats during the same time period. Hence, the diminution of the rise in RT is not due specifically to an attenuation of the endorphin's action. On the other hand, methergoline (n=10) did significantly attenuate the pyrexia induced by the peptide. The reason for this apparent discrepancy in the action of these serotonin antagonists is unclear. The dopamine receptor antagonist, haloperidol (n=11), did not alter β-endorphin hyperthermia. Future research will be required to determine whether there are distinct subpopulations of 5-HT receptors at which these 5-HT antagonists exert their effect.

211.5 ANTICONVULSANT EFFECTS OF OPIATES AND OPIOIDS ON KINDLED SEIZURES IN RATS. S. Caldecott-Hazard*, R.F. Ackermann*, Y. Shavit, J.C. Liebeskind, J. Engel, Jr. Dept. Neurol. & Psychol., UCLA, CA.

EEG afterdischarges (ADs) from intraventricular injections of opioid peptides in rats suggested a role for these substances in certain seizure phenomena (Urca et al.1977). Subsequently, it was found that morphine and naloxone did not affect the ictal phase of seizures in kindled rats, although morphine prolonged and naloxone shortened post-ictal behavioral depression (Frenk et al.1979). It was suggested that opioid peptides are released during ictus and are involved in the post-ictal depressive state. We postulated that if opioids were released by a seizure, they might also affect the elicitation of a subsequent seizure. Therefore, an investigation was made of the effects of morphine, naloxone, an enkephalin analogue, and morphine tolerance and withdrawal on repetitive seizures.

Chronic bipolar stimulating and recording electrodes were implanted in the amygdala and rats were kindled until 3 generalized (stage 5) seizures were produced. Each rat was then injected with either saline, morphine (10 or 50 mg/kg), naloxone (10 mg/kg), or an enkephalin analogue #146104, Eli Lilly (7 mg/kg), and given 7 stimulus trains (60 Hz, 1 sec, 400 μA) spaced at 2 min intervals. The severity of each behavioral seizure was rated according to a modified version of Racine's kindling scale and mean scores were calculated for each rat. Morphine (10 mg/kg) and naloxone did not produce significant changes in seizure severity. Morphine (50 mg/kg)and enkephalin analogue (preliminary results) significantly decreased mean scores of seizure severity. There were fewer behavioral seizures, yet when elicited, they were usually stage 5. A final group of saline-treated kindled rats was tested as before, then made tolerant to morphine (doses increasing from 5-50 mg/kg, given 3 times per day, for 7 days). One group of tolerant rats was tested and compared with another group given naloxone (10 mg/kg to precipitate withdrawal. Whereas tolerant rats showed no significant changes, withdrawal rats had significantly reduced seizure severity scores. Withdrawal rats were retested after 24 hrs of morphine abstinence, and their severity scores were also reduced. These results suggest that opioid peptides are released by the ictal phase of a seizure and that they serve to inhibit the behavioral components of subsequent seizures. Possible mechanisms for these results are discussed.

211.6 IN VIVO RELEASE OF ENKEPHALIN FROM THE GLOBUS PALLIDUS. EFFECT OF DEPOLARIZING AGENTS AND ELECTRICAL STIMULATION OF THE CAUDATE NUCLEUS. A. Bayon, R. Drucker-Colin, L. Lugo*. Centro de Investigaciones en Fisiologia Celular, U.N.A.M., Apartado Postal 70-600, Mexico 20, D.F. and W.J. Shoemaker, R. Azad* and F.E. Bloom. The Salk Institute, P.O. Box 85800, San Diego, CA 92138.

Guide-cannulae were chronically implanted in adult cats (2-2.5 Kg) and albino rats (150-200 g) in order to allow the stereotaxic placement of a push-pull cannula in the globus pallidus. One week after surgery the push-pull cannulae were inserted into the guides and connected to an infusion-withdrawal syringe pump. The unanaesthetized, freely moving, animals were then perfused with a Krebs-Ringer bicarbonate containing BSA (0.1%) and bacitracin (30 ug/ml). Flow rate was 23 μl/min and 15-min fractions were collected in the withdrawal syringe which contained ice cold 2N acetic acid. The mixed contents were boiled (15 min), lyophilized and redissolved to be assayed in a Leu-enkephalin RIA. (3% cross-reaction with Met-enkephalin). A K+ (50mM)-stimulated, Ca++-dependent release of enkephalin was observed in both cat and rat globus pallidus. Veratrine also enhanced the enkephalin release (see Figure). In rats implanted with a bipolar electrode in the caudate nucleus, electrical stimulation also elicited an increased release of enkephalin in the pallidum (see Figure). These findings support the candidacy of enkephalins as neurotransmitters in the globus pallidus and are consistent with the existence of a striato-pallidal enkephalin pathway, postulated on the basis of lesion experiments (Cuello and Paxinos, Nature 271, 178, 1978). 211.7 DISTRIBUTION OF ENKEPHALIN-LIKE IMMUNOREACTIVITY IN THE MOUSE BRAIN: STRAIN COMPARISONS. A.S. Moskowitz, J.C. Liebeskind & L.L. Butcher. Brain Research Institute and Dept. of Psychology, UCLA, Los Angeles, CA 90024.

Several immunohistochemical studies have reported the distribution of enkephalins in rat brain. In the present study, the distribution of methionine enkephalin-like immunoreactivity (met ELI) and leucine enkephalin-like immunoreactivity (leu ELI) was investigated in the mouse brain. Two strains of mice were used: CXBK and C57BL/6BY (Jackson Labs). Baran et.al. (Life Sci., 17: 633, 1975) found fewer central opiate receptors in the CXBK than in the C57BL/6BY strain.

Mice were treated with colchicine (120μg/100g body wt./day, s.c.) on 2 successive days, then perfused with 4% paraformaldehyde. 10μm cryostat sections were cut and stained using the indirect immunofluorescence method. Sections were examined, photographed and counterstained with thionin to verify location of immunofluorescence.

The distribution of ELI in mouse brain correlated well with previous reports on the distribution of enkephalins in rat brain. ELI was observed in cell bodies in anterior olfactory n., frontal cortex, cingulate cortex, n. intersitialis of stria terminalis, n. of diagonal band, caudate-putamen, amygdala, n. reticularis thalami, zona incerta, preoptic area, n. gigantocellularis, lateral n. of medulla, n. centralis caudalis pontis, n. raphe magnus, n. of spinal tract of V, dorsal cochlear n., medial vestibular n., n. of tractus solitarius, medial accessory olivary n., n. commissuralis and ependymal layer of third ventricle. ELI was seen in fibers and terminals in the above areas and was also observed in fibers and terminals in globus pallidus, lateral septal n. and dorsal periaqueductal gray and in fibers in subependymal layer of third ventricle. Met but not leu ELI was observed in fibers, terminals and cell bodies in olfactory tubercle, lateral olfactory area, anterior hypothalamus, dorsal hypothalamus, dorsal tegmental n. and n. raphe pallidus and in fibers and terminals in arcuate n., anterior hippocampus and n. centralis of medulla. Leu but not met ELI was observed in fibers, terminals and cell bodies in anteroventral n. of thalamus, lateral anterior n. of thalamus, ventral and dorsal n. of lateral geniculate, medial and lateral habenular n., areas CA1 and CA2 of hippocampus and granular layer of cerebellum; in cell bodies and fibers in n. reuniens of thalamus and in fibers and terminals in locus coeruleus and main sensory n. of V. No strain differences were observed in the distribution of either met or leu ELI.

211.8 IMMUNOHISTOCHEMICAL LOCALIZATION OF ENKEPHALINS IN SONG-RELATED BRAIN REGIONS OF A PASSERINE BIRD. Susan M. Ryan, Arthur P. Arnold and Robert P. Elde. Dept. Psychol. and Brain Res. Inst., UCLA, Los Angeles, CA 90024 and Dept. Anat., Univ. Minnesota, Minneapolis, MN 55455

Investigations of several passerine bird species have implicated a number of interconnected brain regions in the control of song. This system includes Area X of the lobus parolfactorius, magnocellular nucleus of the anterior neostriatum (MAN), nucleus interface (NIF), caudal nucleus of the ventral hyperstriatum (HVc), intercollicular nucleus (ICo), robust nucleus of the archistriatum (RA), and tracheosyringeal portion of the hypoglossal nerve nucleus (nXIIts). Most of these areas are sexually dimorphic with respect to size and/or androgen accumulation patterns (Nottebohm & Arnold, 1976; Arnold & Saltiel, 1979). Neurochemical investigations have localized AChE, muscarinic receptors, and catecholamines to various nuclei of the zebra finch song system (Ryan & Arnold, 1979; Lewis et al., 1979).

To investigate further the neurochemistry of the song system, enkephalin distribution was examined by fluorescence immunohistochemistry in adult male and female zebra finches (Poephila guttata). Some animals were pretreated with colchicine 24 to 48 hours prior to perfusion in order to aid perikaryon localization. 12μ cryostat sections were incubated with antisera to methionine or leucine enkephalin. Adjacent sections served as reference sections and absorption controls to insure specificity of staining results.

Both methionine and leucine enkephalin immunoreactivity are present in ICo, MAN, NIF, HVc, and RA of both males and females. Neither is present in Area X or in nXIIts. ICo contains a dense network of enkephalin immunoreactive fibers and perikarya, both dorsomedial to and ventrolateral to MLd. A low density of enkephalin immunoreactive fibers and terminals are distributed throughout MAN, NIF, HVc, and RA. Except the parahippocampal area dorsal to HVc, regions immediately adjacent to MAN, NIF, HVc, and RA do not contain enkephalins. Innervation appears specific to these nuclei-- not to larger regions which include them.

HVc and RA, in particular, are important to song production in the adult song bird (Nottebohm et al., 1976). NIF projects to HVc, and MAN projects to both HVc and RA in the canary (Nottebohm & Kelley, 1978). Thus, localization of terminals in these four nuclei suggests a role for enkephalins in song production and/or song perception in passerine birds.

211.9 COMBINED MET-ENKEPHALIN-LIKE IMMUNOREACTIVITY AND ACETYLCHOLINESTERASE STAINING IN NEURONS IN THE LATERAL SUPERIOR OLIVE OF THE GUINEA PIG. R. A. Altschuler, J. Fex and M. Parakkal*. Lab. Neuro-otolaryngology, NINCDS, NIH, Bethesda, MD 20205.

Our observations of Met-enkephalin (ME)-like immunoreactive efferent fibers in the guinea pig cochlea led to an investigation to determine the source of the fibers. Warr & Guinan (Brain Res. 173:152 1979) showed that a class of efferents has its origin in acetylcholinesterase (AChE) staining cells in the lateral superior olive (LSO) of the cat. Our studies showed ME-like immunoreactivity in cells in the guinea pig LSO. Coexistence of putative peptide neurotransmitters and traditional transmitters within a single cell has been demonstrated in many combinations. Lundberg et al. (Neuroscience 4:1539 1980) performed immunofluorescence and AChE staining on identical sections to demonstrate vasoactive intestinal polypeptide-like immunoreactivity and AChE staining in the same cells. The same method was used in this study to determine if the ME-like immunoreactivity seen in the guinea pig LSO was in the same cells that show AChE staining.

10 micron cryostat sections were cut through the brainstem of 275-325 gram female NIH stock guinea pigs. Indirect immunofluorescence using antisera against Met-enkephalin was performed on representative sections. The LSO of these sections was then photographed through a Zeiss microscope under epifluorescent illumination. Coverslips were floated off and sections reprocessed to now show AChE activity. The LSO was rephotographed and immunoreactive and AChE positive cells compared.

Strong ME-like immunoreactivity was seen in cells in the LSO without any pre-treatment of animals with colchicine. This population of immunoreactive cells was represented throughout the entire extent of the LSO with greatest concentration rostrally. When AChE staining was examined on identical sections all the cells of the LSO that exhibited ME-like immunoreactivity showed AChE staining. In addition, these were the only cells of the LSO to have AChE activity. There is thus a coexistence of ME-like immunoreactivity and AChE activity in the same cells. These cells have a different size and distribution than those described by Warr and Guinan in the cat LSO. Studies are therefore underway to determine if the cells described in this study project to the cochlea.

211.10 STRUCTURE-ACTIVITY RELATIONSHIPS OF DYNORPHIN PEPTIDES AT THE OPIATE RECEPTOR OF THE GUINEA PIG ILEUM MYENTERIC PLEXUS, C. Chavkin and A. Goldstein, Addiction Research Foundation and Dept. of Pharmacology, Stanford University, Palo Alto, CA 94304.

Dynorphin, an opioid peptide recently purified from porcine pituitary extracts, was found to be 700 times more potent than [Leu^5]-enkephalin in the guinea pig ileum bioassay (Goldstein et al. Proc. Nat. Acad. Sci. 76:6666 (1979)). Since the [Leu^5]-enkephalin pentapeptide sequence corresponds to the first five amino acids in dynorphin (YGGFLRRIRPKLK...), we were interested in determining which amino acids in the carboxy-terminal extension were responsible for the enhanced potency. The interactions of enkephalin analogues with the opiate receptor binding site in guinea pig ileum has been extensively studied (for recent review, see Morley, Ann. Rev. Pharmacol. Toxicol. 20:81 (1980)). The present study explores a hitherto uncharacterized domain of that binding site.

A series of fragments were enzymatically prepared from synthetic dynorphin-(1-13) and dynorphin-(1-9)(Peninsula Labs) by sequentially removing the carboxy-terminal amino acids to obtain dynorphin-(1-12),-(1-11),-(1-10),-(1-8),-(1-7), and -(1-6). These peptides were purified using a μBondapak HPLC column (Waters), and their identity confirmed by amino acid analysis.

A large drop in potency occurs between dynorphin-(1-11) (IC_{50} 0.54nM) and dynorphin-(1-10) (IC_{50} 14 nM) and also between dynorphin-(1-7) (IC50 28 nM) and dynorphin-(1-6) (IC_{50} 780nM), suggesting that Lys^{11} and Arg^7 are critical residues. It would seem that the dynorphin receptor in the myenteric plexus contains two anionic sites able to interact with the basic amino acids in these positions of the dynorphin sequence. Additional dynorphin analogues are being prepared to map the topography of this binding site more completely.

211.11 CHARACTERIZATION OF NEUROTRANSMITTERS MEDIATING INHIBITION OF LOCUS COERULEUS BY HYPOTHALAMIC ARCUATE NUCLEUS STIMULATION: INTERPLAY BETWEEN ADRENERGIC AND ENDORPHIN SYSTEMS. Howard K. Strahlendorf, Jean C. Strahlendorf†, Charles D. Barnes† and James H. Pirch Departments of Pharmacology and Therapeutics and Physiology†, Texas Tech University Health Sciences Center, Lubbock, TX 79430

The locus coeruleus (LC) has been shown to contain a high density of opiate receptors. Systemically administered and iontophoretically applied opiates exert a potent depressant action on coerulear cell firing rate. Immunohistochemical studies have revealed the existence of β-endorphin containing axons emanating from cell bodies localized in or near the hypothalamic arcuate nucleus (AN) which project to various brain sites including LC. Additionally enkephalin containing neurons are present within and surrounding the LC. We have previously reported that electrical stimulation of the AN produced profound inhibition (>1000 msec) of spontaneous coerulear cell discharges in anesthetized cats and rats. In cats, naloxone (NAL) effectively blocked arcuate-induced inhibition when given intravenously (2.5-5.0 mg/kg) or via microiontophoresis; however, preliminary experiments in rats demonstrated NAL to be less effective against suppression of LC unit activity when given by either route.

In order to further investigate this apparent species difference, we have examined the effects of intravenous and iontophoretic NAL and piperoxane (PIP) on arcuate-elicited inhibition of LC cells in chloral hydrate anesthetized rats. In accord with preliminary observations, NAL in doses up to 10 mg/kg frequently evidences only slight (< 20%) blockade of suppression of LC units by arcuate activation. Iontophoretic NAL antagonizes stimulation produced inhibition in some instances and frequently suppresses LC cell discharges similar to opiate agonists. By contrast, PIP given systemically (0.5 mg/kg) or by iontophoresis antagonizes (approx. 50%) arcuate effects in a majority of cells tested. These results suggest that inhibition of LC neurons by arcuate stimulation in rats may result in part from an axon reflex (autoinhibition) and in part via endorphin release on LC-arcuate synapses. The difference in NAL effectiveness between rat and cat may reflect a species difference with regard to opiate receptor types. (Supported by the Tarbox Parkinson's Disease Institute of Texas Tech Univ. Hlth. Sci. Ctr.)

211.12 EFFECTS OF LEUCINE-ENKEPHALIN AND METHIONINE-ENKEPHALIN ON ISOLATED PERFUSED VASCULAR TISSUE. Robert H. Moore, III and Deborah A. Dowling. Dept. of Physiology, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501.

Preliminary work in our laboratory provided evidence that both leucine-(leu-) enkephalin and methionine-(met-) enkephalin when administered intravenously into pentobarbital-anesthetized cats could alter mean arterial blood pressure and that the responses could be altered by selected pharmacological antagonists. The purpose of this project was to determine the role of vascular tissue in the blood pressure changes seen with the enkephalins and, if the effects can be altered by antagonists. In anesthetized immobilized cats, a femoral artery was exposed and cannulated so that the blood was diverted through a constant flow infusion pump before being reinfused into the artery. Blood flow was maintained at a constant flow for the duration of the experiment; thus, changes in vascular diameter were reflected as changes in pressure. Either leu-enkephalin or met-enkephalin in doses of 0.032, 0.1, 0.32, 1, 3.2, 10, 32, 100 or 320 μg total dose were introduced into the arterial blood as it re-entered the animal distal to the flow pump. Administration of leu-enkephalin produced a dose-dependent drop in the pressure of the perfused limb. A drop of 5% ±1% was seen with a dose of 3.2 μg and extended to a decline of 26% ±4% with a dose of 320 μg. Doses of 1 μg or lower did not induce significant changes. Administration of met-enkephalin also resulted in a dose dependent decline (5±1% with 1 μg; 39±3% with 320 μg). At the three higher doses, met-enkephalin produced a significantly greater decline than did leu-enkephalin. Our results indicate that both enkephalins appear to act on vascular tissue to cause vasodilation. (Supported in part by grants from NIH (#5S08RR091 30-02) and American Heart Association, Missouri Affiliate.)

211.13 ANALGESIA IN MICE AND HUMANS BY D-PHENYLALANINE: RELATION TO BRAIN UPTAKE AND INHIBITION OF ENKEPHALIN DEGRADATION. S. Ehrenpreis, R.C. Balagot*, A.D. Mosanim, K. Kubota*, J. Greenberg*, and C. Okafor*, Chicago Medical School, Chicago, IL 60612.

We have reported that D-phenylalanine (DPA) causes longlasting, naloxone-reversible analgesia in mice (Ehrenpreis et al, in "Endogenous and Exogenous Opiate Agonists and Antagonists", E.L. Way, ed, 1980, p.379). Preliminary studies showed a similar activity in humans. It was postulated that analgesia resulted from inhibition of enkephalin degradation with build-up of the peptides in the CNS. Using a newly developed bioassay procedure for enkephalinases, we have obtained confirmation of this hypothesis by demonstrating that DPA inhibits these enzymes in mouse and guinea pig brain. Met-enkephalin, 3μg/ml, was incubated with suspensions of 20,000xg pellets of brain homogenates. At various times aliquots were boiled to stop the reaction. Residual met-enkephalin was determined from the % inhibition of electrically stimulated guinea pig longitudinal muscle-myenteric plexus preparation. IC_{50} for enkephalinase inhibition by DPA was $3x10^{-2}M$. Other compounds which inhibit enkephalinases (e.g. bacitracin, puromycin) also produce naloxone-reversible analgesia in mice (hot plate method). Order of analgesic potency correlates with potency as enkephalinase inhibitor. Radioactive DPA enters mouse brain slowly, peaking at 30-40 min. and remaining in the brain for very extended periods of time. Uptake into brains of young (3 wk old) mice is much greater than older mice (13 wk). These findings are in accord with the analgesic activity of DPA. DPA provided good to excellent relief in 78% of 43 patients with chronic pain who did not respond to other treatments. Relief was slow in onset and at times of very long duration. The present results provide the pasis for understanding the analgesic properties and mechanism of action of DPA in animals and humans. (Supported in part by a grant from Hoffman-LaRoche and by USPHS Grant 2025).

211.14 DEVELOPMENT OF ENKEPHALIN IN CHICK BRAIN, GUT, ADRENAL AND REMAK'S GANGLION. Miles L. Epstein[o], Iris Lindberg*[+] and June L. Dahl[+]. Departments of Anatomy[o] and Pharmacology[+], University of Wisconsin Medical School, Madison, WI 53706.

We have used sensitive radioimmunoassays to measure the concentrations of met- and leu-enkephalin in the brain, gut, adrenal gland and ganglionated nerve of Remak of the developing chick embryo and the 4-week-old chicken. Both peptides were detectable in brain and gut at 5 days of incubation (d.i.). Enkephalin concentrations, which were greater in brain than gut, increased 10-fold in both tissues by 9 d.i. Concentrations in the medulla-pons and midbrain were twice those in the cerebrum and optic tectum. In all of these brain regions, enkephalin concentrations were highest at 17 d.i. and decreased only slightly thereafter.

A different developmental profile was observed in the gut. There was no significant change in enkephalin concentrations in the midgut and rectum between 13 and 21 d.i. Concentrations in the duodenum were highest at 13 d.i. and decreased gradually to the values observed in the 4-week-old animal. In the adrenal, peak enkephalin levels were observed at 13 d.i., were 50% lower at 21 d.i., and remained constant thereafter. Of all the regions examined, Remak's ganglion contained the highest concentrations of both enkephalins, 10–30 and 2–8 ng per mg protein for met- and leu-enkephalin, respectively. The significance of such high enkephalin levels in this ganglion is presently unclear, but these data suggest a role for met-and leu-enkephalin in the regulation of gut motility.

(This work was supported by the University of Wisconsin Medical School Funds.)

212.1 PROCTOLIN RADIOIMMUNOASSAY ACTIVITY IN ARTHROPOD NERVOUS SYSTEM. T.G. Kingan and M. Titmus*. Department of Biochemistry and Biophysics, Oregon State University, Corvallis, OR 97331 and Laboratory of Neurobiology, Boulevard del Valle 201, San Juan, Puerto Rico 00901.

Proctolin is a peptide neurotransmitter candidate in insect visceral muscle (B.E. Brown, Life Sciences 17:1241, 1975) and has been reported to induce rhythmic contractions in locust extensor tibiae (Piek, et al., Comp. Biochem. Physiol. 62C: 151, 1979). We have prepared and characterized an antiserum against proctolin. The antiserum has been used to quantitate proctolin radioimmunoassay (RIA) activity in the Madeira cockroach (Leucophaea maderae) and in three crustaceans. Proctolin RIA activity was found throughout the central nervous system in Leucophaea, being highest in the 6th abdominal ganglion (.68 ± .02 pmole/ganglion) and lowest in the remaining abdominal ganglia (ave. .11 ± .03 pmole/ganglion). Small amounts of proctolin RIA activity could be detected in skeletal muscle and tracheae; none was detected in fat body or in hemolymph. Brains of all three crustaceans contained measurable proctolin RIA activity: Panulirus interruptus, .73 pmole/ganglion; Cancer magister, .31 pmole/ganglion; Pacifastacus leniusculus, .35 pmole/ganglion.

212.2 SUBSTANCE P RELEASE FROM THE NUCLEUS TRACTUS SOLITARIUS AND TRIGEMINAL SPINAL NUCLEUS IN VITRO. Cinda J. Helke, David M. Jacobowitz and Nguyen B. Thoa*. Lab. of Clin. Sci. NIMH, Bethesda, Md. 20205.

Recent studies have suggested that Substance P (SP) may be a neurotransmitter in baro and/or chemoreceptor afferent nerves projecting to the nucleus tractus solitarius (NTS) (Brain Res. 181:476, 1980; Peptides 1:1, 1980) and in afferent pain fibers projecting to the trigeminal spinal nucleus (nV) (Brain Res. 152: 499, 1978) in addition to the well established system of dorsal root SP fibers which terminate in the dorsal horn of the spinal cord. One of the mechanisms for establishing SP as a transmitter in the latter system was the demonstration that depolarization results in a calcium dependent release of SP. In this study, in vitro SP release from the nV and the NTS region of the rat was investigated utilizing slices (225 µm) of the freshly dissected medullary regions. Slices were suspended in 0.6 ml of a modified Krebs-bicarbonate buffer containing 20 µM bacitracin and maintained at pH 7.4 - 7.6. SP released into the medium was analyzed by radioimmunoassay.

Stimulation with K+ (50 mM) in the presence of calcium (2.5 mM) resulted in a marked increase (250-300%) in SP release from both regions. Omission of calcium from the buffer completely abolished SP release by K+.

Capsaicin has also been reported to stimulate SP release from the spinal cord but not the hypothalamus or substantia nigra (Life Sciences 25:629, 1979) while all of these areas release SP with K+ stimulation. This suggests that capsaicin may stimulate release of SP only in those CNS areas containing the nerve terminals of primary afferent neurons. Thus, SP release by capsaicin stimulation (3.3×10^{-5}M) was also assessed in nV, NTS and hypothalamic slices. In the presence of calcium, capsaicin increased SP release (200%) from the nV and the NTS slices but not from the hypothalamic slices. Incubation with capsaicin in the absence of calcium (1 mM EGTA) produced no increase in SP release.

The ability of K+ and capsaicin to release SP from the nV and NTS supports the hypothesis that SP is a neurotransmitter in afferent nerves projecting to these two medullary regions.

212.3 RELEASE OF BOMBESIN-LIKE PEPTIDES FROM RAT HYPOTHALIMIC AND SPINAL CORD SLICES. Terry W. Moody[1], Nguyen B. Thoa*[2], Thomas L. O'Donohue*[3] and David M. Jacobowitz[3]. [1]Dept. Biochemistry, George Washington Univ. Sch. Med., Washington D.C. 20037, [2]Dept. Anesthiology, Uniformed Services Univ. Sch. Med., Bethesda, MD 20014 and [3]Lab. Clin. Sci., NIMH, Bethesda, MD 20205.

Bombesin, a tetradecapeptide isolated from frog skin, is active in the gastrointestinal tract and brain. Upon central administration bombesin induces hyperglycemia, hypothermia and analgesia with a well defined structure activity relationship, similar to that required for receptor binding.

An extensive network of nerves containing bombesin-like peptides has been identified using an antibody which recognizes the C-terminal of bombesin. High levels of bombesin-like immunoreactivity are present in certain hypothalamic, midbrain and hindbrain nuclei. Because these peptides are localized to synaptosomes they may be important neurotransmitters.

Here the release of bombesin-like peptides from rat hypothalamic and spinal cord slices was investigated. 75 mM KCl and 100 µM veratridine released bombesin-like peptides in a Ca^{++}-dependent manner from both hypothalamic and spinal cord slices. Those peptides released by veratridine in a Ca^{++}-dependent manner were blocked by 1 µM tetrodotoxin. The ability of morphine and capsaicin to stimulate release or inhibit KCl-induced release from hypothalamic and spinal cord slices was determined. Also, the released peptides were characterized using high pressure liquid chromatography techniques. Because various depolarizing stimuli release bombesin-like peptides in a Ca^{++}-dependent manner, these peptides may function as physiologically important neuroregulators.

212.4 ANGIOTENSIN INDUCED PHASIC FIRING OF SPINAL CORD NEURONS IN CULTURE. M. Ian Phillips, Phillip G. Nelson, Elaine Neal and James Quinlan*, Lab. Devel. Neurobiol., NICHD, NIH, Bethesda, MD 20205, and Dept. Physiology, Univ. Iowa, Iowa City, IA 52242.

Angiotensin II (AII) has excitatory effects on neurons in the brain and produces drinking behavior, vasopressin release and blood pressure increase. AII-like immunoreactivity has been found in the brain by immunocytochemistry. AII has also been found in the spinal cord in the substantia gelatinosa by the indirect fluorescence technique. Little is known, however, about the physiological action of AII in the spinal cord. We have investigated the electrophysiological action of AII on spinal cord cells grown in culture. Fetal mouse spinal cord (SC) and dorsal root ganglion (DRG) neurons were grown in dissociated cells cultured for 4-6 weeks (Ransom et al., J. Physiol. 40:1132, 1977).

To show the presence of AII in SC neurons, cultures were fixed in Bouin's fixative and reacted with a primary antiserum against AII. Controls were preabsorbed with antigen. The PAP technique of Sternberger revealed several neurons that stained darkly after appropriate tests with antiserum. The cells were possibly SC neurons and not DRG because of their stellate appearance. Intense staining was seen on the varicosities of neuroprocesses which reached and appeared to contact nonreactive soma. This demonstrated the presence of an AII-like substance in SC cells with possible synaptic contact on other cells in culture.

Intracellular recording was made with 4M K+ acetate (pH 7.6) filled pipettes with resistances of 20-60 MOhms. The cells were maintained in a 6 mM Ca++/6 mM Mg++ medium. AII (10^{-6} M) and saralasin (10^{-5} M) were ejected from separate pressure ejection pipettes. Control ejections were Ca++/Mg++ (6:6) medium. Glutamate (0.5 M) was iontophoresed onto the cell.

Two actions of AII were observed. First, a hyperpolarization of -3 to -18 mV with a duration outlasting the stimulus was seen in 10 out of 16 cells. Second, upon recovery from the hyperpolarization, cells which had only random firing patterns prior to testing became phasic with repeated bursts of spontaneous activity lasting for several seconds after stimulation. Glutamate produced single action potentials or excitation that lasted for the duration of the stimulus. Saralasin and controls tended to produce a hyperpolarization but without inducing phasic firing.

The mechanism of the phasic firing remains to be investigated. The results show a) that SC neurons contain an AII-like peptide and b) the random neuronal firing patterns of neurons can be profoundly altered by a peptide. This points to a different action between neurotransmitters and neuropeptides on neuronal membranes.

212.5 THE REGIONAL ACCUMULATION OF CORTICOTROPIN AND α-MELANOTROPIN IN THE MATURING BRAIN. A. Barnea, G. Cho*, and J.C. Porter. Depts. of Ob-Gyn and Physiology, Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

The current view is that in the brain ACTH is the precursor of α-MSH, and that both peptides are synthesized and stored within the same neurons. Moreover, the perikarya of these neurons are localized primarily in the arcuate nuclei, whereas the axons of these perikarya are distributed in many regions of the brain. We have previously demonstrated that the content of immunoreactive-like (IL) α-MSH in the rat hypothalamus increases progessively during the first 5-6 months of postnatal life. This increase may be a consequence of increased biosynthesis of the precursors of α-MSH and/or a consequence of increased conversion of ACTH to α-MSH. To address these issues, α-MSH-IL and ACTH-IL were quantified in extracts of the medial basal hypothalamus (a region known to contain the perikarya of the ACTH/ α-MSH neurons) and the preoptic anterior hypothalamus (a region known to contain axons of these neurons). Acetic acid extracts were prepared from brain tissue from young male rats (10-21 days of age) and from adult male rats (90-100 days of age). In the medial basal hypothalamus, the concentration (mol/mg protein) of α-MSH-IL as well as that of ACTH-IL increased with age, but the increase occurred in a manner that the molar ratio of α-MSH-IL to ACTH-IL remained constant at about 2.5 regardless of the age of the animals. In the preoptic anterior hypothalamus, the concentration of α-MSH-IL and ACTH-IL also increased with age, but this increase occurred disproportionately in favor of α-MSH-IL. The disproportionate accumulation of α-MSH-IL in this region of the brain was reflected in the molar ratio of α-MSH-IL to ACTH-IL: being 10 in the adult animal compared to 4 in the young animal. The increase in the concentration of both α-MSH-IL and ACTH-IL with age, noted in the region of the brain containing the perikarya of the ACTH/α-MSH neurons (the medial basal hypothalamus) and in the region of the brain containing only axons of these neurons (the preoptic anterior hypothalamus), is consistent with the possibility that the biosynthesis of the precursors of α-MSH increases with age. The preferential accumulation of α-MSH-IL relative to ACTH-IL that occurs between 21 and 90 days of age in the axons of the ACTH/α-MSH neurons can be a consequence of an increased rate of cleavage of ACTH to form α-MSH. Alternatively, this preferential accumulation of α-MSH-IL could be a result of the formation of new axons or axonal processes that contain mostly α-MSH.

212.6 ONTOGENETIC STUDIES ON THE CELLULAR LOCALIZATION OF TRH IN THE RAT CEREBELLUM. Mauro F. Pacheco, Elizabeth N. Crom* and W. Sue T. Griffin. Dept. of Cell Biology, Univ. of Texas Health Science Center at Dallas, Dallas, Texas 75235.

We have previously postulated a physiological role for TRH in the cerebellum based on studies showing: 1) heterogeneous distribution of endogenous TRH in this organ; 2) parafloccular and flocculo-nodular TRH content more highly concentrated than in the hypothalamus; 3) TRH-immunoreactive neuronal elements in the cerebellar cortex and deep cerebellar nuclei; and 4) the uptake of labeled-TRH by rat cerebellar slices by a process sharing many of the properties of an active transport system. The current work was done to investigate the localization of TRH-containing elements at early developmental stages of the cerebellum. Immunohistochemical localization of endogenous TRH was performed by the indirect immunofluorescent technique in fresh frozen coronal sections from the cerebella of 14-day old rat puppies. Immunofluorescent micrographs of these sections showed three distinctive populations of TRH-immunoreactive neuronal elements in the erebellar cortex. The first group was one of rounded cell bodies lacking neuronal processes and located in the external granular layer. The second population was composed of cells located mainly at the level of the Purkinje cell layer, this cells projected long processes which extended along the molecular layer up to the external granular layer. The third group consisted of cells forming a network in the region of the internal granular layer adjacent to the Purkinje cell layer. This latter population of TRH-immunoreactive neurons closely resembles that found in the cerebellar cortex of adult rats. No TRH-immunoreactivity was found on Purkinje cells, nor on cells of the deep regions of the internal granular layer. These observations suggest that cerebellar TRH is synthesized by cellular elements located within the cerebellum and, therefore, is not of hypothalamic origin. Further developmental and histological analysis is needed to clarify the origin and identity of these peptidergic neuronal elements.

212.7 CHOLECYSTOKININ DISTRIBUTION IN THE HIPPOCAMPAL FORMATION AND ITS CONNECTIONS. R.S. Greenwood*, S.E. Godar*, T.A. Reaves, Jr. and J.N. Hayward. Dept. Neurology & Neurobiology Program, University of North Carolina, Chapel Hill, North Carolina 27514.

Cholecystokinin-like (CCK-L) immunoreactivity has been detected in the hippocampal formation in all previous immunocytochemical and radioimmunochemical studies of this structure. This study was undertaken to delineate the distribution of CCK-L immunoreactivity in the hippocampal formation, in afferent or efferent hippocampal pathways and in structures receiving axons from or sending axons to the hippocampus.

A well characterized antibody, specific for the COOH-terminal octapeptide common to CCK and gastrin (AB 4562**, Larsson and Rehfeld, Brain Res. 165:201-218,1979) was used with the indirect immunoperoxidase method to localize CCK-L immunoreactivity in neuronal somata and processes in brain sections from colchicine treated rats.

In Ammon's horn, cell bodies were found in regio inferior and regio superior in all layers at all levels of its septo-temporal axis. Cells in the pyramidal layer were most numerous at or near the junction of regio inferior and regio superior. The fewest cell bodies were found in regio inferior at its dentate end. Cell bodies were also found in the dentate, subiculum, presubiculum, parasubiculum and entorhinal cortex. Processes in the hippocampal formation were most prominent in the subiculum and around pyramidal cells in regio superior and regio inferior.

Fibers were also found in the alveus, ventrolateral fimbria, ventral hippocampal commissure and dorsal hippocampal commissure. CCK-L immunoreactive fibers were numerous in many regions receiving hippocampal efferents, including cingulate and perirhinal cortex, ventrolateral portion of lateral septal nucleus, anterior olfactory nucleus, ventromedial hypothalamic nucleus, nucleus accumbens and the bed nucleus of the stria terminalis. Occasional fibers were also observed in the mammillary complex, septofimbrial nucleus, suprachiasmatic nucleus and ventral premammillary nucleus.

Among regions sending axons to the hippocampal formation, dense populations of CCK-L immunoreactive cell bodies were restricted to the cortical nucleus of the amygdala and the prepyriform, the medial frontal and the cingulate cortex. The supramammillary region, the basolateral nucleus of the amygdala and the frontal and temporal cortex each contain sparse populations of CCK-L immunoreactive cell bodies.

These observations suggest that CCK-L immunoreactivity is present in both intrinsic and extrinsic hippocampal formation pathways. (Supported, in part, by Grant No. NS-13411 from USPHS; ** the CCK-L antiserum a generous gift from Prof. Jens Rehfeld.)

212.8 CHOLECYSTOKININ EXCITES DORSAL HORN INTERNEURONS BOTH IN SITU AND IN VITRO. S. Jeftinija*, V. Miletic and M. Randic (SPON: W. G. VanMeter). Dept. of Vet. Physiology & Pharmacology, Iowa State University, Ames, IA 50011.

Immunohistochemical studies have demonstrated the presence of high densities of cholecystokinin octapeptide (CCK-8)-positive fibers in the superficial layers of the dorsal horn of the guinea pig spinal cord. This area is known to contain neurons involved in mechano-, thermo-, and nociceptive information processing. Since the physiological role of CCK-8 in the spinal cord is at present unknown, it was of interest to study the central effects of synthetic CCK-8 (0.8-4.0 mM, pH 7.2; Boehringer Mannheim) by applying the peptide iontophoretically onto dorsal horn interneurons.

In cat spinal cord in situ and in the rat spinal cord slice preparation, CCK-8 caused a moderate excitation of about half of the tested dorsal horn interneurons in laminae I-VI (27/51). Excitation was observed as initiation of firing in a previously quiescent unit, or as an increase in the rate of spontaneous and/or evoked firing. The excitant response to CCK-8 was relatively slow in onset and recovery. The experiments performed in situ showed CCK-8 to possess an excitatory action in all categories of neurons recognized in spinal preparations of cats in this area on the basis of their excitability to different kinds of afferent input. The excitatory effect of CCK-8 remained if the spinal cord slices were perfused with a low-Ca^{++} Krebs solution. This finding indicates that the peptide is probably acting on postsynaptic sites.

These results indicate that CCK-8 should also be added to the ever growing list of peptides having possible roles as transmitters or modulators at synapses in the dorsal horn of the spinal cord.

212.9 PHARMACOLOGICAL CHARACTERIZATION OF RECIPROCAL HINDLIMB SCRATCHING INDUCED BY INTRACRANIAL SUBSTANCE P. P.J.K.Dobry, M.F. Piercey and L.A.Schroeder*. The Upjohn Company, CNS Research, Kalamazoo, MI 49001.

Male CF-1 mice were injected intracranially (i.c.) with 2 µl drug in saline, given approximately at the midline with a 3.5-mm needle, just anterior to the level of the external auditory meatus. Intracranial substance P (SP) induced the reciprocal hindlimb scratching (RHS) syndrome of Rackham and Share (1979, Neurosci. Abs. 5:615) with an ED50 of 0.03 µg. The C-terminal decapeptide and hexapeptide fragments also induced RHS, but the C-terminal pentapeptide caused no scratching at all. N-terminal fragments (SP 1-10 amide, SP 1-9 amide, SP 1-8 amide) at doses up to 10 µg i.c. induced only one-sided scratching similar to the effect of very low doses of SP. Thus the SP receptor for scratching is similar to that of spinal cord dorsal horn (Piercey and Einspahr, 1980, Brain Res. 187:481-486). SP did not produce scratching when given intravenously (i.v.) or intraperitoneally (i.p.) at doses up to 50 mg/kg. We conclude that peripherally-administered SP does not reach the receptor for RHS.

We confirmed that i.p. morphine (AD50 = 6 mg/kg) antagonized the RHS induced by 0.3 µg i.c. SP, as did i.c. morphine (0.3 µg). However, RHS was also antagonized by a variety of other compounds which can alter motor behavior, amphetamine (4 mg/kg i.p.), baclofen (3 mg/kg), chlorpromazine (5 mg/kg), and cyproheptadine (10 mg/kg). SP's RHS was not antagonized by i.v. sodium cromolyn, nor mimicked by i.v. or i.c. histamine or i.v. Compound 48/80. We conclude that RHS is not caused by histamine release.

Intracranial somatostatin (ED50 = 0.1 µg) induced a weaker, slower onset, one-sided scratching which was indistinguishable from the effect of very low doses of SP. Intravenous somatostatin caused one-sided scratching and was at least as potent as intracranial somatostatin. Thus its site of action may be distant from the i.c. injection site. Morphine (7 mg/kg i.p.) antagonized scratching behavior induced by 1 µg i.c. somatostatin. Thus, consistent with the report that morphine is not an SP receptor antagonist at the SP receptor (Piercey, Einspahr, Dobry, Schroeder and Hollister, 1980, Brain Res. 186:421-434), morphine's effects on RHS seem due to nonspecific disruption of scratching rather than action at the SP receptor.

Intracranial or i.p. kainic acid also causes some weak, one-sided scratching. Intracranial acetylcholine, atropine, bradykinin, DOPA, glutamic acid, histamine, morphine, neurotensin, norepinephrine, and serotonin did not produce scratching.

212.10 CO-EXISTENCE OF DOPAMINE AND CHOLECYSTOKININ (CCK) IN A POPULATION OF MESOLIMBIC NEURONS: IMMUNOHISTOCHEMICAL AND ELECTROPHYSIOLOGICAL STUDIES. B.S. Bunney, L.R. Skirboll+, A.A. Grace, D.W. Hommer+, J. Rehfeld+, M. Bodansky+, M. Goldstein and T. Hökfelt+. Depts. of Pharmacology and Psychiatry, Yale Univ. Schl. Med., New Haven, CT 06510; Dept. of Histology, Karolinska Institute, Stockholm 60 Sweden.

In the past several years, extensive gastrin/CCK immunoreactive systems have been identified in mammalian brain. This immunoreactivity has been shown to correspond mainly with the COOH-terminal octapeptide of CCK. In a more detailed examination of CCK immunoreactivity in rat brain, we found a subpopulation of neurons confined to the ventral tegmental area (A10) of rat brain (extending into the zona compacta and pars lateralis of substantia nigra A9)which show immunoreactivity to both CCK and tyrosine hydroxylase (a marker for dopamine neurons.) These A10 neurons appear to project to limbic areas such as nucleus accumbens, tuberculum olfactorium and the bed nucleus of the stria terminalis where overlapping networks are found. This CCK/dopamine projection was confirmed further using retrograde tracing techniques. Following "True blue" injection into the nucleus accumbens, cells were visualized in A10 which contained retrograde dye as well as showed immunoreacitivity to both CCK and tyrosine hydroxylase antibodies. In an effort to explore the functional significance of this peptide/monoamine co-existence, the effects of CCK-7 on single unit activity in area A9 and A10 of rat brain were examined. Recordings were made from cells whose characteristics in terms of waveform, firing pattern and rate matched those identified as dopaminergic. In the A9 area, CCK-7 (4-100 ug/kg iv) increased firing rate and induced bursting patterns of activity in the majority of cells tested; these same effects were observed in most of the cells to which CCK-7 was applied iontophoretically. In the A10 area, ionotphoretic application of CCK-7 produced an increase in rate and bursting similar to that seen in A9. Histological confirmation of A9 and A10 recording sites revealed that the cells which failed to respond to i.v. or iontophoretic CCK-7 were located in areas which show no immunoreactivity to CCK. In control experiments, equivalent currents ejected from the balance channel containing 4M NaCl or Substance P were ineffective in altering firing rates or patterns in either area. The possible functional role of CCK in the modulation of dopaminergic neuron activity will be discussed.

212.11 EFFECT OF NEUROPEPTIDES ON CALMODULIN-INDUCED ACTIVATION OF PHOSPHODIESTERASE. Mary Sellinger Barnette* and Benjamin Weiss, Dept. of Pharmacol., Med. Col. of Pa., Phila., Pa. 19129.

The activity of a calcium-dependent form of phosphodiesterase (Peak II), which is present in high concentrations in the brain, can be increased 10-fold by the calcium binding protein, calmodulin. This activation is selectively inhibited by several different chemical classes of antipsychotic drugs. The mechanism by which antipsychotics block calmodulin's activity is through the direct calcium-dependent binding of the drug to calmodulin. The recent finding that there are endogenous proteins that can bind to, and thereby modify the actions of, calmodulin, and the evidence that certain neuropeptides produce behavioral effects in animals similar to those of antipsychotics suggested that there may be neuropeptides in brain that can interact with calmodulin. Accordingly, we have examined the effects of various neuropeptides on the calmodulin-induced increase in phosphodiesterase activity. An activatable Peak II phosphodiesterase was prepared from rat caudate nucleus by gel electrophoresis and was assayed by the luciferin-luciferase technique. Calmodulin was purified to homogeneity from beef brain. At concentrations up to 25 µM, the peptides ACTH (4-10), bombesin, des tyr γ-endorphin, δ-sleep inducing factor, leu-enkephalin, met-enkephalin, α-MSH, β-MSH, neurotensin, somatostatin, and substance P failed to inhibit either the basal phosphodiesterase activity or the calmodulin-induced activation of phosphodiesterase. By contrast, ACTH (beef brain), β-endorphin and lysine enriched histone blocked completely the calmodulin-induced activation of phosphodiesterase at concentrations that had virtually no effect on the basal activity; the approximate I_{50} values were 2 I.U/ml, 3 µM and 2 µM, respectively. The potency of histone and β-endorphin in blocking the calmodulin-induced activation of phosphodiesterase is similar to or greater than that of currently available phenothiazine antipsychotics. Although we have not as yet examined a sufficient number of peptides to make any definitive statement regarding the biological significance of the binding of peptides to calmodulin, these results suggest that neuropeptides such as β-endorphin may act as endogenous modulators of calmodulin and raise the possibility that they may function as endogenous antipsychotic materials. Supported by USPHS Grant MH30096.

212.12 NEUROTENSIN (NT) IN THE RAT CENTRAL NERVOUS SYSTEM. J. Koenig*, W.K. Samson* and L. Krulich* (SPON: A. Rupert). Dept. of Physiol., Univ. of Tx. Hlth. Sci. Ctr., Dallas, Texas 75235.

The tridecapeptide NT isolated by Carraway and Leeman (J.B.C. 248: 6854, 1973) from hypothalamic extracts has profound effects on thermoregulation and hormone release from the anterior pituitary. This work describes a new NT RIA and examines the identity of the NT found in the rat hypothalamus. Male New Zealand white rabbits were immunized with synthetic NT conjugated to bovine thyroglobulin by glutaraldehyde. Each animal received the equivalent of one mg of NT initially followed by decreasing monthly amounts. After 4 immunizations, antiserum with a titer of 1:50000 bound 60% of the ^{125}I-NT which was added. This antiserum has a sensitivity of 2.5 pg/tube with 50% binding occurring at 38 pg/tube. This antiserum shows no cross-reaction to LRH, TRH, somatostatin, substance P, met-enkephalin, gastrin, CCK, secretin and bombesin in concentrations of 10 µg/ml. Brain areas were removed by gross dissection and homogenized in 1.0 ml of 0.2 N acetic acid. Extracted protein (P) was determined by the Folin method. For comparison, LRH content was measured by specific RIA. Within the CNS, highest levels of NT (2.31±0.48 pg/µg P, n=5) and LRH (2.89±0.7 pg/µg P, n=5) were detected in the hypothalamus. The midbrain and thalamus contained high levels of NT (1.03±0.15 pg/µg P, n=6 and 0.89±0.08 pg/µg P, n=5) and lower, but readily detectable, levels of LRH. Levels of immunoreactive NT in brain stem, cerebral cortex, cerebellum, anterior and posterior pituitary ranged from 0.24±0.03 pg/µg P in the brain stem to 0.03±0.008 pg/µg P in the cerebellum. NT was not detected in the pineal. LRH in these areas was also below the limit of sensitivity (<2 pg/area). The nature of the material within the preoptic area (POA) and median eminence (ME) that reacts with NT antiserum was examined chromatographically. ME and POA areas were removed from the brains of 18 adult male rats and homogenized in 0.2 N acetic acid. Supernatants were applied to a 0.9x96 cm Sephadex G-25 column equilibrated with 0.2 N acetic acid. Under these conditions, NT from the ME and POA coeluted with synthetic NT, implying that endogenous NT in the POA and ME is chromatographically and immunologically similar to synthetic NT. These findings indicate that: 1) the antibody directed toward synthetic NT detects endogenous levels of NT within the CNS, 2) this NT distribution is heterogeneous within the rat CNS, 3) the endogenous immunoreactive NT in the POA and ME is chromatographically similar to the tridecapeptide. Supported by NIH HD-09988 and AM-10073.

212.13 ANALGESIC EFFECTS OF NON-OPIATE PROOPIOCORTIN FRAGMENTS. J. M. Walker*, H. Akil and S. J. Watson. Mental Health Research Institute, Univ. of Mich., Ann Arbor, MI 48109.

β-endorphin apparently arises from a 31K dalton glycoprotein termed proopiocortin, present both in brain and pituitary. This remarkable precursor also contains the sequences of ACTH 1-39, β-lipotropin, and an unstudied 16K dalton polypeptide which itself may contain other biologically active fragments. Since several putative products of this hormone are transported and packaged in a manner consistent with release from terminals, it seems likely that this set of neurons is releasing more than one neuromodulator. Virtually nothing is known about the physiology of neurons with multiple transmitters. Here we address the core issue of whether the effects of two presumed release products, α-MSH and β-endorphin, produce similar effects. The analgesic effects of β-endorphin have been well characterized. Consequently, several substances containing the core sequence of ACTH 4-10 were injected into the periaqueductal grey and the presence or absence of analgesia was observed.

A total of 34 rats were implanted with chronic indwelling cannulae in the periaqueductal grey, under deep anesthesia, using standard stereotaxic methods. Following recovery, these rats were injected with one or more doses of one of the following: ORG 2766 (an analogue of ACTH 4-9), ACTH 1-24, α-MSH and Des(acetyl)-α-MSH, or the vehicle. The tail flick test was used to measure analgesia.

Results indicated that all substances produced a statistically significant degree of analgesia. In all cases, analysis of variance was used to analyze the data. The enzymatically stable analog, ORG 2766, was considerably more potent than the other substances, though all produced analgesia at concentrations in the range needed for morphine analgesia (for ORG 2766 $P < .0001$, ACTH 1-24 $P < .05$, α-MSH $P < .001$, Des(ac)-α-MSH $P < .001$).

Thus, it was concluded that the same neurons may be producing at least two substances with analgesic potency. Moreover, it might be that these compounds are acting synergistically at the postsynaptic sites. Previous data suggest a role for β-endorphin in the modulation of pain sensitivity. α-MSH may have a similar role.

212.14 PRESENCE OF VASOACTIVE INTESTINAL PEPTIDE (VIP) SENSITIVE ADENYLATE CYCLASE IN RETINA AND COMPARISON WITH ACTIVITY IN BRAIN REGIONS Margaret A. Longshore* and Maynard H. Makman* (SPON: R. Katzman). Departments of Biochemistry and Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, N.Y. 10461.

Vasoactive intestinal peptide (VIP) is an octacosapeptide originally isolated from small intestine, and it has been shown to be selectively distributed in nerve terminals in the gastrointestinal tract and central nervous system (CNS). VIP action appears to involve stimulation of adenylate cyclase (AC) activity. The current study was designed to examine the distribution of VIP sensitive AC within the CNS. We report here the presence of VIP stimulated AC in mammalian retina, a stimulation comparable in magnitude to that found in several brain regions. Also this stimulation in retina is comparable to that of dopamine, the only other transmitter, previously known to activate retinal AC.

Fresh bovine and rabbit retinas and rat brain regions were homogenized and incubated 30 min on ice in the presence of VIP, followed by AC assay as previously described (Brain Res., 153:636, 1978). Conditions for incubation of retinal homogenates were also as described (J. Neurochem., 21:477, 1973). The table below indicates that VIP (10 μM) stimulates AC in bovine and rabbit retina and in selected rat brain regions.

Area	-Gpp(NH)p	% increase	1 μM +Gpp(NH)p	% increase
retina, bovine	62.7 ± 12.1	146	-	-
retina, rabbit	329.1 ± 88.6	466	134.1 ± 44.0	91
frontal cortex, rat	29.6 ± 3.5	111	42.2 ± 2.6	136
striatum, rat	14.6 ± 28.6	8	17.8 ± 4.6	50
hippocampus, rat	5.2 ± 17.9	120	29.2 ± 3.9	142
dentate, rat	113.0 ± 4.2	172	96.4 ± 7.2	772
cerebellum, rat	25.8 ± 16.3	76	19.9 ± 17.8	51

Values represent the amount of cAMP formed in pmoles/mg protein/2.5 min ± SE minus the basal cAMP level/(N=2-7).

There is a large amount of VIP-sensitive AC activity in the rabbit retina which does not appear to be enhanced by guanine nucleotides. Preliminary experiments indicate that glucagon and secretin also cause a small stimulation of AC activity in rabbit retina. In rat brain the largest amount of VIP-sensitive AC activity appears to be in the dentate gyrus and frontal cortex with smaller amounts in the striatum, hippocampus and cerebellum. A significant AC stimulation also occurs with 1 μM VIP in retina and brain.

The present study suggests the presence of a VIP-sensitive AC in mammalian retina and in discrete brain areas. While little is known of the specific function of VIP in the CNS, it seems likely that VIP may play a neuromodulatory role in retina as well as in certain other CNS areas.

Supported by NIH grants MH 15788, NS 09649 and AG 01400.

212.15 SPECIFIC AMINOTRIPEPTIDASE OF RAT BRAIN. L. Sachs* and Neville Marks. Center for Neurochemistry, Rockland Research Institute, Wards Island, N.Y., N.Y. 10035.

Previously it was shown that rat or pig brain contains a puromycin insensitive aminopeptidase cleaving tripeptides more readily than di-, or oligopeptides but it was never established if a specific aminotripeptidase existed per se. Importance is attached to this question since brain or neurosecretory regions contains number of bioactive tripeptides, or ones that can be derived from putative tripeptide precursors (MIF, TRH). For this study, enzyme was purified from rat cytosol fractions by the procedure of Marks et al (1968) (J.Biol.Chem.243, 2882) with modifications using Leu-Gly-Gly as substrate and detecting cleavage by an automated ninhydrin procedure. Preparations were enriched several hundred fold and were utilised for studies on specificity only when it could be demonstrated that they were devoid of activity towards a range of dipeptides, or a variety of oligopeptides (enkephalin, kinins, angiotensins etc). The specificity was examined using over 30 tripeptides including examples with N- and C-terminal substitutions such as D-amino acids or C-terminal amides or esters. Results showed that aminoacylated analogs of glycylglycyl were among the best substrates; when Leu or Ala were N-terminal, rates were highest (100) followed in descending order by Phe (80), Gly (40) and Pro (35). Presence of N-terminal basic residues, or D-amino acids, or α-Glu, or γ-Glu, or presence of Pro in the second position greatly reduced or blocked hydroiysis by brain enzyme. Enzyme failed to hydroiyse a number of tripeptidyl amides including melanostatin (MIF, Pro-Leu-Gly.NH_2).

Purified enzyme was inhibited by paramericuribenzoate, Zn^{2+}, bestatin, antipain, SQ 14,225 (captopril) and benzothonium chloride. It exhibited a pH optima of 7.6 and had an approx. mol. wt of 78 kilodaltons. The role of a specific aminotripeptidase in the CNS is unclear but may be related to the metabolism of tripeptides generated as a result of protein or polypeptide breakdown, or released by specific aminopeptidase present in pituitary known to release N-terminal tripeptides from growth hormone (Doebber et al., Endocrinology, 103, 1794, 1978). Tripeptides have a number of biological roles that include ones with chemotactic actions, some that have inhibitory properties on spinal motoneurons, in addition to the well known tripeptides with endocrinological actions.

212.16 EFFECTS OF STRESS ON α-MSH CONCENTRATIONS IN DISCRETE REGIONS OF THE RAT BRAIN. Tichomir Torda*, Thomas L. O'Donohue*, Juan M. Saavedra and David M. Jacobowitz. (SPON: V. John Massari) Laboratory of Clinical Science, NIMH, Bethesda, Md. 20205

An α-MSH (α-melanocyte stimulating hormone) neuronal system has been identified in the rat, cat and human brain. Neurons containing α-MSH appear to emanate primarily from perikarya in the arcuate nucleus and project extensively throughout the forebrain, midbrain and hindbrain. At present, very little is known of the physiological role of this neuropeptidergic system. The only extraneuronal site known to synthesize α-MSH is the pituitary gland where the intermediate lobe synthesizes most of the α-MSH. The fact that the pituitary α-MSH system is influenced by stress (Kastin et al., 1967; Usategui et al., 1976) suggested that the brain α-MSH system might also be involved in the stress reaction and that this involvement may result in changes in α-MSH concentrations in discrete brain regions in stressed rats.

Forced immobilization, a major stress in rats, was accomplished by placing rats in a prone position with heads inserted through steel wire restraining loops fixed on a stainless steel plate and fastening their limbs to four raised metal strips with adhesive tape. The stress procedure was performed acutely, for 2 1/2 hours per day for one or seven consecutive days. Rats were sacrificed immediately after the final stress.

A single immobilization stress resulted in a 40-60% decrease in α-MSH concentrations in the brain regions studied: the medial preoptic nucleus, anterior hypothalamic nucleus, paraventricular nucleus, periventricular nucleus of the thalamus, median eminence, arcuate nucleus and dorsomedial nucleus. This data suggests that stress increased α-MSH release. In contrast, repeatedly immobilized rats had no significant changes in brain α-MSH concentrations suggesting a time or experience related form of neural adaptation. Pituitary α-MSH decreased only slightly after a single but not repeated immobilizations. Previous behavioral studies indicate that α-MSH administration facilitates performance of a number of adaptive behaviors. The increased α-MSH release in stress may reflect a role of that α-MSH neural system in such processes.

212.17 RESPONSE OF IDENTIFIED MOLLUSCAN NEURONS TO α-MELANOTROPIN AND LYSINE VASOPRESSIN. W. Lichtensteiger, D. Felix* and M. Celio*, Insts. of Pharmacol., Brain Research and Anat., Univ. Zürich, Zürich, Switzerland.

Interactions between small molecular weight neurotransmitters and peptides have been studied at the level of individual identified neurons in an in vitro preparation of the c.n.s. of the snail Planorbis corneus. The studies focussed on the circuitry of the giant dopamine neuron (GDN) of the left pedal ganglion.

Results of immunohistochemical studies suggest that the snail c.n.s. contains peptides related to those of vertebrates. α-Melanotropin (α-MSH)-like immunoreactivity was observed in a number of nerve cells and in nerve fibers in several ganglia. Although the connections of this supposedly peptidergic system have not yet been elucidated, we have checked whether α-MSH might interfere with transmission to the GDN. Several neurons afferent to GDN have been identified by electrophysiology. One excitatory input from a cell in the same ganglion is blocked by dihydro-β-erythroidine administered to the bath and hence, probably mediated through a nicotinic mechanism. The existence of a nicotinic excitatory input to GDN (indicated by our earlier data) has further been confirmed by iontophoresis. α-MSH applied to the GDN by iontophoresis prevented the increase in firing and reduction of membrane resistance induced by iontophoretic acetylcholine (Ach); this effect was reversible. A similar interaction was also seen in other neurons. Resting membrane resistance (checked by injection of hyperpolarizing current) appeared to remain unchanged.

Lysine vasopressin (LVP) which was previously found to affect membrane resistance of GDN (Lichtensteiger and Felix, Neurosci. Abst. Vol. 5, 532, 1979), was also capable of modulating the effect of Ach on GDN. When both substances were given by iontophoresis, the activation of GDN by Ach was enhanced by LVP. The possible occurrence of a related peptide in the snail is presently being investigated by immunohistochemistry.

In conclusion, our data suggest that peptides with structural similarities to the pro-opiocortin family and possibly also to vasopressin may be active in the snail c.n.s..

212.18 ACTIVATION OF PEPTIDERGIC NEURONS ENHANCES THEIR SYNTHESIS OF SECRETORY PROTEINS. R.W.Berry and S.Arch. Dept. Anat. Northwestern Med.Sch., Chicago, IL 60611, and Biol.Dept., Reed College, Portland, OR 97202.

Faced with the necessity of maintaining an adequate supply of their secretory products despite fluctuations in secretory rate, peptidergic neurons may have developed a mechanism for regulating synthesis in accord with demand. We have investigated this possibility using the neurosecretory bag cells of Aplysia, which produce and secrete a peptide egg-laying hormone, ELH. ELH and the larger precursors from which it is derived are readily separated from other bag cell proteins by SDS-PAGE, and bag cell activation with consequent ELH secretion is known to follow exposure to elevated external K^+ solutions. Therefore, to determine whether an augmentation of secretory protein synthesis follows massive activation of these cells, we exposed bag cell organs to elevated external K^+ (100mM) for 4 hr, then measured the incorporation of tritiated leucine into ELH precursors over a 2 hr period. The experimental treatment resulted in a 28% increase in ELH precursor labeling, and this persisted for at least 8 hr following the stimulus, resulting in a total increase of 150% over this period. The experimental treatment had no effect on the rate of loss of label from previously-synthesized ELH precursors, indicating that the enhanced labeling reflects an enhancement of synthesis of these peptides, rather than a decrease in their turnover rate. Elevated external K^+ does not enhance ELH synthesis in clusters of bag cell somata which have been surgically isolated from their neurites, indicating that the augmentation of synthesis is not mediated by direct effects of the high K^+, such as membrane depolarization or alterations in internal ionic concentrations. This experiment also suggests that the enhancement of synthesis is mediated by a secretory process, since the clusters are largely isolated from sites of presynaptic input and ELH secretion. A secretion-linked mechanism is also indicated by the fact that low Ca^{++}/high Mg^{++} media block the effect of high K^+ on ELH synthesis.

Therefore, it appears that these peptidergic cells do respond to activation by increasing their synthesis of the secretory peptide. This augmentation is rapid in onset, modest in magnitude, but long in duration, as might be expected of neurons which contain a large reservoir of the secretory product. A secretory event appears to trigger this process, but whether this involves the receipt of presynaptic transmitter or the secretion of ELH itself remains to be investigated.

212.19 NEURALLY ACTIVE PEPTIDE, ELH, RELEASES EGGS FROM ISOLATED OVOTESTIS OF APLYSIA. B.S. Rothman, G. Weir* and F.E. Dudek. Dept. Physiol., UCSF, San Francisco, CA 94143 and Erindale College, Univ. of Toronto, Mississagua, Ont. Canada L5L 1C6.

Bag cells, a group of neurosecretory cells located in the abdominal ganglion of A. californica, are one of the command elements controlling egg laying behavior. Egg Laying Hormone (ELH), one of several peptides synthesized and released by bag cells, induces egg laying when injected into sexually mature animals. Recent studies have shown that purified ELH excites identified neurons in the abdominal and buccal ganglia. Presumably these effects code for aspects of egg laying behavior.

We are studying another role of ELH in the coordination of egg laying--the release of eggs from the ovotestis. Recent studies in Dudek's laboratory show that a protease sensitive factor in crude extracts of bag cells release eggs in a concentration dependent manner from isolated ovotestis fragments. Superfusates of electrically stimulated bag cells also had egg releasing activity (ERA), and the release of ERA was Ca^{++} dependent. One important question which remains is whether the active factor is ELH and whether other bag cell peptides have ERA. To help answer this question, we purified ELH by a 2-column procedure (Rothman et al, Nsci Abstr 5:260, '79) and tested all fractions for ERA.

The supernate of a bag cell homogenate was applied to a G50 Sephadex column equilibrated with 0.5 M formic acid, the eluate divided into 8 fractions, and the fractions lyophylized. All fractions were assayed for ERA by the method of Tobe and Dudek (Gen. Comp. Endocrinol. 36:618,'78). One fraction, containing material of ca. 4K-10K mw, had 2.8 ± 0.5 (SE) times more ERA than controls (N=10, $p < 0.01$), while the next most active fraction had only half this activity (N=10, $p < 0.1$).

The active material was further purified by cation exchange chromatography using NH_4Ac as an elutant. The peak of material eluting at 0.1 M salt contained 1.6 ± 0.2 times more ERA than controls or the 8 other column fractions (N=7, $p < 0.05$). This material has an amino acid composition in excellent agreement with that of ELH, and is 85 M% pure based on amino acid analysis and TLC. Fluorescamine analysis showed that ELH was present at a concentration of 3×10^{-8} M in the egg release assay. Preliminary dose-response experiments suggest that the threshold for egg release is 4×10^{-9} M.

These data strongly suggest that ELH is the major component with ERA in bag cell extract, and that it acts directly on the ovotestis. They provide further evidence that ELH is the hormone released by bag cells to induce ovulation. Studies

212.20 THE ORIGIN AND NATURE OF PEPTIDERGIC PROCESSES IN THE BASAL GLIAL LAMINA OF THE RAT SUPRAOPTIC NUCLEUS (SON). W.E. Armstrong and T.H. McNeill. Depts. of Anatomy and Neurology, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

In the present study we sought to determine the origin of peptidergic processes in the basal glial lamina of the SON and were particularly interested in comparing their morphology with dorsally-emerging axons of the neurohypophysial tract. The SON of normal rats was examined in 1) Golgi-Cox preparations; 2) 20-50 um vibratome and 6-10 um paraffin sections stained for neurophysin (NP; anti-NP provided by A. Robinson) or vasopressin (VP; anti-VP provided by E. Zimmerman); and 3) material prepared for routine electron microscopy.

In vibratome sections thin, beaded NP-positive fibers could be seen emerging dorsally from the SON to join the neurohypophysial tract. The ventral NP-positive processes in the glial lamina, however, coursed parallel to the pial surface in both the medial and lateral direction. These processes varied in type from fine, linear profiles to conspicuously large (5-10 um di.) processes with occasional bulbous expansions along their length or at their apparent terminations. None of these processes was seen to join the neurohypophysial tract, nor were any processes of similar shape and size seen to emerge dorsally from the SON. Similar results were found in paraffin sections stained for either NP or VP. In Golgi-Cox material, some 90% of the 75 large (20-30 um di.) SON neurons examined to date possessed at least one ventrally directed dendrite. These dendrites frequently invaded the basal glial lamina where some bifurcated. Bulbous expansions along the course of some of these processes were evident, while other processes tapered distally. Identified axons were not observed projecting ventrally but instead ran dorsally. No clear case of collateral axonal branching was observed. At the ultrastructural level, processes in the lamina characterized as dendrites were sometimes seen to contain large (150-200 nm di.) dense-cored vesicles in varying numbers and were frequently postsynaptic to a variety of presynaptic elements. Further analysis with EM-immunocytochemistry is underway.

The combination of these data allow us to suggest that the ventral NP- and VP-positive processes are SON dendrites, or at least processes different in morphology from fibers of the neurohypophysial tract. The contribution of oxytocin-containing processes to the lamina is as yet unknown. Krisch (Cell Tiss. Res. 197: 95, 1979) has concluded that ventral SON processes secrete VP locally. The presence of synapses upon similar processes may suggest that changes in membrane potential (or Ca^{++} influx?) influencing this release could be induced locally.

212.21 Terbium Fluorescence Studies of Angiotensin II. Robert G. Canada* Laboratory of Neurophysiology, National Institute of Neurological and Communicative Disorders and Stroke, NIH, Bethesda, Md. 20205

Angiotensin II (AII) is a potent pressor and has a variety of biological activities. The activity of AII is selectively enhanced *in vivo* and *in vitro* by Na^{+} and Ca^{2+}. In this study, the fluorescent properties of terbium (Tb^{3+}) were used to detect and monitor the metal-peptide interactions of AII. The emission spectrum of Tb^{3+} was enhanced with the binding of AII, and the excitation maximum of the metal shifted to resemble that of the peptide fluorescence. The Tb^{3+} emission spectrum displayed the characteristic quartet at approximately 488,543, 584 and 619nm. The 290nm/260nm intensity ratio of the excitation spectrum was significantly greater for the AII-Tb^{3+} complex than for the free probe. The Tb^{3+} emission intensity at 543nm linearly increased as a function of Tb^{3+} concentration. The dissociation constant for the AII-Tb^{3+} complex was calculated to be about 7×10^{-3}M. The emission intensity of the AII-Tb^{3+} complex at 543 nm was reduced by 0.03M Ca^{2+}, while Na^{+} at the same concentrations had no significant effect. The data suggests that singlet-singlet energy transfer can occur between the hormone and the metal ion, indicating that the Tb^{3+} binding site is in close proximity of the tyrosine residue of AII, and that the hormone has a greater tendency to bind Ca^{2+} than Na^{+}.

212.22 EFFECTS OF NEUROPEPTIDES ON DORSAL HORN INTERNEURONS IN THE RAT SPINAL CORD SLICE PREPARATION. V. Miletic and M. Randic, Dept. of Vet. Physiology & Pharmacology, Iowa State University, Ames, Iowa 50011.

Extensive use of *in vitro* brain slices has been made lately in studies of synaptic function because of a number of advantages this technique offers over the *in vivo* approach. In order to extend our previous *in situ* studies on synaptic function of neuropeptides in the dorsal horn, we have now successfully employed the *in vitro* rat spinal cord slice preparation and demonstrated that the slices are capable of responding to several neuropeptides in a qualitatively similar manner.

Rats (2-35 days old) were anesthetized with ether and, following a laminectomy, a small segment of the lumbosacral spinal cord was quickly removed and cut, by hand with a razor blade, into transverse 300-800 μm thick slices. The slices were then transferred to the recording chamber where they were held on a fine nylon mesh and continuously perfused with a warm (32±1°C), aerated (95% O_2 & 5% CO_2) Krebs solution at a rate of about 3 ml/min. Following an incubation period of 45-60 min, the dorsal horn interneurons were found to be electrophysiologically intact in that they had normal resting potentials and were capable of generating synaptic and action potentials of appropriate size and duration. The tissue can be maintained in good condition for 6-8 hours. Actions of several neuropeptides, known to be present in high concentrations in the dorsal horn, i.e., substance P (SP), methionine-enkephalin (ME), somatostatin (SS), and angiotensin II (AgII), were then examined by applying the peptides into the perfusion medium or by iontophoresis while recording the activity of dorsal horn interneurons extracellularly.

We found that the responses of the dorsal horn interneurons in the rat spinal slices were essentially identical to those observed in previous studies of the cat spinal cord *in situ*. Thus SP powerfully excited almost all interneurons tested (15/16), while ME and SS depressed neuronal discharges in 13/14 and 4/6 units, respectively. AgII had no effect on any of the tested interneurons (n=8) although it was previously reported to be an excitant of hypothalamic neurons, both *in situ* and *in vitro*. In the spinal cord slices perfused with a low Ca^{++}-high Mg^{++} Krebs solution, the observed peptide effects were not modified, suggesting that the peptides were acting directly on postsynaptic sites. Furthermore, it is of interest that in some dorsal horn interneurons the iontophoretic application of ME caused a marked depression of the SP-induced excitation.

These experiments indicate that the *in vitro* rat spinal cord slice preparation can be successfully utilized for further physiological and pharmacological studies of the role of neuropeptides in synaptic transmission processes in the dorsal horn.

213.1 INTERACTION OF EXOGENOUS AND ENDOGENOUSLY RELEASED ADENOSINE WITH SYNAPTIC ACTIVITY IN RAT HIPPOCAMPUS. Thomas Dunwiddie and Barry Hoffer*. Dept. Pharmacology, Univ. of Colorado Health Sciences Center, Denver, CO 80262.

The physiological role of adenosine and related adenine nucleotides was investigated in the hippocampal slice preparation. Two different protocols indicated an interaction between these agents and excitatory synaptic transmission in the CA1 region. First, perfusion of the slice with adenosine and adenine nucleotides reduced the amplitude of synaptically evoked responses, with an apparent EC_{50} of 5 μM. In a second series of experiments, penicillin-induced interictal spiking was slowed by exogenously applied adenosine ($EC_{50} \sim 10$ μM). Perfusion of slices with adenosine deaminase, which catabolizes extracellular adenosine, had the opposite effect on both types of responses. This suggests that the endogenous release of adenosine in the hippocampus in vitro yields extracellular levels which are sufficient to exert a tonic inhibitory effect upon synaptically mediated synaptic responses.

The interaction of adenosine with various adrenergic agents in the hippocampal slice was also investigated. Both adenosine and norepinephrine increase cyclic AMP levels in brain slices, and combinations of these agents have markedly synergistic effects. However, neither the α-adrenergically mediated depression of hippocampal excitability nor the β-adrenergic augmentation of excitability (Mueller, Hoffer and Dunwiddle, this volume) were in any way affected by concurrent application of adenosine.

Taken together, these data suggest endogenously released adenosine is a potent modulator of hippocampal excitatory transmission. In contrast to biochemical studies, however, there is little electrophysiological evidence for the interaction of exogenously applied adenosine with alpha or beta adrenergic agonists.

(This research was supported by ES 02011 to B.J.H and NS 05962-02 to T.V.D.)

213.2 RELEASE OF ATP FROM "AUTONOMIC SYNAPTOSOMES" PREPARED FROM THE MYENTERIC PLEXUS OF GUINEA-PIG ILEUM. T.D.White* and D. Webb* (SPON:R.Leslie). Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada B3H 4H7.

It has been suggested that ATP might be the non-adrenergic non-cholinergic inhibitory neurotransmitter in the myentericplexus of vertebrate intestinal smooth muscle (Burnstock, G., Pharmacol. Rev.,24:509, 1972). Moreover, ATP may be released as a cotransmitter with biogenic amines and acetylcholine to modulate synaptic function. Recently, Miller et al (J. Neurochem., 32:1387,1979) have prepared and isolated "autonomic synaptosomes" from the longitudinal muscle of guinea pig small intestine. We have prepared a crude synaptosomal fraction (P_2) and purified synaptosomal fractions on sucrose density gradients using a modification of their technique and have investigated the ability of depolarizing agents such as elevated extracellular K^+ and veratridine to release ATP from these "autonomic synaptosomes". Release of ATP was directly and continuously monitored by detecting the light produced when the ATP reacted with firefly luciferin-luciferase present in the medium (White, T.D., J. Neurochem., 30: 329, 1978). Both K^+ and veratridine released ATP from these preparations but only the veratridine-induced release was blocked by TTX, indicating the involvement of Na^+-channels. Release of ATP by elevated K^+ and veratridine was restricted to synaptosomal preparations and did not occur from mitochondrial fractions. Elevated extracellular Rb^+ released ATP in a manner similar to elevated K^+, whereas Na^+ and Li^+ did not. Previous studies have shown that both elevated extracellular K^+ and Rb^+ depolarize nerves whereas Na^+ and Li^+ do not (Feng, T.R. and Liu, Y.M., J. Cell. Comp. Physiol., 34: 33, 1949). These findings suggest that depolarization-induced release of ATP occurs from autonomic as well as from CNS nerve-terminals. The nature and function of this release is under investigation. (Supported by the MRC of Canada).

213.3 LOCALIZATION AND CHARACTERIZATION OF A Ca-Mg-ATPase IN RAT BRAIN. R. G. Sorensen* and H. R. Mahler (SPON: R. S. Gurd). Dept. of Chemistry, Indiana University, Bloomington, IN 47405.

We have recently reported the presence of a Ca-Mg-ATPase in a purified synaptic plasma membrane fraction isolated from rat brain cortex [Soc. for Neurosci. 9th Annual Meeting, Vol. 5, p. 309 (1979)]. Maximum activation of this enzyme occurred at a free Ca^{+2} ion concentration of 3-8 μM and the activity required the presence of millimolar concentrations of Mg^{+2} ions. Its activity was further enhanced in the presence of exogenously added calmodulin. We now extend these findings to include a study of the localization of the Ca-Mg-ATPase within various membrane fractions isolated from rat brain cortex and *corpus striatum* and the characterization of this enzyme with respect to its divalent cation requirements and the effects of various known inhibitors of ATPases.

Ca-Mg-ATPase activity was measured in synaptic plasma membrane (SPM), synaptic junctional complex (SJC); postsynaptic density (PSD); P_3B_2, a postsynaptic membrane fraction devoid of PSD, and PSM, a postsynaptic membrane fraction with attached PSD. Studies on the specific and total activities of the enzyme in these various fractions have permitted its assignment to particular structures within the synaptic junction.

Possible assignments of the functional significance of the enzyme in the junction has been aided by the use of specific and characteristic inhibitors such as vanadate, oxalate and DCCD. (Research supported by Research Grant NS 08309 from the NIH.)

213.4 PROSTAGLANDIN MODULATION OF DOPAMINE-MEDIATED NEUROTRANSMISSION IN VIVO AND IN VITRO. R.D. Schwarz*, J.R. Bianchine, and N.J. Uretsky. Dept. of Pharmacology, Ohio State Univ., Colleges of Medicine and Pharmacy, Columbus, Ohio 43214.

Prostaglandins (PGs) have been shown to be involved in normal physiology through-out the body. While PGs have been identified in neural elements, their role in the nervous system is unclear. Current evidence suggests that PGs modulate transmitter release from nerve terminals in the peripheral nervous system. Release of NE has been shown to be reduced by PGE's and facilitated by $PGF_{2\alpha}$ through presynaptic elements which control Ca^{++} flux or binding (Hedqvist theory). A similar role in the CNS has been suggested, but the results are equivocal. The following experiments were designed to examine the role of PGs in modulating dopamine (DA)-mediated mechanisms in the CNS. In vitro studies utilizing the release of ^{3}H-DA from rat, striatal slices were used to study PG modulation of basal and K^+-induced DA release. One hour prior to the experiment, animals were injected with indomethacin (20mg/kg, i.p.) in order to inhibit endogenous PG synthesis. Slices (0.3mm x 0.3mm) were incubated with ^{3}H-DA for 15 min at 37°, washed 4x with media, incubated 15 min with PG present, quickly separated from media by centrifugation, and further incubated for 15 min with PGs in normal media or media with 12.5 mM K^+. Only PGD_2 at 10^{-7}M produced a statistically significant increase in the basal release of ^{3}H-DA. Release by K^+ was significantly inhibited by both PGE_2 and $PGF_{2\alpha}$ at 10^{-6}M. Since release is functionally coupled to synthesis, the effect of PGs on DA synthesis was also measured. Slices were incubated with ^{3}H-tyrosine in the presence of PG amd the formation of both ^{3}H-DA in both tissue and media was measured. In contrast to the release studies, no PG was able to significantly alter the basal or K^+-induced stimulation of synthesis. If PGs are able to alter DA elease, then their administration in vivo should alter DA-mediated behavior. This behavior was evaluated using the mouse-circling model. Male, White Swiss mice, previously lesioned in the left striatum of the brain with 6-hydroxydopamine (16ug/4ul), were administered d-amphetamine (amph; 4mg/kg, i.p.) followed 10 min later by an intraventricular injection of a PG or saline. Other animals received PG or saline without amph. PGE_2 inhibited amph-induced circling at doses of 10 - 1.0ug. $PGF_{2\alpha}$ and PGD_2 also inhibited amph-induced circling at 10 ug, but failed to do so at 1.0ug. None of the PGs produced any circling when administered alone. In summary, it appears that PGs are able to modulate DA-mediated neural mechanisms. The behavioral observation that PGE_2 and $PGF_{2\alpha}$ can block circling may in part be due to their ability to inhibit DA release. (Supported in part by USPHS grant NS 13888).

213.5 HISTAMINE INHIBITS IDENTIFIED NEURONS IN THE SPINY LOBSTER. Brenda J. Claiborne*. (SPON: A. Selverston). Dept. of Biology, University of California, San Diego, La Jolla, Calif. 92093.

Histamine is a putative neurotransmitter in mammals and in the mollusc, Aplysia; however, its role in arthropods is not yet defined. Recent work has shown that the lobster stomatogastric ganglion contains histamine levels that are similar to those in Aplysia ganglia, and exhibits a temperature-dependent uptake system for ^{3}H-histamine (B. Claiborne, unpublished results). The present report characterizes the responses of identified neurons to exogenously-applied histamine.

The stomatogastric nervous system of Panulirus interruptus was prepared for recording as described previously (Mulloney and Selverston, J. Comp. Physiol. 91:1, 1974). Identified neurons in the ganglion were penetrated with two microelectrodes, one for recording and one for current injection. Histamine was applied either iontophoretically to individual somata, or superfused over the ganglion at a concentration of 100 μM. The cells which respond to histamine are the PDs, GMs, LPGs, and EXs. Only one type of histamine response has been found: it is inhibitory, lasts several seconds, desensitizes with repeated histamine applications, and persists in calcium-free saline. The following evidence suggests that the response is due to an increased conductance to chloride: 1) current injection before and after histamine application indicates an increase in membrane conductance, 2) the reversal potential of the response is within 10 mV of the resting potential, 3) the reversal potential becomes less negative following intracellular chloride injection, 4) an increase in external potassium does not significantly alter the reversal potential, whereas 5) a decrease in external chloride does change the reversal potential. Pharmacological studies indicate that the response is not blocked by histamine H_1 or histamine H_2 antagonists, but is blocked by the nonspecific blocker d-tubocurarine. Additional experiments aimed at finding a specific histamine antagonist in this system are in progress.

Supported by NSF grant BNS 79-29182.

213.6 PROPERTIES OF SOLUBLE HISTAMINE H_1 RECEPTORS. Lawrence Toll* and Solomon H. Snyder (SPON: Terry Rogers). Dept. of Pharmacol. Johns Hopkins University School of Medicine, 725 North Wolfe Street, Baltimore, Maryland 21205.

Specific binding to the histamine H_1 receptor in the soluble state has been demonstrated using (^{3}H)-mepyramine, an antihistamine, as the ligand (Gavish et al., Life Sciences., 25:783, 1979). We had previously shown that the tricyclic antidepressant, doxepin, had the highest affinity of any drug tested on the H_1 receptor. Using (^{3}H)-doxepin as a ligand for the H_1 receptor we are able to further characterize binding properties and regulation of binding to the H_1 receptor in the soluble state, and compare this to the membrane bound receptor.

Of a wide variety of detergents evaluated, only digitonin solubilizes membranes in such a fashion that specific H_1 binding of (^{3}H)-doxepin is retained in the soluble state. The association and dissociation rates as well as saturation kinetics give plots for digitonin solubilized receptor which are virtually superimposable with those derived from the membrane bound receptor. The ability of a variety of antihistamines to displace (^{3}H)-doxepin from soluble and membrane bound receptors is also closely correlated, indicating conservation of the binding site upon solubilization.

Some important regulatory aspects of H_1 receptors have been compared in the membrane bound and soluble states. In brain membranes, Na^+ specifically decreases the affinity of histamine and other agonists for the H_1 receptor. In the soluble state, the Na^+ effect on histamine affinity is conserved, indicating a close association between the Na^+ regulatory and histamine binding sites. Membrane bound H_1 receptors are also regulated by divalent cations and guanine nucleotides, which are thought to act at the same or related sites. However, in the soluble state, guanine nucleotides lose their ability to decrease histamine's affinity, while divalent cations retain their ability to increase histamine's affinity.

213.7 STIMULATION IN VIVO OF BRAIN PHOSPHOLIPID TURNOVER BY HISTAMINE. N. Subramanian*, W.L. Whitmore*, F.J. Seidler* and T.A. Slotkin. Dept. of Pharmacology, Duke Univ. Medical Center, Durham, N.C. 27710.

Membrane phospholipid turnover in the brain is controlled in part by central neurotransmitters, including catecholamines and acetylcholine. This effect has served as a marker for specific receptor-mediated cellular stimulation. Histamine, a putative central neurotransmitter, also is capable of stimulating incorporation of radiolabeled inorganic phosphate (P_i) into brain phospholipids, and the mechanism by which this occurs is the subject of the present study. Histamine or histaminergic agonists were administered to rats intracisternally (i.c.), with or without 5 min i.c. pretreatments with antagonists. Five min after receiving agonist + $^{33}P_i$, rats were killed and brain phospholipids extracted. Histamine produced a dose-dependent increase in P_i incorporation, with a maximal effect (100% increase over control) reached by 10 nmols/g of brain weight. The effect could not be mimicked by compound 48/80 (12.5-50 μg/g brain i.c.), a specific releaser of mast cell histamine, indicating lack of involvement of non-neuronal histamine. The stimulation by histamine was not attenuated by prior depletion of catecholamines with reserpine, indicating that the effect was mediated directly by histamine, and not indirectly through histaminergic release of catecholamines. An H_1 receptor was involved in the effect, since 2(2-pyridyl)ethylamine, an H_1 agonist, produced a similar effect, but 4-methylhistamine, an H_2 agonist, did not. Pyrilamine, an H_1 antagonist, blocked the stimulation, but cimetidine, an H_2 antagonist, was ineffective. Histamine-induced stimulation of $^{33}P_i$ incorporation into brain phospholipids in vivo can be a valuable tool for assessing cellular stimulation evoked by H_1 receptors. (Supported by USPHS HL-24115, HD-09713 and DA-00006).

213.8 HISTAMINE: MECHANISMS AND FREQUENCY SPECIFICITY IN NUCLEUS ACCUMBENS. R. B. Chronister, G. C. Palmer, J. F. DeFrance and R. W. Sikes. Depts. Anat. and Pharm., Univ. of S. Ala., Mobile, Ala. 36688 and Dept. Neurobiol. Anat., Univ. Texas Hlth. Sci. Center, Houston, TX 77025.

Histamine is probably one of the least understood aminergic compounds in the CNS. Yet, evidence is accruing that it functions as a neurotransmitter. Histamine has been applied by iontophoresis onto numerous areas of the brain but never onto a system with a known transmitter substrate and one readily controlled. For this reason, we examined the effects of iontophoretic application of H_2 agonists/antagonists onto fimbrial evoked (glutamate-like) responses in rabbit nucleus accumbens. Additional studies were done to characterize potential sites of neurons giving rise to histamine and receptor mechanisms of the histamine systems in nucleus accumbens.

The sites of the neurons appear to be in mamillary complex and related areas (nuclei gemini). Furthermore, the coupling of histamine to adenylate cyclase activity in accumbens is second only to dopamine. This activation can be readily antagonized by H_2 antagonists (metiamide). Therefore, the physiological studies examined the effects of 4-Me-Histamine (H_2 agonist), combined 4-Me-Histamine-metiamide, and metiamide alone on the frequency spectrum of response in nucleus accumbens.

At low frequency (0.5 Hz) stimulation of the fimbria, iontophoresis of 4-Me-Histamine produces a small amount of depression (20%) to the N component. This inhibition has both a rapid onset and offset. At higher frequencies (6 Hz), iontophoresis produces a greater effect. Here the depression (75%) is striking to the tetanic activation. These results demonstrate that H_2 mechanisms preferentially influence higher frequency (Θ range) activity in nucleus accumbens. These phenomenon are all reversed by metiamide.

Metiamide alone also shows frequency related effects. It depresses the component of the evoked potentials and does so more at 6 Hz than at 0.5 Hz. This P component is bicuculine sensitive suggesting that (H_2) histamine functions through GABA mechanisms in nucleus accumbens. The H_1 effects demonstrated pharmacologically were very variable in physiological effect.

These data in conjunction with our observations with dopamine imply the existence of frequency specific effect of aminergic function. Furthermore, the effects can be complimentary in nature. 213.9 TECHNIQUES FOR DETECTING AMINES AND TYROSINE CONTAINING PEPTIDES IN THE CNS OF LOCUST AND OTHER INSECTS. C.A. Bishop*, M. O'Shea* and R.J. Dinerstein. (SPON: B. Wainer). Dept. Pharm. & Physiol. Sci., Univ. of Chicago, 947 E. 58th St., Chicago, IL, 60637.

We have used three techniques which permit the detection of specific amine histofluorescence in identified and identifiable neurons in the CNS of the locust and other insects. Together, these techniques allow us to distinguish among dopamine, octopamine, serotonin, noradrenaline and, in addition, allow for the detection of tyrosine and tyrosine containing peptides. The application of these techniques to the much studied locust nervous system will allow for the identification of transmitters in individually identified neurons.

The detection of monoamines, tyrosine and tyrosine containing peptides in the CNS depends on the generation of detectable fluorophores. For this we have used formaldehyde vapor (Falck et al. 1962. J. Histochem. Cytochem. 10, 348-354), glyoxylic acid (de la Torre & Surgeon, 1976. Neurosci. 1, 451-454) and nitroso-naphthol (Sundler et al. 1976, Histochem. 50, 39-46).

We are applying these techniques first to individually identified and isolated cell bodies of neurons which are known to be octopaminergic (DUM neurons, see O'Shea & Evans, Soc. Neurosci. Abstr., 1977). We have shown that these cells produce observable fluorophores when treated with glyoxylic acid or nitroso-napthol. This approach combined with microspectrofluorometry will allow us to characterize the fluorescence associated with neurons known to contain specific amines. A similar approach is being developed for isolated, identified peptide neurons (see O'Shea & Adams, this issue).

In addition, we have applied histofluorescent techniques to sections of tissue. We have detected, in the locust, fluorescing cell bodies, fibers and fiber varicosities which have the spectral characteristic of catecholamines in vertebrates. By comparing the characteristics of the fluorescence found in sectioned locust tissue with that of the isolated identified octopamine-containing cell bodies, we hope to characterize specific octopamine histofluorescence. This approach may aid in the histofluorescent detection of octopamine in the vertebrate brain.

213.10 HABITUATION AND EFFECTS OF AN OCTOPAMINE AGONIST IN THE DEVELOPING MOTH FLIGHT CONTROL SYSTEM. Sue C. Kinnamon*, Leland W. Klaassen* and Ann E. Kammer. Div. of Biology, Kansas State Univ., Manhattan, KS 66506.

Previous studies have shown that developing Manduca sexta spontaneously produce bouts of activity alternating with periods of inactivity. During activity the flight muscles are excited by patterned motor output similar to that recorded from the flight muscles of flying adults, although the wings are not moved. On the last day of development the amount of spontaneous activity decreases. Thus the developing (pharate) moth provides a suitable preparation in which to examine changes in responsiveness to sensory stimulation with respect to behavioral state. The preparation can also be used to assess the efficacy of a biogenic amine, octopamine, in altering behavioral states.

Wing campaniform sensilla were mechanically stimulated at a rate of approximately 1/sec, and motor output was recorded by fine wires inserted in the indirect flight muscles. In inactive pharate moths tested 1 day before eclosion, the typical response to a stimulus was several cycles of the flight motor pattern. The first few stimuli of a train elicited responses, but with successive stimuli the response usually habituated. In active animals of the same age, stimulation initially increased the amount of motor output. With repeated stimulation the spontaneous activity ceased; then some animals habituated like those in an inactive period, whereas other animals habituated more slowly. Pharate moths tested when quiescent during the last day of development showed greatly reduced responses to sensory stimulation, and the responses habituated more quickly. These results demonstrate that responsiveness to sensory stimulation varies with amount of flight motor pattern being produced spontaneously.

Injection of 6 x 10^{-6} moles of octopamine in active pharate moths (1 day before eclosion) increases the amount of motor output; injection late in an inactive period results in activity. Topical application of 10^{-9} moles of chlordimeform, a putative octopamine agonist, results in continuous flight in adult moths and also in pharate moths examined 1 day before eclosion. Slightly older pharate moths that normally become markedly quiescent before eclosion also respond to treatment with chlordimeform by producing motor output continuously. During the time between treatment and the production of spontaneous activity, sensory stimulation elicited more motor output per response and the response habituated more slowly than in control animals of the same age. The results suggest that octopamine modulates the behavioral state and concomitantly alters the response to sensory stimulation. (Supported by NSF BNS 75-18569)

213.11 MODULATION OF NEUROMUSCULAR TRANSMISSION BY OCTOPAMINE IN DEVELOPING AND ADULT MOTHS (MANDUCA SEXTA). Leland W. Klaassen* and Ann E. Kammer (Spon: Jane A. Westfall). Div. of Biology, Kansas State Univ., Manhattan, KS 66506.

Previous work by several authors has demonstrated that octopamine elicits action potentials and contractures in lobster leg muscles, but in insects it has been shown to have only slight effects on the excitatory junctional potential and tension development of locust extensor tibiae muscle.

The purpose of this study was to examine the effect of octopamine on neural excitation of a developing and mature fast moth muscle.

Stimulating the motor nerve to the dorsal longitudinal flight muscle in developing pharate moths (4 days before eclosion) elicited excitatory junctional potentials (EJPs) that ranged in amplitude from 10-20 mV. Superfusion of 10^{-6} M DL-octopamine increased the amplitude of the EJP to 30-35 mV. This increase in amplitude was sufficient to elicit action potentials in the muscle, which normally does not spike at this age. Superfusion of 10^{-3} M phentolamine decreased the EJP to 5-10 mV. In fully developed adult moth muscle, high concentrations of DL-octopamine had no observable effect on action potentials, i.e. the action potentials of a given fiber before and after treatment were superimposable. Octopamine also had no effect on EJP's which were observed in the absence of spikes by superfusing the preparation with a low calcium saline. Phentolamine treatment of adult muscle, however, reduced the EJP to 10-15 mV, well below the threshold for action potentials in this muscle. These results on the adult muscle can be interpreted to mean that so much octopamine is normally available to the adult neuromuscular junction that exogenous octopamine has no additional effect.

The putative neurotransmitter mediating excitation of this flight muscle is glutamate, as indicated by two observations: the amplitude of the EJP is reduced by applied glutamate (10^{-3} M in the saline) (M. B. Rheuben, 1974), and the muscle membrane is depolarized by 10^{-3} M kainic acid.

Because of the observed effect of octopamine and its antagonist phentolamine on the electrical responses to stimulation of the motor nerve, we suggest that octopamine modulates neuromuscular transmission in both developing and adult fast flight muscle. (Supported by NSF BNS 75-18569)

214.1 INULIN SPACE IN THE SPINAL CORD OF THE SEA LAMPREY. U. Wald* and M.E. Selzer. Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

The spinal cords of large larval and feeding stage adult sea lampreys (Petromyzon marinus) were removed by a ventral dissection and incubated in physiologic solution containing ^{14}C-inulin (1.5 μCi/ml). Incubation times were varied from 0-15 min. at 10°C. After a one second dip in regular lamprey solution to wash off surface radioactivity, the cords were homogenized and the radioactivity measured in a scintillation counter. Inulin uptake in larval cords reached a plateau distribution space of about 33% (vol./wt.) within 2.5 min. The inulin space of adult cord was approximately 18%. This probably represents the extracellular space because the time to plateau correlated well with the time (2 min.) for bath-applied tetrodotoxin (10^{-7}M) to abolish all electrical responses in giant interneurons to intracellular or whole cord stimulation. Mannitol was not an efficient marker of extracellular space since its concentration in spinal cords did not reach a plateau even after 30 min. of incubation.

The inulin space increased with temperature. At incubation temperatures of 5°, 10°, and 20°C, the inulin space of larval cord was 26%, 33%, and 42% respectively.

There was no correlation between larval size (and therefore, presumably, age), and the magnitude of the inulin space. Therefore, the large reduction in cord inulin space between the larval and adult stages probably occurs during transformation, and not gradually during the larval phase. This change correlated with morphological changes in the extracellular space in electron micrographs of lamprey spinal cords, although the latter were always much smaller by planimetric analysis than the inulin space.

In magnitude, temperature sensitivity and developmental change the inulin space of the lamprey spinal cord behaves similarly to the view of the extracellular space of mammalian brain which has emerged in recent years. We believe that the inulin space of the lamprey cord is a useful model for the extracellular space of vertebrate CNS because the small diameter of the cord allows rapid distribution of inluin in the extracellular space, and therefore avoids contamination of results by slow intracellular uptake.

(Supported by NIH grants NS 14257, NS 14037 and 1 K07 NS 11093)

214.2 ASCENDING SPINAL PATHWAYS IN THE SEA LAMPREY. R. G. Northcutt and S. O. E. Ebbesson. Division of Biological Sciences, University of Michigan, Ann Arbor, MI 48109 and Institut für Zoologie der Technischen Hochschule Darmstadt, Darmstadt, Federal Republic of Germany.

Hemisection or complete transection at the 5th to 8th cervical spinal level was performed in 7 adult sea lampreys, Petromyzon marinus, under MS222 anesthesia. Animals were housed postoperatively in fresh water (13-15°C) and allowed to survive 7-35 days before being re-anesthesized and perfused transcardially with 0.7% saline followed by 10% formalin. The brains and rostral spinal cords were removed, albumin-embedded, sectioned, and stained for degenerating fibers and terminals by modifications of the Nauta method. All survival times revealed degenerating fibers; however, shorter survival times revealed more degenerating terminals. The degenerating ascending spinal pathways were primarily ipsilateral to the hemisections, but sparse degeneration was observed in the same contralateral pathways and nuclei even in cases where the lesion did not cross the midline. The ascending spinal pathways consist of dorsal and lateroventral funicular systems. The dorsal funicular system ascends medial to the spinal trigeminal tract and consists of large-caliber fibers which terminate in the funicular nucleus at obex levels as well as continue more rostrally where they divide into dorsal and ventral components. The dorsal component courses along the lateral edge of the dorsal and medial octavolateralis nuclei, where terminals may be given off, and can be traced rostrally where it terminates in the molecular layer of the cerebellum. The ventral component courses through the ventral octavolateralis nucleus and also terminates rostrally in the alar grey immediately beneath the cerebellum. The lateroventral funicular system forms a wedge-shaped zone of degeneration from the level of the vagal motor nucleus to midbrain tegmental levels; terminals are likely given off to all branchiomeric motor nuclei as well as the hindbrain reticular system. No ascending spinal pathways appear to reach tectal or thalamic levels in these animals.

Supported in part by NIH grant EY02485.

214.3 SPINAL CORD PROJECTIONS IN THE ANURAN BRAINSTEM. C. Diakow and R. Woltmann*. Biology Department, Adelphi University, Garden City, New York 11530.

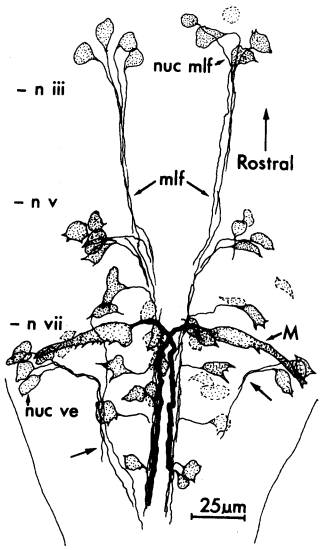
H^3-leucine was injected into the dorsal horns of the spinal cords of 3 female frogs (Rana pipiens) and radioactive label measured in the brainstem.

Injections were performed under Tricaine anesthesia at the level of the brachial enlargement in two frogs and at the sacral enlargement in the third. (Label spread a maximum of 0.4mm and in all cases, the most rostral spread was caudal to the calamus.) Animals were sacrificed 9 or 10 days after injection, the brains fixed in formalin, embedded in paraffin, and sectioned at 10 μ. Sections were coated with Kodak NTB-2 emulsion. After an exposure time of 25 or 31 days, sections were developed and stained with Hematoxylin and Eosin. For each female, five sections at each of 3 levels of the brainstem were studied. Grain counts of several areas on each section were obtained at 1000x. Counts were corrected for background by subtracting counts obtained from the brains of uninjected females processed at the same time as those of experimental females. Corrected grain counts of study areas for each section were compared to counts of a control area in the white matter 0.25mm from the midline. It was concluded that leucine was transported to a study area if the grain count in the study area was significantly higher than that in the control area.

In the caudal medulla at a level which included the nuclei of the tenth and twelfth nerves, there were projections to the tenth nucleus, the reticular nucleus, and in the lateral and medial bundles of the antero-lateral fasciculus. In the medulla at the level of emergence of the seventh nerve, there was also a projection through the lateral and medial bundles. At the midbrain-medulla junction, there were projections to the cerebellar grey, in the spino-cerebellar tract and, in two animals, on the lateral edge of the central grey in the superior reticular nucleus.

214.4 BRAIN NEURONS THAT PROJECT TO THE SPINAL CORD IN YOUNG LARVAE OF THE ZEBRAFISH. Charles B. Kimmel and Susan L. Powell*. Dept. of Biology, Univ. of Oregon, Eugene, OR 97403.

A small number of brainstem neurons project to caudal levels of the spinal cord in the larva of Brachydanio rerio. These cells were identified in animals 6 days after fertilization by backfilling with horseradish peroxidase following transection of the cord at the level of the cloaca. The distribution in the horizontal plane of all cells stained in one animal is shown in the figure. Rostrocaudal levels are indicated by positions of cranial nerve roots. Cells stained in all of the cases were restricted to locations shown in this example. The most rostral cells are within the midbrain nuclei of origin of the medial longitudinal fascicles (nuc mlf). The stained neurons located more caudally also contribute to the mlf. The majority are within the tegmental motor nucleus of the hindbrain, and prominent among them is the pair of Mauthner cells (M), which give rise to thick, crossed axons. All or nearly all of the other axons project ipsilaterally. The other cells in this nucleus are Müller cells, and are arranged in a characteristic ladder-like array. The other contribution of hindbrain neurons is from the vestibular nucleus (nuc ve). The vestibulospinal axons run obliquely through the hindbrain (arrows) before joining the mlf.



The filled cells are the largest ones present. Distinctive cells often have contralateral counterparts. In preparations with the greatest numbers of filled cells a total of 25-30 cells are stained on each side of the midline.

(Supported by NSF grant NS 77-08685, and NIH grant NS 15001.)

214.5 PROJECTIONS FROM BASAL TELENCEPHALON TO SPINAL CORD IN THE LIZARD IGUANA iguana. Laura L. Bruce, Donald B. Newman*+ and Ann B. Butler. Dept. Anat., Georgetown Univ., Washington, D.C. 20007; +Dept. Anat., USUHS, Bethesda, Md. 20014.

To determine whether a telencephalo-spinal connection is present in Iguana iguana, horseradish peroxidase (HRP) was applied by insertion of a gelfoam plug into hemisected spinal cord at upper and lower cervical levels. After a survival time of 2 to 6 days, the iguanas were perfused, and the tissue was processed for the HRP reaction product according to the protocol of deOlmos and Heimer (Neurosci. Lett., 1977). Retrogradely labeled cells were found in all cases in two areas of the basal telencephalon in addition to the typical pattern of labeling in brainstem areas. 1) Most of the labeled telencephalic cells are within or closely associated with the nucleus of the anterior commissure (Northcutt, J. comp. Neur., 1967). These cells are pyramidal and fusiform in shape. 2) A small number of labeled cells are present along the ventrolateral edge of the lateral forebrain bundle. These cells are fusiform in shape.

The presence of telencephalo-spinal projections in reptiles has not been reported previously, although they have been found in the salamander Ambystoma (Kokoros and Northcutt, J. comp. Neur., 1977). Determination of the function of these cells in Iguana and whether or not they are homologous to any cell populations in other vertebrates will require further investigation. Studies are currently underway to determine whether or not similar telencephalo-spinal projections are present in other reptiles and to describe the connections of these cell groups in greater detail.

This work was supported by NSF Grant BNS77-26022 to ABB.

214.6 DESCENDING INPUTS TO THE OPTIC TECTUM IN RANID FROGS. Timothy J. Neary and Walter Wilczynski. Anat. Dept., Creighton Univ., Omaha, NE 68178 and Sec. Neurobiol. and Behav., Cornell Univ., Ithaca, NY 14853.

Descending inputs to the optic tectum in two species of ranid frogs (R. grylio and R. heckscheri) were examined after 40-60 nl injections of 25% HRP into one lobe of the tectum and processing with TMB histochemistry. Results were similar for both species. In the telencephalon, only one population, the anterior entopeduncular nucleus, ipsilateral to the injections, contained labelled cells. In the diencephalon, several populations contained labelled cells: 1) the anterior thalamic nucleus, primarily ipsilateral to the injections, 2) the nucleus of Bellonci and dorsal ventrolateral nucleus, ipsilateral to the injections, 3) the ventromedial thalamic nucleus, primarily ipsilateral to the injections, 4) the posterior thalamic nucleus, ipsilateral to the injections, 5) the posterodorsal division of the lateral nucleus, primarily ipsilateral to the injections, 6) the ventral hypothalamus, bilaterally, 7) the posterior tuberculum, primarily ipsilateral to the injections, 8) the pretectal grey, ipsilateral to the injections, and 9) nucleus lentiformis mesencephali, ipsilateral to the injections. These results suggest several possibilities: 1) that both anterior thalamic and posterior thalamic/pretectal retinorecipient cell populations influence tectal function (Scalia and Gregory, Brain, Behav., Evol., 3:16 '70), 2) that somatosensory input may influence the tectum after processing in the ventromedial thalamic nucleus (Neary and Wilczynski, Brain Res., 138:529 '77), 3) that olfactory input, carried over both the main and accessory olfactory systems, may influence tectal function after processing in the ventral hypothalamus (Neary, Anat. Rec., 196:135A '80), and 4) that gustatory input may influence tectal function after being processed first in the 2° visceral nucleus and then in the ventral hypothalamus (Neary, loc. cit.). Thus, it appears that tectal function is likely to be influenced not only by direct and indirect visual inputs, but also by inputs from mechanical and chemical sensory systems.

Supported by NIH BRS Grant RR05390 to TJN.

214.7 SOME CONNECTIONS OF THE TELEOST TELENCEPHALON. Stephen M. Echteler and William M. Saidel. Scripps Instit. of Oceanog. and Dept. Neurosci., U.C.S.D., La Jolla, CA 92093.

Eversion of the pallium during the development of the teleost telencephalon has produced patterns of cellular organization remarkably different from those found in land vertebrates. Afferent and efferent connections of different regions of the teleost pallium should be determined to permit homologies with regions of the telencephalon of land vertebrates. Previous studies have used methods which do not allow adequate resolution of either the source of the efferent fibers from or the termination of afferents to the telencephalon. In the present study small injections of HRP into the telencephalic regions Dm or Dd-Dl in two species of teleosts (Carassius auratus: Cypriniformes, Cyprinoidei and Paralabrax nebulifer: Perciformes, Serranidae) have been used to trace both afferent and efferent projections of these regions.

Unilateral injections of HRP into Dm revealed retrograde cell labelling in ipsilateral preoptic region (nucleus entopeduncularis) and thalamus (posterior dorsal nucleus and nucleus preglomerulosus). Anterograde labeling of axons and terminals revealed ipsilateral efferent projections, via the lateral forebrain bundle, to optic tectum, nucleus preglomerulosus, and inferior lobe of the hypothalamus. Unilateral Dd-Dl injections resulted in heavy retrograde cell labelling in ipsilateral nucleus preglomerulosus. Anterograde labelling revealed efferent fibers which cross to the contralateral telencephalon, via the anterior commissure, and descend bilaterally in the medial forebrain bundle to terminate in the nucleus preopticus periventricularis, nucleus ventromedialis of the thalamus, and midbrain tegmentum.

The connections described for the telencephalic region Dm of the teleosts in this study are strikingly similar to those reported for the striatum in the amphibian telencephalon; furthermore, the connections described for the telencephalic region Dd-Dl of these teleosts are similar to those reported for the medial and dorsal pallium of amphibians (Kicliter, JCN:185, pp. 75-86, '79). Recently, homologies have been proposed between these regions of the teleost and amphibian telencephalon based upon similarities in cytoarchitecture and regional histochemistry (Northcutt and Bradford, Comp. Neurol. Telenceph., S.O.E. (ed.), Plenum, NY, '80). Our results provide additional support for these homologies on the basis of connections.

This work was supported by grants to T.H. Bullock from NSF and NIH and a Neuropsychobiology Training Grant to A.J. Mandell.

214.8 HRP AND GOLGI INVESTIGATIONS OF GOLDFISH NEUROSECRETORY SYSTEMS. W.A. Gregory and C.D. Tweedle, Dept. of Anatomy and the Neuroscience Program, Michigan State University, East Lansing, Michigan 48824.

As part of an ongoing examination of piscine neuronal development, we are examining the morphology and projections of the magnocellular preoptic nucleus of the common goldfish (Carassius auratus). A topographical segregation of neurons has been shown to exist within the homologous magnocellular nuclei of rats (Armstrong, et al., Neuroscience, in press). The nature of regional differentiation within the hypothalamic magnocellular neurosecretory system of lower vertebrates is less clear. Horseradish peroxidase (.6-2mg Sigma VI) in .1-.2ml of .75% NaCl and 2% DMSO was injected IP into fish weighing 2-5grams and having total lengths of 5-8cm, in order to fill hypophyseal extravascular spaces (Abraham, et al., Cell Tiss. Res., 167:289-296, 1976). Following survival times of 2-10 days, fish were sacrificed, brains removed, sectioned and reacted for the presence of HRP using diaminobenzidine and cobalt intensification, with or without the addition of glucose oxidase (Itoh, et al., Brain Res., 175:341-346, 1979).

Preliminary results show lightly labeled neurons distributed within the preoptic and tuberal nuclear complexes. Since the control of pituitary secretion has been generally attributed to these nuclei, it is likely that many or all of the HRP-labeled cells project to the pituitary. Injections of HRP will be made into the brainstem and spinal cord, in order to determine the location of the preoptic neurons with descending projections (Hoheisel, et al., Cell Tiss. Res., 189:331-345, 1978). Brains from similar fish were processed with a Golgi procedure. Multipolar, bipolar and apparent unipolar neurons of various sizes were seen within the magnocellular preoptic region. Tendencies for neuronal morphological regional specializations were noted.

Supported by NIH BRSG funds.

214.9 MONOAMINE NEURONS IN THE BRAIN OF THE LONGNOSE GAR, Lepisosteus osseus. A. Parent and R.G. Northcutt, Lab. Neurobiol., Fac. Méd., Laval Univ., Québec, Canada and Div. Biol. Sci's, Univ. of Michigan, Ann Arbor, MI 48109.

The morphological organization of monoamine (MA)-containing neurons in the brain of Lepisosteus osseus, one of the few living representatives of the holostean group of ray-finned fishes, was studied by means of fluorescence histochemical methods. The classic Falck-Hillarp procedure (Falck et al., '62) and the more recent cryostat glyoxylic acid method of de la Torre and Surgeon ('76) were used. In this species by far the largest number of MA cells is found within the preoptico-hypothalamic complex. A multitude of small-sized MA cells with short club-like processes protruding into the III ventricle is present along the ependymal wall of the medio-basal hypothalamus and inferior lobes. Both catecholamine (CA) and serotonin (5-HT) type cells occur at this level. However, the 5-HT cells appear to represent only about 30% of the total population. Numerous fibers arise from these CSF-contacting MA cells. Some of them proceed rostrally toward telencephalon while other course dorsally to reach the optic tectum. Many fibers, however arborized directly within hypothalamus, particularly around blood vessels where they form patches of highly fluorescent material. Small CA cells are also scattered along the preoptic recess wall. They do not contact directly the CSF but appear to contribute also to the CA innervation of telencephalon. At brainstem levels CA cells are scattered at the basis of rostral midbrain, within the central portion of rostral medulla and in the area of the vagal lobe (nucleus solitarius). The latter neurons give rise to dense CA innervation of the periventricular gray of IV ventricle. One of the most striking feature of MA systems in Lepisosteus is the remarquable development of the 5-HT neuronal network. There is a prominent 5-HT cell column which extends rostrocaudally, in the raphe region, from caudal midbrain to upper spinal cord levels. In caudal midbrain and isthmus the 5-HT cells also invade the lateral tegmentum. The 5-HT neurons innervate profusely various brainstem structures as well as large portions of telencephalon. In telencephalon the 5-HT innervation is strikingly dense in the dorsal nucleus of area ventralis (Vd) and moderately so in the medial zone of area dorsalis (Dm, rostral pole). By comparison, the CA innervation of telencephalon is weak, except for the olfactory bulb where numerous CA varicosities are found, particularly in the glomerular layer. These findings in Lepisosteus suggest that the organization of the MA neuronal systems in holosteans is significantly different from that found in more advanced fishes such as teleosteans.

214.10 HISTOCHEMICAL STUDY OF THE MONOAMINE-CONTAINING NEURONS IN THE BRAIN OF THE SALAMANDER (Necturus maculosus). L. Dubé* and A. Parent (SPON: L. Larochelle). Lab. Neurobiol., Fac. Méd., Laval Univ., Québec, Canada.

A study of the morphological organization of monoamine (MA)-containing neurons in the brain of the mudpuppy was undertaken by means of the Falck-Hillarp paraformaldehyde histofluorescence method and the cryostat glyoxylic acid procedure of de la Torre and Surgeon ('76). Numerous MA neuronal somata and axonal varicosities are present in this amphibian brain. In the diencephalon a large number of catecholamine (CA) type cell bodies occurs in hypothalamus and thalamus, particularly along ependymal wall. Some of these are small bipolar cells with one short process protruding into the lumen of the ventricle. Other CA cell bodies are closely-packed together within more lateral regions of diencephalon. In the mesencephalon a small group of large-sized CA cells is lying ventromedially in the tegmentum, near the N III root fibers. These neurons give rise to numerous varicose fibers which ascend along the medial and lateral forebrain bundles to arborize profusely within the neuropil of the corpus striatum. In the medulla a few CA cells are scattered in the area of nucleus solitarius. Serotonin (5-HT) type cell bodies are found in the raphe region from caudal midbrain to upper medulla levels. Numerous MA fibers and varicosities can also be visualized at all levels of the neuraxis in Necturus. For example, CA varicosities are found in large number in the olfactory bulb. The corpus striatum, nucleus lateralis septi and the accumbens nucleus also receive a massive CA innervation. CA varicosities occurs in pars dorsalis of the primordium hippocampi whereas 5-HT varicosities predominate in pars ventralis of the same structure. Varicose CA fibers are scattered in the primordium piriforme. At diencephalic levels CA varicosities are encountered in habenula, preoptic area and pars ventralis hypothalami. At brain stem levels MA fibers ascend within the fasciculi ventralis and dorsalis tegmenti. Strong AChE activity can be observed in the neuropil of the corpus striatum, and in the cellular areas of nucleus lateralis septi, the viscinity of N III root fibers and the raphe nuclei. A moderate, AChE activity is detected in the glomerular layer of the olfactory bulb and in the primordium piriforme. These findings suggest that the central MA neurons in salamanders are organized according to a pattern which is in many ways similar to that disclosed in the brain of amniote vertebrates. For example, the meso-striatal CA projection disclosed in Necturus appears equivalent to the nigro-striatal CA pathway present in reptiles, birds and mammals.

(Supported by grant MT-5781 of the MRC of Canada).

214.11 TELENCEPHALIC PROJECTIONS FROM CATECHOLAMINE CELL GROUPS IN THE PIGEON. Cheryl A. Kitt and Steven E. Brauth. Dept. of Psychology University of Maryland, College Park, Maryland 20742.

In pigeons, the telencephalic projections of the locus ceruleus (LoC), nucleus tegmenti pedunculo pontinus (TP) and area ventralis of Tsai (AVT) were traced by autoradiography.

LoC projections terminate principally in the paleostriatal complex. Specifically, the lobus parolfactorious (LPO) receives the heaviest projections from the LoC with the densest accumulations of silver grains lying over its central and caudal portions. Silver grain label was also evident over the paleostriatum augmentatum (PA), especially over its dorsomedial segment, albeit to a much lesser degree than that found in LPO. The paleostriatum primitivum (PP) and nucleus intrapeduncularis (INP) contained only small amounts of silver grain label in these experiments. Very light accumulations of silver grains could also be seen in the nucleus accumbens (Ac), lateral and medial septal areas (SL and SM), hippocampus (Hp), parahippocampal area (APH) and the hyperstriatum dorsale (HD). The hyperstriatum ventrale (HV) contained weak silver grain label. The neostriatum (N), contained only very light label, primarily at caudal levels. In addition, a patch of light silver grain label could be observed within the dorsal portion of the intermediate and posterior divisions of the dorsal archistriatum, as well in the olfactory bulb and tubercle (BO and TO). LoC projections were bilateral, but all projections were far heavier in the hemisphere ipsilateral to the injection site.

TP projections reach primarily the PA, particularly its rostral and lateral components. Silver grain label was also found in LPO, but label was light here compared to that found following the LoC injections. The LPO label in TP cases was most pronounced in its rostral and lateral segments. Accumulations of silver grains could also be seen over INP, Ac, SL, SM, HV, HD and BO neurons. In addition, a consistent patch of silver grain label was seen ventral to PP, INP and LPO, mixed among the fibers of the lateral forebrain bundle. A streak of fine silver grain label could also be seen in the dorsal portion of the intermediate and posterior dorsal archistriatum.

AVT injections revealed a different pattern of telencephalic projections. In these cases the heaviest silver grain label accumulations were observed in the medial and ventral components of LPO, within Ac, in the diagonal band of Broca (FDB), the region ventral to PP and INP and the olfactory tubercle (TO).

Although the projections of LoC, TP and AVT neurons do overlap, each of these cell groups shows unique and distinct patterns of projection upon the avian telencephalon.

215.1 ONTOGENY OF SPONTANEOUS UNIT ACTIVITY IN THE BASAL GANGLIA OF THE CAT. N.A. Buchwald, R.S. Fisher, M.S. Levine, and C.D. Hull. MRRC and BRI, Sch. Med., UCLA, Los Angeles, CA 90024.

In the course of a series of studies on the development of the basal ganglia in the cat, spontaneous extracellular single unit activity was recorded from neurons located in the caudate nucleus (498 units, 15 cats), internal and external pallidum (entopeduncular nucleus and globus pallidus, 138 units, 23 cats) and substantia nigra (249 units, 24 cats). Data were obtained from acutely prepared anesthetized (Halothane-H_2O) cats ranging in age from neonates to adults. Results indicate that 1) neuronal activity in the cat basal ganglia increases as a direct function of age, 2) spontaneous neuronal activity becomes more patterned as a direct function of age, and 3) maturation of spontaneous unit activity in the pallidum and nigra precedes maturation of spontaneous unit activity in the caudate nucleus.

Spontaneous unit activity was analyzed by computation of unit mean interspike intervals (ISI's). In all nuclei of the basal ganglia, ISI's showed a two to threefold decrease between 1-20 days of age and adulthood. Caudate units fired slowly throughout life (group $\bar{X}$ ISI = 4435 msec in 41-80 day old cats, 1694 msec in adults). In contrast, pallidal and nigral unit ISI's decreased markedly prior to 41 days of age, and adult ISI's were much lower in these structures than in the caudate nucleus. In 1-20 day old kittens, pallidal units had a group $\bar{X}$ ISI = 889 msec (346 msec in adults) while nigral units had a group $\bar{X}$ ISI = 1897 msec (589 msec in adults). Burst (3 spikes/10 msec) occurence was analyzed as an indicator of firing patterns. Proportions of units that displayed bursts increased with age in all nuclei of the basal ganglia. In the caudate nucleus, bursts were found in 23% of units in 40-180 day old cats (48% in adults). Pallidal and nigral units showed both a greater tendency to burst in adults, and a greater maturational increase in the amount of bursting. In the pallidum, 5% of units had bursts in 1-20 day old kittens (65% in adults). In the nigra, 13% of units had bursts in 1-20 day old kittens (72% in adults).

When group $\bar{X}$ ISI's were compared across the basal ganglia at each age level, the pallidum and nigra developed in a parallel fashion and were functionally mature by 40-180 days of age. The caudate nucleus lagged behind its target nuclei in rate of maturation since adult ISI levels were not attained prior to 180 days of age. However, the ontogeny of burst patterns was similar for all structures tested and was immature prior to 180 days of age. This suggests that the development of unit firing patterns in the basal ganglia is dependent on the maturation of neuronal activity in the caudate nucleus. (Supported by USPHS HD 05958 and 1T32MH15345).

215.2 BEHAVIORAL EFFECTS OF CHRONIC D-AMPHETAMINE ADMINISTRATION IN DEVELOPING KITTENS. M.S. Levine, C.D. Hull, N.A. Buchwald. Mental Retardation Research Center and Brain Research Institute, School of Medicine, UCLA, Los Angeles, CA 90024.

These experiments were designed to determine the behavioral effects of chronic administration of d-amphetamine in kittens. Fifteen kittens (from 5 litters) received injections of d-amphetamine (5mg/kg i.p.) every other day from about 10 days of age until 60 days of age. Five control animals (1 from each litter) received a similar schedule of saline injections. One of the first effects observed was reduced weight gain by the drug-treated animals compared to saline-treated controls. The d-amphetamine-treated animals were accepted by their mothers and seemed to nurse normally but they did not gain as much weight as their littermate controls. This effect was transient and by 35 days of age there were no differences in body weight between the groups. The behavior of all kittens was monitored after the drug injections to determine if amphetamine produced differing responses when administered at different ages. The types of behaviors occurring after the injections were rated every 3 min for a 15 min period 45 min after the injection. The type of behavior evoked by the d-amphetamine differed according to the age of the kitten. In kittens under 30 days of age the most consistent behavioral response was licking of the forelimbs or floor of the observation chamber. Another response occurring frequently in this age range was slow side-to-side head movements. Saline-injected kittens under 30 days vocalized intensely and frequently for the first 5-10 min of the observation period after which time they became inactive and usually slept. D-amphetamine-treated kittens did not vocalize as frequently but remained active for the duration of the test and for several hours after the injection. After 3 weeks of age d-amphetamine produced marked increases in locomotor activity accompanied by rapid side-to-side head turns. The kitten would walk in one direction, turn its head to one side, then walk in that direction, etc. Behavioral effects of amphetamine up to 5 weeks of age were not observed on the day after injection. After 5 weeks of age d-amphetamine-treated kittens were showing behavioral alterations (stereotypies, locomotor activity increases) on the day following the injection. Thus, there appeared to be a prolonged sensitivity to the repeated injections with increasing age. At about 7 weeks of age d-amphetamine induced vertical and horizontal head movements accompanied by visual tracking. This response is similar to that observed in adult cats. These experiments demonstrate that the behavioral effects of amphetamine administration are age-related in the developing kitten. The adult-like response does not emerge until the animals are almost 7 weeks of age. (Supp. by USPHS HD05958, RR05756, NS12324).

215.3 DEVELOPMENTAL LOCOMOTOR ACTIVITY IN RATS TESTED OVER CLEAN VS. HOME CAGE BEDDING. Judy Buelke-Sam and Carole A. Kimmel* Division of Teratogenesis Research, National Center for Toxicological Research (FDA), Jefferson, AR 72079

Many species that undergo extensive postnatal development display a characteristic pattern of locomotor activity during the developmental period. Campbell and associates have described the normal sequential increase and decrease in activity that occurs in developing rats under a variety of environmental conditions. It is also established that perinatal exposure to agents such as lead, carbon monoxide, x-irradiation and ethanol can result in enhanced and/or prolonged juvenile hyperactivity. These findings suggest that measurements of developmental activity could provide a sensitive and early indicator of toxicity following perinatal insult. In this study, litters from 23 CD rats were used to characterize developmental activity patterns obtained in stainless steel chambers equipped with a single, height-adjustable photobeam detector. The chambers had wire mesh flooring 2.5 cm above a tray which contained clean shavings (C) or an equal volume of shavings removed from each pup's litter cage (HC). They also contained removable partitions, and measured 20 cm x 26 cm with partitions in place, 38 cm x 26 cm with partitions removed. At birth (day 1), litters were culled to 8 pups, 4 of each sex, and 2 of each sex were assigned to each testing condition (C vs. HC). Six litters were tested in the small chamber every second day from postnatal days (PND) 10-28. The other 17 litters were tested on PND 12, 16, 20 and 24. All offspring were tested at 30 and 60 days over C in the large chamber. Animals were weighed following each 30 min session and also checked for the appearance of physical landmarks.

A developmental hyperactivity phase in isolated juvenile rats tested repeatedly in a new apparatus has been confirmed in this study. In C rats of both sexes, and in HC females, short-term activity levels peaked at PND 16. However, HC males displayed a prolonged and even greater elevation in activity from PND 12-16. This overall pattern was found in rats tested either every second day or every fourth day. These data contrast with those reported by Campbell and associates in two respects. First, they reported that the degree of activity was inversely related to the similarity between testing and home environments. We found an increase in activity in the presence of HC olfactory cues, and a shift to earlier, rather than later ages in peak activity levels in a "more familiar" environment (c.f., Campbell and Raskin, J. Comp. Physiol. Psychol., 1978). Second, in this study different patterns of hyperactivity were noted in male vs. female rats; males were more activated in the presence of HC olfactory cues. Testing over HC bedding in this apparatus vs. on HC litter itself may account for the differences reported here.

215.4 HOME ORIENTATION IN NORMAL AND IN D-AMPHETAMINE TREATED RAT PUPS. B. Weston* and J.A. Sechzer. Dept. of Psychiatry, Cornell Univ. Med. College and E.W. Bourne Behavioral Research Lab., The New York Hospital, White Plains, N.Y. 10605.

Home orientation by rat pups has not been investigated. Fleischer and Turkewitz (1978) measured the frequency of returns to the home area of the nest by rat pups. They did not observe the home orientation response where the rat pup either enters the home area of the nest and remains there for a long period or does not leave the home area if placed there initially. This is different from the behavior of other developing altricial species, like kittens, which show highly specific orientation to the home area of their cage.

The present study investigated orientation to the home area of the nesting cage by normal, saline treated, and d-amphetamine treated rat pups. Amphetamine treated pups were injected daily with 2.5 mg/kg/b.w. I.P. of d-amphetamine from 3-21 days of age. Home orientation was individually tested in each rat pup for 2 minutes a day and the pattern and locus of their activity was traced. Home orientation by both normal and saline treated pups was absent and they showed a diffuse pattern of exploration throughout the test sessions. The amphetamine treated pups, by 9-10 days of age, showed a highly specific pattern of home orientation which was maintained until they were 14-15 days old.

These observations suggest that home orientation may be a normal, adaptive behavior in developing rats but that exploration and/or hunger may conflict and interfere with its performance. D-amphetamine, which inhibits exploration in rats and also produces anorexia, may have diminished or suppressed these behaviors and facilitated home orientation behavior.

215.5 NEURAL AND BEHAVIORAL TOXICITY OF TRIETHYLTIN IN DEVELOPING RATS. Patricia Ruppert*, Glendora Heavner*, Karen Kidd* and Lawrence Reiter* (SPON: M. Gage). Neurotoxicology Division, Health Effects Research Laboratory, U. S. Environmental Protection Agency, Research Triangle Park, NC 27711.

Triethyltin (TET) is a highly toxic biocide and industrial catalyst which inhibits oxidative phosphorylation and produces cerebral edema and myelinopathy in the adult animal. We have shown that TET exposure in the adult rat produces a reversible hypoactivity, impairment of neuromotor function, and, at higher doses, hindlimb paralysis. However, little is known about the behavioral and neurotoxic effects of TET in the developing animal. In the present study, rat pups received a single injection of either 0, 3, 6, 9 or 12 mg/kg of triethyltin bromide on Day 5 of postnatal life. Most of the pups receiving 9 or 12 mg/kg died before weaning; histological examination of the brains of survivors indicated extensive damage to the pyriform cortex and amygdala, with shrinking of the dorsal hippocampus and enlargement of the lateral ventricles. For 0, 3 and 6 mg/kg TET-treated pups, whole brain levels of tin, zinc and calcium were analyzed 12 hrs, 24 hrs, 5 days and 10 days after injection to determine the kinetics of tin in developing pups. Pups receiving these lower doses were also tested for behavioral toxicity. Postnatal exposure to TET resulted in permanent hyperactivity in a figure-eight maze which persisted from day 28 through day 258 of age. These morphological and behavioral data indicate that developing animals are uniquely susceptible to the toxicity of TET: acute exposure on Day 5 produces specific brain lesions which are not seen even at lethal doses in the adult, and also produces permanent alterations in behavior.

215.6 EFFECTS OF PERINATAL EXPOSURE TO CHLORDIAZEPOXIDE ON LOCOMOTOR ACTIVITY AND ACTIVE AVOIDANCE IN THE RAT. P. M. Adams. Deptment of Psychiatry & Behavioral Sciences, University of Texas Medical Branch, Galveston, Tesas 77550.

The effects of perinatal exposure to chlordiazepoxide (1 mg/kg) on post-weaning active avoidance acquisition and extinction were studied in F344 rats. Pregnant primaparous females were treated daily on Days 1-21 of pregnancy with chlordiazepoxide or saline (IP). Lactating females were treated with chlordiazepoxide or saline on postnatal Days 1-21. Active avoidance learning and extinction were examined in all litters at thirty days of age. Open field activity was assessed on Days 14 and 21.

Prenatally exposed offspring of either sex were significantly more resistant to extinction compared to the saline-exposed pups. This difference was not due to an increase in spontaneous activity as there were no differences between the prenatal chlordiazepoxide and saline exposed pups. The postnatally exposed chlordiazepoxide pups were also significantly more resistant to extinction than post-natally exposed saline pups. Open field activity was significantly lower on post-natal Days 14 and 21 in the post-natally exposed chlordiazepoxide pups.

There was a significantly greater number of avoidance responses in extinction and faster extinction latencies in the post-natally exposed chlordiazepoxide pups compared to the prenatally exposed chlordiazepoxide pups. These findings support the hypothesis that perinatal exposure to chlordiazepoxide can cause significant alterations in the post-weaning behavior of the offspring regardless of gender.

215.7 EFFECTS OF FETAL TASTE/ODOR CONDITIONING ON NIPPLE PREFERENCE TESTING. G. Stickrod* , D.P. Kimble, Department of Psychology, University of Oregon, Eugene, OR 97403 and W.P. Smotherman, Department of Psychology, Oregon State University, Corvallis, OR 97331.

Taste and odor aversion conditioning have been demonstrated in rats in the first few days of postnatal life. Data to be presented demonstrate that such associations can be formed when fetuses are presented with a compound taste/odor stimulus via its injection into the amnionic fluid, and then injected with lithium chloride (LiCl). Conditioning took place with 20 day old fetuses from Sprague-Dawley female rats. Dams were anesthetized at 20 days of gestation and the uterine horns elevated and exposed through a midline laparotomy. A 26 ga needle was placed within 1 mm of the nose/mouth of the fetus and the amnionic fluid was injected with either saline or apple juice (.04ml). Following the last amnionic injection, each fetus was injected i.p. with LiCl (.02 ml/.15M) or saline. In the Experimental Group (2 mothers) N= 19 pups received apple juice followed by LiCl (AL), while Control Groups (1 mother) N=8 pups received apple juice followed by saline (AS) or (2 mothers) N=22 pups received saline into the amnionic fluid followed by saline i.p. (SS). All injections were accomplished under visual guidance. Females were sutured to close the incision and subsequently delivered pups on the 22nd or 23rd day of gestation. Nipple preference testing of the conditioned fetuses took place on postnatal day 16. Pups were removed 8 hr prior to testing. Dams were anesthetized and placed in a goal box at the end of a 7 x 15 cm plexiglass runway maintained at 35° C. Pups were allowed to approach and suckle until attached to one nipple for 15 sec. Approach trials were repeated until 10 were complete at which time the preferred nipple and at least four others were painted with apple juice. All other nipples were painted with saline. Pups were then run an additional 10 trials and scored for preferences for either apple juice or saline painted nipples. Results indicated that the AL Experimental Group preferred the saline painted to the apple juice painted nipples whereas both the AS and SS Control Groups showed preferences for apple juice over saline painted nipples. Preference for the saline painted nipples shown by AL pups when compared to AS or SS pups was significant by a t-test ($p < .05$) whereas the AS and SS pups did not differ. These data demonstrate in utero conditioning of an aversion to a compound taste/odor stimulus in the fetal rat. This association is a lasting one as evidenced by the nipple preference data collected on day 16 of postnatal life.

215.8 PRENATAL ADMINISTRATION OF KANAMYCIN: EFFECTS ON BEHAVIORAL DEVELOPMENT IN MICE. V. P. Perdue, P. J. Donovick and R. G. Burright*. Dept. of Psychology and Center for Neurobehavioral Sciences, SUNY Binghamton, Binghamton, N.Y. 13901.

The aminoglycoside antibiotics, including gentamicin and kanamycin, are widely prescribed to humans. Most research has focused on their major side effects, ototoxicity and nephrotoxicity, but have ignored possible concomitant behavioral consequences. We have recently shown significant changes in a variety of behaviors including aggression and maze performance. The present investigation examined the behavior of mice from birth to weaning at 21 days of age following prenatal administration of kanamycin.

Virgin female Binghamton heterogeneous stock (HET) mice were housed with sexually inexperienced HET males in standard cages containing nesting material. Females received daily, subcutaneous 400 mg/kg injections of kanamycin, or equal volume (.1ml/10 gm of body weight) injections of normal saline from the day following introduction of the male into the breeding cage until pups were born (mdn=21 days). Neither males nor pups were injected at any time.

Litters were culled to not more than 8 pups with an equal number of males and females wherever possible. On even days postpartum, litters were weighed and their righting reflex was tested. On days 8, 10, 12, and 14 postpartum, each pup's latency to return to the nest in the mother's absence was assessed. At 21 days of age, a 3 min. open field test was conducted under red light with a white strobe light during the second minute. The animals were then tested on a rotating rod to assess vestibular functioning.

Kanamycin administration during gestation altered pup behavior during the first 3 weeks of life. For instance, pups whose mothers were given kanamycin returned to the nest in the absence of their mothers at an earlier age than did their control counterparts. This finding parallels the nest return behavior of genetically deaf pups. Disruption of vestibular functioning following prenatal administration of kanamycin was suggested by later acquisition of the righting reflex and shorter latency to fall from the rotorod. In addition, male mice whose mothers were given kanamycin crossed fewer squares in the open field than did the other groups.

Thus, prenatal administration of kanamycin appears to affect several aspects of behavioral development in mice. In particular, behaviors related to vestibular functioning and exploration of the environment seem to be altered. Our findings point to the importance of continued investigation of the behavioral consequences of this medically important antibiotic.

215.9 OLFACTORY AND VOMERONASAL SYSTEM MEDIATION OF MATERNAL RECOGNITION IN THE DEVELOPING RAT. Martin H. Teicher, Bennett A. Shaywitz, and Augustus R. Lumia*. Section of Pediatric Neurology Yale Univ. School of Medicine, New Haven, Ct. 06510 and Skidmore College, Saratoga Springs, N.Y. 12866.

Recently developed procedures have permitted the precise quantification of a rat pup's immediate arousal response to its' mother or other test stimuli (Teicher & Shaywitz, Physiol. Behav. 23: 481, 1979). Using this apparatus, we demonstrated that 8-9 day old pups emitted 16% more vibrations (a measure of activity) toward their natural mother's ventrum than toward the ventrum of a lactating female with pups of the same age. They also emitted 36% fewer vibrations to a virgin females ventrum, 61% fewer vibrations to a male rat's ventrum, and 88% fewer vibrations to a wooden block or plastic container. Thus, indicating that this was a useful means for studying maternal recognition.

The contribution of both main olfactory bulb (MOB) and vomeronasal (VMN) systems to this capacity were assessed on a set of stimuli that normal pups grade with greater than 85% accuracy (lactating female's ventrum > lactating female's dorsum > heating pad). Pups receiving bilateral olfactory bulbectomies (BOB) (see Teicher et. al., Physiol. Behav. 21: 553, 1978) failed to grade these 3 stimuli when non-deprived, and they emitted many fewer responses to the conspecifics then sham or unilaterally lesioned pups (UOB). When deprived for 24 hours BOB pups responsed differentially to these stimuli, but they emitted their greatest response to the dorsal surface. Sham and UOB pups invariably emitted their maximal response to the ventral surface. Furthermore, the maximal response of the BOB pups was always less than half the maximal response of controls.

Pups receiving selective VMN nerve sections at 5 days of age graded their responses in the same fashion as BOB pups; emitting their maximal response toward the dorsal surface. However, unlike BOB pups, their maximal response was much more vigorous, and was comparable in magnitude to the maximal response emitted by the sham controls. Further studies suggested that the dorsal surface preference of these lesioned pups was tactually mediated, and based on the presence of longer hairs on the dorsal surface.

Overall, destruction of the VMN system with preservation of the MOB system disrupted only the pups' discriminative abilities, without affecting their level of responsiveness, or their ability to suckle. Destruction of both systems, as seen in BOB pups, disrupted discrimination, markedly diminished maternally-directed arousal levels, and produced serious impairments in suckling behavior.

215.10 DEVELOPMENTAL CHANGES IN HEART RATE CONDITIONED RESPONSES IN THE CAT (FELIS CATUS). G.E. Wolfe* and S.S. Soltysik*. (SPON:) S. Eiduson. Mental Retardation Research Center and Department of Psychiatry, UCLA, Los Angeles, CA 90024.

Heart rate (HR) responses to a 5 sec conditioned stimulus (CS, air blow to the back of the cat) paired with a brief electric shock (300 msec, 4 ma, 60 HZ), delivered to the left foot and the tail, show a single pattern in 1 week (N=5) and 4 week (N=7) old kittens, but several patterns in 12 week old (N=9) and adult cats (N=12). Control subjects (N=3, 4, 6, and 4, in the same age groups), which received only unpaired air CS and shock on separate trials (pseudoconditioning), showed much less (in younger subjects) or no HR responses (in adults) to the air blow CS. The infantile pattern of a HR response consists of a deceleration reaching a peak after one sec, followed by a return to or above baseline before the shock. Several patterns seen in adult cats included: pure acceleration, pure deceleration, and combinations of both. These individually specific patterns appear after a few days of training and remain stable over many months.

The emergence of individual specificity in conditioned HR responses to the signal of shock occurs between the 4th and 12th week of postnatal development.

The diversity of conditioned HR responses to the aversive CS in cats has not been noticed in previous studies. It is not known in other experimental animals (except for dogs when weak shock or a trace conditioning procedure is used: Black, A.H. et al., Psychol. Monogr. 76: No. 548, 1962). Cats may be unique animal subjects responding, like Humans, with a variety of autonomic (emotional) patterns to stressful stimuli and thus provide a useful model for developmental studies on genetic and experiential contributions to individual specificity. (Supported by USPHS HD05958)

215.11 BEHAVIORAL EFFECTS OF AMPHETAMINE IN ANIMALS TREATED NEONATALLY WITH 6-HYDROXYDOPA OR 6-HYDROXYDOPAMINE. Jack H. Mclean, Dorothy N. Morgan and Richard M. Kostrzewa. Department of Psychology, University of New Orleans, New Orleans, LA 70122.

Litters of rats were treated within 4 hr of birth with IP injections of either diluent saline (0.85%)-ascorbic acid (0.1%), 6-hydroxydopamine (6-OHDA) (60 µg/g), or 6-hydroxydopa (6-OHDOPA) (60 µg/g). The 6-OHDOPA group received a second injection 48 hr later. The animals were tested for general activity in 11 15-min sessions, beginning on Day 5 of life and continuing at three-day intervals through Day 35. Amphetamine sulfate injections (2 mg/kg, IP) preceded each activity session by 30 min. Activity was compared to animals from a previous study (1), treated identically, except for the amphetamine injections.

Treatment with amphetamine resulted in large increases in activity for all groups. When general activity was broken down into exploratory vs self-directed behavior, it became evident that the activity increment was due primarily to increased exploratory behavior. Number of self-directed responses, however, was decreased by the amphetamine treatment.

1. Dorothy N. Morgan, Jack H. McLean, and Richard M. Kostrzewa. Effects of 6-hydroxydopamine and 6-hydroxydopa on development of behavior. Pharmacology, Biochemistry, and Behavior, 11, 1979, 309-312.

215.12 PRENATAL DEVELOPMENT OF THE SPINAL TRACT OF V AND ITS BEARING ON SPONTANEOUS AND EVOKED ACTIVITY IN RATS. C.H.Narayanan and Y. Narayanan*. Dept.Anat., LSU Sch.Med., New Orleans, LA 70119.

The spinal tract of the trigeminal nerve in rat fetuses was studied in order to understand the neural basis for motor activity patterns involving the head, neck and forelimbs during normal development. Albino rats (Holtzman) from 12-20 days of pregnancy were used. Maternal spinal anesthesia was accomplished by chemomyelotomy at the level of L_1-L_2. Laporotomy was performed and the uterine horns were exteriorized. Recordings of the frequency of movements of the head, forelimbs and oral regions in various combinations were made using an Esterline Angus Event recorder. Evoked activity was studied at each stage using an esthesiometer with fetuses 'ex utero' (Narayanan et al 1971). Fetuses from each age group were sacrificed and processed for paraffin section ing and stained according to the reduced silver method.

The response to exteroceptive stimulation of the perioral region is weak at 16 days of gestation. From then on the fetuses show a progressive increase of response to stimulation of the tri geminal area with clear head extension and forelimb flexion. At 19 days, stimulation of the perioral region produces pronounced trunk movements combined with head movements. The head is turned towards the side of stimulation. Fasciculus gracilis can be iden tified at upper cervical levels beginning from 16 days onwards. At 19 days it is prominent and clearly delimited by the dorsal intermediate septum. At 16 days, the maxillomandibular and ophthalmic divisions of the spinal tract of V appear to have grown into the first and second cervical segments, and at 19 days, the spinal tract is proportionately large and extends as far as C_4. The changing nature and extent of these responses to stimulation can be correlated with the progressive development of the spinal tract of V and of the motor neurons of cervical levels. The morphological changes observed in these centers during development are now being studied at light and EM levels. Supported by the National Institutes of Health-National Institute of Child Health and Human Development. RO1 - HD12064.

215.13 EFFECTS OF CHRONIC CAFFEINE IN DRINKING WATER OF RATS ON NEONATAL DEVELOPMENT AND ON MATERNAL AND OFFSPRING BEHAVIOR. G. L. West†, T. J. Sobotka, R. E. Brodie† and J. M. Beier† Div. of Toxicology, Bureau of Foods, FDA, Washington, D.C. 20204.

Caffeine in concentrations of .0125, .025, or .05% in drinking water was given to pregnant female rats (FDA Osborne-Mendel) throughout gestation and lactation and to their offspring after weaning. Based on body weights and water intake data, dose levels were 17, 31, or 58 mg/kg/day for dams during gestation; 31, 63, or 115 mg/kg/day for dams during lactation; 13, 29, or 54 mg/kg/day for postweanling males; and 20, 41, or 84 mg/kg/day for postweanling females.

Behavior was assessed in dams during gestation and lactation. Physical and neurobehavioral profiles of development were obtained for preweanling pups and subsequent behavioral tests were made on postweanling adolescents.

Water intake was increased ($p<.05$) in the .0125% dams during the second and third weeks of gestation only. Body weight and food intake were relatively unaffected in dams. Photocell activity (PAC) was increased ($p<.05$) during gestation in .025 and .05% dams and was decreased ($p<.05$) during lactation in .0125% dams. Open field (OF) activity was increased ($p<.05$) in .05% dams during gestation only. Pup-retrieval latencies decreased with dose on day of parturition and increased with dose on day 12 of lactation, but neither was significant ($p>.05$). Adjunctive water intake during absence of the pups increased ($p<.05$) in the .025% and .05% dams.

Caffeine at the levels used did not affect length of gestation, litter size, sex ratio, or pup mortality, but did decrease ($p<.05$) body weights in .05% male offspring from birth throughout the 18-wk study. Incisor eruption was delayed ($p<.05$) in both sexes at .025% and .05% and in females only at .0125%. Onset of auditory startle was delayed ($p<.05$) in .05% males and females. Other indices of physical (pinnae, eyes, testes descent and vaginal opening) and behavioral (righting, PAC, OF, swimming) development were relatively unaffected.

Postweanling water intake was increased ($p<.05$) in .025% males and females. Shuttlebox avoidance (CAR) performance was modified ($p<.05$) in the .05% male offspring but was not affected in the females. Postweanling activity measures (PAC, OF, circadian) were relatively unaffected while hypermotility induced by d,l-amphetamine (AMP) was reduced with 1.5 mg/kg AMP and enhanced with 3.0 mg/kg AMP.

Results will be discussed in terms of reported effects of caffeine on endocrine and metabolic systems.

215.14 BEHAVIORAL AND BIOCHEMICAL EFFECTS OF INFANTILE NUTRITIONAL AND ENVIRONMENTAL TREATMENTS. L.S. Crnic, J. Bell*, R. Mangold*, M. Gruenthal*, J. Eiler* and S. Finger. Stolinsky Metabolic Resch Lab.,U. Colo. Med. Sch., Denver, CO 80262 and Dept. Psychol., Washington Univ., St. Louis, MO 63130.

Rats experiencing equivalent malnutrition but different environments were used to answer the question: To what extent are the behavioral and brain effects of infantile malnutrition due to the confounded environmental alterations? Pups separated from their dams for half of each day during the 1st 20 days of life were kept either in an incubator (I) or with a non-lactating, maternally primed female (A). At 20 days, the deficit in body weight was 38% compared to both normals (C) and a group which controlled for the handling involved in deprivation (HC) but declined to 11% in adulthood. Brains at 20 days revealed deficits in the amount of DNA and protein in cerebral cortex and brainstem in both experimental groups. Cerebellar protein was unaffected and DNA decreased only in the A pups. Cell size was reduced in both experimental groups in cortex and cerebellum but only for the A group in the brainstem. The two experimental groups differed from each other in protein concentrations in all brain parts. Thus, both nutritional and environmental manipulations affected brain biochemistry, with the A group the most affected. Although the direction of the effect was the same in the A and I groups, the environmental condition often determined whether the effect reached significance. Adult brains of similarly treated rats have revealed persisting effects.

Open field behavior (at 150,260,300 days in males, 150 and 300 days in females), response to sucrose solutions (males only), shock response thresholds, passive avoidance and spatial alternation maze performance were tested in adulthood. For males, the only behavioral effects were less rearing up on the hind legs in the open field by the A rats in the 1st and 2nd but not 3rd test with more vocalization on handling, and greater suppression of activity by the presence of a social stimulus in the open field compared to other groups. The A females were less active on the 1st day of open field testing, and, along with C females, more hesitant to respond prior to shock on the passive avoidance task The I females were less hesitant than C rats to respond on the 30 min. retention test on this task.

We conclude that the environmental variable influenced both behavior and brain biochemistry, with those more severely impaired biochemically showing more behavioral alterations. However, the magnitude and consistency of the behavioral effects wa unimpressive, especially in the light of the biochemical effects The extensive testing may have moderated any nutritional effects (Supported by grant HD08315)

215.15 ALTERATIONS IN ADULT BRAIN AMINE LEVELS RESULTING FROM NEONATAL HYPOXIA. M. K. Shellenberger, Dept. of Pharmacology and Kansas Center for Mental Retardation, Kansas Univ. Med. Center, Kansas City, KS 66103

The brain of the five day old rat is at approximately the same stage of development as the full term human fetus. Norton and Culver have shown that hypoxia, induced by carbon monoxide (CO), in the rat pup at this age produces hyperactivity in the maturing animal (Exp. Neurol. 50: 80, 1976) and altered caudate neuron morphology (Brain Res. 132: 455, 1977) when the rat reaches adulthood. This hypoxic model is now being used to determine if permanent changes in proposed neurotransmitter agents accompany the morphologic changes.

Infants were bred in our animal facilities. Litters born within 12 hrs were cross fostered with equal numbers of males and females and reduced to 8 pups within 48 hrs. At 5 days of age, groups of 4 pups were exposed to 0.5% CO in a constant flow of air at 4 L/min for 2 hrs at a chamber temp. of 24°C. Other animals were exposed to air alone under the same circumstances. A third group of animals were handled in the same way from birth but were not isolated from the dam nor placed in the chamber. All animals were sacrificed between 16 and 24 weeks of age. The brains were sampled and assays were performed for dopamine (DA), norepinephrine (NE) and 5-hydroxytryptamine (5-HT) in frontal cortex, striatum, midbrain and pons-medulla.

Both treatments were found to produce alterations in biogenic amine levels relative to the untreated group. The 2 hr isolation from the dam in air at 24°C caused increases in DA in frontal cortex and pons-medulla while NE was reduced in cortex, midbrain and pons-medulla. On the other hand, 5-HT was reduced in cortex and pons-medulla but increased in midbrain. CO exposure under these conditions generally tended to reverse or prevent the isolation-induced effects with notable exceptions. Cortical DA levels remained elevated and midbrain NE remained low in CO-exposed females. Effects on striatum were particularly striking as DA was reduced 28% in males and 33% in females while both NE and 5-HT were increased only in females.

These results indicate that a 2 hr isolation from the mother under hypothermic conditions is a sufficient stress in 5 day old rat pups to alter the course of neurochemical maturation in widespread brain areas. This proved to be a confounding factor in studies of hypoxia except in the striatum where CO-induced hypoxia produced clearly different effects. The relationship of these effects to other hypoxia-induced functional, morphologic and neurochemical changes remains to be established. (Supported by USPHS Grant MH 27739).

215.16 ALTERATIONS IN ADULT BRAIN AMINO ACIDS FROM NEONATAL TRAUMA. A. S. Kimes and M. K. Shellenberger, Dept. of Pharmacology, and Kansas Center for Mental Retardation, Kansas Univ. Med. Center, Kansas City, Kansas 66103.

Published studies have shown that hypoxia in the five day old rat, induced by carbon monoxide (CO), results in hyperactivity in the developing animal and persistent changes in caudate neuronal morphology. We have utilized 5 groups of five day old male and female rats to determine if there are persisting neurochemical changes as well. Pups were cross fostered and litters reduced to 8 within 48 hrs of birth. (1) Pups were exposed to 0.5% CO in a constant flow of air of 4 L/min for 2 hrs; chamber temp. 24°C. (2) Pups were exposed to air only for 2 hrs as above. (3) Pups were anesthetized with hypothermia and light ether exposure. The brain was exposed from the coronal suture to the olfactory bulbs and the cortical surface removed by suction from the midline laterally to the orbital area and arteriorly to the frontal poles. (4) Pups were anesthetized as above and the scalp and calvarium opened (sham operated group). (5) A control group was handled as above but not subjected to other traumas. All rats were sacrificed between 16 and 24 weeks old. Brain samples (cortex, striatum, midbrain and pons-medulla were assayed by the o-pthaldialdehyde reaction for Glu, GABA, Asp and Gln.

Significant treatment related effects were seen primarily in Glu and Asp with no significant alterations in GABA levels. The majority of significant alterations were confined to striatum and midbrain and occurred with greater frequency in the females. All treatments tended to increase striatal Glu, compared to the untreated group, in both sexes, with females showing a consistently larger response. Midbrain Glu was increased by operative procedures but not by the exposure conditions. Striatal Asp levels were markedly increased in both sexes by CO exposure and to a lesser extent by operative procedures in females. Exposures, particularly CO, increased midbrain Asp but lesions increased Asp only in males while the sham operation caused an increase in females which was reversed by lesioning. Significant alterations of Gln also occurred in striatum and midbrain.

The metabolic and/or morphologic bases of these changes in amino acid levels are not known. It is clear, however, that situations such as 2 hrs isolation from the mother with accompanying hypothermia are adequately stressful to result in permanent changes in brain amino acid levels. Furthermore, these effects are confounding when other treatments are superimposed. (Supported by USPHS Grant MH 27739. ASK was supported by an RSA (HD-07066).

215.17 BEHAVIORAL AND DENDRITIC SPINE DEFICITS IN MONOCULARLY DEPRIVED RATS: THE ROLE OF REDUCED PHOTIC STIMULATION. M.L. Schwartz and L.A. Rothblat. Dept. of Psychology, George Washington Univ., Washington, D.C. 20052.

Monocular deprivation in the rat significantly reduces the density of dendritic spines in visual cortex contralateral to the deprived eye (Fifkova, J. Comp. Neurol., 140, 1970) and severely impairs the ability of these animals to discriminate complex visual patterns (Rothblat, Schwartz and Kasdan, Br. Res., 158, 1978). Whether these deficits are the result of a reduction in the pattern content of visual stimulation or a decrease in the level of photic stimulation of the retina remains to be determined. The present study was designed to examine the role that levels of retinal stimulation play in the production of these deficits.

All behaviorally tested rats (n=40) were unilaterally lid sutured at 12 days of age (DOA), and then assigned to one of three identical rearing environments which varied only in the level of ambient illumination provided during the light portion of the 12h light/dark cycle. Groups 1 and 2 were reared in an environment with an ambient illumination of 200 lx (normal laboratory level) while groups 3 and 4 were exposed to illumination levels which were 1 and 1.5 log units greater, respectively. These levels were chosen based upon earlier measurements which revealed that lid suture in this species reduces photic retinal stimulation by 1 to 1.5 log units and as such the deprived eye of animals in these groups should receive a "normal" level of photic stimulation in the absence of pattern stimulation. At 45 DOA the rats in groups 2, 3 and 4 were reverse sutured and began behavioral testing using the originally deprived eye. Group 1 served as a control and began testing at the same time using the non-deprived eye. All animals were trained to discriminate between columns and rows of 5mm squares.

The results revealed that rats in groups 2, 3 and 4 were sig. impaired in the acquisition of the discrimination when compared with group 1, however, no difference in performance was found on this task between groups 2, 3 and 4.

Dendritic spine density was examined in four groups (n=20) of rats. Groups 2S, 3S and 4S were MD litter mates of behavioral groups 2, 3 and 4, while rats in group 1S were non-deprived and reared in the 200 lx environment. Spine density comparisons between group 1S and the deprived hemispheres of groups 2S, 3S and 4S revealed a sig. reduction in density for group 2S, but no sig. reduction was found for groups 3S and 4S.

These results suggest that while spine density in visual cortex may be sensitive to the level of retinal photic stimulation, perceptual capacity may be more dependent upon the level of exposure to visual pattern during development. (Supported by NIH Grant 9-R01-EY03304)

215.18 RECOVERY OF FUNCTION AFTER NEUROTOXIC DAMAGE TO THE HIPPOCAMPAL CA3 REGION: IMPORTANCE OF POSTOPERATIVE RECOVERY INTERVAL AND TASK EXPERIENCE. Gail E. Handelmann* and David S. Olton, Dept. of Psychology, The Johns Hopkins Univ., Baltimore, MD 21218

Rats with kainic acid induced damage to hippocampal CA3 pyramidal cells show impaired postoperative retention of spatial maze tasks, with eventual relearning. This experiment evaluates the importance of the length of the postoperative recovery interval and the extent of task experience in facilitating the relearning.

Rats were trained on a T-maze rewarded alternation task, and then given either kainic acid (experimental) or saline (control) injections into the hippocampal CA3 region. Half the rats in each group began postoperative testing 5 d. after surgery; the rest began 30 d. after surgery. Of the rats beginning retesting 5 d. after surgery, half received one daily test session and half received two daily test sessions. The same was true for the rats beginning retesting 30 d. after surgery.

	Days to Criterion			
	5 d. Recovery Interval		30 d. Recovery Interval	
	Kainic Acid	Control	Kainic Acid	Control
One Test Session Per Day	27.7	3.0	16.6	2.0
Two Test Sessions Per Day	13.0	2.9	15.2	2.7

All groups of control rats required a similar number of days to reach criterion. Neither the length of the postoperative recovery interval nor the number of daily test sessions affected the amount of time necessary to reach criterion performance. The number of days of experience was more important than the actual amount of experience.

All experimental groups performed worse than the controls, but all rats eventually relearned the task. The worst performance was shown by the group tested once a day beginning 5 d. after surgery. Performance could be improved significantly by either increasing the amount of task experience or by lengthening the recovery interval. For added experience to improve performance, however, it had to be administered immediately after surgery.

215.19 EFFECTS OF HIBERNATION AND DIFFERENTIAL ENVIRONMENTS ON WEIGHTS AND NUCLEIC ACIDS IN BRAINS OF BELDING'S GROUND SQUIRRELS. Mark R. Rosenzweig, Edward L. Bennett, Paul W. Sherman*, Marie H. Alberti*, Dept. Psychol. and Lawrence Berkeley Lab., Univ. of Calif., Berkeley 94720.

We studied brain development in juvenile Belding's ground squirrels during hibernation in a cold room at 5° C and awake in a laboratory at 20° C. The animals were live-trapped near Tioga Pass, CA. 9/13-14/79 at about 80 days of age. Some were sacrificed for baseline values on 9/18. Others were put into the experimental conditions on 9/21/79 and were sacrificed for brain analyses 2/20/80 at 8 mo of age. During the 5 mo in experimental conditions, the squirrels that remained awake continued to grow in brain weight (+ 5%), body weight, and skeletal development; the hibernators lost large amounts of body weight and decreased only slightly in brain weight (- 2%). The differences in brain weights between hibernators (H) and non-hibernators (NH) were not statistically significant in cerebral cortex but were significant in the rest of the brain and in several specific regions, including the hypothalamus, caudate nucleus, and medulla. Weight differences in brain regions between hibernating and non-hibernating conspecifics do not appear to have been reported previously. In nucleic acid measures, H were significantly lower than NH in total DNA of the olfactory bulbs, hypothalamus, caudate nucleus and medulla, indicating loss of cells; in the latter 3 regions the percentage loss in DNA equalled the percentage loss in weight. Total RNA did not differ between H and NH, but in RNA/wt H exceeded NH significantly in almost every brain region measured. This greater specific RNA of the hibernators runs contrary to some published reports, and this indicates the need for further research which we are pursuing.

We also substantially replicated our study reported at the 1979 Neuroscience meeting (abstract no. 2160) showing that laboratory-born juvenile Belding's ground squirrels assigned to an enriched laboratory environment (EC) developed brain measures similar to those of feral squirrels and significantly greater than those of conspecifics assigned to an impoverished environment in individual cages (IC). Thus, both hibernation and differential experience are demonstrated to produce significant effects on brain weights and brain nucleic acids.

Supported in part by the Division of Biomedical & Environmental Research of U.S. Department of Energy under contract No. W-705-ENG-48, U.S. Public Health Service grant MH 26704-05, and NSF grant BNS-7913754.

215.20 ENRICHED ENVIRONMENTAL REARING INCREASES NEURAL EXCITABILITY AND IMPAIRS BRIGHTNESS DISCRIMINATION LEARNING. S. Kilchenmann*, P.B. Feuerstein*, V. Wolfson*, and W. Fishbein. Psychobiology Laboratory, Dept. of Psychology, The City College of the City University of N.Y., New York, N.Y. 10031.

Considerable research has focused on behavioral, morphological and chemical differences as a function of differential rearing, with the general assumption that enrichment leads to increased complexity and behavioral adaptability. The present experiments add another dimension, that of neural excitability changes resulting from differential rearing.

One hundred thirty four male albino mice (Carworth Farms) are reared for 5 weeks post-weaning in either enriched (EE), social (SE), or isolated (IE) environments. At 56(±2) days of age, subjects are removed. Experiment 1: Subjects are trained on 5 consecutive days in a brightness discrimination task (Y-maze). Results indicate that EE's perform significantly worse on 3 recorded measures (Correct avoidances, Avoidances and Correct discriminations) beginning on day 3 of training, as compared to both SE's and IE's, which do not differ from each other. Experiment 2: Immediately after removal from their respective environments, subjects are administered transcorneal electroconvulsive shock. Duration of tonic and clonic phases and seizure thresholds (mA, rms) are determined. Results reflect the findings in Experiment 1; EE's show significantly lower seizure thresholds compared to SE's and IE's, which do not differ among themselves.

These findings challenge the notion that enrichment increases behavioral adaptability and indicate a correlative relationship between observed behavioral differences and brain excitability in differentially reared animals; the findings further suggest that enrichment in all likelihood leads to higher baseline excitation levels which, when combined with a task that engenders excitation, leads to an overload and subsequent breakdown of task performance.

215.21 PARADOXICAL DEOXYGLUCOSE UPTAKE IN LAYER A OF CAT LATERAL GENICULATE NUCLEUS (LGN) AFTER OPTIC CHIASM SECTION. C. Shaw*, S. Kirby*, F. Leporé, J. P. Guillemot and M. Cynader (SPON: J. Szerb). Dept. of Psychol., Dalhousie Univ., Halifax, N. S. and Dept. of Psychol., Université de Montréal, P. Q., Canada.

Optic chiasm section severs optic nerve fibers crossing to the opposite side of the brain. If this manipulation is performed in young kittens and one eyelid is sutured at the same time, however, the opened eye becomes the major route for effective visual stimulation of neurons near the 17/18 border on both sides of the brain. We sought an anatomic correlation of this phenomenon by applying the ^{14}C-2 deoxyglucose (2 DG) method to this preparation. Two kittens were subjected to optic chiasm section and monocular eyelid suture at 3 weeks of age. They were reared normally until 110-116 days of age when the deprived eye was removed in one of the kittens. The next day, 2 DG (100 µg/Kg I.V.) was injected. As expected, layer A_1 of the LGN ipsilateral to the normal eye was heavily labelled in this kitten. In the other hemisphere, however, layer A of the LGN was instead densely labelled. This labelling was nearly as dense as that found in layer A_1 of the LGN ipsilateral to the normal eye. This is surprising because the combination of enucleation and chiasm section should abolish all retinal input to the LGN ipsilateral to the deprived eye. To rule out incomplete chiasm section as the mechanism underlying these results, we repeated the experiment in another kitten but, in addition, injected ^{3}H-proline into the normal eye. 2 DG results were the same as previously and tritium label was found only on the side of the brain ipsilateral to the normal eye (layer A_1), confirming the completeness of chiasm section.

Two possible sources of the heightened glucose consumption in layer A of the LGN contralateral to the normal eye were considered. One candidate mechanism is a pathway for visual input as follows: normal eye-ipsilateral LGN-ipsilateral cortex-opposite cortex (via corpus callosum)-layer A of LGN (via corticothalmic fibers). To evaluate the functional efficiency of such a pathway, we recorded in the LGN contralateral to the normal eye in another kitten. Visual responses could not be elicited from layer A of this kitten although many cells showed spontaneous activity. The lack of visual responses makes it unlikely that the polysynaptic pathway mentioned above is the source of the heightened 2 DG uptake in layer A. Alternatively, the difference in activity between LGN layers A and A_1 ipsilateral to the deprived eye may reflect differences in the time after denervation for cells in the two layers. Since layer A was denervated in infancy (by chiasm section) and layer A_1 was denervated in adulthood (by enucleation) the increased activity in layer A may reflect different metabolic consequences of neonatal versus adult (or early vs. recent) denervation. Experiments are underway to test these hypotheses.

216.1 POSTNATAL DEVELOPMENT OF THE RAT ACCESSORY OLFACTORY BULB. L. Rosselli-Austin, K. Hamilton* and J. Williams*. Chicago State University, Chicago, Il. 60628.

The rat accessory olfactory bulb (AOB) was studied quantitatively under the light microscope during its development from birth to postnatal day 60. The following parameters were evaluated: total volume of the AOB and its component layers, mitral and internal granule cell numbers, cellular growth, cellular packing densities and granule to mitral cell ratio.

The total volume of the AOB increased 600% from the day of birth to its peak at postnatal day 18. Thereafter the volume declined: the 25- through 60-day age groups had significantly smaller volumes than the 18-day group (Newman-Keuls, $p < .05$). By day 60, the AOB volume showed a 34% reduction from its maximum value. Volumes of the individual layers of the AOB followed this same pattern of growth and decline with the exception of the internal plexiform layer whose volume did not decrease during the period studied. It grew at a moderate rate until day 18 when it reached a plateau, and then underwent a second period of growth between days 25 and 30.

The total number of mitral cells declined dramatically after day 18; by day 60 only 60% of the mean number of mitral cells extant from days 0 through 18 remained. Mitral cell density decreased rapidly during the first postnatal week and then more slowly during the following two weeks. Areas of projected outlines of mitral cell perikarya followed a pattern inverse to that of cell density.

The total number of granule cells rose 300% from days 0 to 18. There was a 24% reduction in number after day 18 but this was not significant. Cell packing density declined during the first week as granule cell diameters increased. Cell diameters of the 16- and the 18-day old groups were significantly larger than the 0- through 3- and the 60-day age groups. The granule to mitral cell ratio rose throughout the early postnatal period and reached an asymptote around day 20.

The postnatal development of the AOB contrasts in many respects with that of the main olfactory bulb (MOB)(Rosselli-Austin, L. and Altman, J. J. Develop. Physiol., 1:295, 1979). While the MOB exhibits tremendous growth and neuronal acquisition, the AOB shows more moderate growth. Moreover, the AOB appears to undergo involutionary changes around the time of weaning while the MOB does not. However, both the MOB and the AOB undergo mitral cell losses at about the same time.

216.2 DEVELOPMENTAL CHANGES IN THE TOPOGRAPHICAL DISTRIBUTION OF CELLS CONTRIBUTING TO THE LATERAL OLFACTORY TRACT. Marjorie R. Grafe and Christiana M. Leonard. Dept. of Neuroscience, University of Florida, Gainesville, Florida 32610.

Developmental changes in the locations of cells in the olfactory bulb which contribute axons to the lateral olfactory tract (LOT) were investigated using retrograde transport of horseradish peroxidase (HRP). HRP was placed in various parts of the olfactory tubercle, LOT, and/or piriform cortex of golden hamsters ages 3, 7, 8, and 20 days. The animals were allowed to survive 24 hours, and frozen sections were cut at 50μ, reacted with TMB, and counterstained with neutral red. The number of labeled mitral and tufted cells were counted on an average of 12 equidistant sections through the olfactory bulb.

In the younger animals (Days 3 and 7, n=10), there was a distinct localization of labeled cells in the medial quadrant of the bulb. A Friedman two-way analysis of variance showed a significant difference in the distribution of labeled cells among the quadrants ($p<.02$). A Wilcoxon test on this group showed that the number of labeled cells in the medial quadrant was greater than in each of the other quadrants ($p=.05$). The number of cells in the medial quadrant was approximately equal to that of the other three quadrants combined. Paired comparisons of the other quadrants showed no differences between them. In animals Day 8 and older (n=7) the cells were distributed equally over all quadrants. Between Days 3 and 20, the average perimeter of the mitral cell layer doubled, and the average number of cells labeled per section increased from 4.7 to 22.4. When pairs of brains from the different age groups with HRP injections of similar size and location are compared, the older brain always has more labeled cells. There was no relation of the number of labeled cells or the distribution of labeled cells to the location of the injection. In contrast, the number of labeled cells does correlate positively with the size of the injection.

We believe this is the first report of a developmental topographical gradient of the cells of origin of the LOT. No such gradient has been reported for cell birth day. This localization may be related to an uneven distribution of the olfactory nerve fibers entering the bulb, or to early topographical differences in functional activity.

Supported by grant NS 13516 to CML and an NSF predoctoral fellowship.

216.3 SENSORY DEPRIVATION AFFECTS THE DEVELOPING OLFACTORY SYSTEM OF MICE. T.E. Benson and J.W. Hinds. Dept. Anat., Boston University School of Medicine, Boston, MA 02118.

Frühwald (Arch. f. Ohren-, Nasen- u. Kehlkopfh., 139: 153-173, 1935) has reported striking qualitative differences in the olfactory epithelium and olfactory bulb (OB) consequent to unilateral nasal occlusion in newborn rabbits. The present study using unilateral, neonatal naris cauterization augments the work of Frühwald and updates our previous communication (Benson, T.E. and D.K. Ryugo, Soc. Neurosci. Abstr., 4: 108, 1978.)

Histological preparations of OB's from 30 day old experimental and control CD-1 mice have been used for morphometric analysis. The volumes of the left control OB's (C_L) do not differ from the right (n=6, paired t-test). In contrast, in the experimental animals the mean volume of the OB's on the deprived (D) side is 26% smaller than that of the non-deprived (ND) side ($P<0.001$, n=7, paired t-test). The volumes of the ND bulbs do not differ from those of the C_L. This suggests there is no compensatory hypertrophy of the ND bulbs. Based on paired t-tests of volumes, the following layers of the D bulbs are significantly smaller than the ND: Glomerular (GL), 24%, $P<0.01$; external plexiform (EPL), 35%, $P<0.01$; mitral cell (MCL), 23%, $P<0.01$; and granule cell (GCL), 29%, $P<0.02$. The olfactory nerve layer (ONL) is 12% smaller and the ventricular/subependymal zone (V) is 11% larger on the D side but not significantly. An analysis of variance comparing the effect of deprivation among layers indicated significant differences ($P<0.001$). An a posteriori analysis (Tukey (b)) showed that V differs from all other layers and EPL and GCL differ from ONL.

Preliminary counts of receptor knobs in 1 µm plastic sections of nasal septum show a magnitude of effect similar to that seen in the ONL. Cell counts in OB's will also use 1 µm sections. So far, in each of two OB's 14 mitral cell nuclei from comparable positions have been reconstructed from serial 1 µm sections. Mean nuclear volume is 639 μm^3 on the D side and 763 μm^3 on the ND with 5.0 and 3.2 nucleoli per nucleus respectively.

Tritiated deoxyglucose radiography shows decreased labeling of the D bulbs on postnatal days 20 and 30.

These results suggest a retardative effect of deprivation on development. For example, the smaller volume of OB layers compared with the large relative size of V, and the smaller size of mitral cell nuclei with a greater number of nucleoli is similar to an earlier developmental stage in control OB's or other developing systems. In addition, our examination of OB's embedded in paraffin and in plastic suggests there is a significant potential for undercounting mitral cells in paraffin sections, especially in the D bulbs. (Supported by U. Vermont GRS grant PHS 5429-40 and USPHS Research grant AG-00001.)

216.4 DEVELOPMENT OF OLFACTORY BULB ELECTRICAL ACTIVITY RECORDED CHRONICALLY FROM 3 TO 90 DAY OLD RATS. C. Robert Almli, William B. Forbes, Mark A. Henault,* Craig A. Velozo,* and Peter J. Morgane. Worcester Foundation for Experimental Biology, Shrewsbury, Ma. 01545 and Psychol. Dept., Ohio Univ., Athens, Ohio 45701.

Bipolar stainless steel electrodes were chronically implanted into the main olfactory bulb (MOB) in male albino rats at 3, 4, 8, 10, 12, 14, 17, 19, 30, or 90 days of age. Electrical slow-wave activity was recorded from the MOB for approximately two hours each day for three successive days. The rats were returned to their home cages between recording sessions. Infant rats with chronic implants continued to suckle from their dam while in the litter cage, and rats of all age groups displayed normal growth over the three day recording period. The electrically shielded recording chamber was equipped with a removable wood-chip floor and a plexiglas window for observation of behavior. Fine wire leads were plugged into the electrode carrier and attached to a multicontact commutater. The electrical signal was recorded on a polygraph and FM tape recorder for computer analysis. The EEG signal was analyzed for frequency content using the Fast Fourier transform. Various 8-sec epochs were digitized at 256 Hz yielding power spectral values with .125 Hz resolution over a frequency range of 0-128 Hz. The electrical signal was also analyzed for respiration using filtering procedures. The behaviors of rats were scored on the polygraph trace as locomotion, moving in place, quiet resting-sleep, and active-REM sleep. Olfactory stimulation consisted of urine soaked home-cage nest material, an anesthetized lactating dam, and powdered rat food.

With and without specific olfactory simulation, two major frequency components were present within the MOB electrical signal, both of which increased in frequency during development. The lower of the two frequency components (which increased from approximately 14 Hz at 10 days of age to 25 Hz at 21 days of age) was correlated with respiration and sniffing suggesting that these were induced waves as defined by Adrian. The upper frequency component (which increased from approximately 40 Hz at 10 days of age to 63 Hz at 21 days of age) was not linked to respiration and therefore appeared to represent intrinsic waves of Adrian. The ontogeny of these frequency components of spontaneous electrical activity recorded from the MOB parallels the neurogenesis of MOB granule cells and the postnatal development of granule-to-mitral cell synapses in the murine MOB.
(Supported by NICHD grant HD 06364)

216.5 FUNCTIONAL ORGANIZATION OF MOUSE & RAT BARREL CORTEX FOLLOWING WHISKER DAMAGE ON DIFFERENT POSTNATAL DAYS. D.J. Simons, D. Durham and T.A. Woolsey. Dept. Anat. and Neurobiol., Washington U. Sch. Med., St. Louis, MO. 63110.

In mice and rats neonatal lesions of the facial vibrissae alter the anatomical organization of barrels in the contralateral SmI cortex. These effects depend on the pattern of whiskers damaged and the developmental age of the animals. To understand the functional correlates of these anatomical changes, the middle row of vibrissae (Row-C) was damaged in mice and rats on postnatal days 1,3 and 5 and the animals were studied as young adults. Using methods previously described (Simons, '78) over 700 single units were characterized in penetrations parallel and perpendicular to the pia; selected recording sites were marked with the dyes Alcian blue, fast green or HRP; electrode tracts were reconstructed from cortical sections with respect to the layer IV barrels and other cortical layers; and the extent of peripheral damage was verified histologically.

In general, the results from both species demonstrate that, as in normal animals, there is an orderly representation of the periphery which coincides with the cytoarchitectonic organization of the barrels. Specific findings were: 1) Units in the enlarged Row-B or Row-D barrels responded primarily to Row-B or -D whiskers (those next to the damaged Row-C). 2) In layer IV units in the altered Row-C zone either could not be driven from the periphery or were driven from tissue associated with the scar. This Row-C zone is wider the later the whiskers are damaged. 3) Units in supra- and infra-granular layers - which in normal animals are activated by a complement of adjacent whiskers - either behaved as if Row-C were absent or incorporated scar tissue in their receptive fields in a topologically correct fashion. Further, responses of these units to scar tissue were qualitatively similar to those elicited from the intact whiskers (e.g. excited or inhibited). 4) Units in SmII which responded to whiskers had receptive fields which paralleled the representation of the periphery found in SmI. 5) In no case was there mapping of non-mystacial pad representations in the barrel cortex, nor were there units with abnormal multiwhisker interactions when laminar boundaries were taken into account.

We conclude that although neonatal damage to the whiskers predictably alters somatotopy, the functional organization within barrel cortex remains largely unchanged.

216.6 CHANGES IN MODALITY CONVERGENCE IN CELLS OF PARTIALLY DEAFFERENTED DORSAL HORN. M.J. Sedivec*, J. Ovelmen-Levitt*, L.M. Mendell, Dept. Physiol., Duke Univ. Med. Ctr, Durham, N.C. 27710

We have analyzed properties of identified spinocervical units in adult cats anesthetized with α-chloralose. Our aim was to examine whether changes in modality convergence would occur in segments subject to chronic partial deafferentation by extradural dorsal rhizotomy. In intact preparations we observed a proportion of units which could be activated by hair stimulation only (38%) and a similar proportion of units which could be excited by hair and by noxious mechanical stimulation (47%). In spinal segments subject to acute dorsal rhizotomy there was a marked increase in the proportion of units which respond to hair only (71%) and a complementary decrease in the number which responded to both hair and noxious pressure (21%). We hypothesize that the functional projection from afferent fibers mediating the noxious pressure response is more completely restricted to the segment of entry than is the projection from afferent fibers responsive to hair displacement. The acutely deafferented spinal cord provides a more appropriate control population of units for the evaluation of the effects of chronic deafferentation than does the intact preparation. In chronically deafferented segments of the spinal cord we noted a virtual reversal in the proportions of units responsive to hair displacement only (17%) and hair and noxious pressure (68%). An increase was also observed in the percentage of neurons responding to temperature changes in chronically deafferented segments (70% of the units) when compared to acutely deafferented segments (10% of the units). These findings support the hypothesis that afferent connections to the chronically deafferented dorsal horn are altered such that units have a much greater probability of exhibiting convergence from multiple peripheral receptor types. Penetration of neurons studied by extracellular recording in intact and acute deafferented preparations did not reveal a substantial subliminal fringe, e.g. "hair only" cells did not have subthreshold responses to noxious stimulation. Therefore, it seems unlikely that the increase in responses following chronic deafferentation reflects a strengthening of previously weak connections on spinocervical neurons. However, we cannot conclude whether the increase in modality convergence reflects appearance of new functional afferent connections onto spinocervical cells or whether the functional convergence from peripheral receptors onto neurons (e.g. in the substantia gelatinosa) which project to these relay cells is altered by the deafferentation. (Supported by NIH grant NS 14899.)

216.7 PATTERNS OF CORTICOCORTICAL FIBER DEVELOPMENT IN THE NEONATAL RAT. H.P. Killackey and R.M. Akers. Dept. of Psychobiology, Univ. of Calif., Irvine 92717.

The granular parietal cortex of the rat (SmI) projects to three ipsilateral cortical sites: the second somatosensory area (SmII), motor cortex (MC), and the surrounding agranular parietal cortex (APC). Autoradiographic analysis of ^{3}H-leucine transport in neonatal rats revealed that each of these projections follows a different developmental schedule.

Rat pups ranging in age from birth (PND 0) to PND 9 received unilateral cortical injections of isotope and were sacrificed 24 hours later. Intracortical transport of label is evident in animals sacrificed as early as PND 1; conspicuous bands of transported label radiate from the injection site, extending through layer VI to presumptive target areas in SmII, MC and APC. Transport of label into the superjacent cortical layers occurs subsequent to PND 1 in each projection site. In SmII transported label appears in the lower one-half of layer V by PND 2, extends to the upper border of layer V by PND 3, and reaches the superficial cortical layers (I-III) by PND 4. From PND 5 to PND 8, labeling in layers I, III and IV increases; by PND 8 the pattern of label distribution is identical to that seen in adults. In MC transported label is confined to layer VI at PND 2, extends through layer V from PND 3 to PND 5, and does not reach the superficial layers until PND 6. Accumulation of label in layers I-III occurs subsequent to PND 6 and continues through PND 9-10. In APC layers V and VI are heavily labeled from PND 2 through PND 4, but transported label does not extend into the superficial cortical layers until PND 5. The adult pattern of label distribution is established in APC by PND 8.

These findings suggest that: 1) the corticocortical axons are located beneath their cortical target areas on the day following birth and subsequently ascend to terminal fields in the superficial layers; and 2) fibers destined for MC invade their terminal fields one to two days after those destined for SmII and APC.

216.8 FUNCTIONAL REORGANIZATION AND SENSORY INTERACTIONS IN CAT SOMATIC SENSORY-MOTOR AND STRIATE CORTEX. Jacqueline Metzler. Sect. of Neurosurgery, Yale Univ. Sch. of Med., New Haven, CT 06510.

Recent studies have demonstrated the effects of selective experience on the functional characteristics of cells in the developing nervous system. This study examined the effect of selective multi-sensory experience on the functional properties of cells in both somatic sensory-motor (SmI) and striate cortex (VI) of adult cats. Four cats were trained to flex one foreleg (FL) when 2 vertical or horizontal bars were presented to the ipsilateral eye. Failure to respond within 2 sec resulted in a mild electric shock to the ipsilateral hindleg (HL) ankle region. Orthogonally oriented bars presented to the other eye required no response and no shock was administered. Each animal, therefore, served as its own control. All cats performed to criterion (90% correct responses on 3 consecutive days) within 8 wks of training, at which time extracellular single-unit activity was recorded in VI and SmI.

Data from the 85 cells examined in VI revealed ocular dominance (OD) and orientation selectivity distributions to be modified as a a result of training. There was a 5-10% increase in the number of units in OD categories 2 and 6, and a corresponding decrease in categories 3-5, relative to controls. Moreover, 10-16% of the cells activated by the eye associated with the FL flexion/HL ankle shock had receptive-field orientations coincident with the bar pattern the eye had been exposed to during training, relative to those driven by the other eye. More striking changes were found in SmI. In all 4 animals, areas in the hemisphere receiving projections from body regions associated with training and responsive to FL and HL stimulation increased significantly relative to the control hemisphere. The area responsive to FL stimulation expanded about 7 mm^2 (30%) relative to the control SmI, shifting its borders an average of 1.75 mm toward the midline. While the region containing cells activated by stimulation of the HL ankle was, at most, 3-4 mm^2 and adjacent to the midline in the control hemisphere, it now averaged 12 mm^2 in the trained SmI, extending up to 5.5 mm lateral to the midline. The majority (66%) of the 63 cells recorded from the trained hemisphere were also responsive to visual stimuli, with the orientation of the bars associated with training generally the most effective, compared to only 19% of the 56 cells examined in the control hemisphere which responded to all stimulus orientations.

Recent results in the spinal cord (Dostrovsky et al., 1976), DCN (Millar et al., 1976), and SmI (Metzler and Marks, 1979; Franck, 1980) indicate that widespread afferent connections may be present throughout the somatosensory system, but are usually ineffective. The changes observed here may be mediated, at least in part, by local strengthening of such previously latent synapses.

216.9 FUNCTIONAL ORGANIZATION OF RACCOON SOMATOSENSORY CORTEX: EFFECTS OF EARLY PERIPHERAL INJURY. A.M. Kelahan, R.H. Ray, L.V. Carson* and G.S. Doetsch. Depts. of Physiology and Surgery (Neurosurg), Med. Coll. Ga., Augusta, Ga. 30912.

The effects of neonatal peripheral lesions on the functional organization of primary somatosensory (SmI) cortex were studied in the adult raccoon, a species noted for it's anatomically well-demarcated forepaw digit representations (Welker et al., Am. Zool., 4:75-94, 1964). Recordings of primary cortical evoked potentials and single or multiple neuron responses were used to map the SmI forepaw area of normal animals and of animals which had the third digit of the left forepaw amputated several weeks after birth.

In normal animals, the focus of the maximum primary response to "punctate" mechanical stimulation of each digit and pad was localized in a separate gyral region. However, considerable overlap of digit and pad responses was observed; peak-to-peak voltages as great as 25% to 50% of the maximum response at one digit focus could sometimes be recorded from an adjacent digit area. These findings were generally consistent with receptive field (RF) maps derived from single or multiple neuron recordings. Threshold RFs were typically small, usually confined to one claw, one palmar segment of a digit or to one pad. However, RFs mapped with suprathreshold stimuli (Force = 2g and 15g) were larger, often including the palmar aspect of an entire digit and sometimes including an adjacent digit and/or pad.

In animals with left digit 3 amputations, normal somatotopic organization seemed to characterize the left (control) SmI cortex. In contrast, dramatic alterations in somatotopy were found within the right (experimental) SmI area. The primary response foci for the intact digits and the pads retained their usual cortical locations, but the entire area normally containing the digit 3 focus was invaded by inputs from all remaining digits and adjacent skin regions. The site normally representing the digit 3 focus gave large responses to stimulation of the digit 3 stump, the four intact digits and the pads. No unresponsive regions were found. In agreement with these results, threshold RFs of neurons within this tissue were generally larger than normal, often including continuous and discontinuous parts of digits 2 and 4 and/or a pad. Suprathreshold RFs were even more extensive, ranging from two digits and adjacent pads, to all four digits plus the digit 3 stump, to the entire paw; these RFs included dorsal paw regions much more often than normal. Finally there was greater variability in RF location as a function of distance across the cortex and of depth within the cortex. These findings demonstrate that early digit amputation has profound effects on the organization of SmI cortex. The cortical area normally representing a digit that was amputated receives widely overlapping inputs from adjacent skin regions, resulting in local disruption of normal somatotopy.

216.10 LONG TERM VISUAL DEPRIVATION IN A HUMAN. B. Gordon and J. Moran*. Dept. of Psychology, Univ. of Oregon, Eugene, OR 97403.

We have made rough preoperative and postoperative measurements of visual function in a patient (D.C.) with a monocular congenital cataract that was removed at 19 years of age. Acuity was measured with square wave patterns which D.C. identified as horizontal or vertical. Preoperatively, he was virtually blind in his deprived eye, failing to resolve 0.1 c/deg. With his normal eye he resolved about 30c/deg. For postoperative testing we refracted D.C. by retinoscopy because he never obtained a corrective lens. One month postoperatively he resolved 0.4 c/deg, and 4 months postoperatively he resolved 0.6 c/deg. His acuity did not improve further over the next 7 months.

For visual field measurements D.C. detected a small light moved behind a plastic hemisphere from its periphery to its center. Both pre- and postoperatively the visual fields of D.C.'s deprived eye were smaller than were the visual fields of his normal eye. Very high contrast conditions were used (light,17 cd/m^2; background, less than 0.0/cd/m^2) because D.C. could not see the light preoperatively under lower contrast. The deficit was greatest in the contralateral field (temporal retina) which was virtually nonexistent preoperatively and immediately postoperatively. By 3.5 months postoperatively the temporal field had increased to 38°, but the other fields showed no clear increase.

After the fields had stabilized, we tried to detect further improvement by making monthly measurements of D.C.'s visual thresholds as a function of field position. D.C. judged whether or not he could see a light behind a window in a cardboard hemicylinder. The lights were placed every 5° along the horizontal meridian. Thresholds did not change over 7 months, but the thresholds of the deprived eye, in contrast to those of the normal eye, varied markedly with field position. By 50° in the ipsilateral field thresholds were about 2X their value 10° from the fixation point. At 40° in the contralateral field thresholds had risen by 30X this value.

A surprising form of binocular inhibition convinced us that D.C.'s deficits were primarily central. Light reaching D.C.'s normal eye elevated deprived eye thresholds as much as 19X at 10° from the fixation point. Thirty-five degrees from the fixation point this inhibition had disappeared.

These results indicate that many of the effects of monocular deprivation are similar in cat, monkey, and man. They also suggest that the failure of cortical cells to respond to the deprived eye might be modified by rigorously excluding all visual stimulation from the normal eye.

216.11 GOLDFISH RETINA HAS TWO KINDS OF GERMINAL CELLS: ONE IS SPECIFIC FOR RODS. P. R. Johns. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

New cells are added to the retina in growing adult goldfish by germinal cells at the retinal margin. This study describes a second type of germinal cell, located in the outer nuclear layer, which only generates new rods.

Dividing cells were identified using ^{3}H-thymidine autoradiography. Goldfish were injected intraperitoneally six times at 8 hour intervals with 5 μCi/g of ^{3}H-thymidine of very high specific activity (95 Ci/mmole). Retinas were prepared for light microscopic autoradiography using JB-4 plastic. Retinas from normal, uninjected fish were prepared for electron microscopy.

At 1 to 5 days after injection, the marginal germinal cells were heavily labeled. By 10 to 20 days they had produced heavily and weakly labeled neurons in all retinal layers. Electron microscopic examination of the newly-formed retina immediately adjacent to the germinal zone revealed that the outer nuclear layer (ONL) was incomplete -- it contained no rods, but only a single row of immature cones. Rod nuclei (smaller, rounder and darker than cone nuclei) first appeared several cell diameters more centrally. This suggests that rods may be produced outside the marginal germinal zone. Autoradiographs revealed a dispersed population of dividing cells in the ONL, lying along the border of the outer plexiform layer (OPL). More than half of these labeled cells were within 0.5 to 1 mm of the margin; the rest were spread out, sometimes in groups, along the central 3 to 4 mm length of retina. In electron micrographs of peripheral retina these cells were tentatively identified; they appeared very similar to marginal germinal cells. By 10 to 20 days the labeled cells in the ONL had divided: there were more of them and many were weakly labeled. Some had moved away from the OPL border and were now among the rod nuclei and, in light microscopic autoradiographs, the labeled cells were indistinguishable from rods. Electron microscopic autoradiographic studies are in progress to confirm that the dividing cells in the ONL are producing rods.

As the goldfish grows, the ratio of rods to ganglion cells increases several fold across the entire retina. This is difficult to explain if new rods are produced only at the margin of the retina; to do so requires that the layers of retinal cells be allowed to slide past one another as the retina grows. The presence of a dispersed rod precursor provides an explanation for the higher proportion of rods in larger fish retinas -- as the retina grows, new rods are inserted into already differentiated regions of retina, where the population of ganglion cells and other retinal neurons is stable.

216.12 DEVELOPMENT OF SINGLE-FIBER TASTE RESPONSES TO MONOCHLORIDE SALTS IN THE RAT'S CHORDA TYMPANI NERVE. D. L. Hill, R. M. Bradley, and C. M. Mistretta. Dept. Oral Biol., Sch. Dent., U. Mich., Ann Arbor, MI 48109.

Integrated recordings from the rat's chorda tympani nerve change developmentally in response to lingually applied monochloride salts (Neurosci. Abst., 5, 127 & 128). Responses to NaCl and LiCl are smaller relative to NH_4Cl in the young rat. Throughout development, though, NaCl and LiCl become more effective stimuli. To learn if young fibers respond to NaCl and LiCl, and to identify possible developmental changes in response frequencies and response-concentration functions, we recorded from single chorda tympani fibers. Solutions of 0.1 M and 0.5 M NH_4Cl, NaCl, LiCl, KCl, and a concentration series of NH_4Cl (0.005-1.0 M) were applied to the anterior tongue for 15 seconds. Each solution was followed by a distilled water rinse.

Data from 19 single fibers in rats 14-20 days old, 16 fibers in rats 24-35 days old, and 20 fibers in adults were similar to integrated data after responses were expressed relative to the NaCl response. All fibers responded to each stimulus. For 0.1 M solutions, response frequencies to NH_4Cl and KCl did not differ for age; frequencies to NaCl and LiCl significantly increased between 20 days of age and adulthood. Response frequencies to 0.5 M NH_4Cl also did not differ with age while frequencies to 0.5 M NaCl, LiCl, and KCl significantly increased between 20 days of age and adulthood. Mean responses for rats 24-35 days of age were intermediate to those for 14-20 day rats and adults. Most young fibers responded maximally to NH_4Cl solutions and most adult fibers responded maximally to NaCl or LiCl, whereas, the majority of fibers in rats 24-35 days old responded similarly to all equimolar salts. No fiber responded maximally to KCl. Response-concentration functions from 6 young and 6 adult fibers for NH_4Cl were similar, and the binding constants calculated for both groups were nearly identical to those reported by Beidler (Prog. Biophys. & Biophys. Chem., 12, 107-151).

In summary, developmental changes in integrated chorda tympani responses cannot be explained by an absence of young fibers responding to NaCl and LiCl. However, they may be explained by developmental increases in frequencies to NaCl and LiCl while frequencies to NH_4Cl remain constant, and by changes in the number of fibers responding maximally to NH_4Cl, or NaCl and LiCl. Since response-concentration functions for NH_4Cl are similar throughout development and NH_4Cl response frequencies do not change, taste receptor membrane sensitivity to NH_4Cl may be stable during development. Conversely, membrane sensitivity to NaCl and LiCl probably changes. (Supported by NIH Postdoctoral Fellowship NS06423 to D.H. and N.S.F. Grant BNS77-09920 to R.M.B. & C.M.M.)

216.13 ULTRASTRUCTURAL CHANGES IN DEVELOPING TASTE BUDS ACCOMPANY FUNCTIONAL CHANGES. Robert M. Bradley, Charlotte M. Mistretta and Soo D. Lee*. Dept. Oral Biol., Sch. Dent., U. Mich., Ann Arbor, MI 48109.

Previous work from this laboratory has demonstrated that electrophysiological taste responses to salts and acids change during development in fetal and newborn sheep. To learn about taste receptor morphology during the period of functional changes, we have studied the ultrastructure of developing taste buds in sheep fungiform papillae. Eight fetuses aged 75-135 days of gestation (term = 147 days), 1 lamb and 1 adult sheep were perfused with buffered glutaraldehyde, the tongues removed, and fungiform papillae dissected and post-fixed in buffered OsO_4. The papillae were embedded in epon and sectioned for electron microscopy.

In the youngest fetuses (75 days), no taste pits or pores are observed. The taste bud consists of a complex arrangement of cells covered by one or two layers of epithelial cells. Between the taste bud cells are large numbers of nerve profiles. In most cells the nucleus has a dense appearance and the cytoplasm contains dark granules. However, the nuclei of a small number of cells are less dense in appearance, and these cells do not have dense cytoplasmic granules. Two cell types are therefore observed --'dark' and 'light'. At 80 days of gestation, taste pits are present. These consist of a shallow depression in the surface of the papilla; the base of this depression is composed of the apices of the taste bud cells. Cells lining the pit terminate either in short microvilli or blunt, club-shaped processes. All cell apices are joined by tight junctions, and nerve profiles are seen close to the pit area. Both light and dark cells are present.

The microvilli have increased in length (but not in number) in fetuses of 100 days. Some club-shaped apical processes are still present. No differences are observed in the apical cytoplasmic contents of those cells that end in either microvilli or club processes. In term fetuses, lambs, and adults, the structure of the taste pit is similar to that in the 100 day fetus. However, the pit now communicates with the surface of the papilla by a narrow taste pore filled with a dense amorphous substance.

In conclusion, taste buds at all ages studied possess at least two cell types, and when a taste pit is present, microvilli and other processes are observed. The apices of the cells are joined by tight junctions from at least 80 days of gestation. Since microvilli and tight junctions are present, there is no reason to propose that chemicals penetrate into the taste bud in fetal animals. Rather, taste stimulation is probably via interaction with microvilli membranes as in adults.

216.14 DEVELOPMENT OF SPINOCEREBELLAR PROJECTIONS IN THE POUCH YOUNG OPOSSUM. James C. Hazlett, Department of Anatomy, Wayne State University, Detroit, MI. 48201.

The present study is part of our ongoing analysis of the development of long ascending pathways in the opossum. Spinal cord lesions (tractotomies or hemisections) were performed at C-2 in seven litters of pouch young opossums ranging in age from 26 to 75 days in the pouch. Results from the three youngest litters will be reported here. The approximate ages of each litter were based on measurements of snout-rump length with subsequent reference to the growth curves determined for the opossum (Cutts et al.,'78). The spinal cord lesions were performed under hypothermic anesthesia and survival times of 6,12,18,24 and 30 to 36 hours were selected in an attempt to increase the successful identification of degenerating axons. Brains were embedded in egg yolk, sectioned in the transverse plane and reacted by the Fink-Schneider technique for degenerating immature axons. In the youngest group studied (26 days in the pouch) axonal debris is present in the brainstem underlying the cerebellum and a very sparse accumulation of axon fragments is observed in the cerebellar peduncles. These latter structures are not well demarcated at this age. Within the cerebellum the only area containing unequivocal degenerating fragments is located in the posterior lobe vermis. At this age it is not certain if this area corresponds to the pyramis. Furthermore, the degenerating fragments are located just below the external granular layer. This lamina of cells is still in the process of inward migration at this time. No degeneration was observed in the anterior lobe. The second group (33 days in the pouch) present approximately the same degeneration picture as observed in the youngest group. However, folial development has progressed sufficiently to permit the identification of major cerebellar subdivisions. In the oldest group (41 days in the pouch) more axonal debris was present in the brainstem than was observed at earlier ages. It is now possible to identify the cerebellar peduncles as separate structures which contain scattered degenerating axon fragments. One folium in the posterior lobe (assumed to be the pyramis) contains an accumulation of degenerating axon fragments on the dorsolateral periphery, bilaterally. In addition, a few widely scattered clumps of axonal debris were identified in the middle of the anterior lobe. This is the first stage in which we observed degeneration in this area. Earlier and later litters of pouch young opossums are being examined in an attempt to 1. determine the time at which spinal axons first encounter the cerebellum and 2. establish the time when the well- known longitudinal orientation is first encountered. 216.16 EFFECTS OF SYNAPTIC ACTIVITY ON THE SIZE OF SOMATIC SPINES AND ON THEIR CONTENT OF SMOOTH ENDOPLASMIC RETICULUM. L. Maler, E. Sas*. Dept. of Anatomy, Sch. of Med., Univ. of Ottawa, Ontario K1N 9A9, Canada.

The size and number of dendritic spines have proven to be a sensitive indicator of synaptic activity in a number of systems. This is especially apparent in the visual system where a number of workers have demonstrated that the integrity of certain spines on the apical dendrites of striate cortex pyramidal neurons is dependent on visual input. We have been studying the posterior lateral line lobe of gymnotid fish - this region of the brain receives a direct input from the electroreceptors distributed over the fish's body surface. Electroreceptor afferents make monosynaptic contacts with interneurons of the posterior lobe, and these interneurons in turn project to the somata, somatic spines of large pyramidal cells of the posterior lobe (Maler, L., J. Comp. Neurol., 183:323, 1979;Maler, L., Sas, E. and Rogers, J., J. Comp. Neurol. in press). The somatic spines of pyramidal neurons are a good system for analyzing the effect of synaptic input on spine structure because i) the peripheral nerve to the electroreceptors is readily accessible to resection or stimulation, and ii) electroreceptor afferents in these fish discharge continuously at very high frequencies (50-250 Hz), which means that deafferention produces a drastic drop in synaptic input.

We have sectioned the electroreceptor afferent nerve peripheral to its ganglion and examined thin sections of the posterior lobe following survival times of 6 hr to 6 days. The overall cytology of the posterior lobe does not change following this treatment; in particular the axon terminals of the local interneurons shows very little alteration. One to three days after nerve section the somatic spines upon which these terminals synapse become shrunken by about 30%-50%; they also show a dramatic decrease in their content of smooth endoplasmic reticulum (SER; 90% loss). After 6 days survival time half the somatic spines remain shrunken and lack SER; the rest return to normal in both size and SER contents. As regeneration proceeds all the spines return to their presurgical appearance. The cell biological and functional implications of these findings will be discussed.

217.1 ANTICONVULSANT TOXICITY: CHRONIC PHENYTOIN EXPOSURE DECREASES NEURONAL NUMBER IN CELL CULTURES FROM FETAL MOUSE CEREBRAL CORTEX. E.A. Neale, K.F. Swaiman,* B.K. Schrier, W.H. Habig,* and P.G. Nelson. Lab. Devel. Neurobiol., NICHD, NIH, Bethesda, MD 20205, Div. of Ped. Neurol., Univ. of Minn., Minneapolis, MN 55455, and Div. Bact. Prod., Bureau of Biologics, NIH, Bethesda, MD 20205.

Phenytoin is an anticonvulsant frequently administered for seizure therapy of pregnant women, neonates, infants and children. Studies were undertaken to evaluate the effect of chronic phenytoin treatment on developing central neurons. Dissociated cell cultures were prepared from 16 day fetal mouse cerebral cortex. After growth for 11 days, phenytoin (mid-therapeutic to toxic levels--15 µg/ml, 25 µg/ml, and 50 µg/ml) was added to the culture medium for an additional 7 days.

Phenytoin-treated and control cultures were assayed for neuronal cell number by phase microscopy, and for ^{125}I-tetanus toxin binding and ^{3}H-γ-aminobutyric acid (GABA) uptake by both scintillation spectrometry and radioautography. In control cultures, morphologically identified neurons grew as networks or aggregates. These cells displayed ultrastructural features typical of neurons, and synaptic profiles were common. After incubation for 30 min. at 37°C in 0.1 uM ^{3}H-GABA and subsequent radioautography, approximately 10-15% of the neurons were heavily labeled with silver grains.

Analysis of phenytoin-treated cultures indicated a drug-related loss of neurons. At the concentrations of phenytoin tested, neuronal cell counts were depressed to approximately 70%, 60%, and 15% respectively, of control values. Decreases in neuronal cell counts were paralleled by decreases in both ^{125}I-tetanus toxin binding and ^{3}H-GABA uptake. The number of neurons radioautographically labeled by high affinity GABA-uptake was depressed to the same extent as total neurons, indicating that the presumed GABAergic neurons were not preferentially spared. In similar preparations (see abstract this volume, D.W. Gallager, et al.), clonazepam-displaceable ^{3}H-diazepam binding (an index of neuronal benzodiazepine receptors) was also significantly depressed.

These studies suggest that therapeutic concentrations of phenytoin may alter numbers of developing neurons. The use of ^{125}I-tetanus toxin binding and ^{3}H-GABA uptake are reliable means of assessing this effect. The utilization of this culture system, in conjuction with quantitative morphological and biochemical techniques, provides a useful approach to the evaluation of drug effects on developing nervous tissue.

217.2 ENHANCEMENT OF SYMPATHETIC NERVE DEVELOPMENT IN THE FETAL ALCOHOL SYNDROME. J.V. Bartolome*, S.M. Schanberg and T.A. Slotkin. (SPON: W.A. Wilson). Dept. of Pharmacology, Duke Univ. Medical Ctr., Durham, N.C. 27710.

Exposure of the fetus to ethanol produces abnormalities in maturation of the nervous system, with potentially serious consequences for subsequent development. Long-term damage can occur in behavior and in function of various organ systems. Previous studies have shown that cardiovascular development may be compromised, and the current work examines whether disturbances in the ontogeny of peripheral sympathetic nerves are involved in the cardiovascular effects. The fetal alcohol syndrome was induced by providing 6.8% ethanol in a liquid diet to pregnant rats from the 13th day of gestation; at parturition, all rats were cross-fostered to normal mothers to ensure adequate maternal care. Development of sympathetic neurotransmission in the heart and adrenal medulla of the offspring was monitored by eliciting reflex central stimulation with insulin-induced hypoglycemia. Stimulation was assessed by measuring secretion of adrenal catecholamines and β-adrenoceptor mediated stimulation of cardiac ornithine decarboxylase activity evoked by the insulin treatment. In control neonates (offspring of mothers given isocaloric liquid diet without ethanol), sympathetic neurotransmission was absent at birth and was first operable toward the end of the first week of postnatal age. In contrast, pups whose mothers received ethanol displayed functional sympathetic reflex responses as early as 2 days of postnatal age. The development of peripheral sympathetic neurotransmission thus occurs precociously in the fetal alcohol syndrome; *this should not be viewed as a beneficial, nor even an innocuous event, since premature exposure of developing tissues to neuronal input may be responsible for the subsequent abnormalities of cellular maturation in those tissues.*

217.3 THE IMPORTANCE OF PRENATAL LEAD(Pb) EXPOSURE TO POSTNATAL BRAIN DEVELOPMENT IN THE RAT PUP. Paul T. McCauley, Annette Tonti and Richard J. Bull, Health Effects Research Laboratory, U.S. Environmental Protection Agency, Cincinnati, Ohio 45268

Previous reports from this laboratory, McCauley et al. (Neuropharmcol. 18:93-101, 1979) document delayed synaptogenesis in the cerebral cortex of male offspring of female rats that were exposed to 200 ppm Pb in drinking water from two weeks prior to breeding until pups were weaned at 21 days of age. Subsequent experiments have demonstrated that the prenatal exposure to Pb played the major role in delayed behavioral development of rat pups (Crofton et al. Life Sciences 26:823-831, 1980). To determine whether the prenatal exposure to Pb played the same role in delaying synaptogenesis, cross-fostering experiments were initiated. Photographs were made (10,000 x mag) of layers 1-3 of the parietal contex and synaptic figures visualized by ethanol-phosphotungstic acid stain were counted blind by four different observers.

The table shows observed synapse counts and blood Pb for 15 day old pups (Prenatal/Postnatal exposure to pup):

Exposure			Synapse/mm^3	Pup Blood Pb Concentration in mg%
Prenatal	Postnatal			
Control	Control	CT/CT	4.15 ± .35	4.6 ± 0.9
Control	Lead	CT/Pb	3.97 ± .64	24.8 ± 1.3
Lead	Control	Pb/CT	2.78 ± .52	6.9 ± 0.9
Lead	Lead	Pb/Pb	2.92 ± .42	30.3 ± 2.9

Synaptic counts in groups Pb/CT and Pb/Pb were statistically different from group CT/CT (P = .026 and P = .025 respectively. CT/Pb pups were not significantly different from CT/CT (P = .82).

The data demonstrates that gestation period is the critical period for low level lead exposure to produce delays in synaptogenesis. Synaptogenesis is clearly less sensitive to low level Pb exposure during lactation despite the fact that pup blood lead levels in the CT/Pb group are considerably greater than the Pb/CT group at 15 days of age. Parallel effects on the development of exploratory and locomotor activity using the same cross-fostering design were seen by Crofton et al. As in the delays in synaptogenesis, delays in behavioral development produced in Pb/Pb animals were almost entirely accounted for in Pb/CT animals. These data strongly suggest that development of the cerebral cortex, a largely postnatal event, is more sensitive to in utero exposure to lead than postnatal exposure to Pb. Current data suggest this result may be related to a peak in blood Pb concentrations in the dam and pup just prior to birth (Bull, et al. Pharmacologist 21:210, 1979.

217.4 SHAKING STIMULATIION ACCELERATES HATCHING TIME IN CHICKEN EGGS. J. H. Gassler*, M. L. Kirby, S. D. Stoney. Depts. of Anatomy and Physiology, Medical College of Georgia, Augusta, GA 30912.

The avian embryo is sensitive to different types of sensory stimulation during development. It is known that light and auditory stimuli given during incubation will accelerate hatching time. The vestibular system matures early in the development of the chick embryo. Its integrity is necessary for hatching to occur. It is not known what effects vestibular stimulation would have on the developing chick embryo. To address this question, White Leghorn chicken eggs were incubated at 37.5±.5°C and 60% humidity in a forced draft incubator, modified to allow shaking of experimental eggs. The experimental egg tray was shaken linearly with a 1.5 inch excursion, 70 cycles per minute on an intermittent schedule (2 hours on, 2 hours off). Shaking began on day 10 (240 hours) and continued until pipping, when the eggs were transferred to a brooder. Control eggs were incubated on a separate stationary tray in the same incubator. Motility was recorded in 13 to 19 day embryos by placing platinum electrodes into holes pierced in the egg and recorded on a Beckman Dynograph. Recordings were made during the following time periods: a) the last 15 minutes of the resting portion of the cycle; b) the first 15 minutes after the shaker was turned on; c) the last 15 minutes of the shaking portion of the cycle; and d) the first 15 minutes after the shaker shut off. Results indicate that hatching time is decreased by 7 hours in experimental eggs. There is no difference in body weights between the two groups. Motility recordings indicate that beginning on day 15, shaken eggs show increased motility when shaking begins, but after 2 hours of stimulation motility has decreased to levels recorded when the shaker is off. Control eggs maintain a constant level of motility during all recording periods.

217.5 EFFECT OF MATERNAL DIETARY PROTEIN RESTRICTION ON ONTOGENY OF OLFACTORY BULB ELECTRICAL ACTIVITY IN THE RAT. W. B. Forbes, C. R. Almli, M. A. Henault,* and C. A. Velozo*. Worcester Foundation for Experimental Biology, Shrewsbury, MA, 01545, and Ohio University, Athens, OH, 45701.

Ontogeny of main olfactory bulb (MOB) EEG was studied in male rats whose dams were fed one of two isocaloric diets containing 8% or 25% casein for five weeks prior to mating, throughout gestation and lactation. Bipolar stainless steel electrodes were chronically implanted in the MOB of rats 3 - 19 days of age. EEG was recorded for two hours on each of 3 consecutive days. Between recording sessions, rats were returned to their home cages. Rats of all dietary and age groups exhibited normal body growth over the three day recording period. Behavior of the pups during recording sessions was monitored visually. Urine-soaked nest material and an anesthetized lactating dam served as specific olfactory stimuli. Multiple 8-sec epochs of MOB electrical activity were digitized at 256 Hz and analyzed using fast-Fourier techniques yielding power spectral values with a resolution of .125 Hz over a range of 0 - 128 Hz.

MOB electrical activity was found to contain two frequency components in rats 10 - 21 days of age. In control (25% casein) rats, the lower frequency component increased from about 14 Hz at 10 days of age to about 25 Hz at 21 days of age. The higher frequency component increased from about 40 Hz at 10 days of age to about 63 Hz at 21 days of age. These two components were interpreted as Adrian's "induced" and "intrinsic" waves, respectively. The effect of maternal dietary protein restriction was to retard this developmental pattern by 1 - 2 days. Since normal EEG ontogeny closely parallels the morphological development of the granule cell population of the MOB, the retardation associated with dietary restriction may be associated with retarded structural ontogeny of this specific class of neuron in the MOB.

217.6 RETARDED BRAIN GROWTH IN NEONATAL RATS EXPOSED TO HYPERPHENYLALANINEMIA IN UTERO

D.A. Spero* and M.C. Yu* (SPON.L. Laemle) Department of Anatomy New Jersey Medical School, Newark, New Jersey 07103.

High levels of phenylalanine in maternal plasma are in most cases caused by a defect in phenylalanine hydroxylase, an hepatic enzyme necessary for the conversion of phenylalanine to tyrosine. Excessive phenylalanine in maternal plasma has been shown to be transported across the placenta and to interfere with the normal processes of prenatal development resulting in a condition known as maternal hyperphenylalaninemia. In the present study hyperphenylalaninemia was induced in 2 groups of pregnant rats from the 14th through the 21st days of gestation in the following manner: Group I received subcutaneous injections of L-phenylalanine (Phe) (250mg./100g.B.W.) plus methylphenylalanine (mPhe) an inhibitor of phenylalanine hydroxylase at a dosage of 300mg./100g.B.W. dissolved in carboxymethycellulose (CMC) two times daily at 12-hr. intervals. Group II was injected with Phe (400 mg /100g.B.W.) in CMC three times daily at 8-hr. intervals. For control, another group of animals were injected with CMC and pair-fed during the treatment period. mPhe/Phe treatment resulted in a 30-fold increase in fetal plasma Phe for approximately 10-hr. postinjection. Phe treatment alone resulted in a 24-fold increase in plasma Phe for 3-hr. postinjection. At day 20 of gestation (D20G) and day 1 (D1) and day 5 (D5) postnatal, the body and brain weights of the mPhe/Phe and Phe treated rats were significantly lower than the control. Light and electron microscopic observations of the cerebral cortex revealed distinct morphological alterations in both treated groups which were not present in the control. These include a decrease in thickness of the cerebral cortices and increased cell packing density, an increase in cell death and in the number of phagocytic cells. The number of pyknotic cells reached a peak at birth in both treatment groups. These changes were more severe in the mPhe/Phe treated group than in the Phe group. Biochemical determinations revealed that the DNA content of the cerebral cortex of both the mPhe/Phe and Phe treated groups were significantly less than the control at D20G, D1 and D5, respectively. These findings suggest that the retarded brain growth in the treated groups may be due in part to increased cell death.

217.7 EFFECTS OF PRENATAL ETHANOL EXPOSURE IN RATS. Francine Lancaster, Bina Mayur* and T. Sámorajski. Dept. of Biology, Texas Woman's University, Houston, TX 77030.

Pregnant (days 5-19 gestation) Long-Evans rats were fed ethanol (6.7% v/v) in a modified Lieber-DeCarli liquid diet. Control groups were: (1) pair-fed liquid diet (2) liquid diet ad libitum (3) lab chow and water ad libitum. After day 19 of gestation, all animals received lab chow and water ad libitum. All litters were culled to seven pups at birth. Biweekly weight records were maintained for all animals. At ages 16, 21, and 30 days experimental pups were injected intraperitoneally with ^{3}H-leucine and control pups with 1-^{14}C-leucine. Synthesis of brain subcellular proteins and quantitative myelin were measured. At the age of 30 days organ/body weight ratios of brain, pituitary, adrenals, heart, spleen, liver, and kidneys were determined. Myelin levels of ethanol animals were lower than those of controls. Spleen/body weight ratios of ethanol animals were higher than all control groups. Supported by grants from TWU and Texas Research Institute for Mental Sciences.

218.1 ADAPTIVE COMPENSATORY RESPONSES AFTER ADRENAL DEMEDULLATION IN RATS. P. Christopher Coburn*, Jean A. Hosutt*, Edward M. Stricker, Michael J. Zigmond, (Sponsor: R. Keller). Departments of Psychology and Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

Bilateral removal of the adrenal medulla in adult male rats was found to greatly impair their maintenance of arterial blood pressure (ABP) during hypovolemia. For example, intact animals did not become hypotensive despite plasma volume deficits of 20-30% induced by subcutaneous treatment with hypertoncotic solutions of polyethylene glycol (PEG). Two days after adrenal demedullation, however, PEG treatment lowered ABP by 30-50 mm Hg while heart rate decreased. These effects were not seen either when PEG-treated rats could compensate behaviorally by drinking isotonic NaCl solution, or when animals were examined 2 wk after adrenal demedullation in the absence of drinking fluids.

Adrenal demedullation also interfered with the maintenance of blood sugar during insulin-induced hypoglycemia. For example, in normal rats blood glucose was depressed to 30-50 mg/100 ml after iv injection of 2U insulin/kg but returned to normal levels of 100-110 mg/100 ml within 90-120 min; in contrast in rats tested 2-3 days after adrenal demedullation blood glucose usually remained depressed throughout the 5-hr period of observation or dropped to such low levels that rats succumbed to hypoglycemic shock. When food was available, adrenal demedullated rats ate so rapidly after insulin treatment that the induced hypoglycemia was blunted. When these experiments were repeated 3 wk later, adrenal demedullated rats maintained a stable hypoglycemia after insulin treatment whether food was available or not. This improvement was abolished after sympathectomy by 6-hydroxydopamine (75 mg/kg, iv). Since epinephrine-induced hyperglycemia was not altered, these findings collectively suggest that a gradual increase in the capacity for NE release from the sympathetic nerves permits the recovery of function after adrenal demedullation. As such, these results parallel our recent findings that the synthesis and release of NE from residual neurons increases following subtotal destruction of noradrenergic nerve terminals in the brain (Acheson et al., Science 207: 537-540, 1980).

218.2 CHANGES IN ADRENAL TETRAHYDROBIOPTERIN (BH_4) INDUCED BY INSULIN AND RESERPINE AND ITS ROLE IN BH_4-DEPENDENT HYDROXYLATION REACTIONS. Martha Abou-Donia*, S. P. Wilson and O. H. Viveros. Dept. of Medicinal Biochemistry, Wellcome Research Laboratories, Research Triangle Park, North Carolina 27709.

BH_4, the cofactor for tyrosine-hydroxylase (TH) and other aromatic amino acid hydroxylases, is present in monoaminergic cells and nerve terminals at limiting concentrations (Mandell, A. J., Ann. Rev. Pharmacol. Toxicol., 18: 461, 1978). Neurogenic stimulation and catecholamine (CA) depletion induce TH synthesis in the adrenal medulla (Viveros et al., Mol. Pharmacol. 5: 69, 1969). TH induction can be functionally expressed only if the concentration of cofactor is maintained or increased. Two days after addition of reserpine (100 nM) to primary cultures of bovine chromaffin cells, total TH activity from lysed cells doubles, while BH_4 levels and tyrosine hydroxylation in intact cells fall to 23 and 72% of control, respectively. Addition of BH_4 (100 μM) to the medium increases tyrosine hydroxylation such that reserpine treated cultures have 38% more activity than controls. In contrast to the effect in culture, administration of reserpine to rats (5 mg/kg, i.p.) increases adrenal gland BH_4 from 287 ± 32 ng/g to 1,044 ± 129 ng/g 24 hr later, and to 768 ± 52 ng/g 24 hr after hypoglycemia, induced by insulin, 10 U/kg i.v. (values are means ± S.E., N=5 for each group). BH_4 levels return to normal 3 days after reserpine. These effects are only partially blocked by splanchnic denervation or chlorisondamine administration (2 x 5 mg/kg). When BH_4 was determined separately in medulla and cortex, insulin and reserpine increased medullary BH_4 by 40% ($p<0.05$ vs control); cortical BH_4 increased by 245% ($p<0.001$). Denervation prevented the increase in medullary BH_4 but not the increase in cortical BH_4 induced by insulin. Both insulin-induced hypoglycemia and reserpine are known to induce ACTH secretion from the hypophysis. This is the first demonstration that increased cellular activity can lead to significant and rapid increases in endogenous cofactor levels. Regulation of BH_4 concentration may occur through changes in the activity of biopterin synthetic enzymes (see these Abstracts: J. C. Nixon et al.). The same stimuli that increase BH_4 also induce TH, dopamine-β-hydroxylase, CA uptake and storage, and opioid peptide synthesis in the adrenal medulla. Control of BH_4 levels has obvious implications for the regulation of monoamine synthesis and the activity of other BH_4 dependent enzymes.

218.3 INDUCTION OF GTP-CYCLOHYDROLASE BY THE STIMULI THAT INCREASE TETRAHYDROBIOPTERIN (BH_4) IN RAT ADRENAL MEDULLA AND CORTEX. J. C. Nixon*, C.-L. Lee*, M. Abou-Donia*, T. Fukushima*, C. A. Nichol*, E. Diliberto*, Jr. and O. H. Viveros. Dept. of Medicinal Biochemistry, Wellcome Research Laboratories, Research Triangle Park, North Carolina 27709.

The activation of adrenal medullary chromaffin cells by reflex neurogenic stimulation and/or catecholamine depletion (reserpine and insulin hypoglycemia) of adrenal cortical cells is accompanied by rapid and significant increases in total biopterin and in the active cofactor, BH_4 (see previous abstract: Abou-Donia, Wilson and Viveros). GTP-cyclohydrolase is the first enzyme in the BH_4 biosynthetic pathway. The activity of this enzyme was determined by a direct measurement of neopterin formed in a reaction utilizing saturating levels of GTP as substrate. The immediate product of this reaction was then oxidized and enzymatically dephosphorylated to yield neopterin, which was quantitated by high-performance liquid-chromatography (Fukushima and Nixon, Anal. Biochem., 102, 176-188,1980). The enzyme was extracted from adrenal medulla and adrenal cortex homogenates and partially purified through a G-25 Sephadex column. While adrenal medulla GTP-cyclohydrolase has a 6-fold higher specific activity [313 ± 17 pmole/hr/mg protein (mean ± S.E., n=5)] than the cortex, the total enzyme activity in the adrenal is 41% cortex, 59% medulla. Reserpine (5 mg/kg i.p., administered 24 hr before sacrifice) increases GTP-cyclohydrolase activity to 147 ± 26 pmole/hr/mg protein in cortex and 722 ± 67 pmole/hr/mg protein in adrenal medulla. Simultaneous injection of reserpine with cycloheximide (1 mg/kg) decreases GTP-cyclohydrolase activity in medulla to 255 ± 35 pmole/hr/mg protein and cortex to 63 ± 15 pmole/hr/mg protein, while cycloheximide does not affect the enzyme activity in the cortex of non-reserpine-treated animals and decreases it by 34% in the adrenal medulla. The activity of dihydropteridine reductase, the enzyme that recycles quinonoid dihydrobiopterin to BH_4, is not altered by reserpine treatment. This is the first demonstration that GTP-cyclohydrolase activity can be controlled and amplified, apparently by an induction of enzyme synthesis, and supports our previous report that endogenous BH_4 levels are regulated by changes in cellular activity. Activation of adrenal medullary cells leads to a coordinated induction of both the synthesis of chromaffin vesicles to take up and store catecholamines and induction of the enzymes necessary for catecholamine synthesis including tyrosine hydroxylase, dopamine-β-hydroxylase and GTP-cyclohydrolase for adequate supply of BH_4.

218.4 PRODUCTION AND RELEASE OF ACETYLCHOLINESTERASE BY ADRENAL CHROMAFFIN CELLS IN CULTURE. Fumio Mizobe* and Bruce G. Livett, Division of Neurology, The Montreal General Hospital and McGill University, Montreal, Canada.

Histochemical studies of the bovine adrenal gland have shown that acetylcholinesterase (AChE) activity occurs both in association with the splanchnic nerve and also in the target chromaffin cells. The origin of this cellular AChE in the chromaffin cells, however, has not been firmly established. We have previously shown that bovine adrenal chromaffin cells can be isolated and maintained as primary cultures under conditions free of non-neuronal cells. The absence of splanchnic nerve influence on these cells in culture therefore provided a convenient system for investigating the origin of the cellular AChE in the adrenal medulla.

The cells when freshly isolated by collagenase perfusion contained only low levels of AChE activity (3.4 ±0.3nmol/min/10^6 cells), but synthesized AChE during the culture period. The total AChE activity increased 6-fold from days 2-15. The non-specific cholinesterase activity of the cells remained at less than 6% of AChE activity. It was also found that AChE activity appeared in the culture medium and increased in activity proportional to the period during which the medium was in contact with the cells. These findings show that chromaffin cells produce and release AChE into their immediate environment. The cumulative amount of AChE activity released into the medium over 15 days reached 60 nmole/min/10^6 cells.

We have examined the role of the nascent AChE on cholinergic stimulus-secretion coupling in the cultured chromaffin cells.[1] A progressive decrease in the efficacy of ACh ($5x10^{-5}$M) to evoke release of (^{3}H) noradrenaline from day 3-15 cultures suggested that exogenously applied ACh was hydrolyzed by the nascent AChE synthesized by the cells, part of which is probably located on the plasma membranes of the chromaffin cells. This conclusion was supported by our finding that nicotine ($5x10^{-6}$M) exhibited a constant agonist activity on the cells throughout the 15 day period and that pre-incubation of 3-15 day old cultures with eserine ($4x10^{-6}$M) or with the non-permeant AChE inhibitor BW284C51 ($5x10^{-7}$M) completely restored the efficacy of ACh as an agonist.

218.5 THE ROLE OF GLUCOCORTICOID STEROIDS IN THE EXPRESSION OF THE ADRENERGIC PHENOTYPE IN THE RAT EMBRYONIC ADRENAL GLAND. M.C. Bohn, M. Goldstein and I.B. Black. Dept. of Neurology, Cornell Univ. Med. Coll., New York, N.Y. 10021 and Dept. Psychiatry, New York Univ. Med. Ctr., New York, N.Y. 10016.

Differentiation of the noradrenergic and adrenergic phenotypes was documented in rat embryonic adrenal medullary cells in vivo from 12.5 days of gestation (E 12.5) to term. The initial appearance of biochemical indices of noradrenergic expression (tyrosine hydroxylase, T-OH; dopamine-β-hydroxylase, DBH, and endogenous catecholamines, CA) and adrenergic expression (phenylethanolamine N-methyltransferase, PNMT) was followed by immunocytochemistry and histofluorescence. At E 13.5, cells containing T-OH, DBH and CA were observed in sympathetic ganglion primordia at the level of the adrenal anlage, along the aorta between sympathetic ganglia and the developing adrenal, and within the adrenal itself. While T-OH, DBH and CA were present in adrenal medullary cells from the earliest stages of adrenal morphogenesis, PNMT, in contrast, was undetectable in ganglion primordia, migrating cells or within the adrenal before 17 days. PNMT initially appeared at E 17 in small clusters of cells scattered throughout the adrenal. The number of PNMT containing cells and the intensity of staining increased dramatically from E 17 to term.

A number of experimental manipulations were employed in vivo to investigate the role of glucocorticoids in differentiation of the adrenergic phenotype. Chronic or acute treatment of mothers and/or embryos with various glucocorticoids, adrenocorticotrophic hormone or s-adenosylmethionine did not result in precocious appearance of PNMT. Moreover, the initial expression of PNMT was not prevented or delayed by embryonic hypophysectomy or by treatment with inhibitors of adrenocortical function. After initial expression of PNMT had occurred, cellular levels of PNMT as indicated by the intensity of immunofluorescence, were augmented by glucocorticoid treatment and diminished by embryonic hypophysectomy.

Consequently, the initial expression of PNMT on E 17.0 (1) is not dependent on normal glucocorticoid levels, (2) cannot be induced prematurely by glucocorticoids, and (3) is independent of the pituitary-adrenal axis. However, the ontogenetic increase in PNMT levels after initial expression has occurred does require intact pituitary-adrenal function. Our observations indicate that different mechanisms regulate initial expression and subsequent modulation of neurotransmitter phenotype.

218.6 Ca^{2+}-INDUCED FUSION OF ISOLATED BOVINE ADRENAL MEDULLARY CHROMAFFIN GRANULES. S.J. Morris[1], D.H. Haynes*[2] and J.D. Robertson[3]. (1) Dept. of Neurochemistry, Max Planck Institute for Biophysical Chemistry, D-3400 Göttingen, FRG, (2) Dept. of Pharmacology, Univ. of Miami Medical School, Miami, FL 33103, and (3) Dept. of Anatomy, Duke Univ. Medical School, Durham, NC 27710.

Chromaffin granules can be demonstrated by thin section TEM techniques to aggregate and fuse in the presence of 1 - 5 mM CaCl. The reaction proceeds by granules aggregating to form pentalaminar double membranes which eventually fuse into a single, continuous trilaminar structure.

The kinetics of Ca^{2+}-promoted aggregation have been investigated in detail (Morris et al., Membrane Biochem. 2:163-202 (1979); Haynes et al., J. Theoret. Biol. 81:713-743 (1979)). Aggregation is initiated by protein-protein contact. Lateral segregation of protein out of the contact region and lateral phase separation of bilayer lipids lead to protein-poor, destabilized bilayer regions in which membrane fusion eventually takes place.

Synexin, a protein which lowers the K_D of Ca^{2+}-aggregation from ∿ 4 mM to ∿ 200 μM, also aggregates other natural and artificial membranes, and therefore probably has no specific role in aggregation in vitro or exocytosis in vivo (Morris and Hughes, Biochem. Biophys. Res. Comm. 91:345-350 (1979)).

218.7 MUSCARINIC REGULATION OF CYCLIC GMP LEVELS AND CATECHOLAMINE SECRETION IN ISOLATED BOVINE ADRENAL CHROMAFFIN CELLS. S. Lemaire, G. Derome, R. Tseng, P. Mercier and I. Lemaire. (SPON. K. Livingston). Laboratory of Molecular Pharmacology, Dept. of Pharmacology, Centre Hospitalier Universitaire, Sherbrooke, Canada J1H 5N4.

Catecholamine secretion and cyclic GMP levels were measured in chromaffin cells isolated from bovine adrenal medulla. ACh and nicotine but not muscarine induced a 7- to 11- fold increase in catecholamine secretion with respective ED_{50} of 10 μM and 2 μM. Cyclic GMP levels were also increased from 3- to 5- fold in the presence of ACh and this stimulation was mimicked by muscarine but not nicotine. Half-maximal stimulations of cyclic GMP levels with ACh and muscarine were respectively observed at 0.1 μM and 0.3 μM. The order of potency of various cholinergic drugs for cyclic GMP stimulation was as follows: ACh > oxotremorine > metacholine > muscarine > furthretonium > arecholine > bethanechol. Pilocarpine, McN-A-343 and AHR-602 were inactive at concentrations between 10^{-8}M and 10^{-3}M. In the presence of isobutylmethylxantine (0.5 mM), ACh stimulation of cyclic GMP accumulation was potentiated 3- fold whereas the secretory effect of nicotine was inhibited by 20%. Further inhibitions of nicotine-induced catecholamine secretion were also obtained in the presence of oxotremorine plus isobutylmethylxanthine or exogenous dibutyryl cyclic GMP. Our results indicate that the nicotinic stimulation of catecholamine secretion from bovine adrenal chromaffin cells may be regulated by cyclic GMP via the stimulation of a muscarinic receptor.

218.8 CENTRAL PATHWAYS REGULATING ADRENAL TYROSINE HYDROXYLASE. Jean-Pierre Gagner*, Serge Gauthier* and Theodore L. Sourkes. Depts. of Biochemistry, Neurology and Neurosurgery, and Psychiatry, McGill University, Montreal, Quebec, Canada.

Investigations of central mechanisms involved in the neural long-term control of adrenal medullary tyrosine hydroxylase activity (ATHA) have implicated inhibitory serotonergic systems (partially localized in the medial raphe nucleus) and excitatory dopaminergic and cholinergic systems, whose effects would be ultimately funnelled through the splanchnic nerves (Quik et al., Brain Res, 122:183, 1977; Lewander et al., JPET, 200:523, 1977).

To assess the role of spinal pathways in ATHA regulation, sympatho-adrenal preganglionic neurons were isolated from their supraspinal afferents by complete cord section at level T2-T3 in rats. This treatment led after 3d to a progressive reduction in ATHA until at least day 10. Vmax for 6,7-dimethyltetrahydropterin in dialyzed homogenates decreased starting at day 3, whereas enzyme activities remained additive in mixing experiments, suggesting reduction in the amount of enzyme protein. Abolition of impulse flow to the adrenal by hemisplanchnicotomy (which itself does not affect ATHA) prevented the decrease of ATHA elicited by subsequent cord section. This result favors a primary neurogenic origin for these effects, which may involve segmental inhibition in the lower part of the cord. This mechanism, possibly mediated by spinal sympatho-inhibitory interneurons (McCall et al., Am J Physiol, 232:H657, 1977), would be unmasked by the disappearance of some transmitters below the level of section.

All centrally active agonists administered after sham-surgery caused distinct increases of ATHA. In spinalized animals quipazine, 5-hydroxytryptophan (with carbidopa) or oxotremorine (with methylatropine) produced decreases of enzyme activity, whereas apomorphine and piribedil had no significant effect. These data suggest that a) 5HT and ACh (muscarinic) receptors with inhibitory actions on ATHA are present in the lower part of the cord, and b) the DA-mediated increase of ATHA originates from area(s) rostral to the thoracic cord.

We reported that cord hemisection at C6-T7 alters a) the resting values of ATHA bilaterally, and b) the inducibility of this enzyme by immobilization stress and by apomorphine (Gauthier et al., Exp Neurol, 66:42, 1979). DA pathway(s) may not mediate predominantly the response of ATHA to immobilization because in addition a) L-dopa alone blocked ATHA increase induced in that way but potentiated that produced by apomorphine (Quik & Sourkes, Biochem Pharmacol, 25:1157, 1976), and b) DA blockers (pimozide, haloperidol) or 6-hydroxydopamine (with protriptyline) did not significantly mitigate the effect of immobilization on ATHA. (Supported by MRC and CRSQ).

219.1 **A SIMPLE METHOD FOR TESTING HUMAN VISUAL PROCESSING.** **W. Riss and M. Cheikin*. Dept. of Anatomy and Cell Biology, SUNY Downstate Med. Ctr., Brooklyn, NY 11203.**

A simple, inexpensive method of testing visual processing in a variety of experimental and clinical settings has been developed. The method relies on the use of a portable movie projector which can run film forward or backward over a range of 3 to 54 frames per second.

In our experimental super 8 mm. films, we have devised tests for measuring thresholds of visual processing and various reaction times to visual displays. There are tests for psychological simultaneity, psychological successiveness, eye movement in horizontal or vertical directions, memory, decision-making latencies, left-versus-right competition and selective attention. For example, eye-movement reaction times can be measured as follows: an initial fixation point is provided and then replaced by a numerical stimulus; at the moment the numerical stimulus disappears, a second stimulus is presented elsewhere for a defined period of time (number of frames); correct reports of the two successive numbers provide a measure of eye-movement reaction time. In another type of test of decision-making time, the number seen first is a logical clue to which of nine fixation points (arranged in a 3x3 array) will be the location of the second stimulus. If a decision is made in time to correctly shift the direction of gaze, the second, briefly presented numeral will be seen at the expected location. Successive trials are systematically arranged to be easier or more difficult for the subject. From similarly constructed films, the additionally mentioned tests are given.

219.2 CONSTRUCT VALIDATION OF VERBAL INFORMATION-PROCESSING SYSTEMS. R. Edward Geiselman,* J. Arthur Woodward,* and Jackson Beatty. (Spon: F. N. Jones). Department of Psychology, UCLA, Los Angeles, CA 90024.

Several physiological and verbal-report measures were recorded as indicants of a small number of hypothetical verbal information processing constructs. The four latent constructs that were studied are: (a) "type of processing" measured in terms of eye movements during study plus a questionnaire, (b) "processing intensity" (activation) measured in terms of heart-rate and GSR variability during study plus a questionnaire, (c) "recall from short-term store" (STS), and (d) "recall from long-term store" (LTS). The recall constructs were measured in terms of six standard verbal-recall performance measures. Alternative individual-differences models specifying the nature of these four constructs and their functional interrelations were evaluated such that a number of predictions made by contemporary theories of verbal learning were assessed. The mathematical identification of the models, the statistical estimation of the parameters, and testing of goodness of fit were all based upon the standard full information maximum likelihood approach.

The analyses showed that a uniprocess conception of memory recall, where STS and LTS are viewed as two general points on a single memory continuum, was as plausible as the dual-process conception. Given the basic uniprocess model, a second experiment confirmed the hypothesis that the "intensity" with which a subject conducts his or her study is associated with an enhancement of memory recall performance that is independent of how the subject studied (meaningful interassociation versus rote learning). However, this enhancement was confined to recall from the portion of the memory continuum that is analogous to LTS. These data bear critically upon the question of process dualism in memory and upon the long-standing question of the effects of "effort" on memory.

Several additional analyses of the eye-movement records suggested that "processing intensity" is not manifested in either the rate of information processing or in the overall number of different bits of information processed. A physiological explanation of the "intensity" construct in terms of neuronal excitability (D. O. Hebb, A textbook of psychology, 1958) was also considered.

219.3 PARKINSON'S DISEASE: DEMENTIA AND AKINESIA. J.A. Mortimer, F.J. Pirozzolo, K. Lawson-Kerr* and D.D. Webster*. Geriat. Res. Educ. & Clin. Ctr., V.A. Medical Center, Minneapolis, MN 55417, and Department of Neurology, University of Minnesota, Minneapolis, MN 55455.

The dementia of Parkinson's disease is increasingly recognized as a characteristic and important feature of the syndrome. Clinical observations have suggested that dementia is more likely to occur in patients with substantial rigidity and akinesia. We have investigated this relationship in Parkinson patients utilizing batteries of motor and neuropsychological tests.

Fifty-seven patients with idiopathic Parkinson's disease of 1 to 37 years duration were administered a series of automated motor tests, enabling quantification of akinesia, rigidity and tremor. In addition, each patient was given a battery of neuropsychological tests, which included measures of language abilities, perception, verbal and non-verbal memory, concept set shifting, oculomotor scanning, fund of information, rapid graphomotor transcoding and depression. Patients with a history of alcoholism, mental illness or other neurologic disease were excluded from the study.

Neuropsychologic measures could be grouped into four categories on the basis of test performance: 1) visual-spatial reasoning, 2) memory, 3) psychomotor speed, and 4) fund of information. Of these, visual-spatial reasoning, psychomotor speed and a specific subset of memory measures showed a significant negative correlation with three different measures of akinesia. The deficits in memory seen with the akinesia were of an attentional nature. Little relationship was evident between the measures of rigidity and tremor, and neuropsychological performance.

Disease duration, age at symptom onset, and the duration of L-dopa therapy were found to have little association with neuropsychologic function. Age at the time of the test was correlated with performance on a small subset of tests, mostly those involving some component of speed. Within this particular sample of patients, age and education level were not correlated significantly.

The findings indicate that the major motor symptom associated with dementia in Parkinson's disease is akinesia, rather than rigidity. That this dementia may not be continuously progressive is suggested by the lack of correlation of neuropsychological measures with disease duration.

219.4 COMPARATIVE NEUROPSYCHOLOGY AND KORSAKOFF'S SYNDROME: SPATIAL AND VISUAL REVERSAL LEARNING. S.M. Zola-Morgan* and M. Oscar-Berman. Boston VA Medical Center, Boston, MA 02130.

The single most obvious symptom of alcoholic Korsakoff's disease is a severe anterograde amnesia. However, there has been increasing evidence that other sensory, cognitive and motivational deficits are an integral part of the disease process.

Damage to diencephalic areas (mammillary bodies and/or dorsomedial nucleus of the thalamus) has been most often linked to the memory impairment. However, Korsakoff patients are known to have diffuse damage outside these areas and recent computerized tomography techniques applied to brains of chronic alcoholics has drawn attention to damage in other areas such as pulvinar, other thalamic nuclei and various neocortical regions.

The effects of neuropathology in humans has rarely been examined in the context of experimental paradigms which are known to be valid and reliable tests of nonhuman functional breakdown following brain damage. This comparative neuropsychological approach might be especially promising in investigating the defects in alcoholic Korsakoff patients. First, a number of tests have been developed which allow us to evaluate several aspects of the Korsakoff syndrome in addition to the memory defect. Second, some of these tests are especially sensitive to damage to specific brain areas in animals and might help us identify more accurately the structures involved in the behavioral defects of the Korsakoff patients.

In the present report we used spatial and visual learning paradigms to evaluate several aspects of the alcoholic Korsakoff syndrome including the ability to acquire new stimulus-reinforcement associations with spatial or visual cues, the development of learning-set strategy, and the manner in which stimuli become invested with motivational significance. Alcoholic Korsakoff patients were compared to a non-alcoholic control group and other brain damaged groups.

The Korsakoff patients were impaired relative to the alcoholics and aphasic groups on some spatial and visual problems. In addition, the patterns of errors exhibited on the reversal tasks by the Korsakoff patients suggested that they have difficulty in forming new associations subsequent to unlearning a related old response. Data from the present investigation along with results from additional experiments in this series suggest that it is unlikely that a single lesion is responsible for the behavioral effects observed; a combination of damage to cortical and/or subcortical structures is implicated.

219.5 INTELLECTUAL FUNCTION AND CEREBRAL BLOOD FLOW IN NORMAL AGING AND DEMENTIA. W. A. Dickinson, R. W. Butler*, and J. H. Halsey*. Department of Neurology, School of Medicine, University of Alabama in Birmingham, Birmingham, AL 35294.

The normal aging process has long been associated with a gradual decline in intellectual abilities. A premature, or unusually rapid progressive loss of intellectual abilities is generally considered diagnostic of a dementing process. Changes in cerebral vasculature and decline in cerebral blood flow rates (rCBF) have been associated with both the normal aging process and dementing processes. Relationships between rCBF and age, rCBF and measured intelligence, and measured intelligence and age were examined in this study.

The non-invasive 133-Xenon inhalation method of measuring regional cerebral blood flow was used in the following study to measure regional rates of cortical gray matter blood flow in groups of young normal subjects (19-32 years), aged normal subjects (55-83 years), and patients diagnosed as suffering from a dementing process (39-75 years). The level of intellectual functioning of all subjects and patients was measured by the Weschler Adult Intelligence Scale (WAIS).

Significant negative correlations were found between age and rCBF ($r = -0.66$, $p < .001$) and between WAIS scores and rCBF ($r = -0.67$, $p < .001$) across all subjects and patients. Young normals, aged normals, and dementia groups were found to significantly differ from each other ($p < .05$) on rCBF and on WAIS scores.

Results of this study support the contentions that intellectual functioning and cerebral blood flow gradually decline with age, that intellectual and cerebral blood flow losses are greater in demented patients than their age matched normal controls, and that losses in intellectual functions and decreases in cerebral blood flow are related to one another in both normal and pathologic conditions. In addition, the results of this study suggest that the noninvasive 133-Xenon inhalation method of measuring regional cerebral blood flow may prove useful as a diagnostic tool in dementia.

219.6 DISCRIMINATION OF SCHIZOPHRENICS WITH AND WITHOUT BRAIN DAMAGE USING THE LURIA-NEBRASKA NEUROPSYCHOLOGICAL BATTERY. A. E. Puente, Dept. of Psychology, Northeast Fl. State Hosp., Macclenny, Fl., 32063, C. Sanders* and N. Lund*, Dept. of Psychology, Univ. of North Fl., Jacksonville, Fl.

Examined the differentiation of schizophrenics with and without brain damage using the Luria-Nebraska Neuropsychology Battery (Purisch, A.D., Golden, C.J., & Hammeke, T.A., J. Consult. Clinical Psychology, 46: 1266, 1978).

Subjects included 40 inpatients at a state hospital. Of these, 17 were diagnosed by a psychiatrist and psychologist as and had a history of schizophrenia. Subjects for this group were excluded if there was a history of seizures, alcoholism, substance abuse, head trauma, or other signs of organicity. The remaining 23 patients were similarly diagnosed as schizophrenics and had a confirmed neurological diagnosis on the basis of a medical examination by a physician and/or had a history of brain damage as documented by such tests as CAT scan, EEG, or X-ray. Since patients were tested exclusively for this investigation and were not part of a clinical referral, consent forms were obtained by the test administrator who was blind to their condition.

Chi squares computed on the scores of the 282 items revealed that schizophrenics without brain damage performed significantly ($p \leq .05$) better on 106 of the measures. Differences between groups on the 14 summary scales were determined using t tests and analyses of variance. Schizophrenics without brain damage performed significantly ($p \leq .01$) on all the scales.

These results indicate that the Luria-Nebraska Battery reliably discriminates between schizophrenics with and without brain damage using 38% of the individual items and the 14 summary scales. Preliminary results also suggest the possibility of developing an abbreviated version of this standardized test.

220.1 LONG-TERM RETENTION OF FOREIGN NEUROMUSCULAR SYNAPSES IN FROGS. Alison Longley, Alan D. Grinnell, and Albert A. Herrera. Jerry Lewis Neuromuscular Research Center, UCLA School of Medicine, Los Angeles, CA 90024, U.S.A.

Suppression of foreign neuromuscular synapses by regenerating original nerves has been reported in axolotls and newts. Mutual suppression between two foreign nerves implanted into a frog skeletal muscle has also been reported. In this study, possible competition between foreign and regenerating original nerves in Rana pipiens is being examined.

Cut ulnar (forelimb flexor) nerves were sutured at the border of the thin cutaneous pectoris (c.p.) muscle on the chest wall, and the cutaneous pectoris nerve was cut or crushed. Control frogs were operated on in the same manner, except that the ulnar nerve was left in the armpit to prevent its reinnervating the c.p. Large, adult frogs were used for all experiments.

Foreign nerve input was still present up to 343 days later in some animals. Both foreign and regenerated original nerves were capable of eliciting muscle twitches, though fewer fibers were innervated by the foreign nerve. Twitch tension was measured in normal (1.8 mM) and low (1.0 mM) calcium Ringer as a measure of synaptic safety factor; junctions which become subthreshold to nerve stimulation in lowered calcium are presumed to be of lower quantal content than those which remain suprathreshold. Twitch tension in 1.0 mM calcium for normal c.p. muscles is 98% of the tension obtained in normal Ringer, but the ratio for the regenerated c.p. nerve was 62% (range: 51-72%), and was 40% (range; 29-60%) for the foreign nerve.

Most fibers were singly innervated, with c.p. innervations predominant, but intracellular recording indicated the presence of some fibers doubly innervated by foreign and original nerves. The double inputs have been found both at the same and at widely separated sites.

Tracing methods for distinguishing the innervation patterns of the two nerves will be discussed, including the use of intracellular staining with the fluorescent dye, lucifer yellow.
This work was supported by research grants from the USPHS (NS06232) and the Muscular Dystrophy Association, and by NRSA postdoctoral fellowships to A.L. and A.A.H.

220.2 MOTONEURON TARGET SELECTIVITY IN CHICKS WITH DELETED, DUPLICATED OR REVERSED LIMB SEGMENTS. Virginia Whitelaw* and Margaret Hollyday. Depts. of Biophysics and Pharmacol. Physiol. Sci., The University of Chicago, Chicago, IL, 60637.

In the normal chick, limb muscles derived from neighboring positions within the same embryonic muscle mass are innervated by adjacent motor pools. This finding suggests that a normal pattern of limb innervation could be achieved by mechanisms which simply maintain neighbor relations among motor axons. Alternatively, motoneurons might be specified in a position dependent way to exhibit target selectivity for particular limb muscles. The relative importance of these two postulated developmental mechanisms was tested using surgical manipulations which disrupt the normal neighbor relations of embryonic leg muscles. Animals were produced having the following abnormalities: 1) deletion of the calf and foot, 2) deletion of the thigh, 3) serial duplications of the calf, and 4) proximo-distal reversals of the calf and thigh. The motor pools supplying both individual muscles and groups of muscles in the manipulated limbs were mapped using intramuscular injections of HRP. From this we determined whether axons maintained neighbor relations and in some cases innervated abnormal targets, or whether they exhibited target selectivity.

Chick embryos were operated on between stages 18-22, which is before axons have grown into the limb bud. HRP injections were made when the embryos were at stage 37-38, which is after the period of naturally occurring cell death and the establishment of the adult pattern of limb innervation. The morphology of the operated legs was determined after the legs were stained for cartilage. Interesting cases were sectioned and reconstructed to identify the muscles.

The results from all cases of partial limb deletions were consistent: muscles received innervation from their normal motor pools. Selective motoneuron death was observed in motor pools where those limb muscles were absent. There was no apparent compression of the motoneuron projections into the partial limb. Results from proximo-distal reversals and limb segment duplications indicate that a muscle receives innervation from its normal motor pool despite its aberrant position or double occurrence. These findings show that motoneurons exhibit target selectivity under experimental conditions which disrupt the normal neighbor relations of those targets. This suggests that target selectivity is a more important developmental mechanism underlying limb innervation than is maintenance of neighbor relations.

220.3 DISTRIBUTION OF IPSILATERALLY AND CONTRALATERALLY PROJECTING RETINAL GANGLION CELLS IN XENOPUS LAEVIS AND ITS RE-ESTABLISHMENT FOLLOWING OPTIC NERVE SECTION. S. Hoskins* and P. Grobstein, Dept. Pharm. Physiol. Sci., Univ. of Chicago, Chicago, IL, 60637.

We have used retrograde HRP transport to assay the retinal distribution of ipsilaterally and contralaterally projecting retinothalamic ganglion cells in post-metamorphic Xenopus laevis and to determine whether the normal distribution is re-established during optic nerve regeneration.

Rostral thalamus (a region including the nucleus of Bellonci, the corpus geniculatum thalamicum, and the rostral visual nucleus) was exposed to HRP by multiple pressure injections of a concentrated solution of HRP in distilled water. After several days survival time, the animals were killed. The retinas were removed, fixed briefly, reacted with diaminobenzidine, and prepared as whole mounts. The brains were also processed to evaluate injection location. Typically, in retinas contralateral to the injection, labelled ganglion cells were distributed throughout the entire retina. In retinas ipsilateral to the injection, labelled cells were widely distributed but largely or completely excluded from a nasodorsal region. The results indicate that a large area of the retina gives rise to both an ipsilateral and a contralateral projection; a dorso-nasal region, however, projects largely or exclusively contralaterally.

In a further series of animals we cut or crushed one optic nerve and four to six weeks later exposed rostral thalamus ipsilateral to that optic nerve to HRP. The retinas and brains from these animals were processed as above. In three animals, a typical pattern of extensive labelling through most of the ipsilateral retina with an absence of significant labelling in the nasodorsal region was observed. In four animals, labelled cells were absent or sparse, perhaps due to incomplete regeneration. However, consistent with the finding in the three animals described, there was in these animals no significant labelling in the nasodorsal retina. These results indicate that the normal retinal distribution of ganglion cells projecting to the ipsilateral thalamus can be re-established during optic nerve regeneration.

It has long been known that mechanisms operating during optic nerve regeneration in the frog are adequate to re-establish normal retinotopy in the contralateral optic tectum. Our studies suggest that such mechanisms are also capable of re-establishing the normal bilaterality of the retino-thalamic projection. In addition, they show that large areas of the retina project bilaterally in Xenopus. There is no line of decussation separating one region projecting strictly contralaterally from another projecting strictly ipsilaterally.

220.4 FORMATION AND LOSS OF A NORMAL IPSILATERAL RETINOFUGAL PROJECTION IN DEVELOPING CHICK. S. C. McLoon and R. D. Lund. Dept. of Anatomy, Medical Univ. of South Carolina, Charleston, S. C. 29403.

Unilateral enucleations performed on chick embryos during their early stages of development resulted in the presence of an ipsilateral retinofugal projection just prior to the time of hatching. Since in rats a similar ipsilateral pathway appears to result from the retention of an embryonic projection, we wondered whether a similar developmental event occurs in the chick, even though in the adult there is normally no ipsilateral projection. Embryos on successive days between days 7 to 16 of incubation received an injection of horseradish peroxidase into the right eye. After 12 hours survival, the embryos were sacrificed and fixed. Sections of the brains were reacted with tetramethyl benzidine and hydrogen peroxide. The left eye was also reacted to be sure that the HRP injection had not involved that eye.

From days 7 to 10 of incubation, HRP label was clearly visible along the optic tract ipsilateral and contralateral to the injected eye. From the chiasm labeled fibers entered the ipsilateral tract along the borders of the alternating laminae of right and left optic axons. The ipsilateral fibers that entered the tract at any one lamina tended to stay together through their entire course. By ten days of incubation, ipsilateral optic fibers could be identified along the border of the lateral geniculate and ectomammillary nuclei and in the superficial layer of the tectum. From days 11 to 14 of incubation an ipsilateral projection cannot be distinguished by the HRP technique. During this time period a large percentage of the retinal ganglion cells normally degenerate, and there is a considerable amount of endogenous peroxidase in the visual pathway which masks the HRP tracer. On days 15 and 16 of incubation, the high endogenous peroxidase level has subsided; no retinal projection can be identified in the ipsilateral optic tract.

It appears, therefore, that in the chick, like the rat, the ipsilateral retinofugal projection resulting from an embryonic enucleation may be due to retention of a normal ipsilateral projection. The loss of the ipsilateral projection in normal development coincides with a period of synap togenesis and cell death in the visual system. The causal interrelation of these events deserves further attention.

220.5 ORDER AND DISORDER IN THE ABERRANT RETINOTHALAMIC PROJECTION IN HAMSTERS WITH EARLY TECTAL ABLATIONS. Roberto Lent* and Gerald E. Schneider. Department of Psychology, M.I.T., Cambridge, MA 02139.

A result of a deep ablation of the superior and inferior colliculi in newborn hamsters is the formation of aberrant terminal fields of retinofugal axons in the lateral posterior (LP) and medial geniculate (MG) thalamic nuclei. We were interested in studying the retinotopic pattern within these axonal populations because no locus specificity for optic tract axons is expected in the MG, and little if any is expected in the LP.

We have aspirated the right superior and inferior colliculi of 10 newborn hamsters within the first 30 hours after birth. After the animals were fully grown (12 weeks), they received left intravitreal injections of tritiated proline and fucose, in addition to focal electrolytic lesions placed in different retinal quadrants. After adequate survival times the animals were sacrificed and perfused, and the brains were cut and processed by the autoradiographic and Fink-Heimer techniques.

Results for all the brains reveal a heavy terminal field in the superficial part of the right LP adjacent to the optic tract, frequently extending over most of the surface of the nucleus. Also, all but 1 hamster have a small terminal field in the MG. Six of the animals have only one restricted focus of degeneration in the LP terminal field, and the others have 2 foci. Projection of these foci to the surface of the diencephalon in order to generate a surface reconstruction reveals a consistent retinotopic distribution of the patches of degeneration. This map has an orientation similar to that displayed in the dorsal and ventral nuclei of the lateral geniculate body (LG) — upper retina represented caudally, nasal retina represented closest to the chiasm. In the MG, although restricted parts of the retina do project to restricted parts of the nucleus, no consistent topographic order has been discerned.

The fact that the nasotemporal axis of the map in LP has a polarity similar to that of the LG suggests that the developing retinothalamic axons follow similar ordering rules in each of these structures. Also, the finding of restricted patches of degeneration within the MG, although without a consistent topography, suggests that retinothalamic axons may attain some orderly distribution even in the absence of adequate polarity cues in the target tissue.

220.6 PREFERENTIAL GROWTH PATTERNS OF CENTRAL VS PERIPHERAL CA NEURITES TO CO-CULTURED IRIS TISSUES. C.F. Dreyfus and S.M. Crain, Dept. of Anatomy, Columbia University, College of P&S and Dept. of Neuroscience, Einstein Medical College, New York, NY.

We have reported previously that catecholaminergic (CA) neurons in fetal mouse brainstem explants from the region of the locus ceruleus grow preferentially toward cells emerging from co-cultured iris explants. This effect does not appear to be mediated by nerve growth factor (NGF) nor by an iris-induced increase in CA neurites (Dreyfus and Crain, Anat. Rec. 196, '80). We have now compared the neuritic growth patterns from central and peripheral CA neurons toward co-cultured iris explants. Portions of brainstem from the region of the locus ceruleus or whole superior cervical ganglia (SCG) were co-cultured with fetal iris (ca. 0.5 mm apart). All tissues were explanted from 18 day fetal mice and maintained up to 2-3 weeks in vitro. The SCG-iris co-cultures were grown in nutrient media (containing human placental serum and chick embryo extract) ± NGF. The brainstem-iris co-cultures were grown in control nutrient media, since these central CA neurites do not appear to be sensitive to NGF (Dreyfus et al., Brain Res., in press). Within 2 days in culture cells grew out in all directions from the iris and contacted the brainstem or the SCG; by 4-7 days these iris cells partially surrounded the co-cultured neural explants. Glyoxylic acid induced histofluorescence revealed that by 7 days, varicose brainstem CA neurites projected heavily toward the iris, arborizing in a network fashion on cells in the iris outgrowth. A few brainstem CA neurites also grew in directions away from the iris. The neuritic branching of these central CA neurons on iris cells resembled patterns seen on neuroglial arrays around co-cultured hippocampal explants, except that no such preferential dense neuritic projections were seen during invasion of the CNS target tissues (Dreyfus et al., Brain Res., 161, '78). In contrast, varicose CA neurites grew out radially from SCG explants as straight projections in all directions. When NGF (30-50U/ml) was reduced or omitted from our nutrient media, these peripheral CA neurites were more abundant and longer in the direction of the iris. In contrast to the brainstem CA neurites, the SCG neurites appeared to grow over the iris cells with fewer arborizations or terminations on them and, in fact, many projected directly into the muscle tissue of the iris explant. Thus, although both central and peripheral CA neurites appear to grow preferentially toward co-cultured iris, the brainstem neurites arborize in a network pattern restricted primarily to the outgrowing iris cells whereas SCG neurites tend to project straight toward the muscle within the iris explant. Supported by grants NS14990 (NIH) and BNS75-03728 (NSF) to SMC, NS12969 (to M.D. Gershon), NS-08770 (to E.R. Peterson) and BRSG grant SO7-RR05395-18 (NIH) to CFD.

221.1 *THE ORIGIN OF BRAINSTEM PROJECTIONS TO THE THORACIC CORD AT DIFFERENT STAGES OF DEVELOPMENT IN THE NORTH AMERICAN OPOSSUM.* T. Cabana* and G.F. Martin (SPON: B. Stokes). Dept. Anat., Sch. Med., The Ohio State Univ., Columbus, Ohio, 43210.

The opossum is born 12 to 13 days after conception and is then available in an external pouch for behavioral observation and experimental manipulation. Previous studies have documented the early growth of brainstem neurites into the spinal cord of the opossum (Martin et al., 1978). Such axons are present in the marginal zone as far caudally as the lumbosacral cord prior to the development of hindlimb motility. In order to identify the suprasegmental origin of spinal axons at different stages of development, horseradish peroxidase (HRP) was injected iontophoretically into the thoracic cord in a developmental series of 24 opossums. Prior to the appearance of spontaneous hindlimb movements (stage I of Martin et al., 1978) and before there is evidence that brainstem axons grow into the intermediate (mantle) zone, HRP injections labelled neurons in the nucleus reticularis medulla oblongata ventralis, the nucleus lateralis reticularis, the medullary raphe nuclei, the nuclei reticularis gigantocellularis and gigantocellularis pars ventralis, the inferior, medial and lateral vestibular nuclei, the pontine reticular formation and the presumptive coeruleus complex. Some of these areas contain neurons which synthesize monoamines at this stage and monoaminergic varicosities are present in the marginal zone of the cord (Humbertson and Martin, 1979). At subsequent stages of development neurons can also be labelled in the spinal trigeminal nuclei, the solitary complex, the dorsal column nuclei, the midbrain tegmentum, the red nucleus, the interstitial tegmental area, the interstitial nucleus, the nucleus of Darkschewitsch and the paraventricular hypothalamic region. Each of these areas has been shown to project to thoracic levels in the adult opossum (Crutcher et al., 1978). These data indicate: 1) that reticular, raphe and vestibular nuclei of the pons and medulla project spinalward very early in development and 2) that sensory relay nuclei as well as cell groups in the mesencephalon and diencephalon innervate spinal levels somewhat later. (Supported by U.S.P.H.S. Grant NS-07410.)

221.2 *GROWTH OF THE CORTICOSPINAL TRACT IN NEONATAL RATS.* D.J. Schreyer*, and E.G. Jones. Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

The rat corticospinal projection was investigated using the anterograde and retrograde transport of horseradish peroxidase as a marker for growing axons and their cells of origin. At birth, corticospinal fibers arise exclusively from large pyramidal cells of an already distinct layer V and form a massive bundle extending just past the pyramidal decussation into the posterior white columns of the upper cervical segments. The decussation is often disorderly at this stage and additional small fiber bundles can be seen both descending through the lateral gray matter of the posterior horn and deflecting rostrally toward the dorsal column nuclei. Over the next few days, the corticospinal tract extends the length of the cord, always led by a few fibers a segment or two ahead of the major bundle. Although terminal ramifications are seen in the pons at birth, outgrowth into the gray matter of the spinal cord segments past the decussation is delayed a few days after the tract has passed by, forming a rostrocaudal, temporal gradient. Complete innervation of the gray matter of the cervical enlargement is not seen until about the time when callosal and thalamic afferents in the cortex change from a diffuse to a more orderly pattern of distribution and when pyramidal cells establish their definitive dendritic configuration (Wise and Jones, J. comp. Neur. 175, 129; 178, 187; Wise, et al. Neuroscience 4, 1275). Older animals display a more orderly decussation, though the lateral fibers persist and extend to lower cervical segments. Terminal ramifications in the gray matter of the lumbosacral enlargement appear only after the first week.

221.3 CHANGES IN TIBIALIS ANTERIOR MUSCLE OF SPINAL CAT WITH LONG-TERM ELECTRICAL STIMULATION. J.T. Mortimer and U. Roessmann*, Applied Neural Control Lab, Dept Biomedical Engineering and Division of Neuropathology, Institute of Pathology, Case Western Reserve University, Cleveland, Ohio 44106.

The affects of electrically induced exercise have been studied in the tibialis anterior muscle of cats that have been paralyzed for more than 7 months. Unstimulated muscles of the spinal animal showed changes that are consistent with disuse. The cross sectional area of all muscle fiber types was uniformly reduced by approximately 30% when compared to a similar group of unspinalized control muscles. The composition of the unstimulated paralyzed muscle in the superficial region was largely FG (65% compared to 37% for the normal). The FO population had decreased from 56% found in the normal to 34%, and the SO group decreased from 7% as found in the normal to 2%. Continuous stimulation of the paralyzed muscle at 10 Hz yielded a fatigue resistant muscle producing a lower peak force than the unstimulated paralyzed control. The muscle was composed almost entirely of SO fibers without significant change in cross sectional area when compared to its unstimulated control. *Employing an interrupted stimulation* pattern produced a fatigue resistant muscle without compromising the peak force production. The cross sectional area of FO fibers in the muscle was unchanged, whereas the SO fibers showed significant hypertrophy compared to the unstimulated paralyzed control. Stimulation for 8 hours at 10 Hz, 2.5 sec on 2.5 sec off (average 5 Hz) resulted in SO fibers with a cross sectional area of 83% of the normal control. Stimulation for 8 hours with a 30 Hz burst pattern, with interrupting rest periods (average frequency 5 Hz), resulted in SO fibers with an average cross sectional area 113% of the normal control SO group. These results are consistent with those found in human spinal cord injury patients, where increased fatigue resistance and increased muscle bulk have been observed with electrically induced excercise (Peckham et al, Clinic Ortho and Relat Res, 1976, 326). They were not found in the stimulated normal cat.

221.4 **MOTOR CORTEX ORGANIZATION AFTER FOCAL INJURY IN THE RAT** **M. G. Boyeson, D. M. Feeney, R. T. Linn, W. G. Dail and H. M. Murray Departments of Psychology and Anatomy, University of New Mexico, Albuquerque, NM 87131**

After injury to a portion of motor cortex there is a severe loss of some motor functions but there is a dramatic recovery within weeks. The hypothesis that neighboring cortical areas take over some functions of the damaged area has a long history as a mechanism of recovery. We directly tested this hypothesis by conducting detailed mapping of the movements evoked by microstimulation of the cortex at varying times after injury. Experiments were conducted in the rat since the motor cortex is readily accessible and shows a reliable organization. A unilateral lesion of the hindlimb (HL) cortical area was performed by undercut laceration, suction ablation or contusion. The hemispheres were exposed under Nembutal anesthesia at 1, 4, 9, 15, 30 days *and 6 mo. - 1 yr after injury. The effects of forelimb (FL) area* lesions were also studied but less extensively. *The cortex was* stimulated with 300 cps train of .5 msec pulses at currents from 5 - 300 μA in a grid pattern of approximately 125 points spaced *.5 mm on each hemisphere. The areas giving rise to FL and HL* movement were studied in detail as was the cortex between these areas we denote as synergistic trunk region (ST). This ST area gave synergistic movement of FL and HL as well as some trunk movement. The type of FL movement evoked from the ST area was stereotyped and qualitatively different from the movements evoked from the FL area. The closer to the FL area within ST the stronger the forelimb component and the closer to the HL area within ST the stronger the HL component. After destruction of HL cortex no HL movements could be evoked by stimulation at any point on the cortex at any time postinjury. The HL component of the response evoked from the ST area also disappeared and did not return. However, the FL component of the response evoked by stimulation in the ST region did recover to its normal extent by 9-15 days. Similar results were seen following lesions of the FL area. The data indicate that after motor cortex injury neighboring intact cortex does not reorganize to take over the function of the damaged area. Additionally the data indicate two remote effects of cortical injury. Within the intact ST area following lesions of the HL area, HL components can no longer be evoked and the ability to evoke FL components is depressed for 9-15 days.

221.5 RECOVERY OF LOCOMOTION FOLLOWING SYMMETRICAL AND ASYMMETRICAL SERIAL LESIONS IN RATS. A. Gentile, J. Held*, R. Muzii*. Teachers College, Columbia University, New York, N.Y. 10027.

In prior study of locomotor deficits resulting from damage to motor cortex in rats, two-stage removals produced a more marked initial impairment followed by faster recovery in comparison to bilateral one-stage removals (Gentile, et.al., Beh. Biol., 1978, 22, 417-455). As serial lesions had been placed asymmetrically (unilateral followed by contralateral cortical ablation), it was proposed that unilateral damage may have stimulated increased synaptic activity in the contralateral homolog which, in turn, may have activated alternative pathways mediating recovery. Symmetrical damage involving simultaneous bilateral removals may have resulted in a different mode of functional reorganization.

The present study examined locomotor performance in rats following first-stage damage of motor cortex placed bilaterally or unilaterally and following second-stage damage extended to equal size bilaterally. Rats were trained preoperatively to traverse a narrow, elevated runway. First-stage lesions were of 4 types: bilateral ($4mm^2$ each side) of either trunk or hindlimb areas (Hall & Lindholm, Brain Res., 1974, 66, 23-38.), bilateral combined trunk and hindlimb areas, or unilateral motor cortex ($18mm^2$). Testing was initiated 14 days postoperatively and continued until preoperative criterion levels were attained. Subsequently, all lesions were expanded to uniform bilateral size ($18mm^2$ each side). After second-stage damage (14 days), testing resumed until criterion levels were re-attained.

Following first-stage removals, the unilateral lesion produced most impairment; the combined trunk and hindlimb lesion resulted in moderate deficit; whereas, trunk or hindlimb lesions produced no impairment in comparison to controls. Movement analysis from high-speed film data indicated a contralateral hindlimb deficit in unilaterally damaged rats.

Following second-stage removals, the expansion of bilateral lesions produced marked lobomotor deficits, with the expanded trunk-hindlimb lesion leading to faster recovery. Contralateral removal following unilateral damage resulted in less impairment than the symmetrical serial lesions. Movement analysis of locomotion following asymmetrical serial lesions now indicated a bilateral hindlimb deficit. These results demonstrate that deficits following second-stage lesions were an inverse function of impairment produced by first-stage damage. Secondly, asymmetrical rather than symmetrical serial lesions resulted in substantial sparing.

221.6 BEHAVIORAL EXAMINATION OF HETEROTOPIC NEURAL TRANSPLANTS IN THE RAT CEREBELLUM Robert B. Wallace, Gopal D. Das*, Michael Molyn*, Charlotte Coren*, and Craig Hawkins*, Developmental Psychobiology Laboratories, University of Hartford, West Hartford, CT 06117.

Recently successful transplantation of embryonic neural tissue into the brains of neonatal and adult host animals has been achieved in several investigations (Das and Hallas, Experientia, 34: 1304, 1978; Stenevi, Björklund and Svengaard, Brain Res., 114: 1, 1976). This transplanted tissue becomes fully integrated into the host brain and, one may conceive, may also be functionally integrated as well. In an effort to test this hypothesis, three groups of male Long-Evans hooded rats were subjected to extended behavioral testing. One group received midline surgical lesions of the cerebellum at 10 days of age; a second group received midline cerebellar transplants of cortical tissue from 17 day embryos at 10 days of age and the third group represented the control condition. All animals were evaluated behaviorally by a battery of tests that included the following: King Emotionality Scale, Neurological Examination, Open Field, Activity Wheel, Elevated Walkway and Rope Climb. Following behavioral testing the animals were sacrificed by transcardial perfusion, the brains cut at 7μ in the coronal plane, and stained with H&E. The results indicated compression lesions of approximately 80% of the host cerebellum and the transplants appeared to be fully integrated with the parenchyma of the host brain. Behavioral results indicated no differences between groups on the King Emotionality Scale; however, on all other tests both control and transplant animals were significantly different from the lesioned animals and not significantly different from each other. It was not possible to run the lesioned animals on the last test (Rope Climb) so impaired were they, but no substantial differences were observed between the control and transplant animals on this task. These data may be taken as suggestive of functional plasticity within this model. Further behavioral testing with this model is intended using other motor systems and also examining the effects of heterotopic tissue transplantation into sensory structures.

221.7 DEVELOPMENT OF THE PRIMARY EVOKED POTENTIAL AND THE STRYCHNINE SPIKE IN MOTOR-SENSORY CEREBRAL CORTEX OF KITTENS. M. D. Mann and K. A. Follett*. Dept. of Physiol. Biophys., Univ. of Nebraska Medical Center, Omaha, NE 68105.

The development of the surface primary evoked potential recorded from the postcruciate forepaw focus and of the corticofugal reflex discharge recorded from the ipsilateral medullary pyramids were studied in kittens at 1,4,7, and 14 days of age, anesthetized with α-chloralose, paralyzed with decamethonium, and artificially respired. The evoked potential and corticofugal reflex discharge were induced by stimulation of each of the 4 paws at frequencies of 1/sec, 1/2sec, 1/5sec, and 1/10sec, using pulses of 25 mA and 0.1 msec. The corticofugal reflex discharge was absent in newborn kittens, making its first appearance at about 14 days. The surface potential evoked by stimulating the contralateral forepaw (CF) was primarily a purely surface-negative event with a latency of 50 msec at 1 day. By 4 days, the initial positivity of the potential had developed, the negativity was reduced in amplitude, and the latency shortened to 37 msec. At 7 days, the positivity was larger but shorter, the negativity was smaller but longer, and the latency dropped to 30 msec. At 14 days, the latency decreased to 18-20 msec and the potential had a larger positivity. Responses to stimulation of the other 3 paws were similar at all ages, usually small, purely negative waves or small negative waves preceded by a smaller positive wave. These were seldom larger than 500 μV peak-to-peak.

Topical application of strychnine sulfate at the recording site produced a strychnine spike in nearly every animal. As in adults, the strychnine spike is an enhancement of both positive and negative phases of the primary evoked potential for CF stimulation, but no change was seen in responses to stimulation of any other paw. At 1 day, the primarily negative response was replaced, following strychnine, with a positive-negative response and, once the positivity developed, it did not disappear for the duration of the experiment--up to 8 hrs. No enhancement of the corticofugal reflex discharge evoked by CF stimulation at weak intensity was seen, as is always seen in adults. The strychnine enhancement seldom lasts longer than 1 hr in adults, but it lasts from 2.5 to more than 4 hrs in kittens.

Towe and Mann (Exp. Neurol. 39:395-413, 1973) concluded that topical strychnine has a direct effect primarily on superficial sa neurons and only an indirect effect on m neurons and that the enhanced discharge of sa neurons accounts for the strychnine spike. On embryological criteria, Mann (Brain Res. Rev. 1:3-45, 1979) deduced that sa neurons were probably still migratory and therefore inactive in newborn somatic cerebral cortex. If this is true, then topical strychnine effects m neurons in newborn cortex.

221.8 REGENERATION OF TROCHLEAR NERVE IN GOLDFISH: MULTIPLE SPROUTS AND ECTOPIC MUSCLE CELLS. S. S. Scherer*, S. S. Easter, Jr., and L. J. Fisher. Departments of Zoology and Anatomy, Univ. Michigan, Ann Arbor, MI 48109.

Cajal reported that peripheral nerve fibers, after being cut or crushed, sprout multiply around the lesion. The number of fibers in the distal stump exceeds the number centrally; this excess is very great at first, diminishes with time, but persists after regeneration and myelination (Cajal, Degeneration and Regeneration in the Nervous System, 1928). These conclusions were based on observations made with the light microscope, which can not resolve small non-myelinated fibers. We have checked these observations electron microscopically.

One trochlear nerve per goldfish (8-10 cm, N=16) was cut or crushed intraorbitally, about 0.5 mm from the superior oblique muscle. Animals were killed 2, 4, 8, 13, and 107 days after surgery. The entire intraorbital portion of the nerve and the attached muscle were prepared for electron microscopy. Cross sections of the nerve were taken both central and peripheral to the lesion. Contralateral (control) nerves were prepared similarly. Electron microscopic photomosaics (6400X) were constructed and the number of fibers counted. Questionable regions on the photomosaics were reexamined on the section at higher magnifications.

The peripheral and central parts of the control nerves and the central stumps of lesioned nerves had about 80 fibers, mostly myelinated. Unmyelinated fibers were first seen in the distal segment at 2 d after surgery, reached a peak of more than 300 at 8 d, and dropped thereafter. The first myelinated fibers in the distal segment were seen at 8 d, and their numbers increased to a mean of 130 by 107 d. Thus, the original light microscopic observations were confirmed electron microscopically.

Ectopic muscle cells were found in and around the regenerated trochlear nerve, hundreds of μm from the superior oblique muscle. They resembled the small red fibers found in normal muscle: they were a few μm in diameter and hundreds of μm long; they had normal sarcomeric structures (Z bands, hexagonally arranged thin and thick filaments, and transverse tubules) and in some cases, synapses. The origin of the presynaptic process is unknown. These mature ectopic muscle cells were present only at 107 d, but fibroblast-like cells with cytoplasmic islands of organized myofilaments were seen at 13 d; they are probably the precursors. It is possible that the regenerating nerve fibers induced the development of the ectopic muscle cells.

222.1 PROGRESSIVE TOPOGRAPHIC REORGANIZATION OF REPRESENTATIONS OF THE HAND WITHIN AREAS 3b AND 1 OF MONKEYS FOLLOWING MEDIAN NERVE SECTION. M. M. Merzenich*, J. H. Kaas, R. J. Nelson, J. Wall, M. Sur, and D. J. Felleman. (Spon. W. Jenkins). Coleman Lab., Univ. of Calif. at San Francisco, San Francisco, CA 94143; and Dept. of Psychology, Vanderbilt University, Nashville, TN 37240.

Microelectrode mapping studies within "SI" in primates have revealed that there are two complete, highly ordered representations of the hand surfaces within cytoarchitectonic Areas 3b and 1. In this study, we ask the question: Is there an occupation of cortex "silenced" by a partial deafferentation of these topographic skin surface representations? To answer this question, the representations of the hand were mapped in detail (receptive fields were defined for neurons, in each of about 200 to 600 penetrations within the hand representation) in normal adult owl and squirrel monkeys and/or: a) Again defined in detail immediately following median nerve section; b) mapped 2-11 months after the median nerve was section and tied (to prevent regeneration); or c) remapped several times during the weeks immediately following nerve section.

The "silenced" area of cortex normally representing the skin innervated by the median nerve was progressively occupied by input from bordering ulnar and radial nerve skin fields. Occupation of "silenced" cortex was complete within about 3 weeks after nerve section. In Area 3b of squirrel monkeys (but not owl monkeys) there was a small, fragmentary representation of the finger dorsi immediately "unmasked" within the former area of representation of the volar surfaces of the fingers innervated by the median nerve. In both species, a field of representation of the finger dorsi expanded progressively in Area 3b. When reorganization was complete, this new representation of the finger dorsi was spectacularly topographic, larger than the former representation of glabrous digits in this cortical region, many times larger than the still existent dorsal finger representations elsewhere in the map, and represented the dorsal surfaces of the fingers corresponding with the anesthetic ventral median nerve digital surfaces. The radial nerve representation of the hand dorsum expanded similarly and topographically, especially in Area 1,into the cortical region formerly representing the radial aspect of the glabrous palm. There was a great expansion of the representation of skin surfaces innervated by the ulnar nerve along the median-ulnar border into the former median nerve cortical territory representing its more medial palmar surfaces. During the observed reorganization process, sites of representation of given skin loci were inconstant, re cortical surface vasculature. Finally, no peripheral sprouting into the median skin field was evident. Considered with studies of sensation in patients with such lesions, these studies indicate: a) That there can be no fixed "perceptual maps" within these cortical fields; and b) that there is likely normal use-dependent competition for cortical territory within these fields in adult owl and squirrel monkeys.

222.2 ORGANIZATION OF THE REPRESENTATIONS OF THE HAND IN AREAS 3b AND 1 OF POSTCENTRAL SOMATOSENSORY CORTEX OF MONKEYS AFTER SECTION AND REGENERATION OF THE MEDIAN NERVE. J. T. Wall, M. M. Merzenich*, M. Sur*, R. J. Nelson, D. J. Felleman*, and J. H. Kaas. Depts. of Psychology and Anatomy, Vanderbilt Univ., Nashville, TN 37240, and The Coleman Memorial Laboratory, Depts. of Otolaryngology and Physiology, Univ. of California at San Francisco, CA 94143.

Previous microelectrode mapping studies have shown that two separate and orderly cutaneous representations of the hand exist in Areas 3b and 1 of monkeys. A second set of investigations revealed that these representations are modified when the median nerve, which innervates the glabrous skin of the radial hand, is transected and prevented from regenerating. Several weeks following the median nerve transection, cortex previously activated by the median nerve is completely responsive in a somatotopically organized manner to stimuli on skin innervated by the ulnar and radial nerves. The present study asks the question of what happens to this reorganized cortex when the median nerve regenerates? To answer this question and obtain information relevant to the issue of recovery of function, the median nerve was sectioned and reconnected by suture of the epineurium in squirrel and owl monkeys. After regeneration periods of 3-12 months, maps of the hand representations in Areas 3b and 1 were derived from multiunit responses recorded in systematic grids with 250-400 recording sites approximately 150-300 μ apart in each animal. Cortical organization following regeneration was abnormal in several ways. 1) Parts of cortex normally activated by the median nerve were activated instead from skin innervated by the radial or ulnar nerves. Thus, regeneration of the median nerve was either incomplete so that some of the cortex taken over by the ulnar and radial nerves after median nerve section remained altered, or regenerated median nerve inputs were unable to displace ulnar and radial inputs and reestablish priority for activating this cortex. 2) Parts of cortex normally activated by the median nerve became reactivated by skin areas innervated by the median nerve. Thus, part of the median nerve was able to regenerate, "compete," and "recapture" parts of its original cortical field. 3) Recording sites in this "recaptured" cortex were typically characterized by multiple and non-overlapping receptive fields, indicating that many regenerated axons grew back to inappropriate skin locations. 4) Cortex driven by the regenerated median nerve exhibited no simple somatotopic organization. Thus, the reoccupation of cortex by the regenerated median nerve did not depend on a normal somatotopic pattern of peripheral connections.

222.3 VARIABILITY IN THE PROPORTIONAL REPRESENTATIONS OF THE HAND IN SOMATOSENSORY CORTEX OF PRIMATES. R. J. Nelson, M. M. Merzenich*, J. Wall, M. Sur, D. J. Felleman and J. H. Kaas, Coleman Mem. Lab., Univ. of Calif. at San Francisco, San Francisco CA, 94143 and Dept. of Psychology, Vanderbilt Univ., Nashville TN, 37240.

The representations of the hand in somatosensory cortical areas 3b and 1 were mapped in normal squirrel monkeys (Saimiri sciureus). At an inter-penetration spacing of 100-300 microns, minimal receptive fields were determined for neurons within each penetration by stimulating the skin surface with hand held probes. Cortical areas of representation of hand surfaces were measured planimetrically. These measurements led to the following conclusions: 1) The total representational area of the hand varies significantly in different individual adult squirrel monkeys. 2) There were large differences in the proportional areas of representation of different skin surfaces of the hand in Areas 3b and 1 in any given individual monkey. 3) The topography of Area 3b, as well as the real and proportional areas of the representation of different hand surfaces is relatively constant. 4) In general, there was a common basic pattern of topographic organization of Area 1 in all squirrel monkeys studied. There was however, significant variability in both the real and proportional areas, and the detailed internal topography of its representation of the hand. For example: a) There was a several-fold variation in the actual or proportional areas of the representation of glabrous digital surfaces within Area 1. b) Significant individual variations in the relative sizes of representations of specific digits in Area 1 were seen. c) The glabrous surface of the first digit may be represented adjacent to the second digit or in a cortical region far removed from the second digit's representation. d) Although the pattern of representation of the hairy surfaces of the hand was similar in different monkeys, there were clear individual differences in the topographic relationships of these skin surfaces to the representations of glabrous digits and palmar pads. e) In some monkeys, the representations of the glabrous digital surfaces were continuous across the 3b-1 border, while in others, a representation of the volar pads (sometimes large in area) intervened.

The fact that proportional representation of the receptor surface in a given cortical area varied in these ways in different individuals, suggests that there are strong "use-dependent" or other mechanisms directing or modifying the representations of different sectors of the skin surface in primates.

222.4 EVIDENCE FOR MODULAR SEGREGATION OF "SLOWLY ADAPTING" AND "RAPIDLY ADAPTING" NEURONS IN AREA 3b OF SOMATOSENSORY CORTEX OF MONKEYS. Mriganka Sur*, John T. Wall, and Jon H. Kaas (SPON: Sandra M. Wall). Depts. of Psychology and Anatomy, Vanderbilt University, Nashville, TN 37240.

Single and multiunit recordings were used to determine the spatial distribution of "slowly adapting" (SA) and "rapidly adapting" (RA) neurons in the representation of the glabrous hand in Area 3b of six owl monkeys anesthetized with ketamine HCL. Responses of neurons to repeated one second step indentations of the skin were recorded and displayed in post-stimulus time histograms. All studied neurons were characterized by transient responses at stimulus onset and often at offset, and by brief periods of reduced activity after each transient burst. However, SA neurons also discharged at higher than spontaneous rates during the maintained indentation. SA neurons were recorded commonly in the middle cortical layers, and most had somewhat higher stimulus thresholds than RA neurons. Of 127 single cells recorded in four intensively studied monkeys, 38 were SA and 89 were RA. Electrode penetrations perpendicular to the cortical surface could be classified as encountering only RA neurons or largely SA neurons. In closely spaced grids of such penetrations placed 100-200 μ apart to span the entire digit 3 or digit 4 representation in Area 3b, it was apparent that SA and RA neurons were not randomly distributed throughout cortex but were grouped separately in predominantly rostrocaudal bands. Electrode penetrations angled mediolaterally relative to the brain surface confirmed these observations. The exact positions of the SA and RA bands varied in the representations of particular digits. Among patterns observed were one SA band flanked by RA bands within a digit representation and bifurcation of bands. Bands also appeared to be continuous across the representations of adjacent digits. SA bands were most narrow caudally, in the representation of the proximal phalanx, and broader rostrally where the distal phalanx is represented. Band widths varied from 200 μ to 600 μ. Receptive fields for neurons in RA and SA bands were seen to overlap so that the entire digital skin was represented by both RA and SA cells separately. These experiments, along with similar data on cynomologus monkeys, suggest a functional segregation of receptor types within Area 3b of postcentral somatic cortex in monkeys. SA cortical bands must receive some of their input from cutaneous slowly adapting peripheral receptors while RA cortical bands can be most easily related to rapidly adapting cutaneous receptors.

222.5 SOMATOTOPIC ORGANIZATION IN THE ANTERIOR ECTOSYLVIAN SULCUS IN THE CAT. H.R. Clemo* and B.E. Stein (SPON: R.F. Spencer). Dept. of Physiology, Medical College of Virginia, Richmond, VA 23298.

It had traditionally been assumed that somatosensory, auditory, and visual cortices each have three distinct topographic representations. Recent observations in the cat showing numerous additional topographically organized areas of visual cortex have fundamentally changed our concept of the organization of sensory cortex. The presence of projections from somatic thalamus to regions outside the traditional somatic cortical areas such as the anterior ectosylvian sulcus (AES) in the cat, raises the possibility that there are more than three somatic cortical representations in this species. The present study examines the somatic representation in the AES.

Receptive fields (RFs) of single and multi-units were recorded in the walls of the AES and along the anterior ectosylvian gyrus (AEG) in 12 cats. The animals were initially anesthetized with ketamine hydrochloride, immobilized with gallamine triethiode and artificially respired with a mixture of 25% O_2 and 75% N_2O.

A complete topographic representation of the body was found on the AEG corresponding to the well known second somatic (SII) area. However, the representation in the AEG was found to extend well beyond the previously described boundaries of SII, reaching the lip of the AES. At the lip of the AES, additional representations of the contralateral forepaw and hindpaw were found which appear to belong to a separate map of the body.

This "new" (SIV) map was a mirror image of that seen in SII: forepaw was rostral on the lip of the AES with forelimb ventral to it (on the medial wall of the AES), and hindlimb was caudal on the lip with the hindlimb ventral. Trunk was represented ventral to the limbs and facial RFs were located in the most rostral portion of the AES.

In addition to a progression of RFs across the body surface in the SIV representation, there was a marked tendency for RFs to increase in size with depth in the AES. Thus the sequence of RFs was often: paw; paw and distal limb; paw and entire limb; paw, limb and trunk. The incidence of bilateral RFs (some covering the entire body) increased in the deep, ventral part of the AES, especially in the fundus and the caudal regions.

Thus, it appears that there are at least four somatotopically organized cortical areas in the cat. The functional roles that these separate sensory regions perform remains to be explained.

222.6 COMMON FEATURES IN ORGANIZATION OF SENSORIMOTOR CORTEX IN PROSIMIAN PRIMATES, GALAGO CRASSICAUDATUS AND NYCTICEBUS COUCANG. Mary Carlson, Carol Welt and Kathleen FitzPatrick, Children's Hospital Medical Center, Boston, MA 02115 and Central Wisconsin Center, Madison, WI 53704.

Our studies of prosimian primates originate from an interest in the evolution of the hand and somatic sensory cortex (SmI) in Old World primates. Our intent is to determine the common features in organization of SmI and adjacent regions in several Lorisidae (two African and one Asian species, each showing unique sulcal patterns and behavioral adaptations) as suggestive of cortical organization in ancestral prosimians.

We have examined the classes of submodal input, topographic organization and cytoarchitectural correlates in SmI in both awake behaving and anethetized Nycticebus, as we have done previously in Galago. Those features in Nycticebus closely resembling Galago are: (1) one precisely organized projection from glabrous palm and digits responding to low threshold (LT) cutaneous stimulation in the rostral region of SmI, with fields on the dorsal glabrous tips at the rostral border of this area; (2) one projection pattern from the dorsal hairy digits located caudally in the hand area with fields on the dorsal hairy digits adjacent to more rostral ventral palm fields; and (3) the correspondence of the LT cutaneous projection area with the dense granular field in sensorimotor cortex.

The differences noted in Nycticebus have been: (1) the consistent finding of a small (less than $1mm^2$) area responding to LT stimulation of glabrous palm and digits, medial to the dorsal hand region and caudal to the major glabrous region in anesthetized animals; (2) more neurons responding to passive joint movement in the dorsal hand region than in the glabrous region in awake animals, which is more consistent with the distribution of submodal input in the Old World simian, Macaca.

We are continuing our study of these novel features in Nycticebus, re-examining these details in Galago, and beginning studies on SmI organization in Perodicticus potto. We believe that intensive analysis of all classes of submodal input, precise topographical details, and morphological and cytoarchitectonic correlates on a variety of prosimian primates is necessary prior to the assessment of homologous areas in the sensorimotor cortex of Old and New World primate species.

222.7 NEURAL CODING OF KINESTHETIC INFORMATION IN SI CORTEX OF MONKEYS. E.P. Gardner and R.M. Costanzo, Dept. of Physiology & Biophysics, NYU Medical Center, 550 First Avenue., New York, N.Y. 10016.

The sense of kinesthesis involves appreciation of joint position or velocity of movement. To study neural mechanisms used to encode kinesthetic information in somatosensory cortex, we recorded in awake monkeys from 228 single neurons responsive to joint movement or specific postures of the forelimb or hand. 37 neurons were identified as joint neurons and 26 as muscle neurons based on responses to joint capsule and muscle belly palpation; the remainder were characterized functionally.

Kinesthetic neurons were divided into 3 groups depending on their firing patterns. Rapidly-adapting neurons (44%) responded only to limb movements, with no tonic responses to limb posture over the entire range of joint excursion. Movements in the preferred direction (on-direction) produced a burst of impulses proportional both to the velocity of movement and to initial limb posture. The remaining 56% showed tonic discharges related to static joint angle over at least part of the range of joint movement. These neurons increased their firing rates with increasing degrees of flexion or extension, showing maximum excitation at the extremes of joint position in the on-direction.

Two populations of tonically active neurons were observed. These were distinguished by their sensitivity to the velocity of movement, the size of their responsive angle, and the phase relation of their responses to sinusoidal joint movement. Slowly-adapting neurons (43%) showed overshooting responses during on-direction movements proportional to the velocity of motion, and low-frequency, irregular discharges during maintained postures. They were excited by movements over most of the range of joint angles, but fired tonically to postures comprising less than 60 deg of joint excursion. Sinusoidal joint movement modulated unit firing rates sinusoidally with maximum activity in phase with joint velocity. We propose that such neurons provide information mainly about velocity and direction of movement, and contribute postural information only at the extremes of joint excursion.

Postural neurons (13%) are relatively insensitive to limb velocity; their firing rates reflect only static joint angle. They show no overshoot in activity during on-direction movements, but simply increase firing to a higher level proportional to the new posture. They are tonically active over the entire range of joint excursion, showing higher and more regular firing rates than slowly-adapting neurons. Sinusoidal limb movements produce maximum firing in phase with limb position. These response features make postural neurons optimally suited for coding joint position. (Supported by NIH Grants NS11862 and RCDA NS00142 and an award from the Irma T. Hirschl Trust).

222.8 MULTIPLE-JOINT NEURONS IN S-I CORTEX. R.M. Costanzo and E.P. Gardner, Dept. of Physiology, NYU Medical Ctr. New York, NY 10016

Kinesthesis involves not only an appreciation of static position or velocity of movement of individual joints, but perception of the angles of adjacent joints relative to one another. This involves synthesis of a picture of the entire body in space, and could be provided by the activity of higher-order feature-detecting neurons which integrate information from several joints. We here report on 54 such multiple-joint neurons (MJNs) in somatosensory cortex of alert monkeys. MJNs receive convergent information from two or more adjacent joints, and use their firing patterns to encode the posture of an entire limb.

Most MJNs in our sample were related to postures of the hand, particularly those involved in grasping. For hand receptive fields, we found an equal number of MJNs as single-joint neurons (SJNs), whereas for elbow and shoulder receptive fields, the ratio of MJNs to SJNs was 1:3. MJNs with hand receptive fields were excited by flexed postures of the digits and wrist, or by extended postures, but not by complex arrangements of individual fingers, nor by extended fingers and flexed wrist or vice versa. MJNs related to proximal joints showed a much greater variety of joint combinations.

Two basic types of joint interactions were observed. The simpler neurons responded to postures of several different joints such as wrist flexion or elbow extension. However, combination of the two preferred postures produced no further increase in firing compared to assumption of either one of them. The more complex cells show facilitation or inhibition between the angles of adjacent joints. For these neurons, responses were graded with joint angle, and there was an optimum or preferred position for both joints which gave the strongest response.

Three-fourths of the MJNs showed tonic discharges proportional to static joint angles, and 1/3 of these cells were insensitive to stimulus velocity (postural kinesthetic neurons). This suggests that MJNs might be important for encoding limb postures rather than the dynamics of movement.

We conclude that MJNs provide a neuronal substrate for extracting postural information from several different populations of simple kinesthetic neurons, and that this activity could be used to depict particular postures of the arm. Such integrated information may be important for motor behavior where one has to orient an entire limb in a specific posture to accomplish the desired goal.
(Supported by NIH Grants NS11862 and RCDA NS00142, and an award from the Irma T. Hirschl Trust).

222.9 AFFERENTS TO IMMATURE SOMATOSENSORY CORTEX IDENTIFIED WITH HORSERADISH PEROXIDASE. D. Kristt and J. Silverman*, Dept. Pathol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Horseradish peroxidase (HRP) was administered to somatosensory cortex of newborn to 6-day-old rats as implanted pellets or as a pressure-injected aqueous solution at low and high doses. Tissue sections were histochemically processed using the tetramethyl benzidine reaction. Implantation of a single pellet was superior to a single injection for delivering low doses to a specific part of somatosensory cortex (predominently SmI). High-dose administrations of HRP as either multiple pellets or injections uncovered many more nuclear groups; some of these have not been previously noted either in infant or adult brain. Both modes of high dose administration revealed the same cell groups, although more neurons/group were labeled after implants, and cells were more densely labeled. The single pellet implants (low dose) demonstrated afferents, ipsilaterally, from the ventral basal complex (VBC), central lateral, ventral medial, and posterior nucleus of the thalamus, the locus coeruleus and scattered somata in the caudal basis pontis (A5). High-dose administration showed, in addition, labeled neurons in all of the intralaminar thalamic nuclei, contralateral locus coeruleus, contralateral somatosensory cortex, contralateral pyriform and the dorsal raphe region of the midbrain. In ipsilateral neocortex, SmII contained labeled neurons. Moderate numbers of labeled neurons were scattered throughout brainstem reticular formation, often in clusters. Other forebrain groups were occasionally labeled. Since it was possible that cortical or subcortical regions adjacent to SmI were actually taking up the HRP after high doses, two further sets of experiments were done. First, multiple pellets were implanted at superficial depths. The only difference in the findings was the absence of labeled cell bodies in contralateral forebrain. In the second series of experiments, cortical or subcortical regions contiguous with SmI were ablated, but this did not alter the findings. Also, deep coronal, hemispheric knife cuts anterior to SmI eliminated labeling of brainstem neurons, predominently in locus coeruleus, but did not affect A5 labeling. These results suggest that terminal uptake is primarily in SmI. Consequently, by the end of the first postnatal week, most of the identified extrinsic inputs to adult SmI are probably already represented. VBC and locus coeruleus appear to provide a relatively dense innervation to rat somatosensory cortex, while few terminals from contralateral SmI are present in the supragranular layers. It also appears that projections from the thalamus and the brainstem reticular formation may be more extensive than was previously recognized, at least during the newborn period.

Grant support: NSF BNS-79-11514 and NIH NS-00279 (TIA).

222.10 THE TERMINAL ARBORS OF VENTROBASAL CELLS PROJECTING TO AREA SI IN CATS. P. Landry* and M. Deschênes* (SPON: R. De Estable-Puig) Lab. of Neurophysiology, Laval Univ. Fac. of Med., Québec, Canada G1K 7P4.

Thalamocortical axons originating in the ventrobasal complex were recorded intraaxonally in the white matter below area SI. These fibers were identified electrophysiologically by their direct response to ventrobasal stimulation and by their transsynaptic responses to stimulation of the medial lemniscus. The receptive field for each fiber was determined and subsequently the fiber was injected intraaxonally with horseradish peroxidase (HRP). The method of perfusion and histochemical visualization of the HRP is described elsewhere (Deschênes, M., Landry, P. and Labelle, A., Neurosci. Letters, 12: 9-15, 1979). Thirteen fibers were injected sufficiently to permit a visualization of most of the terminal arbors. Seven of these fibers were activated by hair displacement; three responded tonically to skin indentation, three were driven by joint movement, and one by stimulation of deep tissue. The cortical territory covered by the main terminal arbor of ventrobasal afferents is around 0.8 to 1.5 mm. All fibers have a common laminar distribution. Most terminals are located in layers VI, IV and the lower part of lamina III. Very few terminals were seen in layer V and none in layers I and II. All hair-driven fibers terminated in area 3b or in the posterior part of area 3a and had very dense terminal plexi. They also sent one or two fine collateral branches in areas 1, 3a, and possibly 2. The terminal arbors that issued from these few collaterals were much less elaborated. Furthermore they reached the same layers as the main terminal arbor. Axons that responded tonically to skin indentation, deep stimuli, or joint movements were mostly located in area 3a. The terminal arbors of all these fibers were much less dense than those driven by hair movement. Within this group, skin driven fibers had a more intricate arbor than units driven by deep tissue distortion or joint movement. Most of the fibers in this group sent collaterals to areas 3b and area 4. Although hair-driven units have a distinctively dense terminal arbor, the morphological criteria separating the units remains to be determined. To answer these topological problems, computer-assisted topographical analysis, which is currently underway, is expected to provide the desired criteria.

222.11 THALAMIC PROJECTION TO AREAS 3a AND 2 IN MONKEYS. D.P. Friedman and E.G. Jones. Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

The thalamic projection to areas 3a and 2 of the macaque somatic sensory cortex has been determined using combined electrophysiological and neuroanatomical techniques. Initially, the ventrobasal complex (VB: the VPLc and VPM nuclei) and the adjacent VPLo nucleus were mapped for somatic responses using standard microelectrode recording techniques in Nembutal anesthetized monkeys. Electrode penetrations entering this region horizontally, from behind, first encountered units which responded to light cutaneous stimulation. Anteriorly, near the border of VPLc and VPLo and still within the zone of lemniscal fiber terminations, as determined in concurrent anatomical experiments, a shift to deep receptive fields (e.g., joint rotation, pulling on tendons or manipulation of muscle bellies) occurred. When the location of this shift was marked with microlesions, it was seen to lie within the anterior 500 µm of VB. Tracks entering VB vertically, from above, often passed through a similarly narrow zone (about 500 µm), within which units also responded to deep stimuli. These vertical tracks then entered the larger "cutaneous core" zone of VB, within which units responded to light tactile stimuli as above. Tracks placed anteriorly, passing through VPLo, but not VPLc, encountered units with deep receptive fields only.

Small injections of tritiated amino acids placed into the anterior portion of VPLc, where responses to deep stimuli were recorded, labelled thalamocortical terminal ramifications in area 3a. Injections placed in the dorsally situated deep zone of VB, irrespective of their anterior-posterior position, labelled areas 3a and 2. Injections confined to VPLo or its extension, VLc, labelled only area 4.

The thalamic projection to area 3a thus arises from a "deep" shell zone of VB which occupies its anterior and dorsal surfaces. The projection to area 2 appears to arise primarily from the dorsal portion of the shell. The larger cutaneous core zone underlying this shell, projects to areas 3b and 1.

222.12 QUANTITATIVE ANALYSIS OF GOLGI-IMPREGNATED STELLATE CELL AXONS AND THEIR PROXIMITY TO DENDRITES IN MOUSE BARREL CORTEX. R.M. Harris and T.A. Woolsey. Dept. Anat. & Neurobiol., Washington U. Med Sch., St. Louis, MO. 63110.

Our previous analyses of neuronal morphology as revealed by Golgi-impregnations in mouse and rat barrel cortex have focused on the dendritic patterns of the stellate cells. From their dendritic morphology these cells can be classified into two types: Class I cells with spiny dendrites and Class II cells with smooth beaded dendrites. These classes can be subdivided further according to their somal position and spacial distribution of dendrites with respect to barrel boundaries. In this study the axons of these cells were examined and the locations of close appositions to dendrites of other impregnated neurons mapped. All data are taken from Golgi-Cox preparations, cut parallel to layer IV at 140µm, counterstained with Nissl to reveal the barrels, and measured with a computer-microscope. Axons which had extensive branching within the section (10% of all cells) were chosen for measurement.

The analysis of the axons revealed: 1) Class I axons are thin and directed to the white matter, with recurrent collaterals in the barrels, while Class II axons are thick, frequently beaded, and directed towards the pia before cascading down into the barrels. 2) The axons tended to be as restricted to a barrel as the dendrites of the same cell were (i.e. most axons were confined to one barrel). 3) The Class I axons had a total length about three times that of Class II axons, and about four times as many branch points. Analysis of the appositions of these axons to impregnated dendrites of other cells revealed: 1) A greater number of appositions occurred near the distal end of dendritic segments. 2) No striking patterns were found, such as an obvious propensity for axons of one cell type to prefer or avoid another cell type, such as might be expected if very specific cell-cell "connections" were being observed.

These results show that the axons of barrel cells of each class are as consistent and distinctive as their dendritic trees. The cells can thus be distinguished by their axonal patterns on purely numerical bases. The new computer programs which were developed to systematically search for sites of apposition between axons and dendrites - a necessary prerequisite for the existence of synaptic contacts - greatly facilitated the collection of these data. The data may be of value for defining "probable" sites of interaction between particular cell types. In particular, the observations of the distribution of appositions along dendritic segments is comparable to White and Rock's ('79) EM mapping of synapses on barrel neurons.

222.13 FEATURES OF S-I CORTICAL ORGANIZATION IN THE CAT DEMONSTRATED BY ANTEROGRADE DEGENERATION AND METABOLIC LABELLING. E. Kosar, P. Hand and T. McKenna* (SPON:L. Ritz). Dept. Animal Biology, Sch. Veterinary Med. and Inst. of Neurological Sci., U. Pennsylvania, Philadelphia, Pa. 19104 and Dept. Physiology, UNC, Chapel Hill, N.C. 27514. Relations between the distribution of thalamocortical connections and of stimulus-related metabolic activity were examined. The Fink-Heimer I technique was employed to demonstrate degenerating thalamocortical connections and the C-14-2-deoxyglucose (2-DG) metabolic labelling method was used to demonstrate regions activated by natural stimulation. Electrolytic microlesions (30-275μ) placed in VPLm led to degenerating fibers terminating within laminae III and IV of areas 3b, 1, and 2. Individual patches of degenerating fibers seen in single coronal sections had well defined radial boundaries, mediolateral dimensions of from 80-120μ, but extended for much longer distances in the A-P dimension of S-I (2500-3000μ). The total pattern of anterograde degeneration resulting from a single thalamic lesion revealed that the patches are arranged in bands that merge and diverge in a zebra-like pattern. C-14-2-DG labelling studies were carried out in unanesthetized cats under neuromuscular block with gallamine. Unilateral brush strokes were applied to the digits of the antebrachium prior to, during, and following intravenous pulse-injection of 150-250 μcuries of 2-DG. After continuous stimulation (interstimulus interval = 3 sec.) for 45 minutes, the animal was sacrificed by i.v. injection of pentobarbital followed by intracardiac perfusion. All subsequent procedures were identical to those described by Sokoloff, et. al. (J. Neurochem. 28: 1977). Preliminary results indicate that 2-DG labelling in the contralateral S-I cortex exists in the form of radially oriented spindle shaped columns, 180-500 microns in mediolateral width, extending through lamina II to VI. The greatest density of labelling was in lamina III and IV. Labelled columns were mainly located in the medial bank of the coronal sulcus, in all cytoarchitectonic areas of S-I. In general, the columnar structures labelled by C-14-2-DG also form sinuous A-P bands. Differences were observed in the pattern of metabolic labelling in S-I and S-II. In S-I, laminae III and IV were densely labelled, whereas in S-II the labelling more uniformly involved laminae II-VI. Reconstructions were prepared to enable comparison of the pattern of A-P bands revealed by the degenerating thalamocortical afferents with the cortical bands exhibiting enhanced metabolic activity in response to continuous tactile stimulation.

222.14 METABOLIC MODULAR ORGANIZATION IN THE SOMATOSENSORY CORTICES OF THE MONKEY. S.Juliano,P.Hand,B.Whitsel. Dept. of Animal Biology, School of Veterinary Medicine,and Institute of Neurological Sciences, Univ. of Pennsylvania, Phila.,PA 19104;Dept. of Physiology, School of Medicine, Univ. of North Carolina, Chapel Hill,NC 27514

Previous (14C)2-deoxyglucose (2DG) investigations by this laboratory, (Anat. Rec., Neurosci. Abs.,1979) have shown a complex pattern of organization of functional columns or modules in the primary somatosensory(SI) and associated cortices of the Cynomolgous monkey,in response to a light cutaneous brush stroke (BrS). Modules ranged in mean diameter from 434 to 651um, and when viewed on unfolded surface reconstructions, formed medio-laterally oriented strips or modules. These results have been extended by using different somatic stimulation on 2 additional paralyzed, unanesthetized monkeys. Each animal received a pulse injection of 2DG and either (a) unilateral flutter-vibration stimulation (FV) at 15cps,from a point source on the distal joint of the index finger, or (b) servo-motor controlled, unilateral, flexion/extension of the elbow joint at 22°/sec. The animal receiving unilateral FV showed functional columns in cortical areas similar to the BrS animals. The sizes of these columns, in mean width, ranged from 486 to 679um. Noticeable differences from the BrS animals were in areas 1,5 and 7 where the mean column widths for the FV animal were larger than those of the BrS animals. When a surface reconstruction for the FV animal was compared to that of a BrS animal stimulated over the same body part, the foci of label in SI were found to be similar in both animals. The FV animal also showed labeling in the form of medio-laterally oriented strips, however, the strips appear wider in a rostral-caudal dimension, and show an additional focus of label in areas 1 and 2. Also, the FV animal has somewhat fewer modules throughout SI and the medio-lateral strips often appear shorter than those of the BrS animal. Preliminary results from the animal with elbow joint movement show columns of similar size to those seen in the other animals, as well medio-lateral strips of functional label in areas 3a and 3b, plus a focus of columnar labeling in areas 1 and 2 at the elbow region of SI.

222.15 SELECTIVE UPTAKE OF [^{3}H] GABA BY INTERNEURONS IN MONKEY SENSORY-MOTOR CORTEX. S.H.C. Hendry and E.G. Jones Dept. of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

[^{3}H] GABA (20 or 50 μCi. per μL) was injected into areas 4, 3, 1 and 2 of the motor and somatic sensory (SI) cortex in Macaca fascicularis, following intravenous administration of the GABA-transaminase inhibitor, aminooxyacetic acid. After 30-40 minutes, blocks from the cortex were fixed by immersion in 3.5% glutaraldehyde and frozen or plastic-embedded sections were processed by standard autoradiographic methods. Neurons which had accumulated [^{3}H] GABA, and were thus presumed to be GABAergic, were identified by heavy concentrations of silver grains overlying their somata. In all areas no pyramidal cells are labelled above background. All labelled neurons are thus considered to have axons that are intrinsic to the cortex. The labelled somata are found in each of the cellular layers of the cortex but their numbers vary with depth, particularly in SI. There, large numbers are present in layers II, IIIB, IV and in the upper part of layer VI; fewer are present in layers IIIA, V or in the deeper part of layer VI. By comparison, the labelled cells in area 4 are more homogeneously distributed throughout layers II, III and V and almost completely absent from layer VI. Labelled somata in SI fall into two size categories: small (7-14 μm) and large (18-25 μm). Two similar groups are found in area 4 but both are somewhat larger. The smaller size group is found in all layers containing labelled cells, but the larger size group is restricted to layers IIIB, IV and V. The larger type in both areas is interpreted as the type 1 (basket) cell of Jones (J. Comp. Neurol. 160:205, 1975). The smaller type probably includes several of the other non-pyramidal cell types identified in Golgi preparations.

222.16 A POSSIBLE CORTICAL PATHWAY FOR SOMATOSENSORY PROCESSING IN MONKEYS. Elisabeth A. Murray, Richard K. Nakamura, and Mortimer Mishkin. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20205.

Anatomical and electrophysiological evidence indicates that both area 5 of the posterior parietal cortex and the second somatosensory area (SII) are possible relays in a processing pathway linking the primary somatosensory area (SI) with the motor and limbic systems. To evaluate these possibilities behaviorally, rhesus monkeys with bilateral lesions of either area 5 or SII were compared with normal controls on a battery of six somatosensory discriminations which required them to differentiate objects on the basis of texture, shape or size. Whereas animals with removals of area 5 showed no impairment relative to the controls in learning any of the tactual discriminations, monkeys with lesions of SII were markedly impaired relative to both of the other groups in learning all tasks except a gross size discrimination. Furthermore, despite learning the size discrimination normally, the SII group was impaired relative to the other groups in subsequent testing of size discrimination thresholds. Although tactual deficits following lesions of area 5 have been reported previously, deficits after such damage were found in the present study only when area 5 lesions were extended slightly rostrally, in a third operated group, to include the dorsomedial part of the hand representation of area 2. The combined results indicate that SII, and not area 5, is a critical station in a somatosensory processing pathway, and suggest that cortical areas to which SII projects may be further links in the pathway; this possibility was examined next.

Anatomical investigations have indicated a projection from SII to part of the insular cortex, and unit recording data show that neurons in the insular and retroinsular regions are activated by somatosensory stimuli. Therefore, a fourth operated group was prepared with bilateral lesions of the insular and retroinsular cortex, made accessible by removal of the supratemporal plane. These animals were impaired in learning four of the tasks, including a roughness discrimination, but were unimpaired in size and roughness discrimination thresholds. Comparison of this profile of deficits with that following SII lesions suggests that the insular/retroinsular cortex is a higher order somatosensory processing area than SII.

The known projection of parts of the insular cortex to the amygdala suggests a sensory-limbic pathway for touch analogous to the one in vision. Just as visual sensory information is relayed to the limbic system through successive links of striate, prestriate, and inferior temporal cortex, a sensory-limbic pathway for touch may proceed from SI to the medial temporal lobe through serial links in SII and the insular/retroinsular cortex.

222.17 CORTICAL BARREL FIELDS OF ADULT MICE AS ANALYZED WITH CYTOCHROME OXIDASE CYTOCHEMISTRY. Margaret Wong-Riley. Dept. Anat., Univ. Calif., San Francisco, CA 94143.

In a previous histochemical study (Wong-Riley and Welt, Proc. Natl. Acad. Sci., in press), the barrel centers (hollows) in layer IV of SmI face cortex of normal mice were found to have a high level of cytochrome oxidase activity, indicating a high degree of oxidative metabolism there. In order to determine the distribution of such enzyme reactivity at the EM level, vibratome-cut sections of normal barrel fields were reacted for cytochrome oxidase activity, and the individual reactive barrels were dissected out under a stereozoom microscope and processed for EM. Thus far, a total of 5000 mitochondria were counted from five large montages, totalling 17,940um^2 in cross-sectional area of barrel centers. Approximately 30% of the mitochondria resided in non-synaptic dendritic profiles (ie., profiles not showing synaptic junctions in the field), 11% in postsynaptic dendrites, 16% in axon terminals making asymmetrical synapses, 10% in processes making symmetrical synapses, 12% in myelinated axons, 12% in perikarya of neurons, and the remaining percentage in non-synaptic axonal profiles, glia and unclassifiable profiles. Mitochondria were classified as darkly-reactive (D), moderately-reactive (M), and lightly-reactive (L). Of the axonal population making asymmetrical synapses, approximately 20% of their mitochondria were D's, 52% M's, and 28% L's. Of the processes making symmetrical synapses, approximately 25% of their mitochondria were D's, 57% M's and 18% L's. Among the non-synaptic dendritic population, however, 67% of their mitochondria were D's, 25% M's and 8% L's. A similar pattern of distribution was found among the postsynaptic dendrites. Thus, dendrites contain the greatest percentage of mitochondria in barrel centers, and the majority of these mitochondria have a high level of cytochrome oxidase activity. In contrast, most of the mitochondria in presynaptic axonal profiles are only moderate to lightly reactive, and the highly reactive ones contribute to only a small percentage of the total mitochondrial population. Studies are under way to determine changes in the distribution pattern of the mitochondrial population in chronically dewhiskered barrel fields of adult mice.

223.1 CONDITIONED CORTICOSTERONE SECRETION TO STIMULI ASSOCIATED WITH STRESS. S. R. Burchfield* (SPON: A. Nonneman). Department of Psychology, University of Kentucky, Lexington, KY 40506.

50 two-month-old male and female Long-Evans' rats were used in a study investigating endocrinological conditioning to cues predictive of stress. A typical classical conditioning paradigm was used. The unconditioned stimulus (USC) was loud noise lasting five minutes. The unconditined response was corticosterone secretion. The conditioned stimulus (CS) was a click which occurred when the automatic timer clicked on to play the noise (gun fire) tape. Control animals were used to determine the basal level of corticosterone secretion, plasma corticosterone levels in response to the click only, and to the noise only. The experimental group was exposed to seven pairings of the CS and UCS at random times, once a day for one week. On the eighth day rats were exposed to the CS only and truncal blood was collected between 3-15 minutes after CS presentation. Results indicated no differences in plasma corticosterone levels ($\bar{X}$ = 3.93 ug/dl) in baseline and click only conditions. Corticosterone was elevated in the females ($\bar{X}$ = 15.47 ug/dl) but not the males ($\bar{X}$ = 4.92 ug/dl) in the noise only condition. Both males and females showed a significant ($P < .05$) elevation of corticosterone response to the click on day eight. Females responded with a higher corticosterone level after the CS ($\bar{X}$ = 36.5 ug/dl) than did males ($\bar{X}$ = 15 ug/dl). A final control group was included to determine if conditioning actually occurred or if the higher corticosterone level represented an altered basal secretion. This group received seven CS-UCS pairings. On day eight, truncal blood was collected in the absence of either the CS or UCS. Males displayed a plasma corticosterone level equal to their basal levels ($\bar{X}$ = 2.0 ug/dl) while females displayed a significantly elevated level, equal to their conditioned response ($\bar{X}$ = 37.6 ug/dl). These data suggest that female rats, after chronic intermittent stress, either alter their basal corticosterone output or experience sensitization (e.g., respond to stimuli not usually considered stressful). Males, however, appear to respond only to the specific stressor and exhibit a normal basal corticosterone level at other times. Possible mechanisms for these results are currently being investigated.

223.2 CHANGES IN PLASMA VASOPRESSIN DURING MOTION SICKNESS IN CATS. R. Fox*, L. Keil, N. Daunton, D. Thomsen*, M. Dictor*, and O. Chee*. NASA Ames Res. Center, Moffett Field, CA 94035 and San Jose State Univ., San Jose, CA 95192.

Changes in levels of plasma vasopressin (AVP) and cortisol (C) have been shown to be correlated with motion sickness and nausea in man. As part of the research aimed at validation of the cat as an appropriate animal model for motion sickness research, levels of these hormones were investigated in the cat during motion sickness elicited by vertical linear acceleration of approximately 0.6 Hz and 1 + 0.6 G.

In Study 1, 15 cats previously screened for susceptibility to motion sickness were prepared with indwelling jugular catheters to permit withdrawal of blood with minimal disruption of the stimulus and minimum stress to the animal. AVP and C were measured in blood samples obtained during exposure to vertical linear acceleration and during control sessions in which the animals were placed in the stationary apparatus. Samples were drawn according to a predetermined time schedule as follows: 10 min and 1 min prior to motion; 1, 5, 10, and 20 min after start of motion. Total duration of exposure to motion was 20 min. The data from this study indicate that both AVP and C are elevated during exposure to motion if emesis occurs. AVP reaches maximum levels during or about the same time as emesis, while C increases gradually throughout the period of vertical acceleration.

In Study 2, four cats were prepared with indwelling catheters and AVP was measured in blood withdrawn during exposure to the vertical linear acceleration. A single pre-motion sample was drawn 5 min prior to motion onset. Two series of samples consisting of three samples drawn at 3-min intervals were obtained during motion. The first series was initiated at emesis, and the second 25 min after emesis. Results show that levels of circulating AVP were elevated (2 to 27 times the control and pre-motion levels) in the samples taken during emesis and decreased, but remained 1 to 6 times above the pre-motion or control levels within 25 min.

The results of these two studies indicate that AVP is elevated during motion-produced emesis in the cat, and that AVP is more closely related to emesis than is C. These findings are in general agreement with those obtained from humans under motion sickness conditions, and indicate that it is appropriate to continue to use the cat in studies of hormone changes during motion sickness.

223.3 A ROLE FOR THE MIDBRAIN CENTRAL GRAY IN ESTROUS BEHAVIOR OF THE CAT. J. D. Rose and L. K. Smucker*. Dept. of Psychol., Univ. of Wyoming, Laramie, WY 82071.

Previous results from single-unit recording and lesion-behavioral experiments have indicated that the lateral caudal medulla plays an essential role in the estrous vocalization and afterreaction responses to genital stimulation in the female cat. Results of neuroanatomical, electrophysiological and estradiol autoradiographic studies suggest that estrogen influences may be transmitted to caudolateral medullary neurons via a projection from the central gray. In the present investigation, the significance of the central gray in estrous behavior was examined by placing lesions in this structure in 5 ovariectomized cats. The lesions produced no marked impairment in estrous behaviors, but instead resulted in the appearance of persistent estrous behavior patterns in the absence of estrogen replacement. These estrous behaviors included lordosis, treading and tail deflection in response to perigenital stimuli and afterreactions following genital stimulation. In all cases, the lesions abolished the typical hostile responses to genital stimulation in the hormonally anestrous condition. Although the lesions eliminated or weakened vocalizations to social or nociceptive stimuli, the estrous cry response to genital stimuli remained largely intact. Subsequent single-unit recording experiments in 10 urethane-sedated estrous and anestrous cats without brain lesions confirmed an earlier observation that most caudolateral medullary neurons show a sustained decline in firing following genital stimulation, whereas the converse, an acceleration is seen in units in anestrous cats. Recordings from medullary units in 3 hormonally anestrous cats which displayed estrous afterreactions to genital stimulation due to central gray lesions revealed a preponderance of units showing the estrous pattern of firing following genital stimulation. In addition, in electrode tracks through the central gray of the animals without brain lesions, fewer spontaneously-active units could be recorded in the estrous animals in the central gray at the A-P level of the trochlear nucleus, but no difference in spontaneous unit activity was seen in more anterior central gray tracks. The region of the central gray showing depressed activity in the estrous animals coincides with that containing the largest number of neurons projecting to the caudolateral medulla (Rose, J. D., Soc. Neurosci. Abstr., 5:457, 1979). The findings from these lesion and recording studies suggest that the central gray normally acts to suppress estrous behaviors in the anestrous cat and that estrogens may promote estrous behaviors through a suppression of the activity of central gray neurons, including those projecting to the caudolateral medulla.

Supported by NIH Grant NS 13748.

223.4 SITE-SPECIFIC INDUCTION OF SEXUAL BEHAVIOR BY INTRACRANIAL ESTRADIOL IMPLANTS IN MALE AND FEMALE HAMSTERS. Joseph F. DeBold, Charles W. Malsbury and Douglas E. Arnoult* Dept. Psychol.,Tufts Univ., Medford, MA; Dept. Psychol., Memorial Univ., St. John's Newfoundland;Dept. Psychol., Carnegie-Mellon Univ., Pittsburgh,PA

Estrogen is necessary for the induction of female sexual receptivity in rodents and a number of other species. Estrogen may also be an important component of androgen action in the maintenance of male sexual behavior. These effects of estrogen appear to be mediated by direct actions on the CNS. In female rats and guinea pigs direct estrogenic stimulation of the ventromedial hypothalamus (VMH) is sufficient to induce sexual receptivity. However in female hamsters the only published report on hypothalamic estrogen implants stresses the importance of the anterior hypothalamus. In castrated male rats estrogen implants into the preoptic area (POA) is particularly effective in restoring mounting behavior while there is little comparable information in other male mammals. The present study compared the location of effective intracranial estradiol (E_2) implants for female sexual receptivity in gonadectomized male and female hamsters and for mounting behavior in castrated male hamsters.

In the first experiment, 2 wk after gonadectomy male and female hamsters were stereotaxically implanted with a single 27g cannula containing crystalline estradiol into one of several brain sites. Males and females received implants in the POA, anterior hypothalamus (AH), VMH and cortico-medial amygdala (CMA). In addition, other females received implants into the bed nucleus of the stria terminalis (bnst), the arcuate (arc) and the central grey. Some animals received instead implants containing cholesterol. One wk later the animals were injected with 500µg progesterone and 4-5 h later tested for sexual receptivity. The best response was seen in females with E_2 implants in the VMH, but a few females with implants in the AH, CMA or bnst also were receptive. Only males with VMH E_2 implants were receptive. Except for a few AH females there was little stimulation of uterine weight suggesting minimal E_2 diffusion.

In the second experiment, males were castrated and then 8-10 wk later were implanted bilaterally with 30 g E_2 or cholesterol cannulae into either the bnst, POA, AH or VMH. All animals also received a subthreshold amount of dihydrotestosterone (50µg/d s.c.) and were tested with a sexually receptive female for mounting 3 or 5 d later and then 3 additional time at 5 d intervals. E_2 implants in or near the POA and bnst were most effective in restoring mounting behavior while VMH implants were least effective.

These experiments demonstrate that the VMH is the most sensitive brain area for estrogenic stimulation of sexual receptivity in both male and female hamsters, however, the same hormone restores mounting behavior most effectively in POA and bnst.

223.5 EFFECTS OF CANNABINOIDS AND SEXUAL STIMULATION ON PITUITARY-GONADAL FUNCTION IN MALE MICE. S. Dalterio,* R. Huffman, A. Bartke,* M. Harper,* C. Sweeney.* Dept. Pharm. & Ob-Gyn, UTHSCSA, San Antonio, TX 78284

A single dose of Δ^9-tetrahydrocannabinol (THC, 50 mg/kg), the main psychoactive constituent of marihuana decreased plasma testosterone (T) (2.46±0.6 vs 0.54±0.2 ng/ml, p<.05), LH (38±8 vs 15±3 ng/ml, p<.01) and FSH levels (1219±53 vs 990±44 ng/ml, p<.01) in immature mice but the same dose of the non-psychoactive cannabinol (CBN) had no effect. Repeated exposure to cannabinoids from 30 days of age to adulthood influenced endocrine responses to mating, although there were no differences between groups in sexual activity during a 1 hr test session. Mice were treated with vehicle (oil), or THC, CBN or cannabidiol (CBD) at a dose of 50 mg/kg and half of each group were either exposed to a sexually receptive female or maintained in an all male group. Twenty hours after sexual experience testicular weights were reduced (p<.02) in THC (269±17 vs 247±7 mg), CBN (294±25 vs 266±3 mg) and CBD (283±17 vs 254±7 mg), but not in control males (289±7 vs 287±11 mg) Similar effects were noted for seminal vesicle weights. Plasma FSH levels were elevated (p<.05) in CBN-treated mice compared to oil-controls after sexual stimulation (1167±91 vs 1515±357 ng/ml) as well as after grouped housing (1179±99 vs 1549±250 ng/ml). Sexual experience resulted in a significant (p<.05) increase in plasma T levels in oil (1.5±0.4 vs 5.3±2.4 ng/ml), CBN (1.0±0.4 vs 2.1±1.2 ng/ml), and CBD (1.0±0.2 vs 5.2±2.8 ng/ml), but not in THC-treated males (4.5±3.4 vs 4.2±3.4 ng/ml). In THC exposed mice plasma LH (29±16 vs <3 ng/ml) and FSH levels (1392±51 vs 1134±74 ng/ml) were reduced (p<.05) in sexually stimulated compared to grouped males. Testicular responsiveness to gonadotropin stimulation in vitro was reduced (p<.05) by exposure to mating stimuli in THC (2757±428 vs 1792±71 ng/ml) and CBN-treated mice (2549±201 vs 1997±154 ng/ml). However, in THC and CBN-exposed animals maintained in all male groups, T production in vitro was elevated compared to oil-controls (1894±246 vs 2757±428 and 2549±201 ng/ml, p<.05). Interference with prostaglandin (PG) synthesis may mediate these effects of cannbinoids and sexual experience since in vitro production of PGE and PGF was reduced (p <.05) in testes (0.23±.01 vs 0.18±0.01, and 0.28±0.02 vs 0.10±0.06 ng/mg protein) and pituitaries (9.2±0.8 vs 6.5±0.2 and 6.8±0.3 vs 4.8±0.2 ng/mg protein) in pooled cannabinoid-treated males compared to oil-controls. These results indicate that both psychoactive and non-psychoactive constituents of marihuana are capable of altering the function of the pituitary-gonadal axis and of influencing the endocrine responsivity to sexual stimulation in male mice. Supported by NIDA grant 1 R01 DA 02342-01.

223.6 MATERNAL BEHAVIOR DEFICITS AND ENDOCRINE RESPONSES IN FIMBRIA-FORNIX LESIONED POST-PARTURIENT RATS. M.K.Steele and S.M.McCann, Physiol. Dept, Univ of Tex Hlth Sci Center, Dallas, TX, 75235.

Various components of maternal behavior, ability to cycle normally, as well as basal and suckling-induced changes in prolactin secretion were evaluated in post-parturient female rats that received bilateral electrolytic lesions of the fimbria-fornix fiber bundle at 10 days of gestation. While lesioned females (n=10) gained more weight over the 7 days of behavioral testing than control animals (n=6), they were deficient in pup-care related behaviors: nest ratings, number of pups nipple attached, number of pups with milk, retrieval of pups to the nest or home quadrant, and pup weight gain over the testing period.

In order to compare behavioral measures (esp. nursing) with possible deficits in prolactin secretion, suckling tests were conducted on experimental and control mothers on day 5 post partum. A chronic indwelling jugular cannula was inserted on the day prior to testing. Females were separated from their pups for 5 hours prior to (basal sample) and 15, 30 and 60 minutes after introduction of the pups. Prolactin levels were measured by RIA and the results indicate that prolactin responses were absent or delayed in 8 of 9 lesioned females, while 6 of 8 control mothers displayed the normal dramatic increase in prolactin levels within 15 minutes of pup introduction. Basal levels of prolactin did not differ between groups.

AFter behavioral testing terminated, resumption of estrous cyclicity was monitored and while all 6 control females rapidly resumed normal 4 or 5 day cycles, only 50 per cent of lesioned females displayed estrous cyclicity. Prolactin levels in blood were also measured during this time and values did not differ between lesioned and control animals.

Experiments in progress may delineate whether the aberrant prolactin responses seen in fimbria=fornix lesioned females are due to a primary endocrine deficiency or are secondary to basic behavioral deficits.

224.1 PERIPHERAL SPROUTING OF HIGH THRESHOLD AFFERENTS IN THE SAPHENOUS NERVE AFTER SCIATIC NERVE SECTION IN THE RAT. B. Pomeranz* and H. Markus. Dept. of Zoology, University of Toronto, Toronto, ONT., CANADA M5S 1A1.

Previous studies have shown that following section and ligation of the sciatic nerve, the saphenous sprouts and reinnervates portions of the denervated paw. Moreover high threshold mechanoreceptive fibres show sprouting, while the low threshold fibres do not (Devor, M. et al., J. Comp. Neurol., 185:211, 1979). We have reexamined this phenomenon in a more quantitative manner and found that high threshold mechanoreceptive afferents do sprout from intact neighbouring nerves; in contrast however high threshold thermosensitive afferents seem to show little or no sprouting. In the study we examined the ventral surface of the rat paw using both temperature and mechanical stimuli. Responses were recorded from various sites on the paw (1) Mechanical Stimulus: the skin was pinched using a pair of serrated forceps and the force required to elicit withdrawal of the leg was determined with a Stratham strain gauge. (2) Temperature Stimulus: a heated probe with feedback temperature control was applied to the skin and the time required to elicit leg withdrawal was measured.

(1) Mechanical: In the normal animal the mean required pressure was 89.60 gm (n=7). In the denervated animal the medial 2/3 of the paw and the medial 2 toes were normal (82.33 gm) (n=7). However the lateral 1/3 and the distal 3 toes required a greater force (418.51 gm) (n=7). This suggested that sprouting occurred beyond the normal boundaries of the saphenous nerve.

(2) Temperature: In the normal animal leg withdrawal was elicited on the average after 3.48 sec (n=6). In the denervated animal a normal response (2.98 sec) (n=7) was elicited only if the heat probe was applied to the medial 1/3 of the paw. When the heat probe was applied to the rest of the paw there was an increase in the time required to elicit a response (12.20 sec) (n=7). One possible conclusion is that the temperature afferents showed little or no sprouting. Hence high intensity mechanoreceptive fibres of the saphenous nerve showed more extensive sprouting than the high intensity thermal-sensitive fibres. Results from electrophysiological recordings will be presented and correlations with the behavioural results will be discussed.

224.2 RELATIONSHIP BETWEEN AXONAL SPROUTING AND NEUROTRANSMITTER ENZYMES IN SUPERIOR CERVICAL GANGLION IN VITRO DURING THE RETROGRADE REACTION. R.A. Ross, T. H. Joh, and D.J Reis, Laboratory of Neurobiology, Cornell Univ. Med. College, NY, NY 10021.

In the superior cervical ganglion (SCG), axonal injury initiates, as part of the retrograde reaction, a decrease in the activities of tyrosine hydroxylase (TH) and dopamine-B-hydroxylase (DBH), enzymes synthesizing norepinephrine. This response is often reversible. A temporal relationship has been suggested between this reversible decrease in enzyme activity and the growth of regenerative sprouts from the injured neurons. The present study was undertaken to test this hypothesis. Specifically, we sought to determine: (a) if, following axonal injury produced by explantation into culture, SCG would show a reversible decrease in TH and DBH activities characteristic of a retrograde reaction and (b) if blockage of axonal sprouting in SCG neurons in vitro would prevent the enzyme changes normally seen.

SCG removed from embryonic rats at 18 days of gestation were cultured on coverslips in media containing 100 ng/ml NGF. Changes in TH and DBH activities were measured in different SCG from 0 to 14 days after explantation. A reversible reduction in TH activity was seen in vitro, reaching a nadir at 20.1% of control (d 0 =1.74±0.23 nmols/h/ganglion) by day 3 and returning to control level by day 12 in culture. The changes in DBH activity were similar to TH in direction, magnitude of decrease (41% of control, d 0 = 0.98±0.09 nmols/h/ganglion), and duration. Immunotitration with a specific antibody to TH showed that the reduction and subsequent increase in TH activity were entirely attributable to changes in the accumulation of enzyme protein.

The SCG undergoes rapid axonal sprouting in vitro. To determine the effect of neurite outgrowth on the retrograde reaction, SCG were grown in suspension culture, a condition which totally inhibits axonal sprouting. Ganglia grown in suspension did not show any decrease in TH or DBH activity for 14 days in culture. SCG grown for 4 days on substrate were transferred into suspension culture. Sprouting ceased and TH activity increased to control level in these ganglia after 2 days (2.10± 0.19 nmols/h/ganglion), a full 5 days before that observed in ganglia grown only on substrate.

We conclude that: (a) removal of SCG into culture initiates a retrograde reaction characterized by a reversible decrease in the activities and amounts of TH and DBH similar to that seen in vivo and (b) arrest of sprouting reverses the reduction in enzyme accumulation. These findings support the hypothesis that the onset and time course of the retrograde reaction is intimately and inversely correlated to the production of axonal sprouts.

224.3 MOSSY AND CLIMBING SPROUTING IN THE CEREBELLAR HEMISPHERE DENERVATED BY PEDUNCULOTOMY IN NEWBORN RATS. P. Angaut ★, R.M. Alvarado-Mallart ★ and C. Sotelo ★ (SPON : M.C. Hepp-Reymond). I.N.S.E.R.M. U-106. 92.150 Suresnes, France.

Most of the developmental changes of the cerebellar cortex, and especially the establishment of synaptic connections, take place after birth in rodents. Newborn to 4-day old rats were subjected to unilateral sections of the middle and inferior cerebellar peduncles. The animals were killed between 2 and 6 months of age and the cerebellar hemisphere ipsilateral to the pedunculotomy was studied. In spite of a total absence of the crossed inferior olivary complex and a partial regression of the crossed pontine gray, the cytology and synaptology of the concerned hemisphere were qualitatively normal, although only scarce climbing terminals were identified. In order to test the hypothesis of a sprouting of mossy and climbing fibers passing through the contralateral peduncle, 2 different approaches were used on rats pedunculotomized at birth : i) the contralateral peduncle was sectioned 2 days before sacrifice and the anterograde degeneration traced at the ultrastructural level; ii) horseradish peroxidase was injected in the hemisphere under concern 2 days before fixation and labeled cells looked for in the remaining ipsilateral inferior olive. These 2 sets of experiments confirmed that the presence of mossy and climbing terminals in this cortical region was due to a sprouting of undamaged afferents ending in the neighboring vermis. The sprouting process is very active for mossy afferents, much less so for climbing fibers. Contrary to what occurs under other conditions of impaired synaptogenesis (e.g. in the agranular cerebellum, Sotelo, C. and Privat, A., Acta Neuropathol., 43, 19-34, 1978), the present results demonstrate that the sprouting consecutive to early suppression of extracerebellar afferents does not induce the formation of heterologous synapses but maintains the specificity of the synaptic connections formed.

224.4 AFFERENT AND EFFERENT CONNECTIONS OF NEOCORTICAL TRANSPLANTS IN THE CEREBELLUM OF ADULT RAT HOSTS. Monica M. Oblinger* and Gopal D. Das* (Spon: C. K. Henrikson). Dept. Biol. Sci., Purdue University, W. Lafayette, Ind. 47907.

Previously reported studies have demonstrated that neocortical transplants in the cerebellum of neonate as well as adult rat hosts survive, grow and differentiate normally. In the case of neonate host animals, such transplants were seen to receive characteristic afferent connections from the host brain and, reciprocally, provide efferent axonal projections to the host brain. Since it was not known whether neocortical transplants placed into the cerebellum of adult host animals would also establish afferent and efferent connections with the host brain, the present investigation was conducted.

Neocortical tissue (3-4mm^3) obtained from 17-day-old rat embryos was transplanted into the right cerebellar hemisphere of 90-day-old Long-Evans rats. After three months the afferent and efferent connections of these transplants were analyzed by means of the Fink-Heimer and HRP procedures.

To study the sprouting of afferent fibers from the host brain electrolytic lesions were made in either the contralateral pontine nuclei, contralateral inferior olivary nuclei or ipsilateral cervical spinal cord. Subsequent degenerating fibers were traced through cerebellar medullary areas, across the interface of cerebellum and transplant, and into areas of the neocortical transplants. In addition, following localized HRP injections into neocortical transplants, labelled neurons were observed in the contralateral inferior olive, contralateral pons and ipsilateral spinal cord. The growth of efferent axons from the transplants into the host brain was studied with the Fink-Heimer procedure following electrolytic lesions in the transplants. Degenerating fibers emerging from the transplants were observed to terminate in the deep cerebellar nuclei as well as in the nearby normal host cerebellar cortex. Numerous intratransplant bundles were also evident.

These results indicate that axons present in the cerebellum of adult animals have a considerable capacity to sprout and innervate a neocortical transplant in the cerebellar hemisphere. The afferent connections of such transplants are characteristic of those of the normal cerebellar hemisphere. Likewise, such transplants provide efferent axons to the deep cerebellar nuclei, an innervation pattern that was characteristic of the normal cerebellar hemisphere which the transplant had replaced.

224.5 NORADRENERGIC SPROUTING IN THE CEREBELLUM OF PCD (PURKINJE CELL DEGENERATION) MUTANT MICE. C. T. Harston and R. M. Kostrzewa. Dept. of Pharmacology, College of Medicine, East Tennessee State University, Johnson City, TN 37601.

In the autosomal recessive mouse mutation known as Purkinje cell degeneration (pcd), the Purkinje cells of the cerebellum spontaneously degenerate in large numbers from 22 to 28 days postnatally, and in adulthood less than 1% of these cells survive (Mullen, R.J., et al., Proc. Nat. Acad. Sci. USA, 73:208, 1976). These Purkinje target cells for noradrenergic efferent fibers of the locus coeruleus (Bloom, F.E., et al., Brain Res., 25:501, 1971) were considered to be of importance in the regulation of noradrenergic input to the cerebellum. Therefore, mice were sacrificed at 35 days postbirth or later, and cryostat sections of the cerebellum were stained by the glyoxylic acid method of de la Torre and Surgeon (Histochem. 49:81, 1976), in order to observe the histofluorescent noradrenergic fibers. It was found that the density of green fluorescent-stained fibers was markedly increased in both the granular and molecular layers of the cerebellum. Accompanying this change was a dramatic increase in the number of intensely-fluorescent particles in both the cerebellar cortex and hippocampus---analogous to the catecholamine-containing bodies found in aging mice (Masuoka, D.T., et al., Brain Res., 169:335, 1969). These alterations in noradrenergic innervation of the cerebellum indicate that the Purkinje target cells normally play an inhibiting role on noradrenergic fiber growth in the adolescent mouse. Moreover, the effects of Purkinje cell loss on the noradrenergic system appears to be of consequence even in regions outside the cerebellum. 224.6 COMPENSATORY INNERVATION IN THE ANOPTHALMIC MUTANT MOUSE: AN ONTOGENETIC BUFFER MECHANISM THAT OFFERS EVOLUTIONARY POTENTIAL. M.J. Katz*, R.J. Lasek, and I.R. Kaiserman-Abramof. Department of Anatomy, Case Western Reserve University, Cleveland OH 44106.

Anopthalmic mutant animals have evolved and successfully colonized caves throughout the world. Thus, anopthalmic mutations can give rise to evolutionarily viable species. How are anopthalmic mutations integrated into functioning nervous systems? We have studied this question in the ZRDCT-An mouse, an anopthalmic mutant that differs from its sighted counterpart by only a single genetic change. In the ZRDCT-An, the retinal ganglion cells all degenerate before they have sent out axons. The anopthalmic dorsal lateral geniculate nucleus (DLGN) has fewer neurons and fewer glia than normal, and its synapses are restructured. A new class of axon terminals forms the large synaptic complexes normally formed by axons of the retinal ganglion cells (Cullen & Kaiserman-Abramof, J. Neurocytol. 5: 407-424, 1976). Interestingly, the projections from the anopthalmic DLGN form a normal pattern on the visual cortex and maintain a normal density and a normal distribution of spines on the cortical pyramidal cells (Kaiserman-Abramof, Brain Res. 179: 385-389, 1979; Kaiserman-Abramof et al., Neuroscience 5: 41-52, 1980). The synaptic changes in the anopthalmic DLGN are an example of compensatory innervation. Many other examples of compensatory innervation have been described, such as collateral sprouting in the hippocampus, the spinal cord, and the cutaneous sensory system. In the anopthalmic mouse, the DLGN compensatory innervation is secondary to the primary effects of the ZRDCT-An mutation (which disrupts normal interactions between the developing optic vesicle and the lens primordium ectoderm). Furthermore, bilateral surgical enucleation of young normal mice produces almost identical compensatory innervation. Thus, the DLGN compensatory innervation has not been directly programmed by the genetic change but rather appears to be a local adjustment in response to conditions in the immediate environment of the developing terminals. The ZRDCT-An mutation is a potential evolutionary change, and the anopthalmic mouse illustrates how such genetic mutations may be integrated into an evolutionarily viable organism. Specifically, compensatory innervation has insured that the anopthalmic DLGN remains part of the intact and well developed thalamocortical circuitry. Compensatory innervation is an exampleof the ontogenetic buffer mechanisms which normally integrate the many varied products of different genes into a harmonious organism. We have proposed that ontogenetic buffer mechanisms also offer evolutionary potential because thay can insure that complex systems willstill function after genetic changes. Ontogenetic buffer mechanisms such as compensatory innervation may be responsible for the viability of the anopthalmic mutants that populate caves today.

224.7 COMPETITION BETWEEN EMBRYONIC SEPTAL IMPLANTS AND ANOMALOUS SYMPATHETIC INGROWTH FOR REINNERVATION OF DEAFFERENTED HIPPOCAMPUS Rebekah Loy and Lawrence F. Kromer. University of California at San Diego, La Jolla, CA 92093

Transection of the fimbria in adult rats permits the anomalous ingrowth into the hippocampus of sympathetic axons which normally innervate the extracerebral vasculature. The stimulus for this axonal sprouting is not known, however several studies suggest that damage to the medial septum is essential to elicit the response. In addition, the anomalous ganglionic axons collateralize in a pattern which closely resembles the distribution of septal afferent axons within the area dentata and CA3. In order to determine more closely the relationship of the sympathetic axonal sprouting to septal deafferentation we have removed the septum from adult female rats while aspirating a cavity in the fimbria. Into this cavity we implanted a 1 mm^3 piece of embryonic septum dissected from 17-day rat fetuses. Additional rats received no implant into the cavity as controls. Animals were allowed to survive from 3 weeks to 3 months. Alternate cryostat sections were treated with glyoxylic acid for the visualization of catecholamines or stained for acetylcholinesterase (AChE). At the earliest survival times the implant had fused to the cut surface of the anterior hippocampal formation and contained many neurons staining positively for AChE. AChE-containing axons also penetrated approximately 1mm caudally within the area dentata and CA3. Alternate sections showed a vigorous sympathetic axonal plexus within and around the granule and CA3 pyramidal cell layers and deep within the hilus. These sympathetic axons were confined, however, to the more caudal levels of the hippocampal formation. At 2 months postoperatively the AChE-containing axons of the implant had extended to midseptotemporal levels and alternate sections again showed very little overlap with the more caudally located sympathetic plexus. By contrast, in rats with no septal implant in the fimbria cavity, the sympathetic axons extended throughout all levels of the hippocampal formation. This, together with our earlier studies, suggest that the sympathetic axons grow into the partially deafferented hippocampal formation beginning at 9-10 days then collateralize throughout the structure by 30 days. The septal implant axons grow in somewhat more slowly, and as they advance caudally appear to cause retraction of the anomalous sympathetic axons. Whether this is due to competition between the two systems for a common postsynaptic target or to competition for some trophic factor in the environment remains to be demonstrated. Supported by NINCDS Grants #NS-14372 (RL) and NS-15207 (LFK).

225.1 DEVELOPMENT AND DEPLOYMENT OF SCHWANN CELLS IN PERIPHERAL NERVES OF TREMBLER ↔ NORMAL MOUSE CHIMAERAS. H.B. Rayburn*, A.C. Peterson and A. Aguayo. Montreal General Hospital Research Institute, Montreal, Quebec, Canada.

The mouse chimaera preparation has been used extensively to investigate cell lineage, clonal deployment and cellular interactions during development. Numerous investigations have successfully addressed these issues in the central nervous system, but peripheral nerves have not received the same attention due to lack of suitable genotype markers for axons and Schwann cells. Previous transplantation studies in mature animals have provided evidence that the myelin deficiency in Schwann cells of Trembler mice results from an intrinsic Schwann cell deficiency (Ann. N.Y. Acad. Sci. 317: pp 512-533, 1979). Therefore, we produced Trembler ↔ normal chimaeras in the hope that myelin phenotypes would permit discrimination of two genotypically distinct classes of Schwann cells. If expression of the appropriate phenotypes did occur, it would provide a unique opportunity to explore the deployment and possible interactions of Schwann cells during primary development.

Trembler ↔ normal chimaeras do demonstrate variable proportions of typically myelinated Schwann cells and Schwann cells revealing the mutant hypomyelinated phenotype; a result predicted from an intrinsic deficiency in the Trembler Schwann cell. In some chimaeras, cross-sections of spinal roots reveal large, relatively coherent patches of Schwann cells demonstrating either normal or Trembler phenotypes. In addition, we have observed both myelinated and hypomyelinated Schwann cells on individual axons. Thus, the Trembler phenotype appears to be expressed in mutant Schwann cells which have undergone their entire primary development in proximity to both genotypically normal Schwann cells and presumably, to axons of both genotypes.

It is also anticipated that analysis of the size and shape of Trembler and normal Schwann cell territories will provide a further understanding of the clonal deployment of Schwann cells during primary development of peripheral nerves.

225.2 IONIC MECHANISMS FOR IMPULSE PROPAGATION IN GROWING NONMYELINATED AXONS: SAXITOXIN BINDING AND ELECTROPHYSIOLOGY. G. Strichartz*, R. Small, C. Nicholson, K. H. Pfenninger, and R. Llinás (SPON: M. E. Hatten). Dept. Physiol. Biophys., SUNY at Stony Brook, NY 11794; Dept. Anatomy, Columbia Univ. P&S, New York; Dept. Phys. & Biophysics, New York Univ. Medical Ctr., New York.

Transection of olfactory nerve in bullfrogs produces a total degeneration of the nerve bundle and its parent neurons. Five to six weeks postoperatively a new fiber bundle is seen in the olfactory canal as the fibers grow synchronously toward the olfactory bulb. Action potentials in this growing nerve may be obtained by direct electrical stimulation in a recording chamber. These compound action potentials have conduction velocities lower than mature nerve and seem to be resistant to tetrodotoxin (10^{-5} M). However, they may be blocked with application of 10^{-3} M cadmium chloride, indicating the presence of calcium-dependent spikes at or near the growth cones. These results are consistent with a reduced density of Na^+ channels shown by (a) the lower density of saxitoxin binding sites (40% of mature), (b) the small depolarization of membrane potentials produced by Na^+-channel activators, such as veratridine and bactrachotoxin, compared with normal olfactory nerve, and (c) the reduced density of intramembranous particles detected by freeze-fracture of the axonal membranes (Small and Pfenninger, this volume). In addition, action potentials in mature nerves are not blocked by 30 nM saxitoxin, consistent with the low saxitoxin affinity (K_D = 30-50 nM) measured in the binding studies; thus, these nerves differ from other nonmyelinated nerves which have a high sensitivity and low K_D values. The present results provide evidence for the participation of Ca^{++}-channels in growing neurites as previously observed in developing Purkinje cells (Llinás and Sugimori, Soc. Neurosci. Abst. 4: 66, 1978) and in regenerating cockroach giant axon (Meiri et al., Soc. Neurosci. Abst. 5: 680, 1979).

225.3 POSTNATAL DEVELOPMENT OF RETINO-GENICULATE AXON ARBORS IN THE KITTEN. C.A. Mason, Dept. of Pharmacology, New York University Medical Center, New York 10016.

The morphology of retino-geniculate axon terminal arbors at different postnatal ages was studied in normal kittens. The maturation of branching patterns and of shape and synaptic relations of terminal swellings was examined. In kittens of 1-8 weeks of age, axons were filled with horseradish peroxidase (HRP) by injections into the optic tract. After 3-8 hours survival and routine aldehyde fixation, brains were processed for light and electron microscopy as previously described (Mason & Robson, Robson & Mason, 1979, Neurosci. 4: 79 and 99).

At 1 week of age, light microscopic observations at low power reveal that axons resemble adult arbors in their "cypress tree" shape and general restriction to intralaminar zones. At higher power, however, there appear to be more divisions of fine terminal branches, some of which bear no swellings. The most striking feature of axons at this age is that many leading tips on a single arbor are enlarged into structures similar to growth cones seen in vitro and in Golgi preparations. These structures consist of broad flanges up to 10 μm long that give rise to two or three filodopia. Other terminal forms not seen in mature axons are ovoid swellings, V-shaped spikes, and small club-shaped endings. At 2 weeks, arbors are less spray-like. Branches still commonly end in growth cones, but also end in more slender terminal swellings having a slightly indented edge. By 4-6 weeks, terminals are grouped in clusters and have fuller shapes with either round or crenulated forms. By 8 weeks, branching patterns of terminal arbors look virtually mature but branches seem to be more heavily laden with terminals than in the adult. Occasionally, a fine branch terminates in a growth cone.

The ultrastructure of axons at 1 week indicates that identified growth cones labeled with HRP contain large vesicles, mitochondria, and microtubules. Synaptic junctions are made by the main flank of growth cones and round clear vesicles are often clustered near the density. By 3 weeks, crenulated terminals contact dendritic and other profiles. Although the retinal terminal is central in this arrangement, glial sheaths are absent and do not appear until after 4 weeks, agreeing with Kalil & Scott (Soc. Neurosci. Abstr. 5: 2660).

These observations indicate that, although retinal axons have reached their targets days before birth and have made synapses by birth (Kalil & Scott), the remodeling of their arborizations and terminals continues for some months after birth. (Supported by NIH Grant EY 02374).

225.4 DEVELOPMENTAL STUDIES OF RAT RETINAL CELL SURFACES USING CELL-TYPE SPECIFIC MONOCLONAL ANTIBODIES. Colin J. Barnstable* (SPON: Torsten N. Wiesel). Dept. of Neurobiology, Harvard Med. Sch., Boston 02115.

A series of monoclonal antibodies have been produced following immunization of BALB/c mice with a membrane preparation isolated from retinas of adult CD rats (Barnstable, Nature, 1980). The specificity of these antibodies has been determined by immunofluorescent labeling of fixed tissue sections.

Using a number of antibodies that specifically label discrete areas of the photoreceptor cell surface, the times at which the corresponding antigens appeared during the postnatal development of the rat retina was studied. RET-P1 is an antibody that labeled the cell bodies, inner segments and outer segments of adult rat photoreceptors. In Tiger Salamander retinas, this antibody labeled rods but not cones. In newborn rats it labeled a small number (< 1%) of cells, many of which had two processes, one ending at the ventricular surface and the other in the middle of the retina. The number of labeled cells increased with time so that by day 6-8 a broad band of cells in the outer portion of the retina showed fluorescence. From the antibody specificity, these were inferred to be photoreceptor precursors. At day 8, when the outer plexiform layer was easily recognizable, a small number of displaced photoreceptor precursors could be seen in the inner nuclear layer although those disappeared later. RET-P2, which, in the adult, labeled only photoreceptor outer segments, labeled small projections at the ventricular surface at day 5--the time of beginning of outer segment formation. An anti-rhodopsin antibody also labeled some of these projections at day 5. RET-P3, which labeled only photoreceptor cell bodies, gave labeling only at day 12-14, the time of eye opening.

A similar analysis of Muller cell development was carried out using five specific antibodies. Only one, RET-G1, labeled cells in newborn rats. This was also the only one of the five to label glia elsewhere in the adult CNS. Another, RET-G2, labeled 7 day old retinas--by which time the cells have undergone significant morphological differentiation. The antigens detected by the other three antibodies did not appear until day 12-14 when the retina was fully formed.

Monolayer cultures of cells dissociated from retinas of different ages have been set up and characterized using the above, and other, monoclonal antibodies. Although the morphology of the cells did not always follow the in vivo pattern, e.g. photoreceptor precursors detected by RET-P1 were spherical and had only one process containing large varicosities. With time these cultures reacted with some of the antibodies detecting antigens characteristic of the later stages of retina development. (Supported by NIH grant EY00606 and the Damon Runyon-Walter Winchell Cancer Fund)

225.5 PROPERTIES AND MATURATION OF AXOLEMMA IN GROWING NEURONS. Rochelle K. Small and Karl H. Pfenninger, Department of Anatomy, Columbia University, College of Physicians and Surgeons, New York, NY 10032.

Intramembranous structure, density of Na^+-channels and electrical excitability were compared in mature and growing axons in order to characterize the properties of growing axolemma. Freeze-fracture analysis of the olfactory nerve of the bullfrog, Rana catesbeiana, reveals the following differences. Axolemma from mature nerve contains an equal density (1100/μm^2) of intramembranous particles (IMPs) throughout and shows a consistent profile of IMPs ranging in diameter from 4.5 to 16 nm; higher IMP densities (2000/μm^2) are observed only at the perikarya. In contrast, rapid addition of new plasma membrane to the growing axon results in heterogeneous membrane composition along the axis of the neurite. Axolemmal IMPs are distributed along the neurite in the form of a distally decreasing, exponential density gradient ($y = 1485e^{-0.49x}$; $r^2 = 0.99$). IMP densities near the perikarya are comparable to levels seen in the mature nerve, but are reduced 10-fold at the growth cones (150/μm^2). Moreover, for individual IMP size classes, density gradients for smaller diameter particles are flatter than those for larger IMPs. In several cases, a narrow zone of increased IMP density was noted in the membrane region immediately proximal to the growth cone. These observations indicate that rapid expansion of the neuritic axolemma results in sequential differentiation of the plasma membrane. Furthermore, they suggest a spatial segregation of the site of addition of membrane matrix (e.g., lipids) needed for elongation, from the site of insertion of those membrane proteins constituting IMPs. New, IMP-free membrane appears primarily at the growth cone, while IMPs may be inserted at the perikaryon and then diffuse within the axolemma into the distal neurite. In addition, functional parameters of excitability (see Strichartz, Small, Nicholson, Pfenninger, Llinás, this volume) indicate a gradual differentiation of the axolemma. The density of saxitoxin binding sites in growing neurites is only 40% of control values, and the impulse has an unusually low conduction velocity and seems to be tetrodotoxin-resistant at the tip. The suggested differences in the number and nature of cation channels are likely to be related to the particular IMP populations that characterize growing and mature axolemma. (Supported by USPHS Grants NS13466 and 07062).

225.6 MECHANISM OF MEMBRANE EXPANSION IN THE GROWING NEURON. Karl H. Pfenninger, Department of Anatomy, Columbia University, College of Physicians and Surgeons, New York, NY 10032.

Neuronal sprouting involves rapid expansion of neuritic plasmalemma. The site and mode of insertion of new membrane components were studied in cultured sprouting neurons of the rat superior cervical ganglion by (i) pulse-chase experiments with ^{3}H-glycerol, followed by biochemical analysis of microsurgically separated perikarya and neurites, and (ii) similar pulse-chase experiments followed by EM radioautography. Control studies show that 99% of bound ^{3}H-glycerol is incorporated into phospholipid (PL), and that 70-80% of labeled PL is retained in the tissue during EM processing. The following results were obtained: Following a 15 min pulse of ^{3}H-glycerol, the specific radioactivity of perikaryal PL reaches a peak and then drops off exponentially (t 1/2 = 90 min) over the next 120 min. In the neurites, by contrast, specific radioactivity of PL increases with a delay of about 60 min. Both the increase in neuritic dpm/μgPL and the rapid decrease of perikaryal dpm/μgPL can be blocked with 2.5 x 10^{-6} M colchicine or 5mM 2,4-dinitrophenol applied after the pulse. Radioautographic analysis of the perikarya of ^{3}H-glycerol-pulsed sprouting neurons reveals, at 15 min, 93% of silver grains over various cytoplasmic organelles, but only 7% over the plasmalemma. At 15 min, growth cones exhibit only a fraction of the labeling seen over perikarya. However, by 30 min, radioactivity in the growth cones has risen several fold, and clusters of large, clear vesicles show the highest number of silver grains per unit area of membrane found in the neurites. At 60 min, the peak of radioactivity has shifted from the vesicles to the plasmalemma of the distal neurite. During these first 60 min, the agranular reticulum of growth cones exhibits fewer silver grain counts than the large vesicles or the plasmalemma. These findings suggest: (i) New PL is synthesized primarily in the perikaryon and then exported by rapid axonal transport to the most distal region of the neurite. (ii) The PL vehicle - and the plasmalemmal precursor - is a large, clear vesicle which is found in subplasmalemmal clusters in the growth cone, where fusion with the cell surface and addition of new membrane components occurs. Thus, newly-synthesized membrane is inserted into plasmalemma predominantly at the tip of the growing neurite. This observation is consistent with earlier freeze-fracture data on the distribution of intramembranous particles (Pfenninger and Bunge, 1974; Small and Pfenninger, this volume) and with the results of lectin pulse-chase experiments which reveal the selective appearance of new surface glycoconjugates in the growth cone region over the clusters of large, clear vesicles. (Supported by NSF grant BNS14071 and NIH grant NS13466).

225.7 GOLGI STUDY OF HIPPOCAMPAL PYRAMIDS IN TWO PRETERM TWIN FETUSES: A COMPUTERIZED MORPHOMETRIC ANALYSIS OF BRANCHING CHARACTERISTICS. A. M. Paldino and D. P. Purpura. Dep't. Neuroscience and the Rose F. Kennedy Center for Research in Mental Retardation and Human Development, Albert Einstein College of Medicine, Bronx, NY 10461.

The computer microscope was utilized to obtain three dimensional information representing neuronal structure and to analyse this information in regards to angles of branching, fiber separations to nodes and terminals, and other statistical parameters reflecting neuronal shape and maturation. Data have been obtained from two twin fetuses of 21 weeks gestation, with no extrauterine survival. Twin A, the first born, succumbed shortly after delivery due to fetal immaturity incompatible with life. This twin had no congenital anomalies and had a body weight of 640 grams. Twin B, a stillborn fetus weighing 600 grams, was delivered shortly after premature rupture of the membranes. Gross and microscopic examination of the brains of these two fetuses revealed no pathological processes.

Golgi impregnated neurons within or near the CA3 zone of the hippocampus were digitized and analysed in regards to statistical parameters considered to be associated with defining dendritic shape and likely to be of major importance in assessing the maturational status of neurons of the immature human cerebral cortex. Preliminary results indicate that the angles of branching (branch and fission angles) at dendritic bifurcations are similar in both infants. For example, in neurons of Twin A, the average dendritic branching angle was computed to be 63^0; for neurons of Twin B, this angle was found to be 64^0. Also, the average dendritic fission angle for neurons of Twin A was 98^0; for neurons of Twin B, this value was 93^0. Distributions concerning the dendritic fiber separation to nodes and terminals for neurons from each infant were also similar; however, some discrepancies were noted at few discrete intervals. Data concerning these parameters for the axonal processes will also be presented.

The emerging data from these twin studies are consistent with recent evidence suggesting that dendritic branch and fission angle values vary indirectly with gestational age, and thus strengthen the hypothesis that these angles are indices which reflect the maturational status of neurons in the human cerebral cortex.

226.1 POSTNATAL DEVELOPMENT OF VISUAL ACUITY, RETINA, AND FOVEAL STRIATE CORTEX OF THE SQUIRREL MONKEY (Saimiri sciureus). J. M. Ordy, K. R. Brizzee and Pam Medart*. Neurobiology Department, Delta Regional Primate Research Center, Tulane University, Covington, La. 70433

Postnatal visual acuity was examined in relation to maturation of the fovea and foveal projection area of the striate cortex in the diurnal squirrel monkey. Optokinetic and visual discrimination tests of acuity from birth to maturity indicated an increase of minimum separable binocular acuity from 72 to 18 minutes by the end of the 1st month, and 1.1 minutes by 6 months, compared to an adult asymptotic acuity of 0.90 minutes of visual angle, at 4 years of age. Ophthalmoscopic observations of the funduscopic appearance indicated a vascular non-pigmented area centralis at birth, and a progressive demarcation of macula, fovea, with their respective light reflexes by 6 months. A foveal depression was present in the retina at birth, but the bipolar cell layer had not thinned completely. From birth to 90 days, there was a significant increase in foveal cone density, outer segment length, and cone layer thickness in the rod-free, all cone foveola. In the occipital cortex, 6 laminae were present at birth, but foveal striate cortex depth increased significantly from 1406 μm to 1648 μm by 90 days. Also, cell packing density decreased, whereas neuropil density increased. Meynert cells in laminae V-VI of the foveal striate cortex appeared well advanced at birth, compared to their appearance at 90 days. The observation of the study, involving acuity, fundus appearance maturation of fovea, cytoarchitecture of foveal striate cortex, and development of Meynert cells, all indicated a progressive developmental sequence in the retina-geniculo-striate projection of the central visual field. (Supported in part by NIH Grant HD09942 and RR0016418.)

226.2 DEVELOPMENTAL FEATURES OF DORSAL LATERAL GENICULATE NUCLEUS IN MONKEYS. Michael D. Gottlieb*, Tauba Pasik, and Pedro Pasik. Dept. Neurol., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029.

The maximal cross-sectional areas of 4200 neuronal somata and their nuclei were measured in coded specimens of 0, 1, 2, 4, 8, 16 week-old and adult monkeys (M. mulatta). Samples consisted of camera lucida drawings of 600 cells per age obtained from six specified locations within laminae (L) in eight equally spaced Nissl-stained coronal sections. The average area of somata varies as a function of age but differently in the parvocellular and magnocellular laminae. In the former, it increases 40% from birth to 2 weeks, then decreases until 8 weeks, and subsequently remains at about 25% above the level for the newborn. The mean cell size in the magnocellular layers changes little before 8 weeks. From 8 to 16 weeks, it grows approximately 38%, and then declines somewhat stabilizing 27% above the level at birth. As expected, both the mean size and the variability are larger in the magnocellular than in the parvocellular laminae at all ages although the differences become less dramatic between 1 and 4 weeks. The average nuclear area does not follow the same pattern in both types of layers. Surprisingly, the nuclei are similar or larger in the parvocellular laminae during the period between 1 and 8 weeks. The mean nuclear size is approximately the same at birth and after 16 weeks within each type of lamina. The dynamics of development however is different, drastic changes occurring at 2 weeks in parvocellular layers (increases of 40%) and at 4 weeks in the magnocellular layers (decreases of 25%).

Comparisons were also made between cells receiving crossed (L6) vs uncrossed (L5) retinal afferents, cells with on-center (L6) vs off-center (L4) receptive fields, and zones representing central vs peripheral retina. In the adult, significant differences are found only for cell and nuclear sizes of central vs peripheral representation in L1, larger values being obtained from the periphery. This difference also occurs during development but the sign is not consistent. A uniform trend is present in parvocellular layers such that the soma and nuclei of peripheral zones are always larger than in central areas at all ages examined, but significant differences are obtained only for nuclear areas at 1, 4, and 8 weeks.

These findings suggest that maturation occurs earlier in parvocellular than in magnocellular laminae as evidenced by the timing of peak cell area (1 to 4 weeks vs > 8 weeks), stabilization of cell size (4 to 8 weeks vs > 8 weeks), and major changes in nuclear size (4 to 8 weeks vs > 16 weeks). Parvocellular layers develop at similar rates regardless of their reported physiological differences. (Aided by NEI Grant EY-01926)

226.3 AN INDIRECT RETINO-HYPOTHALAMIC TRACT IN THE NEWBORN FERRET (MUSTELA PUTORIUS FURO). Josephine B. Cucchiaro* and R.W. Guillery. Neurobiology Program, Department of Pharmacol. & Physiol. Sci., The University of Chicago, Chicago, IL, 60637.

A small bundle of retinofugal axons which takes an indirect, circuitous course around the lateral and dorsal aspects of the thalamus to terminate in the hypothalamus, has been identified in the newborn, but not in the adult ferret. Concentrated (50%-70%) horseradish peroxidase (HRP) was injected into the vitreous of one eye of young ferrets. The animals survived 18 hours before they were perfused through the heart with 4% glutaraldehyde in phosphate buffer (pH 7.4). Frozen sections of the brains were cut and the sections were reacted with 3,3',5,5' tetramethyl benzedine (TMB). Another developmental sequence of ferret material, using the tritiated proline autoradiographic demonstration of retinofugal pathways, and several paraffin embedded Nissl series of ferret brains were also available.

The newborn ferret is relatively immature. Compared to the cat, which is born on the 63rd day of gestation with a fully laminated lateral geniculate nucleus, the ferret is born after 42 days and develops geniculate laminae 15-20 days later. Using the HRP method we have observed the retino-hypothalamic tract in ferrets sacrificed 1, 3 and 5 days after birth. We have not seen clear evidence for this tract in our autoradiographs nor have we been able to demonstrate it by any method in animals 8 days or older. The crossed tract is well defined in 1 day old animals. Its fibers leave the optic tract at the rostrolateral border of the ventral lateral geniculate nucleus, coursing anteromedially around the anterior and dorsal aspect of the thalamus. Near the anterior thalamic nuclei the tract turns in a ventrolateral direction running caudal to the anterior commissure and lateral to the fornix. Finally, the tract terminates dorsomedial to the optic tract in the lateral hypothalamic area. The crossed tract is present at 3 and 5 days, but is small and difficult to trace in the 5 day old animals. A small uncrossed component is present in some of the youngest animals, but could never be traced beyond the anterior thalamic nucleus. The fate of the retino-hypothalamic tract during the development of the visual system remains unclear. It may degenerate, cease transporting HRP, or become so scattered that it can no longer be identified.

226.4 THE DEVELOPMENT OF THE RETINO-GENICULO-CORTICAL PROJECTION IN THE TREE SHREW, TUPAIA BELANGERI G. Rager, R.S. Nowakowski, S. Lausmann+, M. Tanaka+ and A. Schwaier+. Dept. of Neurobiology, Max-Planck-Institute for Biophysical Chemistry, Postfach 968, D-3400 Göttingen, West Germany.

The two eyes of the tree shrew are represented in cortical area 17 not in ocular dominance columns but in ocular dominance sublaminae. We investigated how this projection develops during the postnatal period using neuroanatomical and electrophysiological techniques. Anterograde transport of horseradish peroxidase injected into one eye reveals that three terminal fields can be recognized in the contralateral and two in the ipsilateral lateral geniculate nucleus (CGL) at postnatal day 1 (P1). The contralateral as well as ipsilateral fields seem to be broader and more diffusely labelled than in older animals. Two of the three fields in the contralateral CGL are heavily stained. Between them a diffuse network of labelled fibres and terminals of much lower density can be seen. By P10, a fourth clearly definable field emerges in the position of the diffuse network giving a four field pattern similar to the adult, although the fields are still broader and less well-defined than in the adult.

To study the geniculo-cortical pathway we injected tritiated proline and fucose into the eyes of three animals at PØ, P14 and P44. After 14 days of survival the animals were sacrificed and the brains were processed for autoradiography. Transneuronal transport can be seen in all three animals. In all cases labelled terminals are confined to lamina IV of area 17. The animal injected at PØ does not show any laminar subdivision, while in both of the older animals the ipsilateral projection begins to spare sublamina IVβ (nomenclature according to Hubel, 1975). No clear increase of silver grain density could be found in the contralateral lamina III. These results indicate that the retino-geniculo-cortical projection is first diffuse in the CGL and area 17. The laminar pattern of the adult can be seen only later in development. Thus, although the binocular representation in tree shrews differs from that in cats and rhesus monkeys, the development of the projection seems to be based on similar mechanisms, i.e. the segregation of terminals from a diffuse to a restricted pattern.

Our preliminary electrophysiological results show that electrical stimulation of the optic nerve elicits an evoked potential shortly after birth. A visual evoked response can be obtained a few days before eye opening.

(Supported by the Deutsche Forschungsgemeinschaft.)

226.5 THE DEVELOPMENT OF EFFERENT PROJECTIONS FROM AREA 17 OF THE TREE SHREW, TUPAIA BELANGERI. R.S. Nowakowski and G. Rager. Department of Neurobiology, Max Planck Institute for Biophysical Chemistry, Postfach 968, D-3400 Göttingen, West Germany.

As part of an analysis of the structural and functional development of the visual system of the tree shrew, Tupaia belangeri, the development of the efferent projections from the primary visual cortex has been studied by examining the retrograde and anterograde transport of horseradish peroxidase (HRP; Boehringer Grade I) following small iontophoretic injections. The anterograde transport of HRP from area 17, visualized by using the tetramethylbenzidine technique of Mesulam (1978), indicates that the projection of the cortex to the lateral geniculate is present as early as the day of birth. This is before the individual cell laminae are identifiable in Nissl-stained material. The cortico-thalamic terminals are intermingled with the cells labeled by retrograde transport. Both the labeled terminals and the labeled cells are distributed across the entire width of the lateral geniculate, forming a small cylinder which varies in size with the size of the injection site.

The cortical projection to the tectum develops later than the cortico-thalamic projection. In fact, both anterograde and retrograde transport of HRP indicate that the projection of the cortex to the superior colliculus is not present at birth. At postnatal day 9, however, the cortico-tectal projection can be demonstrated by anterograde transport of HRP. Thus, the development of the cortical projection to the tectum seems to lag behind the development of the cortical projection to the thalamus. This sequence of events may reflect the fact that the cells of origin of the cortico-thalamic pathway (layer VI) are generated earlier than the cells of origin of the cortico-tectal pathway (layer V).

The cortico-cortical fibers also seem to develop after the cortico-geniculate fibers, and we are presently exploring whether they appear before or after the cortico-tectal pathway.

226.6 ORDERED ANOMALOUS RETINAL PROJECTIONS TO THE MEDIAL GENICULATE, VENTROBASAL AND LATERAL POSTERIOR NUCLEI. D.O. Frost. Inst. of Anat., U. of Lausanne, Switzerland.

In newborn Syrian hamsters, two of the retina's principle targets, the superior colliculus (SC) and dorsal lateral geniculate (LGd) nucleus were destroyed, respectively, by a direct lesion and by retrograde degeneration following a lesion of posterior neocortex. Simultaneously, alternative terminal space was made available in the lateral posterior (LP) nucleus by the SC lesion and in the medial geniculate (MG) and/or ventrobasal (VB) nuclei by removing the auditory and/or the somatosensory lemniscal inputs. The SC lesions were always bilateral; the lesions of the auditory and somatosensory lemniscal pathways were either bilateral or ipsilateral to the (always) unilateral cortical lesions. When the operated animals were adults, the projections of the eye contralateral to the cortical lesion and degenerated LGd were traced by making 1 or 2 small peripheral retinal lesions and intraocular injections of 50 μCi of ^{3}H-proline, 5- and 1- days, respectively, prior to sacrifice. Adjacent series of sections from each brain were processed by the Fink-Heimer and autoradiographic techniques. A computer was used to reconstruct surface views of the thalamic nuclei and the patterns of autoradiographic labeling (ARL) and degeneration (D) within their borders. An additional neonatally operated animal with auditory and somatosensory lemniscal lesions survived 14 days following intraocular injection of 400 μCi of ^{3}H-proline.

The neonatal surgical procedures reliably produced in the partially denervated LP, MG and VB, anomalous crossed retinal projections that terminate preferentially near the surfaces of those nuclei. Label was transported transsynaptically to the "auditory" and "somatosensory" cortices in the case with the large injection and long survival time.

The anomalous retinal projections show several signs of order: i) When a nucleus contains both ARL and D only part of the total projection field so revealed contains D. Thus a restricted retinal region gives rise to a restricted part of the projection. ii) Small retinal regions appear to be represented along "lines of projection" in LP, MG and VB, as they normally are in LGd and SC. iii) In most instances, ARL and D are completely or partially segregated. Therefore, different parts of the retina project to different parts of each nucleus. iv) In a given nucleus, lesions in different retinal quadrants produce degeneration at different poles of the anomalous projection. Thus, in each nucleus there is a consistent polarity in the abnormal projection. This is clearest in MG, but also appears to hold for LP and VB.

In some animals, one or more nuclei contain only AR or only D, while the others may contain both ARL and D. Thus each nucleus may contain only a partial representation of the retina and the projections to different nuclei can originate from overlapping or non-overlapping retinal territories.

The anomalous retinal projections to nuclei that normally receive little (LP) or no (MG, VB) retinal input show that the preference of retinal axons for their normal targets is relative, not absolute. If there are positional or polarity cues in LP, MG or VB that contribute to the ordering of an abnormal retinal projection, they can not be specific for the normal afferents of those nuclei. Individual variations in the degree of segregation of ARL and D within a given nucleus suggest variations in the precision of retinotopic ordering of the anomalous projections.

227.1 CHANGES IN SPEECH AND UPPER LIMB MOVEMENTS IN CEREBRAL PALSY PATIENTS AFTER FOCAL CEREBELLAR STIMULATION. L. Robertson. Neurological Sci., Inst., Portland, OR 97209.

Focal electrical stimulation of the cerebellar cortex of patients with various movement disorders has been reported to reduce spasticity and athetosis and improve activities of daily living for some patients. However, the clinical results are very controversial and there is considerable variability in the type and degree of changes observed. A quantitative study of the effects of focal cerebellar stimulation was made on oral-motor control, vocal characteristics, and upper limb skill and reaction time movements in 10 patients with cerebral palsy. The patients were evaluated prior to surgery and after approximately 2 and 6 months of cerebellar stimulation. Four patients were further tested with and without stimulation in a series of evaluations of upper limb movements.

Eight of the ten patients showed a small degree of speech improvement, the other two cases were not affected by the stimulation. Seven of the patients significantly increased their duration of vowel phonation; four cases (all with moderate dysarthria) improved their articulation, particularly for consonants S, Sh, and Th; and two patients had better oral-motor control. Most of the changes in sound production and speech intelligibility appear related to improved intraoral breath control. Thus, cerebellar stimulation may be modifying the coordination of pharyngeal and laryngeal muscles.

Five cases showed some improvement on a motor accuracy test after two months of stimulation. In general, the patients made more straight lines and decreased the frequency of squiggles and loops that are associated with uncontrolled movements. Four of these patients were tested with a reaction time procedure with and without stimulation. During the initial sessions without stimulation, all cases showed a decrement of extension of the nondominate arm. Cerebellar stimulation reduced the reaction time for 3 of the 4 cases. However, after two sessions during which cerebellar stimulation was used, the reaction time for the non-stimulation trials also decreased to the level obtained during stimulation. Subsequently, the presence or absence of stimulation did not influence the reaction. Similar results were obtained for a sequential movement. Initially cerebellar stimulation improved the performance but continued stimulation was not necessary to maintain the new performance level. Thus, these preliminary results suggest that cerebellar stimulation may be helpful during the acquisition of a motor skill, but have little or no influence once the movement has been learned.

227.2 IMMUNOLOGICAL STATUS OF AMYOTROPHIC LATERAL SCLEROSIS PATIENTS--- A LONGITUDINAL STUDY. F.C. Westall and Charles Jablecki*. Autoimmune and Neoplastic Disease Laboratory, Salk Institute for Biological Studies and Department of Neurosciences, University of California, San Diego, CA 92037.

The immunological status of 30 Amyotrophic Lateral Sclerosis (ALS) patients has been assessed over a two year period. Total IgG, IgM, and IgA for the patients were not significantly different from controls. However, patients whose disease process were progressing more rapidly as a group showed lower IgG and IgM values and higher IgA than those who were progressing more slowly. Eighty percent of the patients showed increases in IgA with time. Two patients had IgA values greatly exceeding normal, and in one case the IgA was monoclonal.

The percentages of various subclasses of T and B lymphocytes were estimated. The ALS patients showed a slight increase in the percentage of T cells compared to normal. There was a significant ($p<.001$) reduction of $T\mu$ cells within the ALS population (ALS $T\mu$ = 24% compared to normal $T\mu$ = 47%). No significant differences were found in the $T\gamma$, $B\mu$ and $B\gamma$ classes. We conclude that there are substantial immunological abnormalities in patients with ALS. It may be that these abnormalities reflect an altered host response to an infectious agent.

227.3 EFFECT OF CHRONIC PHENYTOIN ON ULTRASTRUCTURAL MORPHOLOGY AND BENZODIAZEPINE RECEPTOR DENSITY IN RAT BRAIN. P.P. Deshmukh*, T. Mimaki* and H.I. Yamamura (Spon: L. Stern) Dept. of Pharmacology and Psychiatry, University of Arizona HSC, Tucson, AZ 85724.

Phenytoin (DPH-Dilantin®) is the most widely used anticonvulsant in the treatment of epilepsy. Despite the forty years of its use in clinical medicine, the mechanism(s) of action of this compound is not fully understood. The effect of chronic or toxic administration of DPH is still less clearly defined. The clinical evidence relating DPH to possible cerebellar dysfunction was recognized by Merritt and Putnam (1939). They included cerebellar ataxia, tremor, diplopia and nystagmus as part of the symptom complex associated with DPH therapy. Neuropathological changes have been found in the cerebellum of epileptic patients, but whether these changes are associated with the chronic use of DPH in epileptics or with seizure activity or both remains unclear.

Interestingly, DPH and Diazepam- a muscle relaxant- exhibit similarities in their molecular structure. These similarities suggest a steric basis for their anticonvulsant activity. The present investigation was undertaken to correlate ultrastructural changes with the biochemical alterations seen in the neurotransmitter and drug receptors after chronic DPH therapy. Brain benzodiazepine receptors were measured in the cerebellar and cerebral cortex following 14 days and 28 days of DPH administration (200 mg/kg/day i.p.) Control rats were injected with the vehicle alone for same duration of time. Our data show there was no change in the K_d values between controls and the experimental group, but the Bmax was significantly lower in the DPH treated cortex and cerebellum indicating a decreased receptor density. Two areas of vehicle and DPH treated rat brain were processed for electron microscopy. In the cerebellar vermis from DPH treated rat, numerous degenerated Purkinje cells were seen at both time periods. The degree of degeneration varied from one region of the cerebellum to another as well as from one Purkinje neuron to the next. At the electron microscopic level the degenerated Purkinje cells had hyperchromatic nuclei with infolded nuclear envelopes. Clumping of the Nissl substance and hypertrophy of the Golgi apparatus was also evident in the perikaryon. Concommitant with the Purkinje cell degeneration the Bergmann astrocytes showed edematous changes indicative of metabolic alterations. Other cerebellar neurons were unaffected by this treatment. Currently, the cerebral cortex and the hippocampus from the treated rats are being examined for morphological alterations. It is evident from these data that high doses of chronic DPH administration produces degenerative changes in the Purkinje cells and a decrease in the density of the benzodiazepine receptors in the cerebellum.

227.4 GALLOPING FORWARD LOCOMOTION PRODUCED BY LOCALIZED VENTRAL PONTINE TEGMENTUM DAMAGE IN THE RAT: A POSSIBLE ANIMAL ANALOG OF PARKINSONIAN FESTINATION. Jung-Tung Cheng*, Timothy Schallert, Marc De Ryck*, and Philip Teitelbaum. Psychology Department, University of Illinois, Champaign, IL 61820.

Akinesia is a major symptom of parkinsonism. However, some patients, although having difficulty in initiating locomotion, may then rapidly accelerate to the point where they are unable to stop (festination). Rats (n=11) with bilateral electrolytic lesions in the ventral pontine tegmentum (VPT) accelerate their forward locomotion (they walk, then run, then gallop) headlong into an obstacle or over the edge of a high table. They lack lateral head scanning and orienting. Because some parkinsonian patients have damage, not only in the nigrostriatal dopaminergic system, but also in the VPT (Greenfield, et al., J. Neurol., Neurosurg., Psychiat., 1953, 16, 213-226), we suggest that the festination shown by our animals may be analogous to human parkinsonian festination. If so, such festination should coexist with akinesia produced by catecholamine blockade.

Normal rats become completely akinetic when treated with haloperidol (5 mg/kg, i.p., n=5). Such haloperidol treatment does not prevent or even slow down the accelerating forward locomotion seen in rats with ventral pontine tegmental damage (n=8). Indeed, later in their recovery when they have begun to inhibit their forward locomotion (they no longer run into the wall), haloperidol (up to 10 mg/kg) reinstates (i.e., increases) their acceleration making it once again uncontrollable.

We suggest that the festination shown here may represent the action of a forward locomotion subsystem. Such isolated locomotion, though not inhibited by haloperidol, can be abolished by bilateral pressure on the snout. Supported by NIH Grant RO1 NS 11671.

227.5 METHYSERGIDE RELEASES FORWARD LOCOMOTION WITHOUT SUPPORT IN OTHERWISE AKINETIC LATERAL HYPOTHALAMIC RATS. Rebecca M. Chesire* and Philip Teitelbaum. Psychology Department, University of Illinois, Champaign, IL. 61820.

Akinesia, a prominent symptom of parkinsonism, can be produced by damage to dopamine systems in the brain. Animal models suggest that the akinesia results, in part, from excessive inhibition of the remaining neural subsystems involved in locomotion. Thus, anticholinergics (atropine or scopolamine) can release walking in otherwise severely akinetic, catecholamine-depleted rats (6-hydroxydopamine intraventricularly; Schallert et al., Science, 199, 1978). However, atropine is ineffective in rats made akinetic by bilateral electrolytic lateral hypothalamic damage (1 mA for 20-32 sec, anodal), a treatment that also damages the dopaminergic nigrostriatal system. We show here that even on the first day postoperatively, when the akinesia is most profound, methysergide maleate (a serotonin receptor blocker; 45 mg/kg, i.p.) can release vigorous forward locomotion in lateral hypothalamic rats for as long as an hour and a half.

The locomotion is abnormal. On Day 1, when postural support is largely absent in the akinetic animal, such locomotion occurs without support so that the animal appears to be crawling. The animal is propelled straight forward by its hindlegs with its chin dragging along the ground and its forelegs lagging in their associated stepping. Head scanning is completely absent (n=8). Later in recovery (5 days; n=6), when postural support and head scanning have recovered, methysergide-elicited locomotion is integrated with these movement subsystems into a more normal form of locomotion.

These findings indicate that at least two independent inhibitory neural systems, one cholinergic and the other serotonergic, exaggerate the akinesia produced by damage to the nigrostriatal dopaminergic system. They also reveal the independent movement subsystems isolated earlier by us (Golani et al., Brain Research, 164, 1979). Supported by NIH Grant RO1 NS 11671.

227.6 RED NUCLEUS CHANGES IN THE MOUSE MUTANT DYSTONIA MUSCULORUM Edith M. Stanley*, Anne Messer, and Norman L. Strominger; New York State Department of Health and Albany Medical College, Albany, New York 12201.

The mouse mutant dystonia musculorum is an autosomal recessive, progressive neurological disease. Symptoms are first observed in animals of 2 weeks of age and worsen steadily for the next 2 weeks. Little further deterioration occurs after 4 weeks of age. The first descriptions of these animals by Duchen and Janota reported pathology in the sensory afferent systems beginning at birth. We have previously reported a spontaneously occurring allele of this mutation which shows pathology in the red nucleus and the striatum as well as sensory afferents. In this study the effects of the mutation on the red nucleus are examined in both our strain (dt^{Alb}) and the allele carried at the Jackson laboratory (dt^{J}).

The time course and severity of pathology differ in the two strains. The pathology starts earlier and is somewhat more severe in the dt^{J} strain, with the large coarse neurons almost entirely absent in the adult dt^{J} red nucleus. There is a dramatic loss of acetylcholinesterase activity in adult dt^{Alb}, especially after recovery from diisopropyl fluorophosphate (DFP) injection. In animals pretreated for 8-10 hours with 5mg/kg DFP, the dt^{Alb} neurons show little if any staining, while controls show a substantial amount.

The time course of effects shows that the maximum effect of the mutation on the red nucleus at 3-4 weeks matches the time of maximum clinical effect. Clearly the changes in the red nucleus are not solely responsible for the clinical effects, as modest cell changes in young mice show a strain difference which is not reflected in crude clinical analysis of the earliest stages of the disease. The strain differences in mature animals may not be significant, since severely affected cells show greatly reduced cholinesterase, implying a loss of function. There are still many interesting questions to be examined in the red nucleus, as well as in the striatum and afferent sensory pathways of this mutant. With a variety of age and strain differences available, this mutant may offer a possible way of studying both the development and functional effects of progressive hereditary systems degenerations.

Supported by The Hereditary Disease Foundation and The Dystonia Foundation.

228.1 ANTIGEN- AND ACETYLCHOLINE-INDUCED CURRENT NOISE IN THE DENERVATED GUINEA PIG DIAPHRAGM. A.Auerbach* and M.Titmus* (SPON:J.del Castillo). Lab. Neurobiology, UPR Sch. Med., San Juan, PR 00901.

Smooth muscles from animals allergized by injection of an antigen contract when re-exposed to the sensitizing protein (Dale-Schultz reaction). While innervated skeletal muscles do not exhibit antigen sensitivity, the denervated hemidiaphragm of the guinea pig does. Local application of specific antigen has been shown to cause a depolarization and an increase in the conductance of the muscle membrane (de Florida et al, J. gen. Physiol. 51:677,1968). We have used the noise analysis technique to characterize the channels which open across the denervated muscle membrane under the influence of ACh and three antigens: ovalbumin, DNP-BSA (DNP-lysine as hapten), and BSA. Pressure application of antigen to voltage-clamped muscle fibers induces an inward current (up to 120 nA) which is of smooth macroscopic time course. The variance of the current noise increases with the intensity of the inward current. Analysis of the current fluctuations yields a spectrum which can be adequately fit by a single Lorentzian. Channel lifetimes(τ) and conductances (γ) were calculated from the noise spectra; the responses to both ACh and antigens were assumed to reverse at 0 mV. The results (2-10 animals for each ligand) are given below (mean$\pm$sd, number of fibers).

	τ(-100mV) msec	τ(-70mV) msec	γ(all Vm) pS
ACh, 24°	2.6$\pm$0.9 (8)	1.8$\pm$0.5 (11)	63$\pm$17 (29)
Oval., 24°	3.5$\pm$0.9 (3)	2.7$\pm$0.5 (6)	41$\pm$10 (7)
Oval., 16°	8.2$\pm$1.2 (8)	6.0$\pm$1.5 (12)	19$\pm$18 (18)
DNP-lys, 24°	4.2$\pm$0.7 (7)	--	51$\pm$19 (11)

Neither α-bungarotoxin (2.5 ug/ml) nor d-tubocurarine (5 uM) blocks the antigen-induced contraction. Denervated diaphragms also contract in response to bath-applied histamine or norepinepherine (NE) at uM concentrations. We have not been able to elicit current noise of significant variance with pressure application of NE, and we have only infrequently observed histamine-induced current noise. The mechanism of the antigen response is being investigated. Three possibilities will be considered: 1) release of mediators from non-muscle cells, 2) activation of tissue complement, and 3) interaction of antigens with IgG antibodies bound directly to the muscle surface.

We thank P. Specht for help with the computer programming. AA is a MDA Postdoctoral Fellow; supported by P.H.S. Grant NS07464 to J. del Castillo.

228.2 DENERVATION-INDUCED LOSS OF MUSCLE END-PLATE ACETYLCHOLINESTERASE ACTIVITY IS REDUCED BY PROTEASE INHIBITORS. Myron Duell* and Hugo L. Fernandez (SPON: Dr. F. Samson, Jr.). Neuroscience Research Lab, VA Med. Center, Kansas City, MO 64128 and Dept. Physiology, University of Kansas Medical Center.

The protease inhibitors leupeptin and pepstatin, used in combination, partly delay the structural deterioration of avian muscle fibers caused by either muscular dystrophy or denervation. Leupeptin also reduces protein degradation in normal rat skeletal and cardiac muscles, as well as in rat denervated and mouse dystrophic muscles, maintained in vitro. It was of interest to determine whether these effects also extend to any neuromuscular transmission-related protein. We therefore chose to study muscle end-plate acetylcholinesterase (AChE; E.C. 3.1.1.7), because of its important role in transmission, and because its activity rapidly decreases following denervation. Changes in muscle wet weight and protein content were also studied.

Intact and denervated rat anterior gracilis muscles were injected intraarteriallv with the protease inhibitors leupeptin, pepstatin, and aprotinin, either alone or in combination. After 24 hr, 3 mm sections of muscle end-plate regions were weighed and processed for analysis of AChE activity and protein. A combination of the inhibitors partly prevented the early (24 hr) denervation-induced decrease in muscle weight and protein content. Leupeptin and aprotinin, either alone or in combination, markedly reduced the decay of AChE activity in the denervated muscles, whereas pepstatin alone was ineffective. The effects were additive in that the inhibitors in combination were more effective than when they were used separately.

These experiments suggest an important effect of protease inhibitors in partly preventing the denervation-induced decrease in muscle end-plate AChE activity. These effects probably occur through the inactivation of proteolytic enzymes, which otherwise would be increased in denervated muscle. Although the results of the present study are not sufficient to single out the involvement of any particular protease(s), further studies are underway to better define protease participation in end-plate AChE catabolism.

228.3 SHORT-TERM ACTIVATION OF TYROSINE HYDROXYLASE IN RESIDUAL NORADRENERGIC NERVE TERMINALS AFTER INTRAVENTRICULAR 6-HYDROXYDOPAMINE. Ann L. Acheson and Michael J. Zigmond, Dept. of Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

Intracerebroventricular administration of 6-hydroxydopamine (6HDA) produces a rapid and permanent loss of norepinephrine (NE) stores in rat brain due to a selective degeneration of catecholaminergic nerve terminals. We have reported that the decline in NE in noradrenergically innervated areas such as hippocampus is initially accompanied by a proportionate decrease in tyrosine hydroxylase (TH) activity as measured in the presence of saturating cofactor (3 mM 6MPH4). However, this is followed by a gradual increase in the apparent Vmax of TH toward control values, with no change in NE (Acheson et.al., Science 207:537, 1980). We now report a second, more rapid effect of 6HDA lesions on TH activity in residual terminals.

Adult male rats received 6HDA (200 ug free base in 20 ul, ivt.) and were sacrificed 36 hr later. Hippocampal TH activity, assayed at its pH optimum (pH 6.2) in a Tris-acetate buffer in the presence of subsaturating cofactor (0.7 mM), was reduced to 32% of control, a decrease comparable to that of NE levels (27% control). When TH activity from control animals was assayed at pH 6.5, a marked reduction in activity was observed (55% of activity at pH 6.2). In contrast, no decrease in TH activity was observed in samples from lesioned animals (120% of activity at pH 6.2). Thus, at pH 6.5, TH activity in lesioned animals was no longer significantly different from control values. We observe a similar change in the relationship between TH activity and pH when TH is incubated under in vitro phosphorylating conditions (Acheson et.al., Neurosci. Abst. 5:395, 1979). We therefore examined the effect of phosphorylating conditions on TH prepared from hippocampus 36 hr post-6HDA. We observed that while preincubation with ATP, cAMP, and protein kinase increased TH activity from control animals as assayed at pH 6.5 by 150%, there was no effect on TH activity from lesioned animals. The apparent activation of TH in hippocampus is still present 7 days post-lesion but not at 21 days, a time when the increase in the apparent Vmax of TH is present. We conclude that following 6HDA treatment, TH activity in residual terminals is increased by two mechanisms: first, existing TH is rapidly activated, perhaps by a mechanism involving in vivo phosphorylation; second, there is a gradual increase in maximal TH activity. These changes may permit residual neurons to increase synthesis and release of NE, thereby reducing the impact of the lesion.

228.4 QUANTITATIVE HISTOCHEMICAL ANALYSIS OF SINGLE IDENTIFIED BARRELS IN THE MOUSE SmI CORTEX. W.D. Dietrich*, D. Durham, O.H. Lowry and T.A. Woolsey. Depts. Pharm. and Anat. and Neurobiol., Washington U. Sch. Med., St. Louis, MO. 63110.

Individual barrels in the posteromedial barrel subfield of the somatosensory cortex of mice are the cortical anatomical correlates of the large contralateral mystacial vibrissae. Recent studies have shown that following the removal of vibrissae in adult and neonatal mice, a significant decrease occurs in the histochemical staining of the mitochondrial enzymes cytochrome oxidase and succinic dehydrogenase within the corresponding barrels (Wong-Riley and Welt, '79; Durham, Welt and Woolsey, '78). The present study was undertaken to investigate the feasibility of determining various enzyme activities in individual barrels with quantitative histochemical techniques. The analyses were made on frozen sections cut in a cryostat and freeze-dried at -40°C. It was found that individual barrels could be identified in unstained sections and portions of them subsequently dissected and weighed on a quartz fiber balance. Micro-methods which included the use of oil wells and enzymatic cycling amplification were used. Because only small samples were needed (40 ng), levels of several enzymes in the same barrel, or the distribution of an enzyme within a single barrel could be determined. For instance, the activities of the mitochondrial enzymes, malic dehydrogenase (21.6 ± 0.5 mol/kg (dry)/h) and citrate synthase (5.0 ± 0.2 mol/kg (dry)/h) were measured in the same individual barrels. The basal levels of various glycolytic enzymes, including lactic dehydrogenase, hexokinase and P-fructokinase are being determined.

Using the same protocol the activity of various enzymes in the barrels following removal of selected groups of whiskers are being analyzed. Any changes in enzyme activity in the appropriate barrels consequent to the whisker damage can be followed at selected times after the peripheral damage and can be compared directly to activity in barrels in the same section associated with intact vibrissae. The methods developed are useful for describing the baseline levels of a number of biochemical properties of normal barrels and could provide information about changes in any of these parameters in the cortex, as a consequence of chronic sensory deafferentation occurring at least three synapses away.

228.5 (14C)DEOXYGLUCOSE STUDY OF EFFECTS OF SENSORY DEPRIVATION ON FUNCTIONAL ORGANIZATION OF A VIBRISSAL COLUMN IN RAT SI. L.Smith*,P.Hand, M. Kossut*Dept.of Animal Biology,School of Vet. Medicine, and Inst. of Neuro. Sci., Univ. of Penn., Phila.,PA.19104; Dept. of Neurophsiology, Nencki Institute, Warsaw, Poland.

A previous deoxyglucose (2DG) study demonstrated a spindle-shaped column in rat SI activated by stimulation of contralateral facial vibrissa #3 of row C (C3) (Hand et al,Neurosci.Abs.,'78).The effect of unilateral neonatal ablation of all vibrissal follicles, except C3, on the development of a single functional column was studied in 3 month old rats; a larger cortical area was labeled by C3 stimulation and the tapering columnar profile was lost, replaced by diffuse labeling in all layers(Kossut et al, Neurosci.Abs.,'79). The present study was designed to determine to what extent chronic sensory deprivation alone contributed to these changes. Repetitive unilateral vibrissal clipping or plucking was performed from birth on either all vibrissae, except C3, or C3 alone (contralateral vibrissae were unaltered and served as controls). After 2-3 months, either the C3 vibrissa or the surrounding vibrissae B3, C2, C4, and D3 were stroked bilaterally as previously described by Hand et al., following injection of 2DG. The column activated by vibrissa C3 in the former C3 "spared" group retained the characteristic spindle shape and dense labeling in laminae IV but the area labeled was enlarged in all laminae, its limits less sharply labeled. Column diameter was increased by a mean 28% in lamina IV. The local cerebral metabolic rate of glucose (LCMRG) was elevated 15% in lower lamina V. In the latter group (C3 clipped) surrounding columns showed similar spread of label (an 8% increase in LCMRG over control) into the region of the deprived C3 column. Light microscopy showed no alteration in dimension or morphology of layer IV barrels in either group, in agreement with previous reports. In conclusion, a deprivation-induced functional plasticity was detected in the "barrel" column. Metabolic changes seen in this study, however, were less pronounced than those reported after neonatal vibrissal receptor ablation; deprivation alone undoubtedly has a less disruptive effect on developing thalamocortical and corticocortical connectivity. (Supported by grants NS-14935:01,Sloan-76109,& Grass Foundations)

228.6 MORPHOLOGY OF LAMINAE IX NEURONS ROSTRAL AND CAUDAL TO THORACIC SPINAL CORD TRANSECTION IN WEANLING RATS. J. P. Cummings* and D. J. Stelzner, Department of Anatomy, SUNY, Upstate Medical Center, Syracuse, NY 13210.

A recent study in our laboratory has correlated the morphology of laminae IX neurons after thoracic spinal cord transection in neonatal rats with the morphology of laminae IX neurons during the normal developmental sequence. From 5 days to 9 months following transection the laminae IX neurons bordering the lesion retained both their normal size, distribution of their dendritic tree, and other morphological characteristics when compared with tissue taken from control animals of the same age. However, there was a slight increase in the number of varicosities on 2°, 3° and 4° dendrites. These somewhat swollen varicosities with irregular surfaces did not resemble the elongated, smooth varicosities found on the dendrites of the normal adult laminae IX neurons.

The current study was undertaken to correlate the morphology of laminae IX neurons after thoracic spinal cord transection in weanling rats with the morphology of laminae IX neurons following thoracic spinal cord transection in neonatal rats and with developing laminae IX neurons of control animals. A minimum of three weanling transected (24 days of age) animals were studied at 5, 10, 20, 30, 60, 90 and 180 days after transection. Camera-lucida drawings of representative laminae IX neurons from 0-9 mm rostral and 0-9 mm caudal to the stumps of the transected cord were made from coded slides.

Beginning as early as 10 days following transection, the laminae IX neurons within 0-4 mm (rostral and caudal) of the lesion had decreased dendritic fields, loss of dendritic branches and an increase in number of swollen, irregular varicosities along the entire length of their remaining dendrites. There was also a reappearance and an increase in both dendritic and somatic spines at all postoperative survival times. Laminae IX neurons located more than 4 mm from the lesion retained their normal adult morphology.

The laminae IX neurons bordering the lesion site in the current study did take on more characteristics of immature cells than were observed in laminae IX neurons bordering the lesion site in neonatally transected rats. This is probably related to the increased denervation caused by the spinal transection in the weanling rat since synaptogenesis is still ongoing at birth but is complete in the spinal cord by the weanling period. (Supported by Grants NS-14096 and NS-06353)

229.1 PEPTIDE HORMONE INITIATION OF PROGRAMMED CELL DEATH OF THE INTERSEGMENTAL MUSCLES OF THE SILKMOTH ANTHERAEA POLYPHEMUS. L.M.Schwartz* and J.W. Truman (SPON: K.Graubard). Dept. of Zool. NJ-15, Univ. of Washington, Seattle, Wa. 98195

The intersegmental muscles(ISM) are a group of embryonically derived muscles in the abdomens of developing adult Lepidoptera. These muscles provide the force necessary for adult eclosion and then degenerate during the subsequent 36 hrs. Previous work (Lockshin, R.A. and Williams, C.M., J.Insect Physiol. 11:601-610, 1965) has suggested that the trigger for this programmed cell death is the cessation of electrical stimulation to the muscles from the CNS. Working with the silkmoth Antheraea polyphemus, we have determined that ISM degeneration is initiated by a direct action of the eclosion hormone (EH) on the muscles themselves. EH is an 8,500 dalton peptide which is released from the brain prior to adult eclosion and acts directly on the CNS to release the stereotyped eclosion behavior (Truman, J.W., J.Exp. Biol., 74:151-174, 1978).

When animals were ligated between the thorax and abdomen prior to EH release, ISM breakdown was prevented. This muscle retention was reversed by hormone injection. The action of EH is not on the CNS to shut off motor activity, since denervated isolated abdomens did not breakdown their ISM. However, these denervated animals do show normal degeneration when injected with EH. To control for the potential action of EH on the distal stumps of the axons, animals were denervated three weeks earlier, prior to the initiation of adult development. The behavior of their ISM was comparable to the later manipulated animals. These data suggest a direct action of EH on the ISM.

EH acts on the muscles to stimulate the accumulation of cGMP as demonstrated by both biochemical and immunocytochemical techniques. This response is quite dramatic in both its time course and amplitude. Sixty minutes after hormone stimulation, cGMP levels are twenty-two fold over basal levels and are still ten fold higher three and a half hours after hormone exposure. No significant changes were observed in cAMP titers during this time in response to EH injection. Further work is focusing on other biochemical steps involved in this muscle degeneration.

229.2 PROGRAMMED CELL DEATH IN THE NERVOUS SYSTEM OF AN INSECT: HISTOLOGICAL AND PHYSIOLOGICAL ASPECTS. J. W. Truman and R. B. Levine. Dept. of Zoology, Univ. of Washington, Seattle, WA 98195

In the moth Manduca sexta, the emergence of the adult from the pupal cuticle is followed by the death of neurons in the segmental ganglia. The fourth andominal ganglion (A_4) was selected for detailed study. At eclosion this ganglion contains about 70 large motorneurons and approximately 600 interneurons. By 72 hours after eclosion the total number of cells declines to about 350 neurons, a number that then remains stable through the remainder of adult life.

The time course of neuron death was followed by examining serial sectioned material from animals of various ages. Interneuron death began at emergence, peaked at 12 to 14 hours, and was substantially complete by 28 hours. Interneuron loss was more extreme in the anterior half of the ganglion. Among the motorneurons, each cell had its own characteristic time of onset of breakdown. Degeneration onsets ranged from 8 hours in the case of the earliest cells to 30 hours for the latest.

Electrophysiological recordings from identified motorneurons that were destined to die showed that identified inputs into the cells as well as outputs of the cells remained functional well into the early histological stages of degeneration. The first electrical changes seen in the cells were the appearance of excitability in the dendrites. This was followed by an increase in input resistance, the spread of excitability to the soma, and then the breakdown of conduction between the soma and the axon. Thus, in the case of the motorneurons, death does not appear to be due to the withdrawal of inputs to the cell but rather to an intrinsic response of the cell itself.

229.3 **TIME OF CELL ORIGIN AND CELL DEATH IN THE DORSAL MOTOR NUCLEUS OF THE VAGUS.** **L. Wright. Neuroembryology lab., N.C. Found. Mtl. Hlth. Res., Inc., Raleigh, NC 27611.**

In the attempt to understand the mechanisms of cell death, it would be helpful to know more about the range of neural regions in which cell death occurs, and the diversity of characteristics these regions display, including pattern of cell proliferation, and number and type of target regions. The dorsal motor nucleus of the vagus (DMV) was chosen for study because, while it is a motor nucleus, i.e., the source of the preganglionic parasympathetic axons, it does not synapse directly upon muscle, but rather upon parasympathetic ganglia. Thus, this nucleus provides the opportunity to study the patterns of cell proliferation and cell death in a motor nucleus that innervates multiple, non-muscle targets.

The time of origin of cells in the DMV was studied autoradiographically. Chick embryos were injected with (3H)-thymidine at various ages, then sacrificed at day 18, and their brains were processed for autoradiography. Cells in every tenth section throughout the nucleus were evaluated according to the density of label present. Embryos injected with (3H)-thymidine on day 2 of incubation had label in all cells of the DMV, indicating that all the cells were still dividing at this time, and also demonstrating that the label was maintained in the cells from the earliest time of injection to the time of sacrifice at day 18. The peak of heavy label occured on day 2, and the first unlabelled appeared on day 3. Thus the first cells withdraw from the cell cycle prior to day 3. By day 4, 94% of the cells were unlabelled. A caudo-rostral gradient in the cessation of proliferation was indicated, with the caudalmost cells withdrawing from the cell cycle slightly in advance of the middle and rostral cells.

Cell counts of the DMV were made in embryos aged 6 days to hatching, and in one rooster. On day 8, when the DMV could be reliably distinguished from the nucleus intermedius, there were an average of 7464 cells present after Abercrombie's correction. By day twelve, cell death had resulted in a 21% loss of cells. By hatching, 37% of the cells had died, and counts made in the rooster indicated a posthatching loss, producing a total cell loss of 49%. A caudo-rostral gradient in cell death was noted, with the caudal cells undergoing more cell death between days 8-10.

The caudo-rostral gradient and the protracted period of cell death observed are discussed in relation to the competition hypothesis of cell death.

229.4 ROLE OF ACETYLCHOLINE RECEPTOR IN NEURON SURVIVAL DURING DEVELOPMENT. William R. Boydston* and G.S. Sohal (SPON: R.K. Holt). Dept. of Anat., Sch. of Med., Medical College of Georgia, Augusta, GA 30912.

Spontaneous death of motor neurons during the course of normal development has been observed in numerous parts of the nervous system. The reasons for cell loss are unknown, but recently a role for muscle activity in this process has been demonstrated. Continuous paralysis of embryonic neuromuscular transmission with α-bungarotoxin in white Peking duck embryos prevents the death of a significant number of trochlear neurons. Accompanying the increased cell survival is an increase in extrajunctional acetylcholine (ACH) sensitivity in the paralyzed superior oblique muscle and an increased number of nerve terminals per endplate. It is suggested that the increased cell survival may be due to the altered muscle membrane properties which permit the paralyzed muscle cells to maintain additional nerve terminals. Hence, a study was made to determine whether the acetylcholine receptor plays a role in neuron survival.

3.0 ug/g body wt. of the anticholinesterase drug, neostigmine methylsulfate, were applied to the chorioallantoic membrane of white Peking duck embryos on day 11 and continuing daily until sacrifice. Neostigmine has been shown to reduce the number of ACH receptors in adult mammalian muscle. ACH receptor quantification in the developing superior oblique was performed by ^{125}I-α bungarotoxin binding with corresponding cell counts of trochlear neurons made. In addition, the effect of cholinesterase inhibition on muscle differentiation was studied by electron microscopy.

Chronic treatment with neostigmine reduced the number of ACH receptors in the superior oblique muscle by 43% on day 19 (^{125}I cpm/ug protein: control-137.5, treated 78.3). No effect on muscle differentiation was seen. Coinciding with the decreased receptor number is an enhanced loss of trochlear neurons. Cell counts of the trochlear nucleus from neostigmine-treated embryos on day 19 was 830 as compared to 1603 in controls. This represents an additional 48% reduction in trochlear neurons. The size of the initial neuronal population was unaffected as shown by cell counts before the onset of cell death nor was any direct, toxic effect of the drug on trochlear neurons observed. Thus, it is suggested that the ACH receptor number or a signal released by the receptor may play a role in neuron survival during development.

(Supported by a grant from the Muscular Dystrophy Association and by a grant from NIH)

229.5 THE POSSIBLE ROLE OF EXTRAJUNCTIONAL ACETYLCHOLINE RECEPTORS IN EMBRYONIC DEATH OF MOTOR NEURONS. T.L. Creazzo* and G.S. Sohal. Dept. of Anat., Sch. of Med., Medical College of Georgia, Augusta, GA 30912.

Recent reports from this laboratory have demonstrated that pharmacologic blockade of nerve-evoked muscle activity reduces the magnitude of normally occuring embryonic death of motor neurons probably because the target muscle can accept additional axons terminals while rejecting none. In adult paralyzed muscle the ability to accept forgein innervation appears related to the increase in the density of extrajunctional acetylcholine receptors (AchR). Since initially embryonic muscle has a high AchR content, we investigated the content and distribution of AchRs in the normal and paralyzed superior oblique muscle (SOM) of the white Peking duck embryo. The trochlear nerve reaches the SOM on day 10 and cell death begins in the trochlear nucleus on day 13. Interestingly, there is a 4.5 fold decline in the content of I^{125} α-bungarotoxin labelled AchR between days 10 and 12 (day 10: 461.4±49 12: 111.6± 10.0 cpm/ug muscle protein). From day 12 through the remainder of incubation the decline is more gradual (e.g. day 25, 44.1 + 3.0). Muscles paralyzed with curare (2 mg/day) or botulinum toxin (15 ug/day) showed less decline and significantly greater AchR content than normal. For example, the content was 30% greater than normal on day 14, 36% on day 18 and 130% on day 25. Autoradiographic analysis indicates that the increased AchR content of paralyzed muscles is due to a higher extrajunctional AchR density. We suggest that embryonic death of motor neurons may result from the decline in extrajunctional AchR density and subsequent rejection of superfluous axon terminals.

(Supported by a grant from the Muscular Dystrophy Association and by a grant from NIH)

229.6 THE LOCATION OF MOTOR NEURON POOLS RELATED TO SPECIFIC WING AND LEG MUSCLES IN THE CHICK IS NOT ALTERED FOLLOWING THE PREVENTION OF NATURAL CELL DEATH.

R. W. Oppenheim. Neuroembryology Lab., Dept. of Mental Health, Raleigh, N. C. 27611

In previous reports, we have shown that neuromuscular blockade with a variety of pre-and postsynaptic pharmacological agents, during the period of naturally occurring cell death of spinal motor neurons, led to a substantial reduction in the number of such cells which degenerate (i.e. the prevention of cell death) (Pittman, R. & Oppenheim, R. W., Nature, 271:364, 1978; Pittman, R. & Oppenheim, R. W., J. Comp. Neurol., 187:425, 1979). Although wing and leg muscles are somewhat atrophic following such treatment, muscle differentiation appears relatively normal, including the appearance of acetylcholinesterase (ACHE) stained endplates and innervation of these synaptic sites. All muscles examined so far appear hyperinnervated. In some muscles, hyperinnervation is reflected by an increased number of synaptic sites per muscle fiber, whereas in others, the number of sites is relatively unchanged, but the number of axons terminating at each site is increased.

Since cell death has been prevented in these preparations from the earliest stages of limb innervation on days 4 or 5, it was expected that any inappropriate synaptic connections present at that time (or formed later) would be retained as long as the cells and their projections are prevented from regressing. Consequently, I have made small injections of horseradish peroxidase (HRP) into specific wing and leg muscles on embryonic day 10 in order to retrogradely label motor neuron pools in the spinal cord.

The location of HRP labelled motoneurons was found to be the same in control and experimental embryos. The specific muscles and related motor neuron pools that were examined included the gastrocnemius, peroneus, iliofibularis and sartorius in the leg and the biceps, triceps, extensor metacarpi radialis and flexor carpi ulnaris in the wing. In all cases, the rostral-caudal and medio-lateral locations of the specific motor neuron pools were indistinguishable from controls. These results are consistent with previous reports in which lumbar motor neurons of the chick were shown to innervate their appropriate muscles at the onset of innervation, and prior to the beginning of natural cell death (Landmesser, L. & Morris, D., J. Physiol., 249:301, 1975; Landmesser, L., J. Physiol., 284:371, 1978). Thus, the natural cell death of chick spinal motoneurons is not designed to remove inappropriate synaptic connections.

229.7 INTRAUTERINE MOTOR NEURON DEATH IN NORMAL MOUSE AND IN THE WOBBLER MUTANT. P.A. Hanson and N.L. Strominger. Depts. of Neurology, Pediatrics and Anatomy, Albany Medical College, Albany, NY 12208.

Mechanisms of programmed cell death (PCD) have been studied extensively in the chick and amphibian. Alterations in PCD have been produced by limb transplantation or amputation, and by exposure to toxins. Few studies have been concerned with this phenomenon in mammalian ontogenesis. We have studied PCD in the normal mouse in order to generate baseline data to be compared with similar studies on mutant strains.

The mutant mouse wobbler (wr/wr), an autosomal recessive, is a model for infantile spinal muscular atrophy in the human. The wobbler homozygote can be identified by 3 weeks of age; the spinal cord shows a depletion of motor neurons and there is evidence of denervation in the muscle. We have chosen to study this mutant.

Serial transverse sections stained with cresyl violet were prepared throughout the spinal cord. In the normal mouse a population of large motor neurons were counted which were identified after day E12 on the basis of large pale nuclei and prominent nucleoli. Morphometric studies of this population of motor neurons in the entire spinal cord shows a marked reduction in cell numbers from day E12 to E16 with the most prominent cell death on E13-14. Analysis of our data shows a high degree of reproducibility of motor neuron counts in the normal mouse. Thymidine autoradiography of cells generated on days E9-E11 shows their involvement in this PCD.

Preliminary data from runts in the litters of heterozygote wobbler matings, identified at the time of sacrifice by weight and size, show a significant reduction (50%) in the population of large motor neurons on day E18 when compared to their normal litter mates. These findings demonstrate an intrauterine abnormality in the wobbler mouse which may be related to programmed cell death.

(Supported by a grant from the Easter Seal Society).

230.1 RECEPTIVE FIELD PROPERTIES OF NEURONS IN THE VISUAL CORTEX OF THE RAT. J.G. Parnavelas, R.A. Burne, C.-S. Lin and D.J. Woodward. Dept. of Cell Biology, Univ. Tx. Health Sci. Ctr., Dallas, TX 75235.

The receptive field properties of single cells were examined in the visual cortex, area 17, of Long Evans pigmented rats maintained under 1% halothane anesthesia. Extracellular spike responses of neurons were recorded to visual stimuli presented manually or with the aid of a computer-controlled system. Post-stimulus time histogram analysis was used to determine the response characteristics following presentation of the visual stimuli. In addition, an attempt was made to correlate structure and function by intracellularly filling with horseradish peroxidase (HRP) of single electrophysiologically identified neurons in the same cortical area. Beveled glass micropipettes (40-75 Megohm) containing 5% HRP in 0.2 M KCl with 0.1 M Tris buffer at pH 7.6 were used in this study.

Visually responsive neurons comprised more than 75% of the recorded cells. The majority of these neurons responded to both stationary and moving stimuli or only to movement. The remaining cells responded only to stationary stimuli. Cells of the former category were either complex (most frequent), simple or hypercomplex (least frequent). The neurons that responded to stationary stimuli were either on-center, off-center or on-off in type. Cells that responded to movement possessed at least an orientation, a direction or a velocity selectivity. These results indicate that, contrary to the widely held view based on previous studies[1, 2], the majority of neurons in the rat visual cortex have well-defined receptive field properties and are similar to those reported for animals with more highly developed visual systems. To date, all complex cells filled with HRP had the morphological characteristics of pyramidal neurons while the successfully filled simple cells had variable morphology with some being of the pyramidal and others of the non-pyramidal varieties. Our findings clearly demonstrate the feasibility of accurate structural-functional correlations in the rat visual system.

230.2 PRINCIPAL COMPONENTS ANALYSIS PRODUCES A UNIFIED SCHEME FOR CLASSIFYING CELLS IN THE VISUAL CORTEX OF THE CAT. C. Hagerty*, F.C. Lees* and H.V.B. Hirsch. Depts. of Biology and Anthropology, SUNY Albany, Albany, N.Y. 12222.

Cortical cells may differ along many dimensions. When the number of these dimensions becomes large and highly interdependent, statistical techniques are needed to study relationships among them. Such techniques have been developed by numerical taxonomists to study variation within populations of organisms. We have applied these techniques to study a population of cells in the visual cortex of the cat. Eleven physiological properties of a sample of cortical cells were measured and the interrelationships among the response properties examined by principal components analysis. This procedure searches out the smallest number of mathematically independent combinations of the 11 variables which can account for most of the variance in the original data set. Each combination of variables represents an axis of the mathematical space within which the cells are distributed. The particular combination of variables used for each of the axes may characterize underlying mechanisms which generate the physiological properties of the cells.

We identified five major axes which together account for about 70% of the overall variability in the data. The contributing variables on these axes were: (1) peak response, layer, cutoff velocity, receptive field length, spontaneous activity, and eccentricity--all reflecting differences in afferent input to cortex, (2) simple/complex, receptive field width, cutoff velocity, and direction selectivity--all reflecting the presence of sideband inhibition and its contribution to response properties, (3) spontaneous activity and eccentricity--both reflecting differences in afferent input as a function of eccentricity, (4) tuning width and distribution of preferred orientation--reflecting an as yet unknown feature of cortical organization, and (5) ocular dominance--reflecting the distribution of geniculate afferents from the two eyes.

These axes were derived in an objective fashion. They show that certain response properties of cortical cells (e.g. cutoff velocity, receptive field size) are determined both by the type of afferent input and by the influence of sideband inhibition, and that these response properties may be generated by different mechanisms in different cell populations. Finally, the axis produced in a principal components analysis can also be used to classify cortical cells. The results obtained show that variables used in the simple/complex and in the W/X/Y classification must be incorporated in a unified scheme for classifying cortical cells. Supported by NIH grant R01EY01268 to H.V.B.H.

230.3 DIRECTIONAL MOVEMENT SELECTIVITY IN CORTICAL COMPLEX CELLS. J. Anthony Movshon, Elizabeth T. Davis* and Edward H. Adelson*. Psychology Department, New York University, New York, NY 10003.

Complex cells in cat striate cortex are often selective for the direction of movement of visual stimuli. We have studied this selectivity with isotropic random dot patterns and with sinusoidal grating and checkerboard stimuli.

The direction selectivity of complex cells for moving dot fields is broader than their selectivity for the direction of a moving grating. At low stimulus velocities, the preferred direction for a dot field always matches the preferred direction for a moving grating. At higher velocities, however, cells often prefer directions different from the preferred direction for a grating, producing a bi-lobed tuning curve. This behavior may be understood by considering that the moving dot field contains components at all orientations, and that the velocity of each component is scaled by the sine of the angle between its orientation and the overall direction of movement. At low velocities, components oriented orthogonally to the direction of movement are most effective, and the direction preference matches the orientation preference. At high velocities, however, only components whose orientations nearly parallel the direction of motion move slowly enough to be effective, resulting in a disparity between orientation and direction preference.

This suggests that a distinction must be drawn between component motion and pattern motion. Each oriented component of a visual pattern may in principle move in a range of directions; seen alone, each component (e.g. a sinusoidal grating) moves in a direction orthogonal to its orientation. In complex stimuli, however, pattern motion is inferred from the unique conjunction of the possible motions of many oriented components. A neuron selective for direction but not orientation would have the property of extracting the invariant pattern motion from a variety of possible component motions. The observed dependence of direction tuning upon stimulus velocity suggests that striate cortical neurons only signal component motion, and are incapable of sensing pattern motion.

This is further supported by experiments in which gratings of different orientation were superimposed to form sine-wave checkerboards. The direction-selectivity of cortical cells for these stimuli is determined by the orientation of the component gratings (and thus component motion) rather than the direction of pattern motion, even when the angle between the two gratings is widely varied.

We thus offer a definition of a pure direction selective neuron as one sensitive to pattern rather than to component motion. No striate cortical cell type appears to have selectivity of this sort, and studies are in progress to see if it may be found in neurons in the superior colliculus or lateral suprasylvian visual cortex. Meanwhile, it appears that all cortical neurons - even those of the "pure direction selective" type - have a selectivity for direction that is dependent on the orientation components of the stimulating pattern, and not on the direction of movement of local pattern elements.

230.4 ANALYSIS OF NEURAL PROCESSES WHICH CONVERT ELECTRICAL STIMULATION OF STRIATE CORTEX INTO "SENSATION". Edgar A. DeYoe and Robert W. Doty. Center for Brain Research, University of Rochester Medical Center, Rochester, New York 14642.

Electrical stimuli applied directly to striate cortex in man elicit only a sensation of punctate, stationary, slightly flickering white light (e.g., Brindley et al., J. Physiol., 1972; Dobelle and Mladejovsky, J. Physiol., 1974). This surprising uniformity of effect suggests that the neural mechanisms subserving this experience might be sufficiently restricted and unique to be identifiable. Observations on macaques over the past 20 yr strongly suggest that they too have a singularly uniform sensation for such stimulation; for if trained to respond to excitation at one locus in striate cortex, it is consistently found that they respond immediately, without further training, to excitation at any other striate locus. Our present goal is to identify, especially with microstimulation, the characteristics and laminar origin of the neurons in striate cortex responsible for this effect. Six M. nemestrina have been trained to grasp a rod or release contact when and only when cathodal, monophasic pulses are applied to striate cortex, via chronically implanted "macroelectrodes" (127 or 200-μ Pt-W or Pt-Ir), or transdurally advanced, glass-insulated Pt-Ir microelectrodes (ME). In the latter instance head movements are restrained by an individually fitted, fiberglass mask, and the ME passes through a 1-mm hole drilled in the skull during general anesthesia. For 44 macroelectrodes the mean threshold for response at 50 Hz, 0.2-msec pulses, was 109 μA, range 50-350 μA. In contrast, for all penetrations with MEs the range is commonly 15-25 μA, and one monkey could respond consistently to 2-4 μA at restricted loci. The transition from 10 to 90% correct responding occurs within 5-10 μA or less for MEs, whereas a 15-20 μA change is required with the macroelectrodes. Studied with the chronically implanted electrodes, each locus has a characteristic profile of increasing threshold with decreasing pulse frequency, and this profile, ranging from a 2 to 10-fold increase in going from 50 to 1 Hz, is stable, at least over a period of weeks. Preliminary evidence suggests that this function will commonly be much steeper for MEs than for macroelectrodes, i.e., that relatively much more intense currents will be required at 1 Hz for MEs. If the chronaxies are the same at the various pulse frequencies, as seems likely, and assuming the "sensation" is qualitatively unaltered by pulse frequency, as the human data affirm, then analysis of the interplay of temporal versus spatial summation (as revealed by the threshold/pulse frequency functions) at discrete loci within striate cortex may indicate which neuronal types are responsible for the peculiarly uniform percept. (Supported by NIH Contract 70-2279).

230.5 POSSIBLE NEUROTRANSMITTER OF CELLS IN LAYER 6 OF THE VISUAL CORTEX. R.W. Baughman and C.D. Gilbert. Dept. of Neurobiology, Harvard Medical School, Boston, Mass.

Cells in layer 6 project heavily to layer 4 and are the source of the recurrent pathway from the cortex to the lateral geniculate nucleus. We have attempted to characterize the neurotransmitter of these cells as a means to understand their role in cortical and geniculate function. To identify possible neurotransmitters, high pressure liquid chromatography was used to measure release of endogenous compounds from a tissue slice preparation of the visual cortex of the rat. When the K+ concentration of the incubation medium was raised (from 5mM to 50mM) to induce synaptic release, of the compounds measured, marked increases in release rate were observed for aspartate, (Asp) (12-fold), glutamate (Glu) (15-fold) and GABA (6-fold). This increased release was blocked in low Ca2+ high Mg2+ medium. Similar increases in release rate were observed when the tissue slices were treated with 100 micromolar veratradine, which is known to open the voltage sensitive sodium channels, and thereby provides an alternative means of exciting the cells. In this case the increased release was prevented by the sodium channel blocker tetrodotoxin.

To determine whether layer 6 cells might use Asp or Glu as their transmitter, 3H D-Asp was injected into the LGN of the cat in an attempt to label the cells by retrograde transport. In other pathways for which the transmitter is known, such retrograde labeling is specific for the transmitter involved (Streit and Cuenod, 1979). Striking labeling was observed in the layer 6 pyramidal cells and in a diffuse band in layer 4. Following an injection of 3H D-Asp in the cortex, no labeled cell bodies were seen in the LGN, confirming the specificity of the retrograde transport. Diffuse labeling was present in the LGN, however, presumably produced by anterograde transport from the layer 6 cells. Since the geniculate cells did not take up 3H D-Asp, we believe that the band in layer 4 represents filling of the collaterals of layer 6 axons. The cortical injection also provided evidence for the specificity of the uptake of 3H D-Asp by the layer 6 cells in that labeled cells were concentrated in this layer. The results are consistent with the observation that high-affinity uptake of 3H D-Asp is reduced in the LGN following ablation of the visual cortex (Lund-Karlsen and Fonnum, 1978). Although further studies are needed to completely test the specificity of the uptake and transport of 3H D-Asp, the present results suggest that the 6th layer cells participating in the corticogeniculate pathway may use the acidic amino acids Asp or Glu as their neurotransmitter. This research was supported by NEI grants EY00606 and EY01995, and by the Medical and Sloan Foundations.

230.6 LOCALIZATION OF GABA IN THE MONKEY STRIATE CORTEX. A. Hendrickson, S. Hunt*, and J-Y Wu. Dept. Ophthalmology, Univ. Washington Seattle WA 98195, Neurochemical Pharmacology Unit, Cambridge England and Dept. Cell Biology, Baylor Col. Med., Houston TX 77030.

The localization of the neuronal transmitter gamma amino butyric acid (GABA) in Macaca monkey primary visual cortex (striate) has been studied by staining its synthesizing enzyme glutamic acid decarboxylase (GAD) using immunocytochemical methods.

Four normal mature monkeys were studied; two received multiple injections of colchicine (10ug/ul) into one striate cortex 1 day before sacrifice. All were perfused with phosphate-buffered 4% paraformaldehyde or modified paraformaldehyde-lysine-periodate fixative. Frozen sections were cut serially at 25u in planes both perpendicular and parallel to the cortical surface. Seetions were incubated overnight in GAD-specific antiserum diluted 1/150 and then were processed for peroxidase-antiperoxidase staining using standard techniques. Alternate sections were stained for cytochrome oxidase (Wong-Riley 1979).

GAD+ terminals were found in all layers of the cortex, but were most numerous in layers I, IVA and IVC, slightly less in lower II, III and VI, and quite sparse in upper II, IVB and V. GAD+ cell bodies were found in all layers except I and ranged in size from very small to very large. They were common in layers II-IVC and VI, but layer V contained only a few, mainly large GAD+ neurons. On GAD+ neurons, the dendritic tree was usually visible for only a short distance so the specific type(s) of cell remains to be identified. GAD+ terminals could be seen to encase both unlabeled and labeled cell bodies. In sections cut parallel to the surface of the cortex, a regular pattern was found above layer IVA of alternating high and low concentrations of GAD, arranged into dots aligned into rows. This same pattern occurred in neighboring cytochrome oxidase stained sections. In both stains the spacing between rows was 450u±50u. This pattern above IVA resembled the deoxyglucose labeling described previously in Macaca striate cortex (Hendrickson and Wilson 1979). In both methods layer IVC was uniformly labeled while IVA showed a dot and dash pattern. A faint repetition of the dot pattern was also found in VI.

These results indicate that GABA is widely distributed in all striate layers, but has a differential laminar distribution. There was no evidence from either GAD or cytochrome oxidase staining for a differential distribution in layer IV correlated with ocular dominance columns, but above IVA there was a regular alteration of GAD concentration. Experiments are underway to determine if this is an extension of the ocular dominance system into supragranular layers, or represents a separate cortical organization. (Supported by Burroughs-Wellcome and EY-01208)

230.7 COMMISSURAL CONTRIBUTIONS TO VISION MEASURED BY THE 2-DEOXYGLUCOSE TECHNIQUE. K. A. Macko, M. Miyaoka*, C. Kennedy, L. Sokoloff and M. Mishkin. Lab. Neuropsychology and Lab. Cerebral Metabolism, NIMH, Bethesda, MD 20205.

In primates, the cortical pathway for processing visual stimuli proceeds from striate cortex (area OC) through surrounding prestriate cortex (areas OB and OA) to the inferior convexity of the temporal lobe (areas TEO and TE). Portions of each of these visual areas are known to be reciprocally connected through the forebrain commissures. In particular, the representation of the vertical meridian at the OC-OB border as well as selected parts of area OA receive commissural inputs via the splenium of the corpus callosum, while extensive portions of areas TEO and TE, important for higher-order visual function, receive their contralateral input via the splenium and anterior commissure. To quantify the contribution to vision made by these commissural systems, we measured rates of local cerebral glucose utilization (LCGU) throughout the cortical visual system in two different surgical preparations: unilateral optic tract section combined with forebrain commissurotomy (n=5) and unilateral optic tract section alone (n=4). The 2-deoxyglucose method was applied one month postoperatively in awake rhesus monkeys actively viewing visual patterns. The commissural contributions to vision were inferred from differences in LCGU between the deprived hemispheres of the two groups.

From the autoradiographs of each brain, representative sections were chosen at 1 mm intervals throughout the extent of the cortical visual pathway. Weighted averages of LCGU for the entire extent of each visual area were then calculated from these sections by means of a computerized image-processing system. In the intact hemisphere there was a progressive decline in LCGU along the cortical visual pathway from a high of 66 in area OC to a low of 47 μmoles/100g/min in anterior TE. This sequential decline in the intact hemisphere was the same for both the animals with tract section plus commissurotomy and those with tract section only. There were also no differences between operated groups in the visually deprived hemisphere for areas OC through TEO, where LCGU averaged 50% of that in the intact hemisphere (ranging from 40% in OC to 60% in TEO). A difference attributable to visual input via the intact commissures was found in TE, however, where LCGU in animals with combined tract section and commissurotomy remained at 60% of that in the intact hemisphere, whereas in animals with tract section only LCGU reached 80% and 90% of the values in the intact hemisphere for posterior and anterior TE, respectively. These results indicate that commissural inputs contribute more to the visual functions of area TE than to those of any other visual area and that commissural imputs alone may be insufficient to support visual function in areas TEO, OA, and the OC-OB border.

230.8 THE LOCATION OF CALLOSAL PROJECTION NEURONS IN RELATIONSHIP TO MAPS OF THE VISUAL FIELD IN CAT CORTEX. Mark A. Segraves and Alan C. Rosenquist. Dept. Anat., Univ. of Penna., Phila., PA 19104.

A previous report (Segraves, Soc. Neurosci. Abstr., 5:807, 1979) indicated that callosal cells in cat lateral suprasylvian visual areas were distributed throughout a more extensive portion of the map of the visual hemifield than was the case for callosal cells in area 17. The experiment described below was intended to delineate directly the distribution of callosal neurons within each visual field representation. In each cat, we used electrophysiological recording methods to map several visual cortical areas and placed small electrolytic lesions to mark receptive field positions. Following this procedure, the posterior 2/3 of the callosum was cut, and a cotton pleget saturated with 50% HRP placed between the cut ends of the callosum. A 48 hr. survival was used, and the tissue reacted with o-dianisidine.

Callosal cells in area 17 were restricted to a portion of the visual field map extending from the vertical meridian (VM) to not more than 5-10° azimuth. Moving from upper or lower field representations towards the horizontal meridian, callosal cells tended to be located nearer and nearer to the VM. In PMLS, labelled cells were located in all portions of the visual field map. This included callosal cells adjacent to lesions marking receptive fields of 60° azimuth. Despite the wide distribution of callosal cells in PMLS, the highest density of labelled cells was in portions of PMLS representing from the VM out to 20° azimuth.

It is likely that the callosal system may be segregated into multiple components. We would like to suggest two components based upon the distribution of neurons within a visual field map. One population of callosal cells located exclusively within a few degrees of the VM may be important for functions like coarse stereopsis and vergence eye movements. A second population of callosal cells that exists in representations of both central and peripheral vision may be important for functions such as the interhemispheric transfer of visual learning. Our evidence indicates that only the first of these two components exists in area 17, whereas both may be present in area PMLS. (Supported by EY02654 & GM00281)

230.9 LOCATION OF THE TERMINALS OF THE INTERHEMISPHERIC CONNECTIONS OF THE CAT'S VISUAL CORTEX. E. H. Murphy, B. R. Payne and N.Berman. Depts. Anat. and Physiol. Med. Coll. PA, Phila., PA 19129.

The location of axon terminals of cells which form the interhemispheric connections of the cat's visual cortex was determined either by degeneration techniques after transection of the corpus callosum (CCX) or by autoradiography after anterograde transport of tritiated amino acids following multiple injections into one or more visual areas. In the autoradiographic material there is a high density of accumulated label over layers I, III and VI. Discrete injections restricted to the 17/18 border, 18/19 border or lateral suprasylvian (LS) areas show that projections to the contralateral homotopic visual areas terminate mainly in layers III and VI and heterotopic projections terminate mainly in layers I and VI. Interhemispheric projections from more laterally placed areas (LS) to contralateral medial areas (17, 18 and 19) are greater than from 17, 18 and 19 to LS. In area 17 debris after CCX is maximal at the border with area 18 and decreases with distance from that border. A comparison with the visuotopic maps of Tusa et al. (1978, 1979) and Albus and Beckman (1980) and our own physiological recordings from some of these animals indicate that the labeled terminals are located in a region of cortex representing between 2^{o} and 4^{o} of visual space lateral to the 0^{o} vertical meridian (VM). For areas 18 and 19, the representation occupied by labeled terminals estends up to 20^{o} lateral to VM and up to 40^{o} or more for LS areas. The extent of the region receiving information from the contralateral hemisphere varies according to elevation in the visual field such that it is minimal in the region of the 0^{o} horizontal meridian and greater above and below. In addition, some animals show regions of dense labeling at the lateral edge of area 18 which may extend into area 19. These results indicate that visual field representations located away from VM receive substantial inputs from the contralateral hemisphere. Stone et al. (1980) have suggested that areas 17, 18 and 19 receive information primarily from the three subIcasses of ganglion cells X, Y and W respectively. Ganglion cells in the temporal retina project mainly to the ipsilateral visual centers although some project contralaterally. The extent of temporal retina which contains contralaterally projecting ganglion cells is least for the X-cell group, intermediate for the Y-cell group and greatest for the W-cell group. Therefore, the representation of the ipsilateral half field is greatest for the W-group and least for the X-group. This correlates with our finding that the region of visual field connected by interhemispheric pathways is largest for area 19 (W-recipient), somewhat smaller for area 18 (Y-recipient) and least for area 17 (X-recipient). Supported by EY02088 & EY02488.

230.10 LOSS OF BINOCULARITY IN AREA 17 AFTER SECTION OF THE CORPUS CALLOSUM: TIME COURSE AND EXTENT OF THE VISUAL FIELD AFFECTED. B. R. Payne, N. Berman and E. H. Murphy. Depts. Anatomy and Physiology, The Medical College of Pennsylvania, Philadelphia, PA 19129.

We have reported previously that transection of the corpus callosum leads to a significant decrease in the number of neurons in area 17 which may be activated binocularly (Payne et al. Science 207, 1980). We now present data concerning the extent of the visual field affected and post-operative time course of this effect. We recorded from 794 units in area 17 in cats after corpus callosum transection (CCX cats) and 558 units from area 17 in normal cats.

In normal cats the region of maximal binocularity in one hemifield is a vertical strip 12^{o} wide adjacent to the 0^{o} vertical meridian (VM) but excluding units with receptive fields within 4^{o} of the center of area centralis. In this strip 78% of units are binocular. The value decreases to 64% between 12^{o} and 20^{o} from VM and 49% at more lateral locations. Thus, the decline in binocularity begins before the monocular segment is reached. In CCX cats, the major loss of binocularity occurs within the 12^{o} vertical strip which corresponds to the area of maximal binocularity in normal cats. This decline is significant (X^2, 1 df $p < .001$). However, at locations more lateral than 12^{o} the proportion of binocular units increases to reach that found in normal animals (61%). Compared to normal cats, CCX cats also show a significant decrease in the number of binocular units in area centralis (X^2, 1 df $p < 0.02$).

Studies of the time course of these changes show that the decrease in the number of binocular units is progressive in the first two weeks after surgery and the maximal loss occurs between 2 and 4 weeks after transection when only 30% of the units can be activated binocularly. At 8 weeks 48% of the units are binocular and at 8 to 10 months 58% of the units are binocular. These values are significantly different from normal (X^2, 1 df, $p < 0.001$ both cases). With longer survival times normal levels of binocularity are observed between 6^{o} and 12^{o} from VM. Thus, the region of maximal binocularity becomes narrower with longer survival times and is localized to within 6^{o} of VM.

These results show that transection of the corpus callosum reduces the proportion of binocular cells and that this effect is most marked in the area of maximal binocularity observed in area 17 or normal cats. The decrease in binocularity is progressive over the first few postoperative weeks. After several months some recovery does occur.

230.11 BINOCULAR INTERACTIONS IN CAT AREA 18 AND THE 17/18 BORDER. Jill C. Gardner and Max C. Cynader. Dept. of Psychol., Dalhousie Univ., Halifax, N. S., Canada B3H 4J1.

Visual neurons in cat area 18 and near the 17/18 border were tested for their sensitivity to stimuli presented at 7 different binocular disparities. Responses to stimuli moving in-phase (I-P: sideways) and anti-phase (A-P: toward or away from the animal) were compared across the two cortical regions.

The responses of both populations of cortical cells were similar in the following respects: highly sensitive cells were usually found in the supragranular layers and were strongly direction selective. They were driven well through only one eye (ocular dominance (OD) groups 1, 2, 6 and 7) or responded exclusively to binocular and not to monocular stimulation. Non-specific cells were distributed throughout the cortical layers, could be driven well through either eye (OD groups 3, 4 and 5) and were relatively less sensitive to the direction of stimulus motion. Units strongly dominated by one eye showed direction selective inhibition from the non-dominant eye which produced large inhibitory interactions to I-P movement. Sensitivity to binocular disparity was thus greater for stimuli moving I-P than A-P. The degree of binocular facilitation, however, was similar across both conditions.

Though both regions contained neurons with marked disparity sensitivity, units near the 17/18 border showed larger disparity-specific interactions. This difference was attributed to stronger inhibitory interactions at the 17/18 border. To determine whether the greater sensitivity of cells in this region was due to the influence of the corpus callosum, binocular interactions were examined near the intact 17/18 border of cats with large unilateral visual cortex lesions. In these cats, many of the units displayed strong binocular interactions similar to those found in normal cats, but overall, responses in lesioned animals showed reduced sensitivity to binocular disparity. There was a decrease in strenth of the inhibitory component of the response to both I-P and A-P movement and an increase in the number of cells which showed little or no disparity tuning.

These data suggest that the projection of the corpus callosum to the cat 17/18 border has a significant effect on binocular visual responses. Interruption of the callosal pathway with unilateral visual cortex lesions had no effect on facilitory responses but produced a clear reduction in the strength of inhibitory interactions. The callosal pathway thus appears to have an important influence on the inhibitory networks underlying the disparity-sensitive response of visual neurons. 230.12 NEURONS SENSITIVE TO DYNAMIC RANDOM-DOT STEREOGRAMS IN AREAS 17 AND 18 OF RHESUS MONKEY CORTEX. G.F. Poggio, Dept. of Physiology, Johns Hopkins Medical School, Baltimore, MD 21205.

The results of recent experiments in alert, visually active macaques using contrast bar stimuli have confirmed the existance in visual cortex of neurons sensitive to standing binocular disparity, and have indicated that mechanisms processing stereoscopic information are present at early stages of binocular interaction in the visual pathways. Although these findings show that positional disparity influences the neuron's response, they do not provide conclusive evidence that disparity alone is sufficient to evoke it and thus leave undetermined the role of these neurons in mechanisms of stereoscopic depth perception. In order to obtain a better understanding of the functional significance of disparity sensitive neurons in A17 & A18, experiments were performed in alert rhesus monkeys in which the disparity sensitivity of cortical neurons was tested with two stimulus configurations. Visual patterns were generated on paired CRT screens using a dot matrix display and presented dichoptically moving or stationary over the neuron's receptive field while the animal steadily fixated a small target. Firstly, binocular disparity sensitivity was assessed with a luminous solid bar figure of selected size and orientation appearing over a background of dynamic noise of lower dot density, at a series of crossed, zero and uncrossed disparities. Secondly, the neuron's sensitivity was tested with pure disparity stereograms: the density difference between figure and background was eliminated; the figure, now embedded in the ground, was no longer present monocularly and the only remaining basis for the neuron's response to the figure, was binocular positional disparity (Julesz, 1971). Preliminary results show that many cortical neurons that respond to disparate contrast stimuli also respond quite selectively, and usually in the same qualitative fashion, to dynamic random-dot stereograms over the same disparity range. All types of stereoscopic neurons we had previously observed - Tuned excitatory, Tuned inhibitory, Near and Far (Poggio and Fischer, 1977) - were found to be sensitive to pure disparity stimuli. For any one neuron, the binocular response to random-dot patterns is usually weaker than the response to contrast figures, but several neurons were encountered that gave equally strong responses to both. Also, the latency of the response to noise patterns is commonly two to three times longer than the latency of the response to solid figures. These observations provide evidence that there are neurons in A17 & A18 of the macaque cortex that are sensitive purely to binocular positional disparity, and suggest that these neurons are part of basic cortical mechanisms of binocular depth perception. (Supported by NIH Grant EY02966).

230.13 CHOLINESTERASE POSITIVE ACTIVITY FOUND IN NEURONS OF THE BASAL FOREBRAIN THAT PROJECT TO VISUAL CORTEX IN THE GREY SQUIRREL (Sciurus carolinensis). Richard Rieck* and Harry J. Gould, III. Dept. Anat., Univ. Cincinnati College of Medicine, Cincinnati, Ohio 45267.

Direct connections between the basal forebrain and the visual cortex were studied in the grey squirrel using horseradish peroxidase (HRP) and acetylcholinesterase (AChE) histochemistry. Discrete pressure injections of HRP were made in the visual cortices of the grey squirrel. Following a three day survival each animal was perfused and the brain was cut perpendicular to the long axis of the cerebral hemispheres.

Neurons of the basal forebrain that were labelled with HRP were observed in both the vertical and horizontal limbs of the diagonal band of Broca (DBB), the lateral preoptic area (LPOA) and the caudal sublenticular substantia innominata (SI). An analysis of cell sizes in the DBB, LPOA, and SI revealed a population of large labelled neurons that project to cortex in addition to the smaller non-labelled neurons in each region. Groups of large neurons in the basal forebrain also demonstrated cholinesterase activity following processing for AChE histochemistry. Double labelling with HRP and AChE histochemical techniques confirmed that the neurons projecting to neocortex from the DBB, LPOA and SI form a component of the cholinesterase positive population of neurons.

Previous double labelling studies have demonstrated that AChE positive neurons of the basal forebrain project to premotor cortex (Hardy, et al., Neurosci. Let., 3:1, 1976; Mesulam and Van Hoesen, Br. Res., 109:152, 1976). From the results of the present study, we conclude that AChE positive neurons of the basal forebrain also give rise to a projection to primary visual cortex.

230.14 ACTIVE DIRECTED GAZE CONTROLS THE EXCITABILITY OF THE LIGHT SENSITIVE NEURONS OF THE INFERIOR PARIETAL LOBULE IN THE WAKING MONKEY. B. C. Motter* and V. B. Mountcastle, The Johns Hopkins University School of Medicine, Baltimore, Md., 21205.

The response fields of light sensitive neurons of the inferior parietal lobule (area 7) may cover large parts of both halves of the visual field, but commonly exempt a central zone of 2-4° radius. This "foveal sparing" and the remarkable sensitivity to extrafoveal stimuli during target fixation may both be due to a precise connectivity linking retina and parietal lobe of the cerebral cortex; alternatively, they may be controlled dynamicly by the act of fixation with or without attention. We tested these alternatives by examining the sensitivity of parietal cells to light stimuli in three behavioral states: (1) during attentive fixation of a luminous target in the detection-reaction time task; (2) during eye pauses in the intertrial interval, as the animal awaited the onset of the target light initiating a new trial; and, (3) during eye pauses in behaviorally quiescent periods when the animal was not engaged in any task.

The receptive fields and response patterns were determined for conditions (1) and (2) simultaneously. For condition (2) the stimulus was the appearance of the fixation target initiating a new trial. This new target, physically identical to the test stimuli of (1), usually evoked an on-to-target saccade, which we take to indicate an attentive state, but one that differs from that of condition (1), in which the animal attentively awaited the dimming of the target light.

Visually evoked responses for the majority of neurons were reduced or absent during the intertrial interval of (2), as compared with those evoked from the same retinal areas by identi cal stimuli during the intratrial interval of (1). When the animal sat quietly, performing no task and attending to no target (3), the stimuli appearing within previously defined response fields were ineffective for many cells, and evoked diminished responses in others. Test lights appearing coincident with the instantaneous line of gaze were ineffective stimuli for the majority of cells, under all three behavioral conditions.

The results indicate that the act of fixation accompanied by directed attention to a particular target facilitates the response of parietal light sensitive neurons to stimuli in their non-foveal receptive fields. Whether foveal sparing is due to a dynamic suppression of responses to foveal lights, or to a precise connectivity alone, is unknown. (Supported by USPHS Grant 5-RO-1-EY03167-02).

230.15 THE DIRECTION OF GAZE INFLUENCES THE RESPONSE OF MANY LIGHT SENSITIVE NEURONS OF THE INFERIOR PARIETAL LOBULE (AREA 7) IN WAKING MONKEYS. R. A. Andersen and V. B. Mountcastle, The Johns Hopkins Un. School of Medicine, Baltimore, Md., 21205.

The properties of many light sensitive cells of the inferior parietal lobule are influenced by the direction of gaze. Thus light stimuli delivered to retinotopically similar points in their response areas produce different responses for different angles of gaze, with the head fixed, even though the response areas are oriented in retinal coordinates.

This effect was studied in two behavioral states. In state 1, light sensitivity was tested with a projected image as the animal attentively fixated a small lighted target whose dimming he had to detect for liquid reward. A difference in the response as a function of line of gaze was found for both stationary and moving stimuli, and was observed unchanged in darkness. In state 2, the animal sat awaiting the appearance of a target light indicating the onset of a behavioral trial. When the target light appeared within the previously established response area of the neuron, the magnitude of the response evoked by it varied with the instan taneous line of gaze at the moment of light onset; the response could vary from maximum to none with a gaze change of 20°. The results indicate that the influence of the line of gaze upon the excitability of the system linking retina and parietal cortex exists both for attentive fixation of a target, and for the eye pauses that occur during the intertrial intervals.

A smaller group of light sensitive cells of the parietal cortex is also active during fixation into a restricted region of space. The response areas of these cells are also oriented in retinotopic coordinates; their gaze fields generally lie in the area in space occupied by the response area when the eyes are in neutral position. Many are vigorously active during slow pursuit movements, when those movements are made within the gaze field of the cell; the excitatory directions are usually identical for tracking and light stimuli. Many of these more complex cells respond differentially with different angles of gaze, as described above.

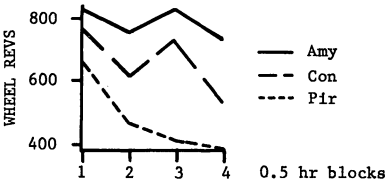
The spatial attribute of the influence of the angle of gaze upon the responses of light sensitive cells, as well as the properties of the smaller group of cells with complex properties, suggest that area 7 contributes to neural mechanisms important for spatial orientation and perception. This idea is consistent with the defects in spatial perception that follow parietal lobe lesions in monkeys and in humans. (Supported by USPHS Grant 5-RO-1-EY03167-02).

231.1 RECIPROCITY OF AMYGDALOID AND PIRIFORM MODULATION OF ACTIVITY IN HYPERACTIVE RATS. Irwin N. Lourie* and Michael M. Krieger* (SPON: Nagendran S. Thampi). Res. Dept., Norristown State Hospital, Norristown, PA 19401.

Sprague-Dawley derived rats (n=18) inbred for hyperactivity using running wheel measures for 26 generations were run for 16 consecutive days in an ad lib access, 12 hr light/dark paradigm. The subjects were then divided into 3 equal groups based on total activity and acquisition rate criteria. Group one received a radiofrequency generated lesion directed at the center of the Amygdala (Amy). Group two received a similar lesion directed at the lateral adjacent piriform cortical area (Pir) and the third group served as a sham operated control (Con). After 16 days of recovery the following experimental program was followed: 1 - Reacquisition to ad lib wheel running (RAW) for 16 days in which daily total activity as well as consecutive 15 min samples during the dark cycle were collected; 2 - A 2 hr forced running paradigm (FR2) run for 2 days in which animals were placed in closed off wheels during the light cycle with 30 min and total time data collected.

There are three constellations of RAW effects: initial rates, maximum activity and dark cycle patterns. Amy and Pir show a tripling and doubling respectively of initial rates up to day 5 after which their rates rapidly dissipate and maximal activity tends to be depressed in the lesioned groups. Each group can be distinguished by its dark cycle patterns with controls peaking at 3, 6 and 9 hrs. Amy shows activation at end of 12 hr cycle and Pir at the beginning. FR2 data shows a distinct and opposite lesion effect. This is shown in the accompanying graph.

There are two known influences on the expression of RAW rates, circadian and estral. These apparently have little influence on FR2 behavior. A possible explanation for these effects lies in the dual olfactory system which has been demonstrated by Raisman (Exp. Brain Res. 14:395, 1972) in which the main and accessory olfactory traits can be distinguished by projections to Pir and Amy respectively. These experiments demonstrate that these systems may also be characterized by differences in their excitatory or inhibitory influences on short term hyperactive behavior.



231.2 UNIT ACTIVITY OF TRIGEMINAL GANGLION NEURONS RECORDED DURING JAW OPENING AND CLOSING. N. F. Capra and G. B. Gatipon. Departments of Anatomy and Pharmacology, University of Mississippi Medical Center, Jackson, Ms 39216.

The identification of temporomandibular joint (TMJ) afferents, in cats with perikarya located in caudal and lateral regions of the trigeminal ganglion, (Romfh et al. 1979), prompted an electrophysiological investigation of the functional properties of neurons in this area. Cats were prepared for surgery under Halothane anesthesia. After placement in a stereotaxic apparatus, each cat was immobilized with Pavulon and was artifically respirated. Prerecording surgery consisted of precollicular decerebration and removal of restricted portions of the left cerebral hemisphere to expose the left trigeminal ganglion. A small portion of the bony tentorium was then removed and the dura investing the ganglion was incised.

A stepping motor was attached to the right mandible via a short metal rod, so that movements of the motor produced small angular deviations of the jaw. The motor was activated by a stimulator which also triggered an oscilloscope. In this manner, unit activity could be directly correlated with jaw movements which occured during a single sweep of the oscilloscope. An effort was made to identify somesthetic receptive fields for those neurons encountered in a single electrode penetration that did not respond to jaw movements. Action potentials recorded from glass or metal microelectrodes were amplified, displayed on an oscilloscope, and channeled to a window discriminator. The discriminator produced a square wave pulse for each action potential and the pulses were recorded on magnetic tape for subsequent analysis.

Three classes of neurons responsive to jaw movements can be described on the basis of data obtained from twenty-five units. Included are: (1) cells that responded to jaw closing movements (9 units); (2) cells responsive to jaw opening movements (5 units); and cells that were sensitive to both opening and closing of the jaw (5 units). The remaining cells were activated by tooth contact, probing of the oral mucosa, cutaneous stimulation near the mandible and TMJ region, or manually induced medio-lateral movements of the jaw. Several of the units that responded to movements were also activated by tactile stimuli.

The results of the present report suggest that a population of neuronal perikarya located in the caudal and lateral region of the trigeminal ganglion are capable of coding neural information related to changes in jaw position and that some of these neurons can also be activated by low threshold mechanoreceptors located outside the TMJ.

231.3 MOTONEURON EXCITABILITY CHANGES BY DESENSITIZATION OF CUTANEOUS RECEPTORS. M.A. Sabbahi, C.J. De Luca and W.R. Powers*. Dept. of Health Sciences, Boston Univ., Boston, and Liberty Mutual Research Center, Hopkinton, MA.

H-reflex recovery curves have been used clinically as a measure of the excitability of the motoneuron pool. However, interpretation of these curves is difficult because of the unknown factors involved in the primary inhibition period and recovery period. In this study desensitization of different skin areas and dermatomes was investigated to determine its effect on the recovery of the motoneuron pool of the soleus muscle.

Experiments were performed on 53 adult normal subjects. The H-reflex was elicited by stimulating the posterior tibial nerve unifocally using one millisecond pulses every five seconds, while recording the soleus evoked response with surface electrodes. Recovery of the motoneuron pool was tested using identical pairs of stimuli with variable interstimulus intervals. Topical anesthesia (20% Benzocaine) was sprayed separately to the skin areas overlying the calf, tibialis anterior, quadriceps, or hamstring muscles. In three subjects the total skin area of the lower limb was sprayed. In another group, topical anesthesia was applied to either L2, L3, L4, L5, S1 or S2 dermatomes and the H-reflex recovery curve was studied at 15 and 30 min. intervals.

The amplitude of the H-reflex was significantly ($p<0.001$) facilitated after anesthesia was applied to different skin areas and dermatomes, except those of the anterior tibial skin area and S1 dermatome. In those cases where the amplitude of the H-reflex was significantly increased after the application of anesthesia, the initial recovery occurred 10-80 msec. earlier than when no anesthesia was applied. This had no correlation with the skin area or dermatome desensitized by the anesthesia. The primary inhibition period continuously decreased after the application of anesthesia. After the initial recovery was obtained the amplitude of the test H-reflex recovered faster post-anesthesia. When the total skin areas of the lower limb were desensitized no summation effect on the recovery cycle was noticed.

From these results, it is possible to speculate that cutaneous afferents input may be an important inhibitory factor influencing the excitability of the motoneuron pool, as measured by the H-reflex recovery curve.

231.4 FICTIVE SCRATCH REFLEX IN TURTLE: POSTSYNAPTIC POTENTIALS IN MOTOR NEURONS. Paul S.G. Stein, Margaret L. Grossman*, Joel A. Berenbeim*, and Paul R. Lennard. Department of Biology, Washington University, St. Louis, MO 63130.

A low-spinal turtle will produce a scratch reflex in response to gentle mechanical stimulation of the shell (Valk-Fai and Crowe, J. Comp. Physiol. 125:351,1978). The motor neuron activity patterns characteristic of this reflex can also be produced after the preparation is immobilized with the neuromuscular blocking agent, Flaxedil (Stein and Grossman, Soc. Neurosci. Abstr. 5:497,1979). Since these motor patterns are produced in the absence of a "real" movement, they are termed a "fictive" scratch reflex (Berkinblit et al., J. Neurophysiol. 41:1040,1978).

The fictive scratch reflex in turtle is composed of an A phase in which knee extensor (KE) motor neurons (MNs) are active and a B phase in which hip retractor-knee flexor (HR-KF) MNs are active. The KE MNs active near the onset of the A phase are termed A1 MNs and those KE MNs which begin activity late in the A phase are termed A2 MNs. Microelectrodes filled with 4M KAc were utilized to obtain intracellular recordings from A1, A2, and B MNs. The A MNs were identified by their antidromic action potential (AP) in response to stimulation of the nerve to the KE musculature; the B MNs were identified by their antidromic APs in response to stimulation of the nerve to the HR-KF musculature.

During the early portion of the A phase A1 MNs depolarized and discharged APs, and B MNs hyperpolarized. During the late portion of the A phase A1 MNs shifted from depolarization to hyperpolarization, A2 MNs discharged APs, and B MNs shifted from hyperpolarization to depolarization. During the B phase the A1 MNs were hyperpolarized, and the B MNs were depolarized and discharged APs. The trajectory of membrane voltage in the A1 MNs was opposite that of the B MNs, i.e., depolarization in one MN type was co-active with hyperpolarization of the other MN type.

These data suggest that the following synergies exist within the scratch generator: interneurons which depolarize A1 MNs are co-active with interneurons which hyperpolarize B MNs, and interneurons which depolarize B MNs are co-active with interneurons which hyperpolarize A1 MNs.

231.5 NEUROLOGICAL DEFICITS FOLLOWING POSTARCUATE LESIONS IN MONKEYS. G. Rizzolatti*, M. Matelli* and G. Pavesi* (SPON: J. M. Sprague). Istituto di Fisiologia Umana, Universita di Parma, 43100 Parma (Italy).

We reported previously (Exp.Brain Res., 36:R19, 1979) that neurons in the posterior bank of the arcuate sulcus (inferior limb) can be driven by somatic, or by somatic and visual stimuli (bimodal neurons). Bimodal neurons respond to visual stimuli presented in the peripersonal space of the animal and their visual receptive fields are spatially related to the tactile fields.

In the present experiment we examined the deficits following lesions of the postarcuate cortex in three monkeys (Macaca irus). In two monkeys (S1 and S2) small unilateral lesions were made in the postarcuate cortex where mouth and peribuccal space are represented; in the third (L1) the whole posterior bank of the arcuate sulcus was ablated unilaterally; the same lesion was made in S1 contralateral to the first ablation, one month later. After the operation, S1 and S2 did not show any obvious sensorial or motor deficits except for a tendency of S2 to use the hand ipsilateral to the lesion. When examined in the primate chair it appeared that stimuli touching the face or presented near it on the contralateral side were responded to slowly and did not elicit the normal mouth and face movements. This defect, although reduced (especially in S1), was still present 4 weeks after the operation. Neurological deficits were more severe in L1 and S1 (second ablation). These animals did not use the contralateral limbs in "voluntary" movements, and, in "automatic" movements, they moved without normal dexterity. Head and eyes were deviated ipsilaterally (very slightly in S1). The animals were poorly responsive to tactile and nociceptive stimuli applied to contralateral parts of the body and did not show any clear sign of emotion during the stimulation. L1 neglected visual stimuli in the contralateral hemifield and particularly those presented in the peripersonal space. S1 had only a neglect for these last stimuli. Ipsilateral deviation of the head and the eyes disappeared after a few days; the other deficits, although less severe, were present one month after surgery.

We have previously proposed that neurons in postarcuate cortex elaborate somatic and visual information from the peripersonal space in order to organize patterns of movements. The results of the experiments with small lesions are consistent with this idea. However, the deficits following large lesions suggest that the postarcuate cortex is not only involved in organization of movement but also in perception of stimuli from contralateral side of the body and contralateral peripersonal space. Aided by NIH Grant 2 RO1 EY00577.

231.6 THE EFFECTS OF CORTICAL LESIONS ON VISUAL GUIDANCE OF THE HAND. S. Buchbinder*, B. Dixon*, Y. W. Hwang*, J. G. May* and M. Glickstein. Walter S. Hunter Lab. of Psychology, Brown University, Providence, RI 02912.

We have been studying performance of monkeys with cortical lesions on a task which requires precise orientation of the wrist and fingers, under visual guidance (Haaxma and Kuypers, Brain 98, 1975) in order to analyze which neural pathways may be involved.

In two monkeys, two-stage lesions were made in extrastriate visual areas that project to the pontine nuclei (Glickstein, et al., J. Comp. Neurol., in press). The lesions included both banks of the superior temporal sulcus medial to its confluence with the lateral fissure, the gyrus between these two fissures, and the anterior bank of the parieto-occipital fissure. In three out of four cases, this lesion produced irreversible loss of the animals' ability to guide visually wrist and finger movements of the contralateral hand. In one case, the first operation failed to produce a permanent impairment in the contralateral hand which we believe to be due to an incomplete lesion. Both animals were within normal limits on visual discrimination learning, and both could still use their fingers in a precision grip under tactile control. In one case, the second lesion not only caused impairment in the guidance of the contralateral hand, but further impaired performance with the hand ipsilateral to the second lesion.

In two cases, control lesions were made in the frontal lobe which included both banks of the arcuate fissure and the gyrus enclosed by this fissure. These frontal lesions produced only mild and transient impairment in hand use. In another control case, large bilateral lesions were made of the inferotemporal cortex which caused no deficit in visual guidance of the hand, although visual discrimination performance was impaired.

Thus, lesions which destroyed the cells which relay visual information from the cortex to cerebellum by way of the pons cause lasting impairment of visual guidance of the hand. Control lesions in inferotemporal and frontal cortex do not. The results suggest that the corticopontocerebellar pathway may be involved in visual guidance of the wrist and fingers.

231.7 DIFFERENCES BETWEEN MOTOR CORTEX PYRAMIDAL TRACT NEURONS (PTNs) AND CORTICORUBRAL NEURONS (CRNs) DURING VOLUNTARY MOVEMENT IN THE MONKEY. C. Fromm*, E.V. Evarts, and J. Kröller*. Lab. of Neurophysiology, NIMH, Bethesda, MD 20205.

Following microelectrode recordings from red nucleus (RN) (Shinoda et al., this vol.), stimulating electrodes were permanently implanted in RN (2 pairs of electrodes) and in PT (1 pair) to allow antidromic identification of 3 classes of motor cortex neurons: PTNs, CRNs and PT-CRNs (i.e., neurons with branches to both PT and RN). CRNs commonly had conduction velocities ranging from 8-20 m/s and were usually antidromically driven by the RN electrode pair which was situated at the dorsolateral boundary of the posterior parvocellular RN. The PT-CRNs belonged mostly to the fast subset of the PTN population (50-60 m/s) and were more often driven by stimulation of the RN electrode pair situated at the caudal pole of the magnocellular RN. 22 CRNs, 27 PT-CRNs and 196 PTNs were extensively studied using the same paradigm as in the prior RN recordings. In general, the low frequency irregular discharge and the rather slight changes of discharge with active movement shown by the CRNs were markedly different from the regular tonic discharge and intense movement-related modulation of the PTNs. In order to compare CRNs and PT-CRNs with PTNs in exactly the same motor cortex loci, analyses were restricted to a subgroup of 98 PTNs which had been recorded in the same 38 penetrations with the CRNs and PT-CRNs. A major difference between the 3 subsets was in their time of discharge with respect to movement onset: 90% of the PTNs changed frequency before start of the movement and 10% at or after movement, whereas only 26% of CRNs changed before movement, the remaining 74% showing changes only at or after movement onset; the PT-CRN population was intermediate. This same conclusion was reached by comparing timing of neurons within each of the individual penetrations (Ps) taken separately. For 10 Ps, PTNs clearly preceded CRNs, with only 3 Ps showing overlap and no Ps showing CRNs prior to PTNs. For 9 Ps, PTNs preceded PT-CRNs and in 8 Ps, PTNs and PT-CRNs overlapped. The 3 subgroups also differed with respect to effects of different steady state loads: whereas different loads were associated with marked changes of discharge frequency in a majority (67%) of PTNs, the effects of different loads were slight and found in only 30% of PT-CRNs and virtually absent in CRNs. Another difference was that the incidence of short (<50 ms) latency responses to passive ramp displacements was lower in the CRNs (23%) as compared to the PTNs (62%).

These findings point to clearly different functional roles for CRN and PTN outputs from motor cortex, and are consistent with the characteristics of RN discharge observed during prior RN recordings in the same monkey.

231.8 UNIT ACTIVITY IN MONKEY RED NUCLEUS DURING SKILLED MOVEMENTS. N.J. Kohlerman, A.R. Gibson and J.C. Houk. Dept. of Physiology, Northwestern Medical School, Chicago, Illinois 60611.

The rubrospinal tract is the primary component of the lateral descending motor pathway (Lawrence and Kuypers, Brain 91:15-36). Magnocellular RN neurons receive their major input from deep cerebellar nuclei as well as a projection from motor cortex. To clarify mechanisms of descending motor control, we studied response patterns of rubral units during controlled movements.

A rhesus monkey has been trained to maintain an oscilloscope trace within target boundaries. The target either steps or ramps to various positions, and the monkey must reacquire the target. Each device requires movements primarily about one joint; movements about finger, wrist, elbow or shoulder joints can be studied separately. We have collected data on 85 well isolated units in arm related areas of the red nucleus during the use of one or several of the devices. These units show increases from low resting rates (~25 spikes/sec) to rates of over 200 spikes/sec during movements. Optimal relations between movements and discharge rate are generally seen on only one device; i.e., a cell responding well to wrist rotations shows variable and weaker relations to elbow movements. Most neurons fire optimally to finger or wrist movements; only one cell was optimally related to elbow movements. On the optimal device, unit discharge is tightly locked to movement, and the units fire preferentially to either flexion or extension. Increases in neural discharge lead the movement by a consistent latency. Typical lead times are 120 ms, while some units have lead times over 200 ms, and others show leads as short as 66 ms. Latency of increase in discharge rate is well correlated (r as high as .98) with latency of movement over a reaction time range of 300 ms to several seconds. Duration of discharge increase also correlates well (r as high as .98) with duration of movement. Discharge rate correlates well (r≈.8-.9) with the velocity of movement, and the increment in the number of spikes correlates well (r≈.8-.9) with the amplitude of movement. The relation between discharge rate and velocity plots as a straight line over an approximately 10 fold range in velocity and 7 fold range in rate. No tonic discharges relating to holding position have been observed, nor are there any changes in tonic discharge when the devices are force loaded.

Our data suggest that, in arm related areas of red nucleus, unit discharges are command signals for movement about finger, wrist or elbow joints. Work by other investigators suggest that these signals are generated in the cerebellum, although the relative contributions of cerebellar and cortical inputs to the red nucleus remains to be clarified.

Supported by NIH grant # 5R01NS14703-02.

231.9 ACTIVITY OF ZONA INCERTA NEURONS IN THE BEHAVING PRIMATE.
M.D. Crutcher, M.H. Branch*, M.R. DeLong and A.P. Georgopoulos.
Dept. of Physiology, Johns Hopkins School of Medicine, Baltimore, Md. 21205

The functional properties of neurons in the Zona Incerta (ZI) were examined during the course of studies in the subthalamic region of the primate. 75 ZI neurons were isolated in 35 histologically verified penetrations in 3 rhesus monkeys. Their responses to active movements and "passive manipulations" of the limbs were examined. 29 neurons (39%) were related to arm, 8 (11%) to leg, and 13 (17%) to orofacial movements, and 6 (8%) to visual stimuli or eye movements. The remaining 19 (25%) neurons were not clearly related to movement or to visual or somatic stimulation. Of the 37 neurons related to limb movements 3 (8%) were clearly modulated by passive manipulations; only three of the neurons related to arm movements were related to finger, wrist or elbow movements. A striking finding of this study was the large proportion of neurons (18/75) which were activated when the animal reached for objects of interest. Cells within single or adjacent penetrations often showed similar functional properties. This clustering of neurons with similar properties suggests the possibility of a somatotopic organization, but the limited number of neurons studied precludes an immediate resolution of this issue.

The activity of ZI cells related to arm movements was also studied during the performance of a visuomotor tracking task in which the monkey was required to follow a visual target with side-to-side movements of the arm. The manipulandum was a lightweight handle which the animal could grasp and move along a horizontal path. The display consisted of 2 rows of light emitting diodes. The upper row indicated the position of the target and the lower the position of the handle. The animals first held in a starting position for at least 1 sec., and then made step movements in response to a sudden jump of the target lamp to a new position. Animals performed this task using mainly forearm musculature. Of 23 neurons studied 11 (48%) were clearly related to task performance; 5 (22%) showed directional effects. Nine neurons were clearly related to arm movements outside the context of the task, but were not active within the the task. The preferential activation of a subset of ZI neurons during reaching suggests an involvement of this structure in projection movements of the limbs into extrapersonal space. The results of this study together with the fact that ZI is a target of cerebellar projections indicate that ZI participates in motor function. Its exact role in motor control remains to be elucidated.

231.10 WHAT IS THE ROLE OF VESTIBULAR INPUTS IN POSTURE CONTROL?
F.O. Black[1], L.M. Nashner[2] and C. Wall III, Neurological Sci. Inst., Portland, OR 97209 and Div. Vestibular Disorders, Dept. Otolaryngology, Univ. of Pittsburgh School of Medicine, Eye & Ear Hospital, Pittsburgh, PA 15213.

The role of the vestibular system in the control of postural equilibrium is difficult to assess because it is probably less sensitive to body motions than are the other two sensory modalities which also provide redundant orientational information; namely, vision and somatosensation. Because vestibular inputs are not subject to the unexpected, external perturbations common within the other two modalities (e.g., motion of objects in the visual surrounds and/or motion or compliance of the supporting floor), vestibular inputs might be critically important at a higher level of control. One example of this higher control would be the adaptive reorganizing of visual and somatosensory control strategies to suit particular task conditions. This hypothesis of adaptive control has been tested by evaluating the equilibrium controls in a group of seven patients with clinically well documented vestibular deficits (but otherwise neurologically normal) during two different tasks requiring: (1) direct vestibular control of equilibrium and (2) reorganization of the somatosensory and visual controls.

Direct vestibular control was assessed while subjects stood upon a movable platform and within a movable visual surround using a technique which stabilized the rotational position of the ankle joints and of the visual surrounds.

The capability of patients to adapt to appropriately unsuspected conflicts between visual and somatosensory inputs was assessed by transiently moving the platform and/or visual surrounds.

Patients with complete loss of vestibular inputs were unstable during the task requiring direct vestibular control and were also unable to adapt appropriately during visual-somatosensory conflicts (although adaptive changes were clearly evident). Patients with partial vestibular lesions, while still able to stabilize when direct vestibular controls were required, demonstrated clear deficits in their ability to adapt appropriately during sensory conflicts. Some of these patients chose a highly adaptive (but often inappropriate) strategy of control, while others maintained a fixed strategy.

231.11 ANALYSIS OF DISCHARGE PATTERNS OF SINGLE HYPOGLOSSAL NERVE FIBER DURING HYPERCAPNIA AND HYPOXIA. J. Mitra.
Case Western Reserve University, Cleveland, Ohio.

Recent studies have indicated that the integrated electrical activity of the hypoglossal nerve has both phasic and tonic activity. The phasic activity is curvilinearly related to phrenic nerve activity during hypercapnia and hypoxia (Weiner et al. FASEB Abst. 1980; ATS Abst. 1980). The purpose of the present study was to investigate the effects of CO_2 and low O_2 on the behaviour of single hypoglossal motoneuron. The study was done on chloralose anesthetized cats. We found three types of discharge patterns during eupnea. Type I - low CO_2 threshold respiratory modulated phasic units. Type II - non phasic with higher threshold for CO_2 and hypoxia. Fibers of this group showed respiratory modulation at higher CO_2 level and hypoxia. Type III - non phasic and did not show respiratory modulation at any of the levels of CO_2 (6 to 10%) and hypoxia (12% O_2) we studied and remained so throughout the experiment. These fibers increased discharge rate progressively with increase in CO_2 level or hypoxia.

It seems to us that the curvilinear relationship of hypoglossal activity is due to involvement of Type I and Type II fibers. The tonic activity may be due to Type III fibers.

232.1 DEVELOPMENT OF SYNAPTIC EFFICACY AT AN IDENTIFIED MOLLUSCAN SYNAPSE. Peter A. Pawson and Ronald Chase. Dept. Biology, McGill Univ., Montréal, Que., H3A 1B1.

The terrestrial snail Achatina fulica produces large clutches of eggs (>100) which hatch synchronously. The large size of the embryos permits the early identification of individual neurones by unique electrophysiological and morphological criteria. We have taken advantage of these conditions to study the development of a monosynaptic chemical synapse between two giant neurones located in the sub-oesophageal ganglia. The transmission was studied by intracellular stimulation of the pre-synaptic neurone (V2) while simultaneously recording the evoked EPSPs in the post-synaptic cell (RPr1). The period of analysis extended from late embryonic stages (pre-hatching) to sexual maturity (7 months).

We examined the passive membrane properties of the post-synaptic cell to determine whether developmental changes in these properties might contribute to a perceived change in synaptic efficacy. The I-V plot exhibits the same degree of linearity through out the period of study. A semi-log plot of the cell's input resistance vs. age shows a linear decline over the same period. Spontaneous EPSPs in young RPr1 neurones are faster rising and have larger amplitudes, indicating less electrotonic attenuation of synaptic potentials in younger animals. This property is shared by the V2-RPr1 EPSP, i.e. it has a faster rise-time and shorter half-width in young snails.

During the initial weeks post-hatching, transmission at the V2-RPr1 synapse is characterized by the frequent absence of evokeable EPSPs, even in high Ca^{++} and low Mg^{++} Ringers, or when using a stimulus frequency (0.2Hz) which produces marked facilitation of the EPSP in older animals. The absence of the evoked EPSP cannot be accounted for by RPr1's passive properties, as the synapse is electrically closer at this stage. At later times, when the EPSP is readily elicited at a low frequency (0.02Hz) of stimulation, the most prominent change is a progressive increase in the degree of frequency dependent facilitation.

We performed a quantal analysis on the developing synapse to determine pre- and post-synaptic contributions to the changes in synaptic efficacy. Values for quantal content (M) and quantal size (Q) were determined from amplitude histograms of the evoked EPSPs, from an analysis of failures and from an analysis of variance of the EPSPs. Q shows a 4-fold decrease from the time of hatching to 6 months of age, paralleling in order of magnitude and time course the decline in RPr1's input resistance. M shows a progressive, several-fold increase with age; especially in terms of the facilitated quantal content. The results demonstrate a developmental increase in efficacy at a specific chemical synapse, due mainly to changes in pre-synaptic release.

232.2 DEVELOPMENT OF SYNAPTIC PLASTICITY: THE EMERGENCE OF POST-TETANIC POTENTIATION AT IDENTIFIED SYNAPSES IN APLYSIA. H. Ohmori* and S.G. Rayport. Division of Neurobiology & Behavior, Depts. Physiology & Psychiatry, Columbia University, P & S, New York, N.Y. 10032.

Despite the extensive information now available on synapse formation, little is known about the development of synaptic plasticity. As part of a larger study designed to investigate the ontogeny of various forms of plasticity in Aplysia, we have begun to analyze the emergence of post-tetanic potentiation (PTP) in the inhibitory synapses made by cholinergic cell L10 onto its follower cells and of the excitatory postsynaptic potential onto R15 (RC1-R15) resulting from threshold stimulation of the right connective (Frazier et al., 67; Barondes et al., 77).

We first examined PTP by looking at the inhibitory synapses L10 makes onto left-upper-quadrant cells in animals ranging from 2 milligram juveniles (stage 11) to 300 gram adults (stage 13). An L10 spike was evoked every 5 sec until a stable control PSP was achieved, then L10 was stimulated at 5 hz for 30 sec. The amount of PTP was measured as per cent increase of the post-tetanus PSP over control. In early stage 11 there was no PTP (98 $\pm$ 11%) even though the synaptic connection was present and produced a significant PSP of 11.3 $\pm$ 7.3 mV with the membrane hyperpolarized 50 mV below the PSP reversal potential. PTP first appeared in late stage 11 and gradually increased until it reached a maximum of 230 $\pm$ 60% in stage 12 animals.

As PTP developed, the synapse itself became functionally less effective although it increased in size. In early stage 11, the input impedance of the postsynaptic cells was 270 $\pm$ 60 MΩ ; it decreased by a factor of 40, to 7.2 $\pm$ 3.3 MΩ in stage 13 adults. Over the same developmental range, the amplitude of the control PSP decreased about 3-fold (from 11.3 $\pm$ 7.3 to 3.6 $\pm$ 2.7 mV), suggesting that the synaptic current (the ratio of the control PSP to the input impedance of the follower cell) increased about 12 times during this phase of development.

We next investigated the development of PTP in the RC1-R15 connection and found that PTP emerges here synchronously with that in the L10 synapses and has an essentially similar developmental program.

Although we do not know when in development these synapses first form, synapse formation long precedes the emergence of plasticity in both synapses. Indeed, the complete expression of the phenotype of these synapses emerges in several developmental steps that extend over a number of weeks and encompass a significant portion of the total time of the animal's development, about 50 of 120 days. Thus there is a discrete interval when synaptic transmission is well developed but not capable of modulation by activity and this implies that the mechanisms underlying PTP are distinct from those involved in synapse formation.

232.3 INNERVATION OF ANTENNAE AND LEGS IN DROSOPHILA: WILD-TYPE AND HOMEOTIC MUTANTS. S. Green* (SPON: R. Greenspan) Div. of Biol., Calif. Inst. Technol., Pasadena, CA 91125

Homeotic mutations transform one appendage into another. The innervation of such appendages is compared with the wild-type in order to study: (1) How does the afferent projection select its targets in the CNS? (2) How does CNS development depend on an appropriate afferent projection? (3) Is position in the CNS determined by the same sets of genes that determine position in other tissues?

The mutation spineless-aristapedia (ss^a) transforms distal antenna to tarsus. Filling neurons with cobalt from wild-type and transformed antennae, I find that the projections are identical in spite of the fact that the tarsus contains different types of sensillae than antennae. This is all the more striking considering the extreme dissimilarity between the simple tarsal sensory projection to the thoracic ganglion and the complex antennal projection to the brain. The mutation antennaless removes one or both antennae. The morphology of brains from ss^a and antennaless flies appears wild-type in silver stained preparations.

HRP fills from each of the three different legs gives a characteristic pattern of motorneurons and sensory axons in the thoracic ganglion. The abdominal legs caused by the mutation bithoraxoid send their afferents into the CNS along an abdominal nerve or, occasionally, along the metathoracic (third) leg nerve. In either case, sensory neuropil of the metathoracic neuromere is the target but the precise pattern depends on the route taken. Occasionally metathoracic leg motorneurons innervate these abdominal legs, initially taking a 'normal' route through the metathoracic leg nerve. Results from bithoraxoid and ss^a suggest that the sensory neurons are largely guided to the vicinity of their targets by their path and will make functionally appropriate connections only if brought to close proximity with the target.

Mutations in the bithorax genes (BX) affect position determination in the thorax and abdomen. The combination of BX genes we use transforms metathorax to mesothorax. The motorneurons of the metathoracic neuromere of these animals resemble those of the wild-type mesothorax in morphology and relative position. Therefore, position in the nervous system, the cuticle, and possibly the mesoderm as well is determined in parallel by this set of genes.

232.4 REORGANIZATION OF THE MOTH NERVOUS SYSTEM DURING METAMORPHOSIS. R.B. Levine and J.W. Truman Dept. of Zoology, Univ. of Washington, Seattle, WA. 98195

During metamorphosis the holometabolous insects undergo significant changes in morphology and behavior. The nervous systems of these insects must adapt accordingly. In an investigation of this process we have focused on the motor neurons innervating the abdominal musculature of Manduca sexta. The intersegmental muscles of the abdomen are of embryonic origin and persist throughout larval, pupal, and early adult stages. They are innervated by the same excitatory motor neurons at all stages. The basic dendritic morphology of these motor neurons changes very little during metamorphosis, although there is a slight increase in the extent of dendritic branching. Other larval muscles degenerate at the onset of pupation. Of the motor neurons which innervate them, some degenerate during the pupal stage, while others are maintained and later innervate newly-generated adult muscles. The dendrites of motor neurons in the latter group undergo significant structural reorganization during pupation.

The motor neurons, including those undergoing dendritic reorganization, continue to be electrically excitable and to receive synaptic inputs throughout metamorphosis. Some inputs are maintained throughout post-embryonic life. One is from abdominal stretch receptors. These sensory neurons excite ipsilateral motor neurons monosynaptically, and inhibit contralateral motor neurons through a polysynaptic pathway. Other sources of innervation are present for only part of the insect's life in accordance with the different behaviors in which the motor neurons participate at different stages. An example is the excitation derived by the intersegmental motor neurons from sensory hairs embedded in the cuticular "gin traps". This polysynaptic pathway mediates a pupal-specific defensive behavior(Bate, 1973). Thus while much of the abdominal nervous system is conserved during metamorphosis, new elements are added to the basic framework. All of the motor neurons present in the adult were also present and functional in the larva, although some have been respecified. Some aspects of neuronal circuitry remain constant, while other pathways are unique to a particular stage in the animal's life.

232.5 EXPERIMENTAL ANALYSIS OF A SOMATOTOPIC MAP IN THE CRICKET NERVOUS SYSTEM. R.K. Murphey and S. Johnson*. Dept. of Biol. Sci. SUNY Albany, Albany, N.Y. 12222.

Last year in this space I demonstrated the existence of a somatotopic map between the peripheral and central nervous system (CNS) of crickets. We have now stained most of the sensory neurons in this equilibrium detecting system with cobalt. These studies have demonstrated that the position of the terminal arborization in the CNS is a joint function of the position of the sensory cell body on the circumference of the cercus and its proximo-distal position on the cercus. The receptors are arranged in columns running proximo-distally on the cone-shaped cercal appendage. All of the sensory neurons within a column have similar axon trajectories and similar target regions in the CNS. For example, a neuron (#60) in one column enters the ganglion medially in the cercal nerve and terminates in ventro-medial neuropile. All the neurons in this column terminate in this same ventro-medial area of neuropile.

We have begun our analysis of the rules by which sensory neurons find their target areas by surgically manipulating the cercus (see also Walthall and Murphey this volume). We removed the right cercus from a specimen and implanted it in the left socket of another specimen. This asks the question: How does a regenerating neuron interact with a target region which is the mirror image of its normal target? Typically the surgery altered the axon trajectory. For example a neuron which normally entered the ganglion medially entered laterally after surgery. However, this same neuron arborized in the target area appropriate for its position on the cercus. These results demonstrate first that the axon trajectory can be altered by surgery; second, that transplanted right neurons do not cross the midline to innervate their normal target area; third, in spite of the surgery a right sensory cell terminates in the area of left neuropile homologous to its normal target area. Since these sensory neurons were present before the surgical exchange, it appears that we cannot reprogram an identified neuron by merely altering the medio-lateral coordinates of its target area. Errors in the regeneration process were observed but they occurred with equal frequency in the left-to-right transplant and in the right-to-right transplant used as a control. The physiology of the postsynaptic neurons is consistent with these morphological results (Sakaguchi and Murphey, this volume). The results suggest that the developmental instructions, obtained by sensory neurons when they differentiate in the periphery, are very stable and that these insect sensory neurons do not alter their connectivity when faced with an altered set of body axes. Supported by NSF and NIH research grants to R.K.M.

232.6 BIRTH ORDER VS. POSITIONAL CUES IN THE REGENERATION OF A TOPOGRAPHIC PROJECTION IN THE CRICKET CNS. W.W. Walthall and R.K. Murphey. Dept. of Biol. Sci. SUNY Albany, Albany, N.Y. 12222.

An orderly array of clavate hairs is located at the base of the cricket cercus. These uniquely identifiable receptors are associated with single sensory neurons whose axons form a topographic projection in the terminal abdominal ganglion (Murphey, Neuroscience Abstract #841, 1979). The receptor array is organized into columns which run approximately parallel to the longitudinal axis of the cercus. All of the sensilla within a column have the same circumferential position, and their associated axons project to and terminate within approximately the same region. Yet within one of these regions the terminal projections are not evenly distributed.

The sensory neurons of the older, more distal clavate hairs project farther into the area designated by the cell's circumferential position and the younger more proximal hairs are restricted to more peripheral regions of the same area. Two possible mechanisms for this aspect of the projection pattern are time of arrival (birth order) and the sensory cell body's proximo-distal position. To distinguish between these possibilities the axons of the cercal nerve were severed, either by removing and then reimplanting the cercus, or by cutting or crushing the cercal nerve. This was done to remove any competitive advantage that older hairs might possess as a result of their early arrival in the CNS.

The morphology of single sensory axons that have regenerated their terminal arbors revealed the reconstruction of a normal projection pattern. In other words, the terminal arbor was still correlated with the cell body's position in the proximo-distal axis of the cercus. The regenerating axons are not following their old paths since they sometimes take radically different paths into the target region. Furthermore, extracellular recordings from the second order interneurons of treated animals revealed the restoration of correct physiologic connections by the regeneration process. Thus, it appears that a regenerating axon extracts important guidance cues from its cell body's proximo-distal position, and birth order or competitive interactions do not play a role in the reconstruction of this map. However, this result could be explained by differential rates of axonal regeneration, and experiments are underway in which the neurons of selected hairs will be killed and the axons of the remaining receptors subsequently forced to regenerate in the absence of neighboring hairs. Supported by NIH grant R01NS1557101 to R.K.M.

232.7 RE-ESTABLISHMENT OF FUNCTIONAL NEURONAL CONNECTIONS FOLLOWING TRANSPLANTATION OF A SENSORY APPENDAGE IN THE EQUILIBRIUM DETECTING SYSTEM OF THE CRICKET. Donald S. Sakaguchi* and R.K. Murphey (SPON: Charles Edwards). Dept. of Biol. Sci., SUNY Albany, Albany, N.Y. 12222.

The cricket (Acheta domesticus) has a pair of large bilaterally symmetrical sensory appendages at the tip of its abdomen called cerci. Peripheral sensory neurons associated with club-shaped sensilla called clavate hairs are located at the base of each cercus. The clavate sensory receptors are equilibrium detectors which signal information regarding the animal's position in the gravity field (Bischof, 1975). We have recently demonstrated that these receptors excite at least two pairs of large bilaterally symmetric interneurons (IN) whose axons can readily be recorded in the paired connectives just anterior to the genital ganglion. One of these neurons has been injected with the dye Lucifer Yellow and its cell body shown to be located at the anterior-lateral edge of the ganglion. When the specimen's position is altered from its normal up-right position, the IN are activated. Rolling the animal to its right excites the right equilibrium interneurons and simultaneously silences the left equilibrium interneurons. The complementary response occurs when the animal is rolled to its left. If the clavate hairs are immobilized with vaseline, the IN response to positional changes is blocked.

The cerci can be transplanted in various positions or orientations. If a cercus is amputated and then reimplanted in its original socket, functional and selective restoration of the original connectivity is demonstrated. When a right cercus from a donor animal is grafted onto the left socket of a host, the medio-lateral axes are reversed with respect to the body of the host. Recordings from the host IN revealed that connections were re-established with the appropriate type of IN ipsilateral to the graft. (These results corroborate the findings of Palka and Schubiger, 1975, in which they examined the cricket filiform hair system.) From the reimplantation results we conclude that regeneration in this system will re-establish normal connectivity. The right-left exchange experiments show that left equilibrium interneurons will be reinnervated by the clavate afferents from a transplanted right cercus. Physiologically the animal behaves as though it has two right cerci. This implies that mismatching axes of a sensory appendage in relation to the normal body position does not alter the resulting connectivity diagram. The sensory neuron is thus developmentally specified in such a manner that it restores functional connections with the appropriate type of interneuron despite a drastic alteration from its normal innervation pathway. Supported by NIH Grant R01NS1557101 to R.K.M.

232.8 COMPENSATORY GROWTH AND REINNERVATION OF AN AUDITORY INTERNEURON AS A CONSEQUENCE OF PARTIAL DEAFFERENTATION. Ronald R. Hoy and Sharon R. Rollins*. Section of Neurobiology & Behavior, Cornell University, Ithaca, N.Y. 14853.

In earlier studies we observed the effect of witholding auditory afferent innervation from an unique identified auditory interneuron in the prothoracic ganglion of a cricket Teleogryllus oceanicus during postembryonic development (Hoy, Casaday, &Rollins Soc. Neurosci. Abst. 4). Unilateral deprivation of innervation from auditory afferents during postembryonic development has bizzare consequences for the growth of the interneuron's dendritic field; specifically, the normally ipsilateral dendritic projection of the neuron becomes a contralateral projection, due to the aberrant growth of its medial dendrites into the contralateral half of the auditory ganglion.

The neuron, interneuron-1 (int-1),was described in Teleogryllus by Casaday & Hoy (J.Comp.Physiol. 121: 1-13, 1977) as having a unique morphology and the unusual physiological characteristic of being inhibited by 5 kHz tones; later, Moiseff & Hoy (Soc. Neurosci. Abst. 5, 1979) reported that int-1 is excited by ultrasound. These unique properties serve as a physiological "fingerprint" for its identification; thus far, int-1 is the only acoustic interneuron that we have found with these properties.

We now report that the aberrant growth of dendrites in response to unilateral deafferentation occurs even in adult animals. There is no response to acoustic stimulation from an unilaterally deafferented int-1 for about one week following amputation of the ear. However, during the second postoperative week the deafferented int-1 begins to respond to sound, with the vigor of its responses increasing over the next several weeks. Recovery of response properties occurs in the sense that the cell is inhibited by 5 kHz tones and excited by ultrasound. While the quality of the response in the reafferented neuron is normal, it does not appear to achieve the same level of excitability to ultrasound as does its contralateral, nondeprived, homologue. The restoration of the qualities of the auditory response implies that the crossover dendrites achieve a normal quality of synaptic input from the afferents of the contralateral ear. They apparently successfully compete with its nondeprived contralateral homologue for afferent innervation.

232.9 LONG TERM SURVIVAL OF ANUCLEATE GLIAL SEGMENTS DURING NERVE REGENERATION. E.J. Elliott* and K.J. Muller. Dept. of Embryology, Carnegie Institution of Washington, Baltimore, Maryland 21210.

As a first step in studying the role of glia in axon regeneration in the medicinal leech, we have studied the behavior of the glial cell itself after nerve injury. Identified neurons in segmental ganglia of the leech c.n.s. will regenerate axons severed by a crush of the connectives that link adjacent ganglia, and within one or two months will reconnect specifically with their normal targets. Crushing a connective also severs processes of the single large glial cell that ensheathes the axons of each connective, and thus divides the cell into a nucleated segment and an anucleate glial segment or stump.

We have found that the nucleated segment of glial cell remains intact, with no sign of degeneration or of cell division. Surprisingly, the anucleate stump also survives for up to a year, maintaining both its resting potential and a normal morphology as determined by e.m. examination. During this time, the glial stump remains isolated from the nucleated portion. Horseradish peroxidase injected into the stump diffuses readily within it but does not travel into the nucleated segment, indicating that the divided portions do not fuse. Nor do the stump and nucleated regions become electrically coupled, as has been shown during regeneration of some neurons in the leech. When intracellularly injected, Lucifer Yellow dye crosses between most electrically coupled neurons or glia in the leech, but does not pass between the glial stump and nucleated segment. Moreover, current injected into glial cytoplasm on one side of a crush is not detected with a nearby second intracellular electrode in glial cytoplasm on the other side of the crush. Thus, the nucleated glial segment and the anucleate glial stump remain separate but morphologically intact and physiologically normal over the time period (3-8 weeks) required for functional axonal regeneration.

After some time, which varies among animals from 2 months to over a year, the anucleate glial stump atrophies, the numerous glial filaments diminish, and electrode penetration becomes difficult. Within about 3 months the nucleated portion of the injured glial cell sends processes across the crush which ensheathe some axons. Axons are also ensheathed by processes of microglia that have invaded or proliferated within the connective and seem to be phagocytic. In an attempt to determine whether the persistence of the glial stump retards growth of the nucleated glial cell, we have begun selectively to destroy glial stumps by intracellular injection of protease. These experiments, and others in which the entire glial cell is destroyed, should also provide direct information on the role of glia in axon regeneration. (Supported in part by a National Multiple Sclerosis Society Fellowship to E.J.E. and NIH grant NS 15014.)

232.10 SELECTIVE NEURITE ATROPHY DURING DEVELOPMENT OF CELLS IN THE LEECH CNS. Bruce G. Wallace. Dept. Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305

The central nervous system of the medicinal leech consists of a chain of 21 free segmental ganglia linked together and to fused head and tail ganglia by connectives. In the adult, the morphology of several identified neurons varies from ganglion to ganglion in a characteristic fashion: the arborization of cells in ganglia near the anterior or posterior ends of the chain is more extensive than that of their homologues in centrally located ganglia. For example, an annulus erector (AE) motor neuron located in any one of the 2nd through the 17th free segmental ganglia arborizes in the neuropile of that ganglion and sends branches out each of the contralateral roots to innervate muscles in the body wall. The branching pattern is similar for the AE cell in the first free segmental ganglion, except that in addition it sends a branch rostrally through the contralateral connective into the head ganglion and out through several roots from the head ganglion to the periphery. Likewise, the AE cell in ganglia 18 sends branches caudally through the contralateral connective and innervates the body wall through roots from several more posterior ganglia.

The morphology of mechanosensory cells responding to light touch (T cells) varies in a similar way. Each T cell in ganglia from the middle of the chain regularly sends a process out one or both ipsilateral roots as well as down the anterior and posterior ipsilateral connectives and out through roots from adjacent ganglia. The arborization of cells in ganglia near the head and tail spans more than three ganglia. Thus, in addition to the normal projections, a T cell near the head innervates the skin through roots from a second more rostral ganglion, a T cell near the tail through roots from several more caudal ganglia.

The creation of this branching pattern has been investigated by injecting cells in ganglia from embryonic leeches with the fluorescent dye Lucifer Yellow. Early in development homologous cells all along the ganglionic chain have a similar morphology, more extensive than that found in the adult. For example, in every segmental ganglion, AE motor neurons send processes down both the anterior and posterior contralateral connectives. T cells all send processes into the connectives past the adjacent ganglia. During development these "extra" processes fail to increase significantly in caliber and near the end of embryogenesis they disappear. Cells in ganglia in the middle of the chain lose both the anterior and posterior branches, cells near the head lose only the posterior branches, cells near the tail only the anterior branches. In this way, a segmental gradient in the morphology of homologous cells is established during development by the selective atrophy of neurites.

232.11 ROLE OF SENSORY ACTIVITY IN BEHAVIORAL RECOVERY OF THE DIRECTIONAL ESCAPE RESPONSE IN THE COCKROACH. S.F. Volman, J.M. Camhi, and N. Vardi. Dept. of Neurobiology and Behavior, Cornell University, Ithaca N.Y. 14850

Behavioral plasticity has been demonstrated in the escape behavior of the cockroach Periplaneta americana (Vardi and Camhi, Neurosci. Abst. 1979). These insects respond to small, abrupt wind puffs by turning away from the wind source. For instance, wind from the front left normally elicits a large turn to the right. The wind is detected by a bilateral pair of abdominal appendages called cerci, and the escape response is mediated partly by a group of individually identified giant interneurons. If one cercus is ablated, or if its fine filiform hairs are chronically immobilized with Eastman 910 adhesive, the animal initially makes inappropriate turns. For example, if the left cercus is removed, the animal now responds to wind from the front left by turning to the left, toward the wind source. By about 30 days after cercal ablation or covering, the animals' turns are significantly corrected; that is, they more often turn appropriately away from a wind source on the deafferented side. This recovery is correlated with changes in the response properties of the giant interneurons.

Animals in previous experiments showed similar recovery regardless of whether one cercus had been silenced by ablation or by immobilization of the hairs. Thus we hypothesized that a long term imbalance of activity in the two cercal sensory nerves might be adequate to initiate the recovery process. To test this idea, we prepared late instar nymphs with the left cercus ablated and the right cercus covered with adhesive. Of these animals, we tested the seven individuals that molted to adulthood between 28 and 36 days after cercal treatment. The small bud that appeared at molting on the ablated side was removed immediately, as in previous experiments. The glued side now had a new, free set of filiform hairs. In the behavioral test, these animals showed no recovery of turning; that is, they performed as if they had been deafferented on the left side for one day rather than one month.

In another experiment, animals were confined individually in small plastic cups after just ablating one cercus. These cups afforded minimal ambient wind and, since there was practically no walking space, minimal relative wind. (In all other experiments, animals had been kept in large, communal cages with screened sides.) After one month, these animals had recovered significantly less than the ones kept in large cages. Another group was ablated on one side and kept in the same cups but given wind therapy (extra ambient wind) for 8-10 hr/day. After 30 days, their behavioral recovery was significantly greater than that of cockroaches in cups but without wind.

(Supported by NSF Grant #BNS 7909663)

232.12 NEURAL BASIS OF BEHAVIORAL CORRECTION FOLLOWING UNILATERAL CERCAL ABLATION IN THE COCKROACH. Noga Vardi and Jeffrey M. Camhi. Sect. Neurobiology and Behavior, Cornell Univ., Ithaca, N.Y. 14850

Cockroaches (Periplaneta americana) respond to minute wind puffs by turning away from the wind source and running. They use this wind-mediated response to escape from the strikes of natural predators. The wind receptors are filiform hairs located on the cerci — two abdominal appendages. These receptors excite 7 bilateral pairs of giant interneurons (GI's) which appear to be involved in mediating the directional motor output of the legs. If one ablates the left cercus and tests the turning behavior the next day, most of the turns are to the left, regardless of wind direction. After one month, however, the animals correct, making more right turns in response to wind from the left.

Correlated with this behavioral change we find a pronounced enhancement in the responses of 5 of the 7 left GI's one month after ablation.* The enhanced response of the left GI's is driven by receptors of the right cercus since: a) the response is eliminated after immobilizing sensory hairs on the right cercus, and b) in one group of animals we ablated the left cercus and after a month ablated the right cercus, then tested the behavior the next day. In a second group we ablated both cerci and tested the behavior on the next day. The percent of responses was low in both groups and not significantly different. This suggests that enhancement of input from non-cercal receptors had not occurred during the one month of correction.

We wished to determine whether the observed enhancement in the number of spikes in the deprived (left) GI's by itself could explain the observed behavioral correction. We recorded from the right GI's of behaviorally corrected animals. In spite of the enhancement of the left GI's, on average they gave fewer action potentials than did the right GI's in response to wind from the left. Thus the number of spikes could not by itself explain the corrected behavior. Therefore, we also investigated whether the left GI's showed recovery in terms of latency. We recorded the total spike activity of the left connective and the right connective in response to wind puffs from the left front, using two pairs of hook electrodes situated at the same relative position on the nerve cord. One day after left cercal ablation, in only 12% of the trials did the first spike occur in the left connective. At one month the first spike occurred in the left connective on 54% of the trials. This difference is statistically significant (χ^2 test, $p < 0.005$). The percent recovery based on these latency measurements is close to the percent behavioral recovery and therefore may account for our behavioral results.

This work was supported by NSF grant BNS 79-09663.

*A preliminary account based on two GI's has already been presented (Vardi and Camhi, Neurosci. Abst., 1979).

233.1 IDENTIFICATION OF SYNAPTIC BOUTONS FOR PEPTIDERGIC TRANSMISSION IN SYMPATHETIC GANGLIA. L. Y. Jan*, Y. N. Jan* and M. S. Brownfield* (SPON: B. Libet). Dept. of Physiology, Univ. of California, School of Medicine, San Francisco, CA 94143

In sympathetic ganglia of the bullfrog a peptide which resembles luteinizing hormone-releasing hormone (LHRH) probably functions as the transmitter for the late slow excitatory postsynaptic potential (epsp), a signal that lasts several minutes, because (i) Radioimmunoassays indicated that a LHRH-like peptide was contained in sympathetic ganglia. Five days after preganglionic axons were cut, this substance disappeared from ganglia but tripled in spinal nerves proximal to the cut region; (ii) The LHRH-like substance can be released from ganglia with isotonic KCl or with nerve stimulation, a release that requires Ca^{2+}; (iii) LHRH acts directly on sympathetic neurons and produces a depolarizing response lasting for minutes; (iv) The LHRH response and the late slow epsp are associated with similar changes in membrane conductance and excitability of the postsynaptic cell, and they interact with the cholinergic epsp's in a parallel manner; (v) Both responses are blocked by certain analogs of LHRH, which antagonize the effects of LHRH in the rat (see Jan, Jan & Kuffler, Proc. Natl. Acad. Sci. USA, 76, 1501-1505, 1979; ibid, in press, 1980).

To directly examine the possibility that the LHRH-like substance is contained in presynaptic elements, we stained sympathetic ganglia immunohistochemically by using various antisera specific for LHRH and the peroxidase-antiperoxidase technique of Sternberger. The LHRH-like immunoreactivity was found in synaptic boutons around sympathetic neurons. No staining was obtained if the primary LHRH antisera were pre-adsorbed with LHRH. Cutting preganglionic fibers for the late slow epsp also abolished staining for the LHRH-like immunoreactivity. Therefore, the LHRH-like substance is probably contained in presynaptic nerve terminals for the late slow epsp.

An interesting feature of the late slow epsp is its delayed onset and slow time course. Typically, a late slow epsp lasts for several minutes, which is about 10000 times slower than the conventional fast synaptic potentials. Several factors may attribute to the slowness of this peptidergic synaptic potential. For instance, the distance between the peptidergic terminal and the postsynaptic cell body could be an important factor. Physiological and anatomical experiments have been done to address this question. Results from these experiments will be discussed.

233.2 RIA AND HPLC EVIDENCE FOR THE PRESENCE OF METHIONINE ENKEPHALIN AND CHOLECYSTOKININ IN THE NEURAL RETINA OF SEVERAL VERTEBRATE SPECIES. L. E. Eiden, M. C. Beinfeld* and R. L. Eskay*. Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

The amount (ng/retina) of immunoreactive (IR) cholecystokinin (CCK) in the retina of several vertebrate species, as determined by radioimmunoassay (RIA) of methanolic (90%) extracts of tissue, is as follows: 15-day-old chick, 0.04; monkey, 0.6; rat, 0.2; frog, 1.7; cow, 3.4. The quantity (ng/retina) of IR-methionine enkephalin (Met Enk), as determined by RIA of 2 N acetic acid, boiled extracts of tissue, is as follows: rat, less than 0.005; monkey, less than 0.01; cow, less than 0.1; frog, 4.6; 5-day-old chick, 7.8. The addition of increasing volumes of retinal samples containing IR-CCK or IR-Met Enk to each of the standard assay systems, resulted in an inhibition of binding of labelled peptide that paralleled the standard curve preparation. In order to characterize further the IR-retinal peptides, pools of retinal tissue were extracted and dried down. The residue was resuspended in distilled water and passed through a Waters C_{18} Sep Pak. Each Sep Pak was eluted with either a solution of acid-ethanol (Met Enk) or a solution of 90% methanol (CCK). The eluate was evaporated to dryness and the residue was resuspended in distilled water. An aliquot of this solution was injected on either a Supelco reverse phase C_{18} column or a molecular sieve column (Varian 2000 SW micropack). The C_{18} column was eluted with acetonitrile-phosphoric acid-triethylamine buffer; whereas, the molecular sieve column was eluted with 0.1 M sodium phosphate buffer, pH 7.0. One ml fractions per min were collected, lyophilized, and reconstituted in assay buffer for RIA. On the basis of reverse phase HPLC, the Met Enk-like IR in retinal tissue was found to have the same retention time as synthetic Met Enk. Furthermore, on the basis of reverse phase HPLC and a molecular sieve column, the CCK-like IR in the bovine retina was found to be the sulfated octapeptide (CCK8).

233.3 THE IDENTITY AND HYPOTHALAMIC ORIGIN OF CHOLECYSTOKININ IN RAT BRAIN AND POSTERIOR PITUITARY AND ITS POSSIBLE ROLE IN REGULATION OF NEUROSECRETION. M.C. Beinfeld*, D.K. Meyer*, and Michael J. Brownstein* (SPON: Y.P. Loh). Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

The distribution of cholecystokinin (CCK) was measured in rat brain utilizing a RIA and was found to be in agreement with previous studies of CCK distribution by the technique of immunohistochemistry. CCK was present in high concentrations in cerebral cortex and striatum and widely distributed in the central nervous system. The CCK concentration in posterior pituitary was similar to cerebral cortex. No CCK was detected in intermediate and anterior lobes of the pituitary.

The CCK-like immunoreactivity in rat brain was found to be sulfated octapeptide (CCK8) on the basis of Sephadex G-50 and HPLC chromatography. The predominant CCK-like material in posterior pituitary was also CCK8. In contrast to previous reports on porcine pituitary (Rehfeld, J., Nature 271:771, 1978), no gastrin was found in rat pituitary.

In order to determine the origin of CCK fibers in the posterior pituitary the CCK content of posterior pituitary was measured after pituitary stalk sectioning or electrolytic lesioning of the paraventricular (PVN) nucleus. Pituitary stalk sectioning resulted in complete loss of CCK. PVN lesioning resulted in about 60% loss of CCK. These results indicate that all of the pituitary CCK has an extrapituitary source and that about 60% of it is made in PVN.

To determine whether CCK8 might be secreted in parallel with vasopressin and/or oxytocin, the posterior pituitary CCK content was determined in lactating rats and rats given 2% saline to drink. In lactating rats pituitary CCK was reduced to 17% of control and in salt treated animals CCK was reduced to 20% of controls. Since CCK was reduced under conditions where release of vasopressin and oxytocin are altered, it is possible that CCK may be involved in the regulation of vasopressin or oxytocin neurosecretion.

233.4 DISTRIBUTION OF SOMATOSTATIN, SUBSTANCE P, AND NEUROTENSIN IN THE BASAL GANGLIA OF THE HUMAN. P.E. Cooper, M.H. Fernstrom, S.E. Leeman and J.B. Martin. Depts. of Neurol. and Physiol., Harvard Med. Sch. and Mass. Gen. Hosp., Boston, MA 02115.

Abnormalities of the CNS neurotransmitters dopamine, acetylcholine and GABA have been implicated in the pathophysiology of Parkinsonism, Alzheimer's disease, and Huntington's chorea respectively. Experimental evidence indicates that small molecular weight peptides are widely distributed in selective neuronal pathways in the CNS where they are postulated to exert both neuroendocrine and neurotransmitter/neuromodulator functions. It is possible that abnormalities in peptide distribution and/or concentration, analogous to those already documented for other neurotransmitters, may contribute to the clinical-pathological features of a variety of neurological disorders. Before assessment of peptide levels in pathological specimens, it is important to determine the distribution and concentration in normals and to assess stability. In addition, if appropriate animal models of disease are to be developed, peptide mapping carried out in the human should be compared to that in disorders induced in animals.
