Ten brains were obtained post-mortem from patients (6 males, 4 females) with negative neurological histories, dying of non-neurological disorders. The mean age was 56 yr (range: 39-82) and the interval between death and autopsy was 13h (range: 4.25-20). Samples were homogenized in acid solution and somatostatin, substance P and neurotensin were measured by specific radioimmunoassay (RIA). The following results were obtained:

AREA SAMPLED	SOMATOSTATIN	SUBSTANCE P	NEUROTENSIN
	(pmol/g tissue-wet ± SEM)		
Caudate - head	107.5 ± 15.9	112.6 ± 12.1	2.9 ± 0.4
Putamen	86.1 ± 13.4	81.3 ± 11.3	2.5 ± 0.3
Globus pallidus			
- internal	15.9 ± 4.9	518.0 ± 151.4	9.8 ± 1.1
- external	18.3 ± 3.1	123.8 ± 23.8	9.7 ± 1.3
Subthalamic nuc.	99.5 ± 26.3	20.7 ± 3.3	9.7 ± 3.7
Amygdala	339.4 ± 47.0	25.9 ± 3.0	5.4 ± 1.1
Substantia nigra	23.8 ± 2.9	921.6 ± 155.9	23.4 ± 2.0

For each peptide there was a unique pattern of distribution in the basal ganglia. For a single peptide in a single region, variations from brain to brain were small. There was no correlation between peptide levels and age, interval between death and autopsy, or storage time prior to assay. Recoveries of peptide added to brain before RIA were >90%. Human post-mortem brain is suitable for RIA measurement of peptides. If valid comparisons are to be made between individual brains and groups of brains, the quantitative technique of RIA is preferrable to immunohistochemistry. The pattern of peptide distribution in the human is similar to that seen in a variety of animal species.

233.5 THE PRESENCE OF SUBSTANCE P-LIKE IMMUNOREACTIVITY IN THE ANTERIOR PITUITARY GLAND OF THE GUINEA PIG. Louis DePalatis, Raymond H. Ho and Robert P. Fiorindo (SPON: R. Rosenberg). Departments of Anatomy and Physiology, The Ohio State University, Columbus, Ohio 43210.

We have used the indirect peroxidase anti-peroxidase method of Sternberger to localize Substance P-like immunoreactivity (SPLI) in the anterior pituitary gland of the adult guinea pig. Animals were fixed by intracardiac perfusion with Bouin's fluid for 15 min. after which the pituitary glands were removed and immersion-fixed in Bouin's fluid for an additional 24 hrs. Immunohistochemical processing was done on 5 μm tissue sections. SPLI was localized within the cytoplasmic compartments of anterior pituitary cells in both the male and female guinea pig. The SPLI-positive cells were visualized predominantely in the medial region of the rostral portion of the anterior pituitary gland with fewer numbers of immunoreactive cells in the lateral and caudal regions. The processing of adjacent tissue sections for the localization of various glycoprotein hormones revealed that the SPLI endocrine cells also contained immunoreactive TSH, but not FSH or LH. SPLI was not visualized in anterior pituitary gland cells of the domestic fowl, frog and turtle, or of other rodent species, i.e., rat and mouse. The specificity of the immunostaining was established in control experiments in which SP- and rat-TSH-antisera pretreated with an excess of the respective antigens did not localize the aforementioned immunoreactivities on adjacent sections. Incubation of tissue sections with SP-antiserum that was pretreated with 10 μg/ml of either luteinizing hormone-releasing hormone, somatostatin, methionine enkephalin, crude bovine neurophysins, r-TSH, r-LH, r-FSH, r-GH, or r-prolactin revealed that the antiserum did not significantly cross-react with any of these antigens. Thus, we conclude that the guinea pig anterior pituitary gland contains a SP-like product that is found within thyrotrophs. This finding in the guinea pig anterior pituitary suggests that the SPLI may be indicative of: 1) the presence of the immunoreactive substance bound to intracellular receptor sites in the thyrotrophs or 2) the endogenous synthesis of a SP-like compound by thyrotroph cells in this species. (Supported by the Snyder Fund and the Graduate School, The Ohio State University).

233.6 γ_3-MELANOCYTE STIMULATING HORMONE (γ_3-MSH): ELECTROGRAPHIC, THERMOREGULATORY, AND BEHAVIORAL EFFECTS. S.J. Henriksen, A.L. Benabid, S. Madamba, F.E. Bloom, and N. Ling*. A.V. Davis Ctr. for Behav. Neurobiol. and *Neuroendocrinology Laboratories, The Salk Inst., La Jolla, CA 92037.

γ_3-MSH is a twenty-seven residue peptide (1) whose sequence, bounded by basic residues, is contained within the cryptic portion of the recently sequenced ACTH/β-LPH precursor pro-hormone (2). Although the sequence of γ_3-MSH resembles that of α-MSH and β-MSH, γ_3-MSH has neither significant melanocyte stimulating activity nor hypophysiotropic activity (1). In order to investigate possible physiological actions of γ_3-MSH we have administered this peptide centrally to rats and subsequently monitored electrographic, thermoregulatory, and behavioral sequelae. Sprague-Dawley rats prepared with cortical and subcortical electrode arrays as well as a cannula aimed at the lateral ventricle, were given intraventricular or intracisternal injections of γ_3-MSH (1-10 nM in 10 μl Ringers) synthesized utilizing solid phase methodology. Ventricular injections of γ_3-MSH (5-10 nM) resulted in the development of a striking behavioral syndrome including: transient behavioral hyperactivity; "barrel-rolling"; cortical desynchronization; and profound hypothermia. Doses of γ_3-MSH over 10nM resulted in apparent anoxia and subsequent death. Lower doses resulted in transient "barrel-rolling" and a longer lasting (up to 2 hrs) hypothermia. Peak temperature decreases following γ_3-MSH occurred 15-30 min. after administration. In rats maintained in ambient temperatures of 24° C, rectally monitored temperature decreases of over 4 ° C were observed following γ_3-MSH. Intracisternally administered γ_3-MSH appeared to produce greater effects on temperature than on behavioral activity. Chloral hydrate and halothane anesthesized rats had an attenuated temperature response to γ_3-MSH. Since immunohistochemical studies in our lab (Bloom et al, in preparation, and McGinty et al. this volume) have localized numerous γ_3-MSH immunoreactive cell bodies in the arcuate zone of the rat hypothalamus, these data suggest a possible role of γ_3-MSH in thermoregulation. 1) N. Ling et al. Life Sciences 25, 1773, 1979; 2) S. Nakanishi et al. Nature 278, 923, 1979 (Supported by DA 01785).

233.7 EVIDENCE THAT DEACETYLATED α-MSH IS A BEHAVIORALLY INACTIVE PRECURSOR OF α-MSH PRESENT IN RAT AND HUMAN BRAIN. Thomas L. O'Donohue*, Gail E. Handelmann*, Ted Chaconas*, David S. Olton, Russell L. Miller* and David M. Jacobowitz. Dept. of Pharmacology, Howard University, Wash., D.C,; Dept. of Psychology, Johns Hopkins Univ., Baltimore, Md.; Lab. of Clin. Sci., NIMH, Bethesda, Md. 20205.

An extensive system of neurons containing α-MSH-like immunoreactivity has been identified in the rat and human brain. Four peaks of α-MSH-like immunoreactivity in the rat and human brain were identified by the use of high pressure liquid chromatography and a radioimmunoassay for α-melanocyte stimulating hormone. The most hydrophobic peptide eluted at the same time as standard α-MSH, an N-acetylated tridecapeptide amide. The second most hydrophobic peptide coeluted with deacetylated α-MSH in the rat and human brain and rat pituitary gland. The other two more hydrophyllic peptides are methionine sulfoxide forms of the acetylated and deacetylated forms of the α-MSH which are produced artifactually during extraction.

In order to determine relative potencies of the α-MSH and deacetylated α-MSH, the effect of these peptides on three behavioral tests sensitive to MSH-like peptides were studied. Intraventricular administration of 2 μg or 6 μg of α-MSH in the rat produces, in a dose-response fashion, vigorous grooming behavior and the stretch-yawn-syndrome which is characterized by an unusual sequence of vigorous bouts of stretching and yawning. In contrast, deacetylated α-MSH failed to elicit either behavior at either dose. The 6 μg dose of the deacetylated α-MSH sulfoxide was active in inducing the grooming response while α-MSH sulfoxide was inactive. α-MSH and α-MSH sulfoxide also markedly increase the rate of acquisition of a Y-maze visual discrimination task and rats administered α-MSH (40 μg/kg ip.) learned the task in less than one-half the number of trials required by control rats. Neither the deacetylated α-MSH nor the deacetylated α-MSH sulfoxide were active in the test.

These data indicate that the deacetylated form of α-MSH has to be acetylated for activation. It is therefore proposed that an intraneuronal acetylating system may determine the activity of released α-MSH.

233.8 COEXISTENCE OF GASTRIN FAMILY PEPTIDE WITH ACTH, α-MSH, OXYTOCIN OR DOPAMINE IN THE SAME CELL. A STUDY IN THE CNS, HYPOPHYSIS AND GUT OF RAT, OX, DOG, MONKEY AND HUMAN. J.J. Vanderhaeghen and F. Lotstra* Department of Pathology (Neuropathology), Free Univ. of Brussels, Brugmann Univ.Hospital, Queen Elisabeth Medical Foundation, 1, av. Jean Crocq, B - 1020 Brussels, Belgium.

Peptidic material related to the gastrin family as been discovered in the brain of several vertebrates (Vanderhaeghen, J.J., Signeau, J.C. & Gepts, W.(1975)Nature, 257, 604-605.) and was later shown to consist mainly in the COOH terminal oct. of CCK (Dockray, G.J. (1976), Nature, 264, 568-570.) in its complete biologically active sulfated form (Robberecht, P., Deschodt-Lanckman, M. & Vanderhaeghen, J.J. (1978), Proc.Natl.Acad.Sci. USA, 75, 524-528). Antral forms of the gastrin family have been reported in the porcine hypophysis. Recently immunohistochemistry has localized gastrin family peptide in rat hypophyseal posterior lobe fibers and in hypothalamic neurosecretory magnocellular cell bodies of supraoptic, circular and paraventricular nuclei (Vanderhaeghen, J.J., De Mey, J., Lotstra, F. & Gilles, C.(1978), Acta Neurol.Belg. 79,62-63), (Loren, I., Alumets, J., Hakanson, R. & Sundler, F. (1979) Histochemistry, 59, 249-257), (Vanderhaeghen, J.J., Lotstra, F., De Mey, J. & Gilles ,C. (1980) Proc. Natl. Acad.Sci. USA, 77, 1190-1194) as well as in cell bodies of A10, A9 and A8 dopamine regions of Dahlstrom and Fuxe.(Vanderhaeghen, J.J., Lotstra, F., De Mey, J. & Gilles, C. (1980) Proc. Natl. Acad.Sci. USA, 77, 1190-1194). Gastrin family peptides have also been reported to coexist in the same cell with other peptides or neurotransmitters in the gut and pancreas. Using PAP technique combine with serial sections and double staining procedures we report the presence of gastrin family peptide in hypophyseal anterior and intermediate lobe cells sometimes together with respectively ACTH or α-MSH in the same cell (ox, dog, monkey and human). Gastrin family peptide in the hypothalamic neurosecretory magnocellular nuclei coexists frequently with oxytocine. After stereotaxic mesencephalic lesion obtained by injection of 6-OH dopamine it will be showned that gastrin family peptide diminishes in dopamine mesencephalic nuclei and their rostral projection (Nucleus Accumbens, Caudate Putamen, Tuberculum Olfactorium). The significance of coexistence of gastrin family peptide with several other peptides or neurotransmitters in one cell will be discussed.

233.9 NEUROPHYSIN FIBERS IN RAT AND MOUSE CINGULATE CORTEX. G.E. Hoffman. Dept. Anatomy, Univ. Rochester, Sch. Med. Dent., Rochester, NY 14642.

Localization of neurophysin has been successfully used to trace the projections of the peptide neurons containing oxytocin and vasopressin. Most of the studies have utilized paraffin-embedded brains. Thus, some of the more diffuse projections of these systems may have been missed due to the difficulties in tracing single axons for long distances in the relatively thin sections. For this reason, neurophysin systems were examined in thick sections of freshly fixed rat and mouse brains. To accomplish this, animals were anesthetized with pentobarbital, heparinized and perfused transaortically with saline followed by 10% neutral formalin or Zamboni's fixative. The brains were removed and sectioned on a vibrating microtome at 50 or 75 um. The sections were rinsed in PBS and incubated with anti-rat neurophysin (provided by Dr. A Robinson) at a dilution of 1:1000 for 24 hrs. at 4°C. The sections were further processed for immunocytochemistry by the procedure of Grzanna et al. The results, in addition to confirming previous projections of the neurophysin systems, revealed a projection to the cingulate cortex. Beaded neurophysin fibers were observed in all layers of the rostral half of the cingulate cortex. At the medial surface of the cingulate cortex scattered neurophysin-containing fibers were found within the induseum griseum. The possible source of these fibers, as determined from Halasz knife cuts, as well as their association with vasopressin or oxytocin will be discussed. The presence of neurophysin fibers in the cingulate cortex may explain the role of these peptides in memory and learning.

233.10 CHOLECYSTOKININ RECEPTOR BINDING IN MAMMALIAN BRAIN. R.B. Innis and S.H. Snyder. Dept. Pharmacology, Johns Hopkins School of Medicine, Baltimore, Maryland 21205.

Cholecystokinin (CCK), a peptide hormone of 33 amino acids which stimulates pancreatic secretion, is found in high concentration in mammalian brain. CCK has been localized within neurons of the central and peripheral nervous systems and has been shown to have potent excitatory electrophysiological actions on central neurons. To further support CCK's role as a peptide neurotransmitter or neuromodulator, we have investigated high affinity receptor binding of CCK to mammalian brain membranes.

^{125}I-Bolton Hunter labeled CCK (^{125}I-BH-CCK) is the only iodinated form of CCK which demonstrates high affinity binding to membranes prepared from rat pancreas or guinea pig brain. Specific binding is markedly enhanced by incubating tissue with 10^{-4} M bacitracin, a proteolytic inhibitor. Monovalent cations at about 100 mM inhibit 50% of specifically bound ^{125}I-BH-CCK, and 5 mM calcium or magnesium enhances binding 2-3 fold. In both brain and pancreas, ^{125}I-BH-CCK binds saturably with a dissociation constant (K_D) of 5×10^{-10} M. The specificity of binding, demonstrated by displacement studies with numerous peptides and other putative neurotransmitters, supports the role of this binding site as the biological receptor. In close parallel to their potencies in stimulating pancreatic secretion, CCK-8 is 2-4 times more potent than CCK-33 in displacing ^{125}I-BH-CCK from both tissues, and the desulfated form of CCK-8 is virtually inactive. Although human gastrin I and pentagastrin show the expected low affinities for the pancreatic receptor binding, they are almost as potent as CCK-8 at the brain receptor. Because gastrin, pentagastrin and CCK share the same C-terminal pentapeptide sequence and because the tetrapeptide of CCK (CCK-4) is the predominant molecular form in the brain, one may speculate that the binding in brain represents the CCK-4 receptor. However, a Hill coefficient of 0.7 for displacement by CCK-33 and a biphasic dissociation curve in brain and pancreas supports the existence of at least two receptor sites for CCK.

The connection between CCK's actions in the pancreas and adenylate cyclase is unclear. We have shown that guanyl nucleotides modulate receptor binding in pancreas and brain in a manner typical of other peptide hormones whose actions are associated with stimulation of adenylate cyclase. For example, GTP and GppNHp inhibit 50% of specifically bound ^{125}I-BH-CCK at a concentration of about 2 μM, although GMP, ATP and ADP are virtually inactive. We have also shown that analogs of cGMP inhibit binding in both brain and pancreas in close parallel to their potencies in antagonizing CCK stimulated amylase release by the pancreas.

233.11 THE EFFECT OF CYCLO (LEU-GLY) ON DRUG-INDUCED DOPAMINE RECEPTOR HYPERSENSITIVITY. Jack Lee*, Ronald F. Ritzmann and Hemendra N. Bhargava*, Dept. Physiol. Biophys. & Dept. Pharmacog. Pharmacol., Univ. Ill. Med. Ctr., Chicago, IL 60612.

The effect of cyclo (Leu-Gly) (0.18 μmole/mouse) on the development of behavioral supersensitivity of dopamine (DA) receptors induced by (a) chronic morphine treatment (b) chronic haloperidol administration and (c) lesioning of neurons by injections of 6-hydroxydopamine (6-OHDA) was investigated in male Swiss Webster mice. The sensitivity of DA receptors was assessed by determining the responses (locomotor activity and body temperature) to apomorphine (APO). Morphine was administered by s.c. implantation of a morphine pellet (each containing 75 mg of free base) for 3 days. Cyclo (Leu-Gly) was injected s.c. 2 hr prior to pellet implantation. This procedure induces a high degree of tolerance to and physical dependence on morphine. Haloperidol (1 mg/kg/day) was injected daily for 21 days. Cyclo (Leu-Gly) was injected 1 h prior to each haloperidol injection. Lesions of DA neurons were produced by injecting ip pargyline (75 mg/kg) followed 30 min later by injecting desmethylimipramine (40 mg/kg) (ip). After an additional 30 min each mouse received an intracerebral injection of 6-OHDA (75 μg). Seventy two hours later mice were injected with cyclo (Leu-Gly) (0.18 μ mole/mouse). The injections of cyclo (Leu-Gly) were repeated daily for the next 11 days. Appropriate controls (placebo pellet or saline injections) were run at the same time.

The DA receptor sensitivity was measured at (a) 24 h after morphine or placebo pellet removal (b) 48 h after the last haloperidol injection and (c) 14 days after 6-OHDA injection, using an appropriate dose of APO. All the 3 methods used produced supersensitivity of DA receptors as evidenced by enhanced locomotor and hypothermic response to APO compared to their controls. Administration of cyclo (Leu-Gly) prior to morphine pellet implantation, haloperidol injection or after 6-OHDA injection prevented the development of DA receptor supersensitivity. This was evidenced by the blockade of enhanced responses to APO.

Several studies link the development of neuroleptic induced dyskinesias and morphine induced tolerance and dependence with enhanced sensitivity of brain DA receptors. Since DA receptor supersensitivity was blocked by cyclo (Leu-Gly), this agent or related compounds may be useful in treating dyskinesias and opiate tolerance-dependence process. (Supported by NIH grants DA-02542 and DA-02598 and Ill. Dept. Ment. Hlth. & Develop. Disabil. #904-02).

234.1 COMPRESSION OF PREGANGLIONIC AXONS INTO AN EXPERIMENTALLY REDUCED SYMPATHETIC GANGLION. A. J. Smolen and T. Lindley*. Dept. of Anatomy, Med. Coll. of Pa., Philadelphia, PA 19129.

The mechanisms by which various neural centers achieve numerical balance with the target neurons which they innervate has been studied extensively in the developing (or regenerating) avian and amphibian nervous systems. It generally has been concluded that removing the normal target results in an exaggerated loss of its afferent neurons, and conversely, that experimentally increasing the size of the target results in the maintenance of an increased number of afferent neurons.

Similarly, it has previously been shown in the superior cervical sympathetic ganglion (SCG) of the neonatal rat that, after cutting all of the postganglionic axons, there is a nearly complete direct retrograde cell death of the ganglionic neurons. In this case, the preganglionic axons are completely deprived of their target, and so undergo a transneuronal retrograde loss.

The present experiment was undertaken in order to define the effect on the preganglionic input of removing only a portion of their target neurons in the SCG, at a time before most of the ganglionic synapses are formed. We cut the internal carotid postganglionic nerve in rats at 3 days after birth, a time when there is only about 20% of the normal adult number of synapses in the ganglion. We left intact the other major postganglionic nerve, the external carotid nerve. Unoperated littermates served as controls. Two months later we removed the ganglia and their preganglionic chains and, using morphometric methods, obtained estimates of the numbers of ganglionic neurons, synapses, and preganglionic axons.

In the operated animals there was a marked reduction in the number of ganglionic neurons, with a somewhat smaller reduction in the number of synapses. There was no change in the number of preganglionic axons.

	CONTROL	OPERATED	
Ganglionic neurons	13,960±300	6,230±620	P<.01
Ganglionic synapses	4,370,000±100,000	2,840,000±410,000	P<.05
Preganglionic axons	5,900±1,030	5,640±350	N.S.

From these results we conclude that reducing the target at this stage of development does not result in a retrograde transneuronal loss of a proportion of the preganglionic axons. Instead, all of the preganglionic axons survive, and are compressed onto a smaller number of target neurons. There is, however, no marked hyperinnervation of the remaining ganglion cells. Thus, each preganglionic axons makes fewer synapses in the reduced ganglion than it would in the normal ganglion.
(Supported by NIH Grant NS 15952).

234.2 DEVELOPMENTAL PLASTICITY OF THE CORTICOSPINAL TRACT (CST) FOLLOWING MIDTHORACIC SPINAL CORD "OVER-HEMISECTION" IN THE NEONATAL RAT. D. R. Bernstein* and D. J. Stelzner, Department of Anatomy, SUNY Upstate Medical Center, Syracuse, NY 13210.

Animals receiving midthoracic spinal cord (T_8-T_{10}) "over-hemisection" - including right hemicord and left dorsal funiculus (df) - at birth, survived 3-12 mo. prior to stereotaxic unilateral ^{3}H-proline injection of either sensori-motor cortex (SMI). Similarly injected normal adult rats served as controls. After 48 hrs., rats were sacrificed and the brain and spinal cord examined using standard autogradiographic techniques. The injections labeled and the contralateral corticospinal tract (CST) within the df in controls. Labeled axons were also found sparsely in the contralateral lateral funiculus (LCT) and central gray below the df. Thus the "over-hemisection" given to neonates severs the matrix that most developing CST fibers would traverse at a later stage. Following injection of the appropriate SMI cortex, the right or left CST was studied. The left CST appeared normal rostral to the lesion zone and labeled fibers bypassed the lesioned left df by swinging through the left gray matter to form a greatly expanded left LCT in the intact matrix at the lesion zone. Caudal to the lesion, tract fibers: a) remained primarily in the LCT, but also in the left dorsal and central gray; b) were not found in either df; c) terminated correctly within the left gray matter, as well as in the appropriate but "wrong-side" gray where label density is nearly equal bilaterally. In contrast, the right CST was observed to distribute normally to within 1-1.5 segments above the fully transected right hemicord where label distribution spread to fill the entire hemicord creating a neuroma-like formation. None, or only minor, label was observed caudal to the lesion zone.

In a second experiment the right SMI cortex was ablated at the same time that the thoracic lesion was made, either at birth or at 6 days of age. By the later period nearly all CST fibers have grown through the pyramidal decussation and at least some of the axons have grown through thoracic spinal cord. The right CST was found to project around the thoracic lesion site in animals operated at both ages. Thus the left CST axons in some manner exclude the right CST axons from growing around the "over-hemisection". The projection of the right CST axons in this instance was similar to the left CST described above.
(Supported by Grant NS 14096)

234.3 EXPANSION OF THE CROSSED PARABIGEMINO-TECTAL PROJECTION IN ONE-EYED RATS. J. A. Stevenson and R. D. Lund. Dept. Anatomy, Medical Univ. of South Carolina, Charleston, S. C. 29403.

The parabigeminal nucleus (PBG) of the rat projects bilaterally to superficial (retino-recipient) layers of the superior colliculus (SC). In the albino rat the PBG is composed of three subunits. The ipsilateral PBG-SC projection arises from dorsal and ventral subnuclei and terminates across the full extent of SC. The crossed projection originates from cells of the middle subnucleus, and its terminal field is restricted to the anterior half of the SC in normal animals (Watanabe and Kawana, '79).

Degeneration studies after PBG lesions and examination of PBG cell labeling after horseradish peroxidase (HRP) injections into SC of adult pigmented rats demonstrate a PBG-SC projection generally similar to that of albinos. The termination of the crossed projection is restricted primarily to the anterior half of SC. However, light degeneration limited to the medial bank of SC was seen extending toward, but not reaching, the posterior pole of SC. Animals subjected to unilateral eye removal at birth showed an expanded crossed PBG-SC projection to the SC contralateral to the removed eye. While heaviest medially, this projection to superficial layers filled nearly the entire extent of SC. Only a small area at the postero-lateral border was free of degeneration following PBG lesion. PBG cell labeling following HRP injections in the posterior half of such SC confirm the expanded projection and demonstrate its origin in the appropriate PBG subnucleus.

This result demonstrates plasticity in a secondary visual pathway as an indirect effect of an early retinal lesion. It suggests that either interactions between retinal and PBG afferents to SC normally restrict the field of PBG termination or that the abnormal ipsilateral retinotectal projection, caused by early eye removal, induces expansion of the crossed PBG-SC terminal field.
(Supported by USPHS Grants EY 05381 and EY 03414 from the National Institutes of Health.)

234.4 TEMPORAL SENSITIVITY OF THE VISUAL PATHWAYS IN NORMAL AND MONOCULARLY DEPRIVED CATS. Kim R. Jones* and M.A. Berkley. Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306.

Single unit recordings from the LGN of monocularly deprived (MD) cats are remarkable in that few Y-cell responses can be observed in the deprived laminae. However, it has recently been reported that in the optic radiation of these cats, single-unit penetrations display a normal complement of Y-cells driven by the deprived eye (Eysel, et al., Exp. Brain Res., 34: 521 (1979). This finding has prompted the suggestion that Y-cell numbers in the deprived geniculate are in fact normal, and that the loss seen physiologically is the result of a sampling bias reflecting preferential shrinkage of Y-cell cell bodies.

Since knowledge of the physiological state of the geniculate following visual deprivation is of some importance, the present experiment was designed to measure activity in the LGN in such a way so that cell size was not a significant factor. Accordingly, the temporal modulation sensitivity in both normal and MD cats was assessed using an averaged evoked potential technique.

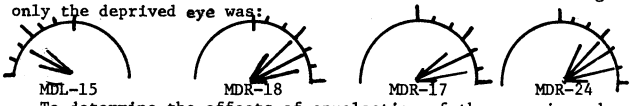
A sinusoidally-modulated luminous stimulus, variable in both frequency and modulation depth, was used to elicit geniculate responses. By presenting a number of modulation depths at each frequency of stimulation, a linear function relating the amplitude of the evoked response to the log of the modulation depth could be obtained for each individual frequency. The zero-response intercept of this function was taken as the modulation threshold. Plotting these thresholds as a function of the stimulating frequency resulted in a temporal modulation sensitivity function, or TMSF.

Comparison of geniculate TMSFs in normal cats revealed no significant differences after stimulation of either eye. In MD cats, however, the TMSF derived via stimulation of the deprived eye was significantly depressed when compared to that derived via stimulation of the normal eye. To localize this temporal deficit, TMSFs were also derived from evoked potentials recorded from optic tracts and visual cortices of MD cats. No differences in sensitivity between the normal and deprived eyes were seen in the optic tract TMSFs, but the TMSFs derived from visual cortex exhibited even greater differences than were observed in the LGN. It was concluded that monocular deprivation causes deficits in the processing of temporal information that are first evidenced in the geniculate and further intensified at the level of visual cortex, a conclusion consistent with a loss of Y-cell function in LGN.

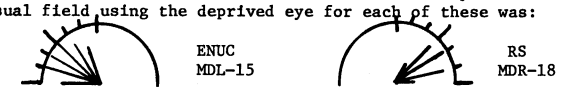
Supported by NSF grant SMI76-22831 and NIH grants MH-11218 and EY-00953.

234.5 THE EXTENT OF THE VISUAL FIELD IN MONOCULARLY DEPRIVED CATS AND ITS PERMANENCE. Douglas C. Smith, Robert N. Holdefer*, Tom M. Reeves, and Jeanne A. Dorsett*. Dept. of Psychology, Southern Illinois University-Carbondale, Carbondale, IL. 62901.

We have been measuring visual orienting behavior in monocularly deprived (MD) cats for two reasons. First, recent investigations by von Hof-van Duin (1977) and Heitlander and Hoffmann (1978) have reported visual orienting in MD cats using the deprived eye over a much larger portion of the visual field (i.e, entire ipsilateral hemifield) than that reported by Sherman(1973) (45-90 deg. ipsilateral). Although the methods of testing were different, Heitlander and Hoffmann found visual orienting in a portion of the binocular visual field using Sherman's methods. The second reason was to determine whether the removal of the experienced eye might result in an expansion of the deprived eye's visual field correlated with the increase in the percent of cells responding to the deprived eye known to occur in striate cortex and the superior colliculus following this manipulation (Kratz et. al.,1976; Hoffmann and Cynader, 1977). Visual field perimetry was done using Sherman's (1973) techniques. MD was 7 mo in duration and all cats had perfect closures. The percent correct at each guideline (15 deg. apart) was determined using a minimum of 60 trials. Each cat was tested through the experienced eye, binocularly and through the deprived eye in this order. The monocular visual field for each of the 4 MD cats tested using only the deprived eye was:



To determine the effects of enucleation of the experienced eye a reverse-suture (RS) control was used for comparison. The visual field using the deprived eye for each of these was:



Comparison of the postenucleation orienting behavior of the enucleated cat (MDL-15) with its baseline performance (above) shows an increase in the visual field occurred following enucleation of the experienced eye which does not occur following RS. This increase was apparent in the first session postenucleation. An additional cat in each condition is being tested and the results will be presented. We conclude that the extent of the visual field using the deprived eye is limited to the ipsilateral monocular visual field and that enucleation apparently leads to an increase in the visual field which does not occur following RS.

234.6 THE EFFECT OF EARLY UNILATERAL EYE ENUCLEATION ON BILATERALLY PROJECTING RETINAL GANGLION CELLS IN HAMSTERS. Karen Hsiao* and Gerald E. Schneider (SPON: W. Rosenblith). Department of Psychology, M.I.T., Cambridge, MA 02139.

Neonatal monocular enucleation in hamsters results in an enhanced ipsilateral projection from the remaining eye (Finlay et al, JCN, 1979). In order to determine what portion of the enhanced ipsilateral projection was due to collateral sprouting of contralaterally projecting optic axons, a double labelling technique using horseradish peroxidase (HRP) and nuclear yellow (NY) was employed.

Hamsters at ages between 0 and 3 days underwent removal of one eye. As adults at least 8 weeks old, their optic tracts were sectioned below the lateral geniculate nucleus. A NY pellet was placed in one optic tract cut, and an HRP pellet was placed in the other. The optimum transport times to the retina, 12-14 mm away, for NY and HRP were 48 hr and 24 hr, respectively. The hamsters were perfused, and their retinas flat-mounted and processed using the TMB method (Mesulam, 1978). The retinas were scanned under UV epi-illumination. The positions and numbers of the ipsilaterally projecting retinal ganglion cells (RGCs), and of the doubly labelled cells, which represented bilaterally projecting RGCs, were noted.

The normal hamster retina contains 770(SD=150) ipsilaterally projecting RGCs, only 4(SD=2) of which project bilaterally. Ipsilaterally projecting RGCs are concentrated in a crescent-shaped area in the temporal retina, and are dispersed among contralaterally projecting RGCs. Hamsters with early unilateral eye enucleations experienced nearly a two-fold increase in the number of ipsilaterally projecting RGCs, bringing the total number to 1370(SD=230), and at least a four-fold increase in the number of bilaterally projecting RGCs, bringing the total number to 18(SD=6). The bilaterally projecting RGCs tended to be situated in the region outside the temporal crescent in the outer third of the retina, and particularly in the upper retina.

Although the number of ipsilaterally projecting RGCs increased by about 600 in hamsters with neonatal eye enucleations, only about 14 of these projected bilaterally in the adult. Thus, approximately 2% of the enhanced ipsilateral projection appears to be due to collateralization of the contralateral projection at the chiasm. It seems possible that the enhanced ipsilateral projection results mainly from a diminished incidence of cell death in the developing population of ipsilaterally projecting RGCs.

234.7 A CROSSED CORTICOTECTAL PROJECTION AFTER EARLY TECTAL LESION IN THE HAMSTER. Steven L. Wertheim* and Gerald E. Schneider (SPON: N. Hebben). Dept. of Psych., M.I.T., Cambridge,MA 02139.

In the normal adult hamster the projection from the visual cortex to the superior colliculus (SC) is strictly ipsilateral. In order to investigate possible plasticity in the corticotectal projection, we have performed unilateral heat lesions of the superficial layers of the SC on the day of birth in ten Syrian hamsters. In three of these animals, the eye ipsilateral to the tectal lesion was removed simultaneously. At maturity the projection from the visual cortex ipsilateral to the lesion was traced with the Fink-Heimer technique. The projection from the contralateral eye was traced in the same animal with the autoradiographic method.

We have found a crossed projection to the undamaged SC from the visual cortex in these animals, in addition to the previously described anomalous recrossing retinotectal projection. The crossed corticotectal projection shares several distinctive properties with the recrossed retinotectal projection in the same animal. Most of the aberrant corticotectal fibers cross the midline within the bundle of recrossing retinofugal fibers. In the animals with tectal lesion alone, the crossed corticotectal projection is restricted to a medial zone of the contralateral SC, as is the anomalous retinal projection to that SC. In two animals with relatively strong crossed corticotectal projections, the lateral borders of the two aberrant projections appear to coincide. This correspondence is less precise in cases with a weaker crossed cortical projection. The rostro-caudal extent of crossed corticotectal termination is more limited than that of the aberrant retinal projections. There is no clear tendency for these aberrant cortical and retinal terminals to avoid overlap. However, definite segregation is seen in the tissue remaining on the side of the lesion where there are dense anomalous projections from both sources.

Ipsilateral eye removal in combination with tectal lesion results in an increased lateral distribution of crossed corticotectal, as well as retinotectal, fibers. The crossed cortical projection does not reach the lateral border of the SC as does the aberrant retinal projection. It appears restricted to the dorsal part of the superficial gray layer, thus avoiding the main region of termination of the other visual cortex.

These results indicate that normal and anomalous development of corticotectal and retinotectal fibers may be influenced by similar factors, and that the distribution of corticotectal axons may be strongly influenced by retinofugal axons.

234.8 EFFECTS OF NEONATAL LESIONS OF SOMATOSENSORY CORTICES IN THE POSTNATAL DEVELOPMENT OF CALLOSAL CONNECTIONS. R. Caminiti and G. M. Innocenti. Inst. of Physiol., University of Ancona, Italy and Inst. of Anat., University of Lausanne, Switzerland.

In the neonate cat, neurons projecting through the corpus callosum occupy the entire tangential extent of the sensory areas and subsequently become confined to restricted regions (callosal efferent zones).

The distribution of S1 (first somatosensory area) and S2 (second somatosensory area) neurons projecting to the contralateral S2 was studied with horseradish peroxidase (visualized with tetramethylbenzidine) in normal adult cats and in cats aged between 129 and 248 days in which the injected S2 area had been deprived of some of its input by an earlier lesion (on postnatal days 3 to 30; day of birth = day 0) of ipsilateral S1, alone (8 cats) or combined with a lesion of contralateral S2 (4 cats). In animals with S1 lesions, as in the normal controls, labeled neurons were selectively distributed to the regions of the trunk representation and to parts of the forelimb and hindlimb representations; however, the wide acallosal region in the forepaw representation was smaller than normal and it contained scattered labeled neurons in three of the four animals whose S1 had been lesioned during the first postnatal week. In these animals, the distribution of labeled neurons in the contralateral S2 was apparently normal. Furthermore, the additional lesion of this area during the first postnatal week (one animal) did not increase the degree of filling in of the normally acallosal parts of S1.

The filling in observed in these experiments is very modest considering the number of afferent axons to S2 eliminated by the lesion and considering the widespread distribution of neurons projecting through the corpus callosum in neonatal S1. It suggests however, that competition between callosal and other axons may be to some extent responsible for the disappearence of juvenile neurons which project through the corpus callosum.

234.9 ULTRASTRUCTURAL STUDY OF DEVELOPMENTAL CHANGES IN SYNAPTIC ORGANIZATION OF THE CHICK VESTIBULAR SYSTEM: TANGENTIAL NUCLEUS. K. D. Peusner. Department of Anatomy, Jefferson Medical College, Philadelphia, PA. 19107.

The tangential nucleus is a component of the avian lateral vestibular complex (Cajal). The largest primary vestibular afferents, the colossal vestibular fibers, form very large axosomatic endings, the spoon endings, on the principal cells of the chick tangential nucleus in late embryos (Peusner and Morest). In 15 and 16 day embryos, the lengths of spoons often exceed the length of the principal cell soma, measured at 32 um, and spoons form immature and mature vesiculated synapses and gap junctions at the spoon-principal cell interface. In addition, the principal cell somata are contacted by a small number of small-sized terminals of unknown fiber origins as early as 8-9 days. But even by 16 days in the embryo, these small-sized terminals, which contain both round and elongated synaptic vesicles, form only morphologically immature synaptic vesicle complexes with the principal cell. A few small-sized terminals may insert themselves into rare enlargements of the extracellular space at the spoon-principal cell interface. Undoubtedly, the spoon is the major afferent input to the principal cell soma in late embryos. However, from hatching through adult ages, spoons undergo a progressive transformation in ultrastructural constituents and atrophy such that in young adults, spoon remnants measure less than 5 um in length and contain extremely electron-dense axoplasm. Atrophied and degenerating spoon processes join the principal cell by numerous and lengthy gap junctions. In hatchlings, small-sized terminals are a regular feature, inserted into enlargements of the extracellular space at the spoon-principal cell interface. Although spoons have atrophied considerably in young adults, the principal cell exhibits somatic surfaces encapsulated by small-sized terminals. These small-sized terminals interlock with neighboring terminals. All small-sized terminals contain both round and elongated synaptic vesicles and form nearly symmetrical synaptic membrane complexes with the principal cell. In conclusion, this study documents a major developmental change in synaptic organization of the adult vestibular system. The evidence supports developmental remodeling of synaptic endings in the adult central nervous system. Supported by USPHS grant #1 RO1 NS15633.

235.1 LONG-TERM BEHAVIORAL AND NEURONAL CHANGES INDUCED BY SECTION OF INTERGANGLIONIC CONNECTIVES IN LEECHES. B. Granzow, E. Freed* and B. Kristan. Department of Biology, University of California, San Diego, La Jolla, CA 92093

Although swimming motor output can be generated in a completely isolated nerve cord of the leech, a single segmental ganglion cannot generate swimming motor output when its connections with the rest of the nerve cord are severed. However, a ganglion which is isolated by cutting both its anterior and posterior connectives, if left in situ with its lateral nerve roots intact, will regain its ability to generate swimming motor output within ten days of isolation (Kristan and Guthrie, Brain Res., 131:191-195, 1977). Behavioral observations of the operated leeches revealed that over a period of several days the body wall segment which is innervated by the isolated ganglion gradually develops definite alternating dorsal and ventral longitudinal muscle contractions which are accompanied by body flattening. This swimming motor pattern can occur 'spontaneously' or be evoked by tactile and electrical stimuli applied to the skin of that segment. The swimming motor output (consisting of alternating bursts in dorsal and ventral motoneurons) has also been recorded from chronically isolated ganglia, both when the ganglion remained connected to its body wall and when the ganglion was completely isolated. In the latter case the motor output was evoked by intracellular stimulation of the swim-initiating interneuron, cell 204, and was the same as that generated by the whole isolated nerve cord both qualitatively and quantitatively. We are now analyzing the cellular bases of the changes which occur, to account for the ability of the chronically isolated ganglion to generate the swimming motor output. We are using intracellular recordings to test for changes in efficacy of connections between swim related neurons and HRP injections to look for anatomical changes of these cells. We have evidence for strengthening of excitation both in the pathway from mechanoreceptors to cell 204 and from cell 204 onto the central pattern generators.

235.2 VISUALIZATION OF LIVING, INTRACELLULARLY STAINED NEURONS USING A SILICON INTENSIFIED TARGET CAMERA. S. B. Kater and R. D. Hadley. Dept. of Zoology, Univ. of Iowa, Iowa City, Iowa 52242.

Visualization of neurons stained intracellularly with fluorescent markers relies upon exciting the fluorophore with intense ultraviolet or blue light. The intensity of the exciting source determines the intensity of the emitted fluorescence. There are two problems commonly associated with this technology, especially when employing it with living neurons: 1) intense illumination can be fatal to living cells, and 2) intense illumination can produce rapid fading of the fluorophore, rendering it an inadequate marker in both living and fixed materials. Such problems are especially limiting under circumstances where one observes changes in neuronal morphology over time as for growing neurons.

We employ the fluorophores Lucifer Yellow and 6-carboxy-fluorescein to examine the growing processes of living, regenerating neurons of the snail Helisoma. Buccal ganglia are maintained in organ culture and regenerating identified neurons are filled with dye by intracellular iontophoresis. The growing processes can then be observed in situ both within the neuropile and specified nerve trunks. Extremely low levels of exciting light are employed (≠1/1000 the amount used for normal fluorescence photomicroscopy) and essentially no image is seen by eye directly through the microscope oculars. An attached Silicon Intensified Target camera produces a vivid image of sufficient quality to study the dynamics of neuronal path-finding involved in specific synaptic formation in this system (fine processes, etc.). Appropriate controls indicate that with 6-carboxy-fluorescein we can safely monitor the behavior of growing neurons in the environment of the neuronal and glial elements with which associations normally are made. Thus, studies on the dynamics of neuronal growth on a normal biological substrate can be performed using a nondamaging optical technique.

235.3 DEGENERATION AND REGENERATION OF A CENTRAL PATHWAY IN THE GOLDFISH AN EM STUDY. R.L. Levine and G.M. Bray. Dept. Biol., McGill Univ., Montréal, P.Q., Canada H3A 1B1 and Neurol. and Neurosurg., McGill Univ., Montréal Gen. Hosp.

After unilateral tectal lobe removal in the goldfish, the efferent pathways from that lobe undergo Wallerian degeneration (Levine, R.L., ARVO '80). In addition, the optic fibers which were severed by the lesion regenerate into most of the degenerating tectal efferent tracts (Lo, R.Y.S. and Levine, R.L., J. Comp. Neurol., 1980). We have studied these two processes, i.e., degeneration and regeneration, in a particular pathway, i.e., the tractus rotundus.

In the normal animal the tractus rotundus is a bundle of fine (<1.5μ diameter) myelinated fibers which runs between the nucleus rotundus and the vertical limb of the horizontal commissure. In the animals we examined (7.5-8.0 cm length) the bundle was 100μ in diameter and contained approximately 20,000 axons. The thalamomammillary bundle lies immediately adjacent to the tractus on its medial surface and consists of several hundred small (1.5-3μ) myelinated axons. Finally, between 100 and 200 larger myelinated axons (3-5μ) form a shell around the dorsal and lateral aspects of the tractus rotundus.

After tectal lobe removal there is a rapid degeneration of nearly all of the fibers in the tractus rotundus on the operated side. Myelin degeneration is seen throughout the bundle by three days postoperative. Phagocytosis of the degenerating myelin also occurs rapidly and the majority of the debris has been removed by 14 days postoperative. Neither the thalamomammillary tract nor the large lateral fibers associated with the tractus show a major degenerative response to tectal removal. Concurrent with the degeneration in the tractus rotundus, optic fibers begin to regenerate into it. The first optic axons are seen as small fascicles among the glia and myelin debris at 7 days postoperative, and by 32 days postoperative they occupy most of the tractus.

Even at this early stage of investigation, some important generalizations may be made. First, the regenerating optic fibers appear to be confined to the boundaries of the degenerating tractus rotundus. They do not invade the immediately adjacent, parallel bundles which are not degenerating. Secondly, at this time, we have seen no cells in the tractus which appear similar to astrocytes (as they have been described in other lower vertebrates (Stensaas, L.J., J. Neurocytol., 6: 269, 1977). These observations accord with those of Achúcarro (1915) who found that astrocytes in the teleost brain tend to remain near the ependymal lining of the ventricular system. A corollary of this is that we have not seen radially arranged glial 'channels' comparable to those described by other workers in regenerating central paths in the lower vertebrates.

235.4 GROWTH RESPONSE MECHANISMS IN REACTIVE SYNAPTOGENESIS Stephen D. Collins and Robert L. Gulley Dept. Anat. Sch. Med. Case Western Reserve Univ. Cleveland OH 44106 and N.I.H., Bethesda MD. 20014

Many investigators have reported reorganization of synaptic connections in the adult CNS following partial deafferentation. Reorganization may involve the growth of new connections or the rearrangement of existing synapses. A quantitative morphological study of a well defined primary sensory nucleus which undergoes synaptic reorganization was performed to determine the mechanisms of response of intact afferents following partial deafferentation. In the rostral pole of the anteroventral cochlear nucleus of the guinea pig, four morphological types of boutons synapse on the somas of a homogeneous population large spherical cells. The four classes of boutons (primary auditory or E-bouton, O-bouton, F-bouton and S.R.-bouton) appose 46, 13, 5 and 4% of the spherical cell perimeter, respectively(Schwartz&Gulley,'78). Ablation of the cochlea causes rapid and complete degeneration of the large calyceal E-bouton which is followed by an increase in the total apposition of O- and F-bouton classes. The O-boutons double and the F-boutons triple their total apposition three weeks after cochlear ablation. No change in average spherical cell diameter occurs prior to 30 days post-cochlear ablation(Collins&Gulley,'79)

The cochlear nuclei from 20 guinea pigs at survival times of 7,14,21,30 and 180 days were studied in the electron microscope. The perimeters of spherical cell somas and the appositional length of each bouton apposing the somas were measured. The average number and the average length of O-boutons and F-boutons apposing a standard length of spherical cell membrane were determined. Two distinct growth mechanisms were observed for the two bouton classes. The number of O-boutons remained approximately constant through the 180 day study period while the median length of O-boutons increased 80%, from 0.9 microns to 1.6 microns. In contrast, the median length of F-boutons increased only slightly, while the number of F-boutons increased 142%.

These results demonstrate a specific mechanism of response by individual classes of neurons in a primary sensory nucleus to partial deafferentation of a common postsynaptic neuron. The F-bouton class adds, either by collateral sprouting or paraterminal sprouting, new boutons following calyceal terminal degeneration whereas the O-bouton class undergoes bouton enlargement, a form of contact synaptogenesis. The growth mechanism specificity of each neuronal class may determine innervation characteristics in injured and developing nervous systems.

235.5 TOPOGRAPHIC ORGANIZATION OF NORMAL AND REGROWING PYRAMIDAL TRACT AXONS. K. Kalil, M. Volz,* and T. Reh. Dept. of Anatomy and Neurosciences Training Program, Univ. of Wis., Madison, WI 53706.

In the infant hamster, severed pyramidal tract axons regrow along an anomalous route to innervate their normal terminal areas in the dorsal column nuclei and the cervical spinal cord (Kalil and Reh, 1979, Science 205). However, it is not known whether the cortical cells giving rise to the new pathway occupy the same cortical region as the normal pyramidal tract neurons and whether the topography of the normal corticospinal projection is maintained by the regrowing pathway.

In normal adult hamsters the topographic organization of the pyramidal tract neurons was plotted by injecting horseradish peroxidase (HRP) into localized regions of the dorsal column and trigeminal nuclei, and the cervical and lumbar enlargements of the spinal cord. In addition, injections of HRP directly into the medullary pyramid revealed the entire extent of cortical neurons giving rise to the pyramidal tract. This region extends rostro-caudally over a surprisingly large region of the cerebral cortex from the very frontal pole of the hemisphere to a level approximating the parietal cortex and mediolaterally from the midline to the rhinal sulcus. This cortical area encompasses MI, SI and SII but also extends rostrally into a region which would include the premotor and frontal cortices.

Within this region the topography of the sensorimotor cortex is similar to that described in the rat (Wise et al., 1979, Neurosci). The lumbar region is confined to a narrow posteromedial strip of cortex extending no more than 2mm. from the midline. The representation of the cervical cord lies rostral and lateral to the lumbar area and does not overlap it. The trigeminal and DCN projections arise from a large zone of the sensorimotor cortex lateral to the cervical projection zone. In all cases the cells are heavily labeled and occupy a continuous band in the deep part of layer 5 only.

Parallel HRP experiments are in progress on adult animals with infant lesions of the pyramidal tract to determine whether regrowing axons maintain this topography.

Supported by NIH grant NS-14428 and NIH training grant GM07507.

235.6 FUNCTIONAL ROLE OF REGROWING PYRAMIDAL TRACT FIBERS IN THE NEONATAL HAMSTER. T. Reh and K. Kalil. Neuroscience Training Program and Dept. of Anatomy, Univ. of Wis., Madison, WI 53706.

We have shown in previous reports that axons of the pyramidal tract regrow when severed in the infant hamster. The regrowing fibers follow an abnormal route, but nevertheless reach and form synapses in their normal terminal areas, the dorsal column nuclei and the dorsal horn of the spinal cord (Kalil and Reh, 1979, Science 205:1158-1161; Reh and Kalil, 1979, Soc. Neurosci. Abstr. 2157). We now present evidence that this new pathway may be functionally useful in the animal's behavior.

Several qualitative and quantitative tests have been employed to determine whether the infant lesioned animals recover or retain any of those abilities mediated by the pyramidal tract. Previous studies of motor behavior in rodents with adult pyramidal tract lesions have shown deficits in the fine manipulatory movements of the forepaws. Hamsters with adult lesions can no longer hold and rotate sunflower seeds while eating, but instead use the affected forelimb as a passive support while the normal paw attempts to grasp and rotate the seeds. These animals also have difficulty in accurate limb placement when crossing difficult terrain, and they no longer display the tactile placing response.

We examined neonatally lesioned animals for deficits in these behaviors: seed handling, accurate limb placement, and tactile placing. The animals were filmed with a 16mm camera and the film was analyzed for both qualitative and quantitative behavioral deficits. Animals receiving pyramidal tract lesions in the first two weeks of life, in contrast to those lesioned as adults, do not show qualitative behavioral deficits in the tests, since they manipulate seeds in a normal manner and show normal tactile placing responses and accurate limb placement of both fore- and hindlimbs. However, preliminary evidence suggests some quantitative differences between neonatally lesioned and normal hamsters. The present results show that new axonal growth following neonatal pyramidotomy may be important in the recovery or sparing of motor function. Experiments are in progress to determine whether the recovered behaviors are lost when the new pathway is destroyed in the adult animal.

Supported by NIH grant NS-14428 and NIH training grant GM07507.

235.7 TWO AXONALLY TRANSPORTED PROTEINS ASSOCIATED WITH GROWING AXONS IN RABBITS. J. H. P. Skene* and M. Willard* (SPON: C. J. Cornbrooks). Depts. of Anatomy-Neurobiology and Biochemistry, Washington Univ. Sch. of Med., St. Louis, MO 63110.

To explore the molecular events which control axon growth, we have compared the proteins transported rapidly along growing and non-growing axons in neonatal and adult rabbits. We labeled retinal ganglion cell proteins by intraocular injection of ^{35}S-methionine in rabbits of various ages and recovered labeled rapidly transported proteins in the optic nerves 3 hours after isotope injection; the labeled proteins were analyzed by one- and two-dimensional electrophoresis and fluorography. We found two polypeptides (GAP-23, mol. wt. 23K; GAP-43, mol. wt. 43K) which were labeled in neonatal optic nerves, but whose labeling relative to total rapidly transported radioactivity declined precipitously 7-21 days after birth. When these polypeptides could be detected in adult rabbit optic nerves, their relative labeling was less than 1/9 the level found in neonates. GAP-23 and GAP-43 resemble two rapidly transported polypeptides (GAP-24; GAP-43) induced during optic nerve regeneration in toads. GAP-23 and GAP-43 are also transported in regenerating hypoglossal nerves of adult rabbits; GAP-43 is induced by axotomy, while GAP-23 is transported in undamaged motor axons and not further induced by injury. CNS (optic nerve) axotomy in adult rabbits does not re-induce transport of the GAPs, and the injured axons do not regenerate. We interpret these observations as follows (the "GAP hypothesis"): 1. a neuronal "growth state" can be defined as a discrete program of gene expression, which includes expression of genes for the GAPs; 2. the growth state can be subdivided into a "synaptogenic state" characterized by transport of GAP-23 but not GAP-43, and an "axon elongation state" requiring both GAPs; 3. the failure of mammalian CNS neurons to express GAP genes after axotomy underlies their failure to regenerate damaged axons.

235.8 NERVE GROWTH FACTOR INCREASES ORNITHINE DECARBOXYLASE ACTIVITY IN GOLDFISH RETINAL EXPLANTS. Michal Schwartz, Shinichi Kohsaka* and Bernard W. Agranoff. Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109.

Prior crush of the goldfish optic nerve greatly enhances neuritic outgrowth upon subsequent explantation of the retina. In the present study, we demonstrate that the addition of β-NGF from mouse salivary gland to the explants increases the activity of ornithine decarboxylase (ODC), a rate-limiting enzyme of polyamine synthesis. ODC activity in post-crush retinal explants is maximal 6 h after explantation in the presence of either NGF (1 μg/ml) or of fetal calf serum (10%). The observed increase (5 to 6-fold) following addition of NGF is inhibited by the presence of antisera to NGF or the ODC inhibitor, diaminopropane (1.0 mM). Post-crush retinal explants have higher initial ODC levels (Kohsaka and Agranoff, abstracts, this meeting) and demonstrate a larger response to the NGF addition than do control retinas. The results suggest a difference in affinity and/or the number of receptors for NGF or NGF-like molecules in the two retinal preparations. The results are of interest in view of the reported enhancement of goldfish ganglion cell morphological responses to axotomy following intraocular injection of NGF (Turner et al., Society for Neuroscience Abstracts 5, 684, 1979). A possible role for ODC in nerve growth is discussed in view of an apparent dissociation of effects of NGF on ODC activity and neurite outgrowth in cultured PC-12 cells.

235.9 GLIAL SCAR FORMATION IN THE BRAIN OF ADULT RATS IS INHIBITED BY IMPLANTS OF EMBRYONIC CNS TISSUE. Lawrence F. Kromer. Dept. of Neurosciences, UCSD, La Jolla, CA 92093.

Axonal connections are reported to develop between intracephalic implants of embryonic CNS tissue and the CNS of the adult rat host (Björklund & Stenevi,'76,'77; Kromer, et al.,'80a, 80b). Since axonal growth occurs between the two tissues, the question arises whether an intervening zone of astroglial processes is present or whether the embryonic CNS implant prevents the formation of a glial scar in this transition area.

Embryonic hippocampal (HPC) tissue (taken from 7-25mm fetuses, approximately embryonic days 10-18) was transplanted into a cavity produced by transecting the fornix-fimbria at the rostral end of the HPC in adult female albino rats. The implants were allowed to survive in situ for 2-6 months. Several specimens were reacted with antiserum against glial fibrillary acidic protein (GFA) and prepared according to the peroxidase-anti-peroxidase method, others were prepared for electron microscopy(EM), and a third group of implants was injected with horseradish peroxidase (HRP) in order to anterogradely label axons.

The HRP experiments indicated that axons originating in the implant can enter the adult host CNS at regions where the implant had fused with areas of the host brain that contained neuropil consisting of few myelinated axonal bundles, e.g. the molecular layers of the dentate gyrus, subiculum, and cingulate cortex. However, HRP labeled axons appeared to be deflected from the densely myelinated fiber tracts of the corpus callosum and fimbria. Specimens which were incubated with GFA antiserum indicated that there was no astrocytic reaction in the host HPC or cingulate cortex and no glial scar formation was present along the border between the neuropils of the implant and the host. In the EM material there was no astroglial or microglial barrier between the host neuropil and the HPC implant. Moreover, in many specimens it was impossible to identify the precise border between the two tissues since there was a continuous neuropil of axons and dendrites. Conversely, at regions where the implant had fused with the myelinated fiber tracts of the host, there were layers of astrocytic processes separating the implant from the host CNS.

The results suggest that implants of embryonic telencephalic tissue placed in the telencephalon of an adult rat (homotypic tissues) can: 1) prevent an astrocytic reaction in the host telencephalon and 2) inhibit the formation of a glial barrier along the transition zone between the implant and host neuropils but not between the implant and densely myelinated areas of the adult host. Moreover, axons from the implant can grow across the border of the implant and host neuropils but not into myelinated fiber tracts of the adult host. (Supported by NIH grant NS-15270.)

235.10 BRAIN TRANSPLANTS IN AN ANIMAL "MODEL" OF HUNTINGTON'S DISEASE. H. Kimura*, P.L. McGeer, Y. Noda* and E.G. McGeer. Kinsmen Laboratory of Neurological Research, University of B.C., Vancouver, B.C., Canada. V6T 1W5.

Recent reports (1) indicate that embryonic brain tissue transplanted to CNS sites in the adult can not only survive but can also develop functional connections. We now report that neostriatal cells from neonatal rats form viable transplants in the striata of adult host animals in which striatal neurons have undergone degneration following injection of kainic acid (KA). Four to six weeks after the unilateral injection of 5 nmoles KA into the striatum of 300 g male Wistar rats, neonatal (1 day) striatal cells were injected into the lesioned area. Four weeks later, animals were examined for surviving transplants by three different methods: histological examination, metabolism following parenteral ^{14}C-deoxyglucose (DG) administration, and histofluorescent techniques. Histological examination revealed a small core of neurons in various stages of development in the center of the gliotic and otherwise neuron-free striatal tissue. The transplanted neurons were more darkly stained than surrounding endogenous counterparts and showed new vascularization. ^{14}C-DG autoradiograms showed a greater accumulation of label in the transplanted tissue than in the surrounding lesioned striatum. The autoradiographic density of the transplanted tissue was similar to that in the contralateral (unlesioned) striatum. These experiments indicated that transplanted tissue survived and was metabolically active in the host striatum.

Furthermore, fluorescence histochemistry for catecholaminergic neurons showed particularly bright fluorescence in varicosities situated in and around the transplanted neuronal cell mass. Such fluorescence is seen in neonatal animals and indicates formation of new neuronal connections. Thus, transplanted neurons may not only survive but may become innervated by the dopaminergic terminals spared by the KA lesion.

Supported by the Garfield-Weston Foundation, the Hereditary Disease Foundation and the Medical Research Council of Canada.

236.1 VASCULAR AFFERENT CONNECTIONS IN THE FELINE CENTRAL NERVOUS SYSTEM. F. J. Thompson, J. R. Wald*, D. A. Lerner*, A. Blackwelder* and M. DiGaetano*. Dept. of Neuroscience, Univ. of Florida Coll. of Med., Gainesville, FL. 32610.

Recently, details of the projection of low threshold venous afferent fibers to the spinal cord (Thompson and Barnes, Brain Res. 177:561, 1979) and to the motor cortex (Thompson et. al., J. Autonom. Ner. Syst., in press) were reported. The present studies have specifically examined connections of peripheral vascular afferents to lumbar motoneurons and to motor cortex neurons.

The experiments were carried out on α-chloralose anesthetized cats and also decerebrate-spinal cats. The vascular afferents studied were electrically activated in the wall of a segment of femoral vein (hindlimb studies), and in the wall of the bracheal-cephalic vein (forelimb studies).

Facilitatory connections to lumbar motoneurons were revealed by recording electrical activity in the ipsilateral hindlimb muscles. EMGs elicited by femoral venous afferent stimulation were recorded in both flexor and extensor muscles acting on the thigh, shank, and foot: gracilis m., biceps femoris m., sartorius m., tensor fascia latae m., vastus lateralis m., anterior tibial m., medial gastrocnemius m., and lateral gastrocnemius m. The facilitation has also been examined in single motoneurons identified by antidromit stimulation of the muscle nerve.

Cortical mapping experiments have shown that (forelimb) bracheal-cephalic venous afferents project to the cortex of the lateral sigmoid gyrus; the (hindlimb) femoral venous afferents project to the cortex of the medial postcruciate gyrus. These two regions represented the primary projection foci, and overlap the cortical regions known to be motor cortex for the fore- and hindlimb musculature respectively. Microstimulation in the depth of the lateral sigmoid cortex in the region of cortical neurons activated by stimulation of (forelimb) bracheal-cephalic venous afferents, produced activation of musculature in same forelimb. Cortical neurons activated by bracheal-cephalic venous afferent stimulation were identified to project into the pyramidal tract by antidromic stimulation of the medullary pyramid.

These studies indicate that limb venous afferents activate effector neurons of the somatomotor system. The involvement of these connections in the reflex control of skeletal muscle venous counterpressure will be discussed. (Supported by NIH, NHLBI, 1 RO1 HL/HD 25614-01).

236.2 SYMPATHOINHIBITORY EFFECTS ELICITED BY STIMULATION OF BARORECEPTOR A- AND C- FIBERS. A.T. Zielinski* and G.L. Gebber. Dept. of Pharmacol./Toxicol., Michigan State Univ., E.Lansing, MI 48824.

A comparison was made of inhibition of renal sympathetic nerve discharge (SND) produced by selective activation of baroreceptor A- and C-fibers of the rabbit aortic depressor nerve. Inhibition of SND locked to single shocks applied to the aortic nerve was viewed as a computer-averaged positive potential. Aortic nerve activity was routinely monitored. A-fibers were selectively activated with low intensity (5-10 V) square wave pulses of 0.1 ms duration. Higher intensity triangular pulses of longer duration were used to block conduction in A-fibers during concomitant activation of C-fibers. Outward current flow at the cathode activated both A- and C-fibers; however, conduction in A-fibers was selectively blocked at the more centrally located anode due to the arrival of action potentials near the peak of inward current flow. The onset latency of inhibition of SND produced by A-fiber stimulation was 139±7 ms while the duration of inhibition was 190±7 ms (9 experiments). Corresponding values for the onset latency and duration of inhibition produced by C-fiber stimulation were 262±12 ms and 212±16 ms, respectively. Differences in axonal conduction velocity could not account for that difference (123 ms) between the onsets of inhibition of SND produced by A- and C-fiber stimulation. In this regard, antidromic conduction times from the medulla to the electrode on the aortic nerve for A- and C-fibers were separated by only 78±4 ms. This observation suggests that baroreceptor A- and C-fibers engage separate central circuits. This contention is supported by the results of experiments in which the medullary depressor region was stimulated. It was found that onsets of inhibition of SND evoked from different medullary sites in the same rabbit could vary by as much as 60 ms. Inhibition of SND elicited by A- or C-fiber stimulation was unaffected by midcollicular decerebration. Thus, the difference (≈45 ms) in the central delays of inhibition evoked by A- and C-fibers cannot be explained by a forebrain loop in the C-fiber pathway. Renal nerve responses elicited by stimulation of descending spinal excitatory tracts were depressed during inhibition of spontaneous SND produced by A- or C-fiber activation. The degree of depression of the spinal → renal nerve response accompanying aortic nerve stimulation was greater than that observed following C_1 spinal transection. These results suggest that activation of either fiber type leads to spinal inhibition. (Supported by PHS Grant HL-13187.)

236.3 BRAIN STEM NEURONAL TYPES WITH ACTIVITY PATTERNS RELATED TO SYMPATHETIC NERVE DISCHARGE (SND) IN THE BARORECEPTOR DENERVATED CAT. Susan M. Barman and Gerard L. Gebber. Dept. of Pharmacol./Toxicol., Michigan State Univ., East Lansing, MI 48824.

Using the method of spike-triggered averaging, two categories of brain stem units whose spontaneous discharges were related to inferior cardiac SND were identified in cats with sectioned carotid sinus, aortic depressor and vagus nerves. The discharges of S units (N=47) were related only to SND, while those of SE units (N=18) were related both to SND and EEG activity. Each of the 2 categories of neurons could be subdivided into 2 groups depending upon whether their discharges occurred during the rising or falling phase of 2-6/s slow waves of SND. S and SE units were intermingled primarily in nucleus reticularis ventralis at caudal medullary levels and in nucleus reticularis parvocellularis at mid- and rostral medullary levels. Autocorrelograms of S unit discharges and inferior cardiac SND contained the same rhythm (2-6 c/s). This rhythm was different from that contained in both SE unit discharges and EEG activity in experiments in which crosscorrelation analysis failed to reveal a relationship between cortical activity and SND. In other experiments, sympathetic nerve and cortical rhythms were locked to each other. Only SE units were located in these cats, and the rhythm contained within the autocorrelograms of their discharges was the same as that observed in SND and EEG activity (delta-theta range). These data suggest that 1) S units comprise or receive inputs from the brain stem oscillator responsible for the 2-6 c/s rhythm in SND; 2) SE units are contained in the brain stem "sympathetic" network since SND could be entrained to a cortical rhythm in some baroreceptor denervated cats; and 3) SE units are connected in series with S units since only SE units were found in experiments in which SND was entrained to a cortical rhythm. (Supported by PHS Grant HL-13187 and a Michigan Heart Association Grant-in-Aid.)

236.4 BIOCHEMICAL EVIDENCE FOR THE ROLE OF GLUTAMATE AS A NEUROTRANSMITTER OF BARORECEPTOR AFFERENTS. M.H. Perrone* W.T. Talman, and D.J. Reis. (SPON: M.D. Coughlin) Laboratory of Neurobiology, Department of Neurology, Cornell University Medical College, New York, NY 10021.

The middle third of the nucleus tractus solitarius (NTS) is the principal site of termination of primary baroreceptor afferents. We sought to determine if this region is innervated by fibers containing glutamate and if so if those fibers arose from vagal afferents, some of which are from baroreceptors. Male Sprague-Dawley rats were decapitated and a 1 mm saggital section of the brainstem was removed at the level of the obex. Samples of the NTS were removed with microbore punches (500-1000 μ i.d.) and homogenized in 0.32 M sucrose. The uptake of [^{3}H]-l-glu measured in the low speed supernatant from the NTS was characterized by high affinity (Km = 2.6 μM), Na^+-dependence, and sensitivity to osmotic shock. The uptake (pMoles/mg protein/min) of 1μM [^{3}H]-l-glu in the NTS (202±12; n=4; mean±SEM) is greater ($p<.05$) than that in homogenates of adjacent lateral NTS or hypoglossal nucleus or the spinal trigeminal nucleus (51±10; n=5). It is almost two-fold greater than that in the septum (77±10; n=4) or nucleus (98±12; n=4) accumbens and is of the same magnitude as that of the hippocampus (219±17; n=4), regions presumed to be heavily innervated by glutamatergic fibers. Unilateral ablation of the nodose ganglion, the site of cell bodies of vagal afferents, leads within 24 h to a 40% reduction ($p<.01$) in the V_{max} (but not the K_m) of high affinity uptake of l-glu restricted to the middle third of the NTS bilaterally. Sucrose density centrifugation demonstrated that the decreased uptake in NTS is confined to the synaptosomal fraction. There was no change in the Na^+-dependent uptake of 1 μM ^{3}H-GABA. Endogenous glutamate levels were decreased ($p<.001$) 35% in the NTS 7 days after unilateral extirpation of the nodose ganglion without change in the content of GABA, glycine, aspartate, or glutamine. We conclude that some vagal afferents terminating in NTS are glutamatergic. These findings are consistent with the view (Talman et al, Neurosci. Abst., 1980) that the neurotransmitter of baroreceptor afferent fibers is glutamate.

(Supported by HL 18974)

236.5 PHARMACOLOGICAL EVIDENCE FOR L-GLUTAMATE AS THE NEUROTRANSMITTER OF PRIMARY BAROREFLEX AFFERENTS. W. T. Talman, M. H. Perrone*, and D.J. Reis. Laboratory of Neurobiology, Dept. of Neurology, Cornell University Medical College, New York, NY, 10021.

To examine the possibility that L-Glutamate (L-Glu) is a neurotransmitter of baroreceptor afferent nerve fibers, we determined in rat the effects on mean arterial pressure (MAP) and heart rate (HR) of microinjections into the nucleus tractus solitarii (NTS) of: (a) L-Glu; (b) its agonists, D-Glu, kainic acid (KA), and L-Aspartate (L-Asp); and (c) an antagonist, glutamate diethylester (GDE). Unilateral microinjection of 0.1 µl of L-Glu, D-Glu, L-Asp, KA, GDE, or saline were made into NTS of 60 adult rats anesthetized with ∝-chloralose. L-Glu elicited a dose dependent fall of MAP and HR. The threshold dose was 5 ng (3×10^{-11} moles). The maximal response (at 1000 ng) was a fall of MAP of 37±3.5 mm Hg (mean ± SEM) and slowing of the HR by 53±10.9 beats/ min. The relative potencies were KA > L-Glu ≥ L-Asp > D-Glu. The effective sites for L-Glu were restricted to the intermediate third of the NTS. Unilateral microinjection of GDE (15 µg; $6X10^{-8}$ moles) into the NTS did not change MAP or HR. However, GDE totally blocked the response to L-Glu. Before GDE, L-Glu (50 ng; $3X10^{-10}$ moles) significantly ($p<0.001$) lowered MAP (mmHg) by 23±4.1 from 83±3.7 to 59±7.4 and HR (beats/min) by 25±7.2 from 320±8.2 to 295±1.0, but after GDE the microinjection of L-Glu caused no significant change in MAP (0±0.8) or HR (-1±1.2). The simultaneous microinjection of 15 µg GDE into the NTS bilaterally totally abolished ($p<0.01$) the reflex fall in HR induced by raising MAP 40-50 mmHg by phenylephrine i.v. Within the 2 minutes after bilateral microinjections of GDE, MAP rose from 99±7.2 to 153±8.4 mmHg. The time courses of the antagonism of the L-Glu response, the inhibition of the baroreflex, and the hypertensive response were the same. We conclude that the microinjection of L-Glu or its agonists into NTS simulates baroreflexes, that the effect is blocked by a specific L-Glu antagonist GDE, and that GDE produces signs of arterial baroreceptor blockade. The study suggests (a) that there are L-Glu receptors on neurons in NTS mediating baroreflexes and (b) that L-Glu is naturally released in NTS to exert transient inhibition of sympathetic neurons and excitation of cardiovagal neurons. Taken with the biochemical data (Perrone, et al., Neurosci. Abst., 1980) it offers further support that L-Glu is the neurotransmitter of baroreceptor afferent nerves.

236.6 SPINAL CORD REGULATION OF SYMPATHETIC OUTFLOW IN NORMOTENSIVE AND SPONTANEOUSLY HYPERTENSIVE RATS. Frank W. Marcoux and David Whitehorn. Dept. of Physiol. & Biophys., College of Med., Univ. of Vermont, Burlington, VT 05405.

The organization of sympatho-excitatory and inhibitory pathways playing down upon the spinal preganglionic neurons and their local circuitry has, to date, been studied most in the cat. Central hyper-responsiveness of sympathetic outflow components has been associated with hypertension as expressed in the spontaneously hypertensive rat (SHR). Measurements of the reactivity of spinal sympathetic circuits to direct stimulation were made to elucidate the role which spinal neurons play in the overall sympathetic hyper-responsiveness seen in the SHR.

Age-matched male SHR and normotensive controls (WKY), weighing 250-350g, were anesthetized (α-chloralose, 100 mg/kg) and artificially ventilated. Monopolar stimulation (500µA, 100µs pulses delivered at 80Hz for 0.5s) was applied to the cervical (C2-C3) dorsolateral funiculus (DLF) and sympathetic responses were recorded from a branch of the pre-celiac splanchnic nerve (activity was filtered, 300-3000Hz, and digitally integrated). The portion of the response due to activation of descending spinal elements alone was defined as that part which was unchanged in magnitude following ipsilateral dorsolateral quadrant section central to the stimulating electrode (the first 40-60ms of the response with 30-50ms onset latency). The remainder of the response, which was diminished in magnitude following dorsolateral quadrant section, was considered to be mediated largely by supra-spinal elements.

Comparison of the magnitude of the spinal sympathetic response as a percent of spontaneous activity between 8 SHR and 8 WKY showed a tendency for hyper-responsiveness in the SHR (310±35%) over WKY (268±35%). Values are given as the mean ± S.E. Similar results were observed when anesthesia blood pressure levels were adjusted by phenylephrine infusion (1-2 µg/min) to levels more representative of awake blood pressure for each strain. When the ganglionic blocker, hexamethonium, was given (25mg/kg) and only pure preganglionic nerve recordings were compared, the tendency for SHR spinal hyper-responsiveness was reduced.

Complete ipsilateral hemisection central to the stimulating electrode often revealed an enhanced spinally mediated sympathetic response compared to that observed in the dorsolateral quadrant sectioned cord. This suggests that preganglionic neurons are normally under a tonic inhibitory influence driven supra-spinally and descending in the ventral cord. Supported by NIH HL 24110.

236.7 THE A5 CATECHOLAMINE GROUP AS A MEDIATOR OF PRESSOR RESPONSES IN RAT. J.J. Neil* and A.D. Loewy (SPON: R.M. Burde), Dept. of Anatomy & Neurobiology, Washington Univ. School of Med., St. Louis, MO 63110.

Electrical stimulation of the A5 catecholamine cell group in the rat leads to a rapid blood pressure increase with no change in heart rate. Anatomically, this cell group has been shown to project to the intermediolateral cell column (IML) of the spinal cord using anterograde labeled amino acid transport. The object of this study is to determine if stimulation of the A5 cell group activates the sympathetic nervous system via the direct spinal cord pathway.

First, midbrain hemisections were performed in adult rats just rostral to the A5 cell group (to eliminate axons of passage). Two weeks later, these animals were stimulated at A5 with a monopolar electrode both before and after acute spinal cord transection. Pressor responses were elicited in all animals stimulated (5-25µA, 100Hz, 1 msec pulses, 5 sec trains), and spinal cord transection at the C8 level abolished the pressor responses at stimulus intensities up to 50-100µA. Both electrode position and the extent of hemisection were verified histologically in these and all following animals.

Secondly, A5 stimulation was carried out in midbrain-hemisected animals which had been guanethidine sympathectomized. Four of seven animals were adrenalectomized acutely before A5 stimulation. In all animals, no pressor response or heart rate change could be elicited with A5 stimulation. The extent of sympathectomy was evaluated in each animal via electrical stimulation of a pithing rod inserted into the spinal canal at the end of each experiment.

Finally, in order to determine if the pressor response is mediated via the A5 projection to the IML, midbrain-hemisected rats were injected intraspinally with 2µl of 12mg/ml 6-hydroxy-dopamine bilaterally at C8. After four weeks these rats were stimulated at A5. Pressor responses could be elicited from all animals stimulated, even though spinal norepinephrine in the same animals was less than 3% of controls using the trihydroxyindole fluorescent catecholamine assay.

These results suggest that the A5 pressor response is mediated via the sympathetic nervous system, but that the direct A5-IML projection is not necessary for the response. Hence, it seems likely that one of the other A5 projections activates a non-noradrenergic pathway leading to the IML. (Supported by USPHS-grants NS12751 and GM07200, and a grant-in-aid (80 723) from the American Heart Association)

236.8 PATHWAYS MEDIATING SYMPATHO-SYMPATHETIC REFLEXES OF CARDIAC ORIGIN L.C. Weaver, S. Donoghue*and R. Oehl* Depts. of Physiol., Mich. State Univ., E. Lansing, MI, and Univ. of Birmingham, B'Ham, U.K.

Afferent neurons contained within cardiac sympathetic nerves can initiate excitation of central sympathetic outflow. While it is known that cardio-cardiac sympathetic reflexes can be mediated solely within the spinal cord, the central pathways important for excitation of other sympathetic neurons have not been elucidated. Therefore, in this investigation, the contributions of spinal and supraspinal pathways to cardiac sympathetic afferent (CSA) excitation of renal nerve activity were ascertained. CSA neurons were chemically excited by epicardial application of bradykinin or potassium chloride in chloralose anesthetized, vagotomized, sino-aortic denervated cats. Multifiber renal nerve responses were compared prior to and following midcollicular decerebration or high cervical spinal cord transection. Activation of CSA nerves caused excitation of renal nerve activity and pressor responses in intact cats. Responses were unchanged or increased following decerebration. After cord transection, reflex excitation of renal nerve activity was diminished; however, since basal activity also was decreased, the reflexes constituted the same percent change as had been observed in the intact cat. Concentrations of chemicals required to elicit reflexes were increased 2-10 fold after cord section. Pressor responses to CSA stimulation were insignificant in spinalized cats. When excitability of preganglionic neurons was increased by electrically stimulating excitatory tracts in the cervical cord, spinally mediated reflex changes in renal nerve activity were more apparent. These results illustrate that supracollicular neurons are not essential to these excitatory sympathetic reflexes and that at least a portion of these reflexes can be mediated solely within the spinal cord. It was considered possible that (1) medullary neurons simply provide tonic facilitation of reflexes localized within the spinal cord, or (2) the CSA's influence medullary neurons to initiate facilitation of spinal reflexes, or (3) the CSA's excite medullary neurons to initiate supraspinal reflexes which are dependent of spinal reflexes. The last two possibilities require that CSA neurons have synaptic influences on medullary neurons involved in control of sympathetic preganglionic activity. Such influences were investigated in cats in which inferior cardiac nerves were stimulated electrically and the medulla 2 mm rostral and caudal to the obex searched with microelectrodes for responsive neurons. Neurons excited with latencies from 10-300 ms were distributed widely in areas such as the Nucleus Tractus Solitarius, Spinal Trigeminal Nucleus, Inferior Olivary Nucleus and throughout the reticular formation. These results are consistent with the contention that medullary neurons actively contribute to the excitatory reflexes initiated by cardiac sympathetic afferent neurons. (Supported by NIH grant HL21436).

236.9 CARDIAC VAGAL AND SYMPATHETIC DISCHARGES DURING STIMULATION OF HYPOTHALAMIC "DEFENSE AREA". Kiyomi Koizumi and Mark Kollai. Depts. of Physiol., Semmelweis Med. Univ., Budapest and State Univ. of New York, Downstate Med. Ctr., Brooklyn, NY 11203.

We have previously shown that the activity of vagal and sympathetic fibers innervating the heart changes reciprocally in one situation, but in other circumstances co-activation of the two systems occurs (J. aut. nerv. Syst., 1:33,'80). We wish to investigate this relationship during stimulation of the hypothalamic "defense area". In chloralose anesthetized, artificially ventilated dogs, recordings were made from both cardiac vagal and sympathetic nerves simultaneously. The phrenic nerve activity, blood pressure, heart rate and blood flow to the hind limb muscles were also monitored. Stimulation of the hypothalamic "defense area" produced a strong pressor response, tachycardia and 5-8 fold increase in muscle blood flow which was blocked by atropine. There was an immediate cessation of vagal discharges and enormous increase in sympathetic activity which continued throughout the stimulation. At the cessation of the stimulus, vagal discharges suddenly increased greatly, while sympathetic discharges almost ceased. This reversal in response was partly due to baroreceptor excitation and partly due to the direct "after-effect" of the stimulus, since such response, though smaller, was still observed after complete baroreceptor denervation. The inhibition of vagal activity produced by the hypothalamic stimulation was strong enough to prevent appearance of a baroreceptor reflex during stimulation even when the blood pressure reached over 200 mmHg, and strong vagal excitation caused by electrical stimulation of a carotid sinus nerve was also inhibited during such stimulus. Stimulation of the same "defense area" with single or a short train of pulses evoked inhibition of vagal discharges followed by mild excitation of the activity, while in response of sympathetic nerve reverse sequence occurred. The results show that a clear-cut reciprocal control between vagal and aympathetic nerves occurs in "defense reactions", though the pattern can be modified by the extent of the activity in baroreceptors involved. (Supported by grants from Hung. Min. Health 1-07-0301-06-1/K and USPHS NS-847; Fogarty Int'l. Ctr. FO6 TW 374).

236.10 AREA SPECIFIC CONTROL OF PRESSOR-CARDIOACCELERATORY ESB DURING INSTRUMENTAL CARDIOVASCULAR CONDITIONING IN THE MONKEY (Macaca mulatta) J. A. Joseph and B. T. Engel. Gerontology Res. Ctr., NIA, Baltimore, MD 21224.

Each of four monkeys was operantly conditioned to slow (S) or speed (F) heart rate (HR), or had its HR monitored (NF). Each experimental session was divided into a baseline (256 sec) and a conditioning or monitoring session (1024 sec) which was further subdivided into 16, 64 sec segments. HR, systolic (SBP) and diastolic (DBP) blood pressures were recorded throughout each experiment on a beat-by-beat basis, and averages for baseline and each 64 sec segment were automatically computed. Animals were signalled to slow HR by a red cue light or to speed HR by a green cue light. Correct performance was signalled by a yellow light and incorrect performance was punished by a 10 ma, .45 sec shock to the tail delivered on an 8 sec, fixed interval schedule. NF was unsignalled and unreinforced. During each even numbered segment of each session an animal received electrical stimulation to the brain (ESB) in one of four regions: (I) lenticular nucleus, globus pallidus, ventromedial tegmentum; (II) anterior or dorsomedial hypothalamus; (III) posterior or lateral hypothalamus; (IV) subthalamic nucleus. Stimulation was chosen on the basis of pilot studies with each animal such that stimulation resulted in an increase (Δ) of HR of 10-20 beats/min and an increase in BP of 10-20 mm Hg. There were significant interactions between experimental conditions and ESB when changes in HR, SBP or DBP from baseline to each stimulation (ST) or non-stimulation ($\overline{ST}$) segment was analyzed using a 2 (ST; $\overline{ST}$) by a 3 (S, F, NF) mixed model, analysis of variance: (A) For each animal during slow sessions Δ HR was significantly attenuated when ESB was given in regions I or III but not when regions II or IV were stimulated; (B) During speeding Δ HR either was enhanced or was similar to Δ HR during NF but this varied among animals; (C) BP was not reliably altered during ST--i.e., there were no consistent effects across animals. Thus, these experiments show that animals can alter the effect of ESB through behavioral conditioning, and that the degree of alteration can be very great. Results for a typical animal are shown below for Δ HR (in BPM). Note that the scores in this table are changes from baseline. Thus, ST effects are superimposed on pre-existing performance levels. Compare ST with $\overline{ST}$ across conditions.

	S		NF		F	
REGION	ST	$\overline{ST}$	ST	$\overline{ST}$	ST	$\overline{ST}$
I	-32.3	-33.8	1.1	-7.3	20.5	13.5
II	- 3.9	-21.2	51.1	29.8	42.0	26.4
III	-14.1	-14.1	-1.0	-10.8	22.5	8.6
IV	11.0	-10.3	23.0	9.6	29.8	14.0

236.11 GLOBAL INCREASE IN CEREBRAL BLOOD FLOW INDEPENDENT OF LOCAL GLUCOSE METABOLISM ELICITED BY ELECTRICAL STIMULATION OF FASTIGIAL NUCLEUS IN RAT. M. Nakai, C. Iadecola, L.W. Tucker, and D.J. Reis. Laboratory of Neurobiology, Dept. of Neurology, Cornell Univ. Med. College, New York, NY.

Electrical stimulation of the rostral fastigial nucleus (FN) of rabbit will increase cerebral blood flow (CBF) up to two-fold in the parietal cortex, measured by H_2-clearance (MacKenzie et al., Neurosci. Abs., 1977). In the present study we sought to determine whether FN stimulation in rat also increases CBF and, if so, whether the increase in CBF is: (a) restricted to cerebral cortex or is more widespread; and (b) associated with a corresponding increase in glucose metabolic rate (GMR). Rats were anesthetized (chloralose), paralyzed and ventilated. The FN was stimulated electrically. Blood pressure was maintained constantly in the autoregulated range (130 mm Hg) in stimulated and controlled animals. Local CBF and GMR were determined autoradiographically by the ^{14}C-iodoantipyrine (IAP) technique or ^{14}C-2-deoxyglucose (2-DG) methods, respectively. In controls, CBF closely corresponded to GMR in all 24 brain regions sampled (R = 0.951). With FN stimulation, CBF increased in all 24 areas averaging 183 $\pm$ 4.5% (n=7)($p < .025 - .005$). Increases in CBF ranged from 157% (cerebellar grey) to 226% (sensory-motor cortex) of control. Most marked changes were throughout the cerebral cortex but also substantially in white matter, basal ganglia, and midline thalamic and brainstem nuclei. The GMR increased in only 12 of 24 areas averaging 130.7 $\pm$ 3.9% ($p < .05$, n = 8) and ranging from anterior thalamus (116%) to central thalamic nuclei (166%). Most of the cerebral cortex was not changed. Most increases were seen along the major projection pathway of FN. FN stimulation also increased CBF when measured by the IAP technique using regional dissection. The increases averaged 209 $\pm$ 17% ($p < .005$, n = 7) and ranged from 117% (hippocampus) to 302% (parietal cortex) of control. The two- to three-fold increases of CBF seen in all areas of the brain were not affected by acute sympathectomy and were only slightly attenuated by spinal cord transection. We conclude that stimulation of projections originating in or connecting with FN will evoke a powerful and global vasodilatation of cerebral vessels not necessarily associated with altered cerebral metabolism. The vasodilation is probably mediated by intrinsic pathways in brain.

(Supported by NIH grant HL18974)

236.12 THE EFFECTS OF CENTRAL CATECHOLAMINERGIC LESIONS ON DEVELOPMENT OF THE CARDIAC SYMPATHETIC AXIS. R. Deskin*, E. Mills*, W.L. Whitmore*, F.J. Seidler* and T.A. Slotkin. (SPON: A. Tadepalli). Dept. Pharmacology, Duke U. Med. Ctr., Durham, N.C. 27710.

In order to assess what role the central nervous system (CNS) plays in cardiac growth and development, neonatal rats were treated intracisternally with 6-hydroxydopamine (6-OHDA) to destroy central catecholaminergic nerve terminals. The extent and duration of the lesion was estimated by measurement of whole brain tyrosine hydroxylase activity, which was markedly reduced throughout the entire course of development. Specificity for the CNS was confirmed by the marked reduction of accumulation of radiolabelled monoamines into brain synaptosomal fractions, compared to no effect on uptake into preparations from peripheral neurons (heart synaptic vesicles). Cardiac development was impaired in the 6-OHDA-treated animals, as assessed by the ratio of heart/body weight (an index of organ growth) and by ornithine decarboxylase activity (an index of cellular maturation). The defects did not appear until the second to third week of postnatal age; because this corresponds to the age at which tonic sympathetic control of the heart first appears, baroreceptor-mediated cardiac sympathetic reflexes and basal autonomic input to the heart were evaluated. Although the reflexes developed normally as assessed both physiologically (carotid occlusion test) and biochemically (stimulation of cardiac ornithine decarboxylase by hydralazine-induced hypotension), there was evidence for abnormalities in both parasympathetic and sympathetic tone. Vagal input was elevated in the treated rats, as shown by a subnormal heart rate which became normal after vagotomy. Salt load, which normally causes a centrally-mediated increase in sympathetic outflow, had a severely attenuated effect in the lesioned animals. Thus, destruction of central catecholaminergic nerve terminals in the neonate does not alter maturation of the sympathetic neurons per se, but results in an abnormality in the balance of parasympathetic and sympathetic tone, which may be responsible for subsequent specific defects in cardiac development and in cardiovascular function. Pretreatment of the animals with desmethylimipramine prior to 6-OHDA produced a relatively specific lesion of dopaminergic nerve terminals, and results obtained for cardiac growth and ornithine decarboxylase were virtually identical to those obtained with 6-OHDA alone, suggesting that the effects on central dopamine are more important than on norepinephrine in producing defective cardiac development. (Supported by USPHS HL-24115, HL-NS-22861 and DA-00006).

236.13 CARDIAC GNAGLION CELLS LABELED BY QUINUCLIDINYL BENZYLATE.
E.M. Landau, Dept. of Neurobiology, Harvard Univ. Sch. of Med. Present address: Dept. of Physiology and Pharmacology, Sackler Sch. of Med., Tel-Aviv Univ., Israel (Spon.: S.G. Matsumoto)

An attempt was made to study the localization of muscarinic receptors in the necturus cardiac ganglion cells. For this purpose, radioactive quinuclidinyl benzylate (H^3-QNB-16.4 Ci/mmol) was employed. H^3-QNB at a concentration of 10 nM blocked the hyper-polarizing response of the gangion cells to Betanachol. The blocking effect of QNB was partially reversible after prolonged wash-out. For the morphological studies, cells were exposed to 20 nM of H^3-QNB for one hour. The cells were then frozen, lyophylized, embedded in epon and sectioned for light microscopy. The sections were coated with Kodak fine grain emulsion and allowed to develop for six months. Care was taken to avoid exposure of the sections to water or water vapor. The autoradiograms showed a clear labeling of the cytoplasm of the ganglion cells. Similar labeling was also found in experiments where 25 μM of atropine were added in addition to 20 nM H^3-QNB. In view of the higher oil-water partition of QNB, it is suggested that in our experiments an intracellular precursor of the muscarinic receptor was labeled by H^3-QNB.

237.1 NYSTAGMUS GENERATION IN THE PRESENCE OF STATIC AND ROTATING GRAVITY VECTORS. T. Raphan, B. Cohen, D. Dennett*, V. Henn*. Depts. of Neurology, Mt. Sinai School of Medicine, New York, N.Y. 10029, and University of Zurich, Switzerland.

Rotation in darkness about an axis coincident with the gravity vector (vertical axis rotation,VAR) evokes per rotatory nystagmus whose slow phase velocity decays to zero with a time constant of 12-30 sec. If head velocity is set to zero after per rotatory nystagmus has disappeared, the characteristics of the per and post rotatory nystagmus are approximately equal. These characteristics are maintained when monkeys are tilted as long as the axis of rotation is coincident with the gravity vector. Optokinetic nystagmus (OKN) and optokinetic after nystagmus (OKAN) induced when monkeys are tilted from the vertical have approximately the same characteristics as the OKN and OKAN induced when the animals are upright. OKAN is somewhat modified for angles of tilt close to 90°. This indicates that a static gravity vector i.e. one that does not rotate relative to the head has little or no effect on the horizontal per and post rotatory nystagmus. OKN and OKAN are similarly unaffected by a static gravity vector. In contrast, rotation in darkness about an axis tilted with regard to gravity (off vertical axis rotation, OVAR) causes indefinite prolongation of nystagmus. This effect occurs at angles of tilt from 5-90°. Steady state velocities increase approximately linearly with rotational velocity and are maintained up to about 50-60°/sec. There is oscillation in slow phase velocity associated with head position and dependent on the speed of rotation. If the monkey is rotated about a vertical axis and then the axis is tilted after the velocity of the per rotatory nystagmus has decayed to zero, slow phase velocity rises to a steady state value with a time constant of 10-15 sec. When the animal is returned to the VAR position the nystagmus decays with about the same time constant as it rose. The OVAR post rotatory response has a peak velocity that is the difference between the VAR post rotatory velocity and the slow phase velocity when the head was stopped at the end of OVAR stimulation. The time constant of the post rotatory response is about 5 seconds and is similar to the characteristics of post rotatory nystagmus during visual suppression. Tilts during post rotatory nystagmus and OKAN also cause suppression of slow phase velocity similar to that of visual suppression. The data indicate that continuous changes in head position with regard to gravity activates the velocity storage integrator to sustain the nystagmus. Stopping after OVAR and tilts during post rotatory nystagmus or OKAN suppress the integrator. These characteristics contribute to better ocular compensation for head movement in space.

237.2 CONSEQUENCES OF MONOCULAR DEPRIVATION OR CORTICAL LESIONS UPON MONOCULAR HORIZONTAL OPTOKINETIC NYSTAGMUS IN THE CAT. N.P. Strong*, R. Malach* and R.C. Van Sluyters. School of Optometry, University of California, Berkeley, CA 94720.

It has been proposed that there are different central pathways mediating monocular optokinetic nystagmus (OKN) in the two horizontal directions. One pathway transmits information concerning stimuli moving from temporal-to-nasal (N) and the other information about stimuli moving in the opposite, nasal-to-temporal (T) direction (Hoffmann, K-P., in Developmental Neurobiology of Vision, R. Freeman (ed), 63-72, 1979). Previous work has indicated that the quality of monocular OKN in these two directions may be different in both time course of appearance and susceptibility to deprivation; and it has been suggested that both bilateral cortical lesions (Wood, C.C., Spear, P.D. and Braun, J.J., Brain Res., 60:231-237, 1973) and monocular deprivation (MD) (van Hof-van Duin, J., Arch. Ital. Biol., 116:471-477, 1978) disrupt the pathway for T-OKN from both eyes at the cortical level, whereas the generation of N-OKN is independent of cortex.

In a series of control experiments, we have studied the ontogenesis of monocular OKN in kittens using DC electrooculographic recording techniques that permit quantitative analysis of OKN performance. The amount of asymmetry in N- versus T-OKN was determined in normal kittens of various ages using measurements of both slow-phase gain and beat frequency. In comparing the consequences of MD or cortical lesions upon monocular OKN, we have found that the effects of MD are confined solely to the deprived eye and that T-OKN is disrupted much more than N-OKN. Unilateral cortical lesions involving removal of the entire posterior neocortex produce an equivalent breakdown of T-OKN through the eye ipsilateral to the lesion; however N-OKN through this eye is not severely disturbed.

237.3 NEURONAL ACTIVITY IN THE FLOCCULUS DURING OPTOKINETIC NYSTAGMUS AND AFTER-NYSTAGMUS IN THE ALERT MONKEY. W. Waespe*and V. Henn* (SPON: M.B.Bender). Dept. of Neurol., Zuerich Univ., USZ, Zuerich 8091-CH.

Single cell activity in the flocculus was recorded extracellularly during vestibular and optokinetic stimulation. Animals were rotated about a vertical axis in light or darkness, or a fullfield optokinetic drum was rotated around the stationary monkey at constant velocities between 15 and 160 deg/sec. Neurons were classified as Purkinje-cells (P-cells) and Non-Purkinje-cells (Non-P-cells). Non-P-cells, reflecting the input activity to the flocculus, showed a behavior similar to neurons in the vestibular nuclei (Waespe & Henn, Exp. Brain Res., 27, 523-538, 1977). They had a long decay time constant (10-50 sec). There was an equal number of type I and type II neurons. All Non-P-cells were also modulated during optokinetic stimulation. Changes in activity were similar when vestibular nystagmus (VN) and optokinetic nystagmus (OKN) were in the same direction except that during optokinetic stimulation neuronal activity increased monotonically only up to constant velocities of 60 deg/sec whereas OKN slow phase velocity reached higher values. During optokinetic after-nystagmus (OKAN) neuronal activity reflected slow-phase velocity. Only about 10-15% of P-cells were modulated by these stimulus paradigms. Simple spike activity of P-cells was only weakly modulated during vestibular stimulation. About half of these P-cells were also influenced by optokinetic stimulation. However, in contrast to the Non-P-cells, P-cells were modulated only at velocities of 60 deg/sec or more. Furthermore they were activated by vestibular and optokinetic stimuli in the same direction, which elicited VN and OKN into opposite directions. During OKAN P-cell activity showed no relation to the slow-phase velocity of nystagmus.

The results suggest a complementary mode of information processing in the flocculus and vestibular nuclei during optokinetic stimulation. P-cells respond to stimulus values beyond the working range of the vestibular nuclei neurons. The data support findings of lesion studies which show that after flocculectomy monkeys were unable to produce OKN with slow-phase velocities of more than 40-60 deg/sec, the saturation velocity of the vestibular nuclei neurons.

237.4 CHANGES IN CEREBELLAR ACTIVITY DURING ADAPTIVE GAIN CONTROL OF THE VESTIBULO-OCULAR REFLEX (VOR) OF GOLDFISH, J.J. Michnovicz*, J.O. Schairer*and M. V. L. Bennett, Div. Cellular Neurobiology, Dept. Neuroscience. A. Einstein Col. Med., Bronx, New York 10461.

Goldfish have been shown to undergo a relatively rapid adaptive gain control of the VOR when presented with different combinations of vestibular and optokinetic stimuli (Schairer and Bennett, Soc. Neur. Abs. 3: 485, 1977). Upon ablation of the cerebellum, the fish loses this adaptive capacity, while the VOR functions essentially as before. In order to elucidate the role of the cerebellum in this behavior, extracellular recordings were made in the vestibulo-cerebellum during adaptive modification of the VOR.

Restrained, unanesthetized goldfish were placed in a clear tank which was secured to a movable platform and surrounded by a vertically striped optokinetic drum. Rotation was in the horizontal plane at 0.125 hz. Eye position was monitored with a magnetic search coil. VOR gain is expressed as eye velocity/table velocity. Instantaneous firing rates were calculated using a spike discriminator, and gain of the unit was measured as impulses per second/table velocity. Records were taken under four conditions: 1) dark, in which the platform was rotated in the dark; 2) training toward VOR gain of 1, in which the platform was rotated in the light with the drum stationary; 3) training toward 0, in which the fish and drum were rotated together in the light; 4) training toward 2, in which the platform and drum were rotated in the light equally and oppositely.

The effects of optokinetic stimulation on cerebellar units responding to rotation were of two types, immediate and retained. Six units immediately changed in firing frequency as the light was switched on so that the fish could see the drum moving with it (training toward 0). Four units increased in firing rate an average of about 60% while the VOR gain dropped about 70%. Two units decreased in firing rate about 40% in the light when the VOR gain decreased about 70%. One unit showing an increase was followed for over 3 hours. During this period, training toward 0 was maintained for 90 minutes. At the end, the gain of the VOR in the dark had decreased by 69% from its original value, while the firing rate had risen to a level 67% above its original value in the dark. Subsequent training in the opposite direction (toward 2) showed corresponding reversal of changes in both VOR gain and firing gain. A second unit that showed an immediate gain increase in the light gradually increased further in gain during a 1 hour session of training toward 0, but was not tested in the dark. The relative rapidity of these changes may allow further analysis of the cellular mechanisms of this form of learning.

237.5 PLASTICITY OF EYE MOVEMENT DIRECTION IN THE VESTIBULO-OCULAR REFLEX (VOR). L. W. Schultheis* and D. A. Robinson (SPON: W. M. King). The Wilmer Institute, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

It has been shown that signals from each semicircular canal reach all extraocular muscles. A head rotation vector is encoded in the planes of the canals on primary vestibular afferents and in the planes of the eye muscles on motoneurons. The projections from the vestibular to the oculomotor nuclei constitute a transformation from the canal to the muscle coordinate systems. These projections insure that the eye moves in the right direction as well as speed. Just as the eye speed relative to head speed has been shown to be plastic, we wanted to determine whether eye direction was also plastic.

Subjects nodded their heads vertically and tracked a target which was displaced horizontally in proportion to vertical, angular head displacement. It is known (Science, 160: 429, 1968) that after 10 min exposure a stationary target appears to move horizontally during vertical head rotation. This illusion is consistent with the idea that vertical head movements were creating reflex horizontal eye movements. We recorded eye movements in five subjects in such a situation and confirmed this hypothesis. The cross-axis ratio (horizontal eye velocity/vertical head velocity measured in the dark) could be increased from zero (normal) to 0.2 in about 0.5 hr. Efforts to obtain a similar result in the monkey, however, using Dove prisms at 45° to associate vertical, retinal image slip with horizontal head rotation gave negative results (Neurosci. Abstr., 5: 371, 1979).

Nevertheless, for further neural studies, we tried to demonstate this phenomenon in the cat. The head was immobilized by a skull implant and eye and head movements recorded by the magnetic field-search coil method. The animals were oscillated in pitch inside an optokinetic drum which moved horizontally in proportion to vertical head rotation. After 5 hr the cross-axis ratio in three animals was 0.24 (range 0.18 to 0.28). The change was plastic: the ratio did not change after 1-3 hr in darkness. The ratio returned to zero within 0.5 hr upon rotation with the drum stationary. The cross-axis ratio for a fixed exposure time increased if the drum displacement was increased relative to head displacement. Plastic changes did not occur in stroboscopic illumination (3.7 flashes/sec).

These results indicate that in humans and cats the VOR can be twisted so that vertical canal stimulation produces a horizontal component of eye movements.

237.6 DIFFERENCES IN DYNAMICS OF MOTOR OUTPUT TO EYE AND NECK MUSCLES. J. Goldberg*, G. Bilotto, B. W. Peterson, and V. J. Wilson. The Rockefeller University, New York, N.Y. 10021

The dynamics of the vestibuloocular reflex (VOR), vestibulocollic reflex (VCR), and cervicocollic reflex (CCR) were investigated in precollicular decerebrate cats using horizontal angular rotations in which angular position was modulated by single sinusoids or summed multiple sinusoids in the frequency range 0.05 - 4 Hz. Using rotational amplitudes of 1 - 20°, we obtained linear sinusoidal modulation of eye position and head position which at higher frequencies was in a direction approximately opposite (compensatory) to that of the applied rotation.

Dynamics in the VOR system were investigated by recording single unit activity of antidromically identified abducens motoneurons with tungsten microelectrodes and horizontal eye position with bitemporal Ag-AgCl EOG electrodes. The abducens motor signal displayed the characteristics of a first order lead system when measured against horizontal eye position: phase lead tended toward 90° at higher frequencies and gain increased at 20 db/decade. Estimates of the time constant of the lead term ranged from 0.5 to 1.7 seconds.

Dynamics in the neck motor system were investigated by recording EMG activity of dorsal neck muscles under three conditions: whole body rotation with the head fixed to the turntable, body rotation with the head free to move, and body rotation with the head fixed in space. Neck motor signals measured with respect to platform position (or to compensatory head position when the head was free) displayed the characteristics of a second order lead system under all three conditions: phase lead at the upper end of the frequency range (4 Hz) exceeded 120° and was still increasing, gain rose at 40 db/decade. Estimated time constants of the two lead terms ranged from 0.05 to 0.15 seconds. This dynamic behavior was unaffected by a bilateral section of the medial longitudinal fasciculus at the level of the obex (see also Wilson et al., J. Neurophysiol. 42 (1979) 331-346). Thus the phase lead does not depend on the integrity of the three-neuron VCR arcs, which traditionally have been thought to carry the high frequency phase-advanced signal.

These results indicate that the horizontal gaze control system produces output signals with different dynamics to drive the eyes and head even in response to identical vestibular stimuli. As noted by others, the extraocular motor signals appear to be well adapted to overcome the predominantly viscous load presented by the eye mechanics. The neck motor signal would similarly appear to be well suited to compensate for the predominantly inertial load of the head-neck system. Supported by grants EY 02249, EY 00100, NS 02619.

237.7 THE CERVICOOCULAR REFLEX OF THE RABBIT AND ITS LINEAR SUMMATION WITH THE VESTIBULOOCULAR REFLEX. N. H. Barmack, V. E. Pettorossi* and M. A. Nastos* Neurological Sciences Institute of Good Samaritan Hospital & Medical Center, Portland, Oregon 97210.

The vertical vestibuloocular reflex (VVOR) has a higher gain than does the horizontal vestibuloocular reflex (HVOR) during low frequency, sinusoidal, whole-body rotation. This difference can be ascribed to the contribution of the utricular otoliths to the VVOR. During normal head movements, neck proprioceptors might partly compensate for this reduced low frequency gain of the HVOR. We have measured the horizontal (HCOR) and vertical (VCOR) cervicoocular reflexes of rabbits evoked by sinusoidal oscillation of the body about the fixed head (±10 degs, 0.005-0.800 Hz). When the body of a rabbit was rotated horizontally clockwise (as viewed from above) in total darkness, clockwise conjugate eye movements were evoked. When the body was rotated about the longitudinal axis onto the right side, the right eye rotated down in its orbit and the left eye rotated up. The mean gain of the HCOR (eye velocity/body velocity) rose from 0.21 at 0.005 Hz to 0.27 at 0.020 Hz and then declined to 0.06 at 0.3 Hz. Eye position led body position by 18 degs at 0.005 Hz, reversed to a lag of 23 degs at 0.08 Hz, and reversed again to a lead of 5 degs at 0.4 Hz. The gain of the VCOR was reduced relative to the gain of the HCOR by a factor of 2-3. The HCOR and HVOR were measured separately and in combination (HCOR + HVOR) by rotation of the head about the fixed body. These reflexes combine linearly. The latency and pattern of horizontal eye movements evoked by horizontal step-angular (20 deg) displacements of the body were also studied. The initial compensatory eye movement evoked by step stimulation had a mean latency of 37 ±13 msec (N=9). This initial low velocity compensatory eye movement was usually followed by a fast compensatory eye movement at a mean latency of 300 ±70 msec. During conjoint neck proprioceptive and vestibular step stimulation (HCOR + HVOR) the fast compensatory eye movements evoked by neck proprioceptive stimulation (HCOR) effectively canceled the vestibularly-induced anticompensatory resetting eye movements (HVOR). This cancellation would enable maintenance of horizontally eccentric eye position during active head movements. The relative movements of the first three cervical vertebrae during stimulation of the HCOR and VCOR were measured. For the HCOR, the largest angular displacement (74%) occurs between C_1 and C_2. For the VCOR, the largest relative angular displacement (45%) occurs between C_2 and C_3. We conclude that the HCOR partially compensates for the absence of otolithic information concerning low frequencies of horizontal head movement. 237.8 ELECTROPHYSIOLOGICAL IDENTIFICATION AND PHYSIOLOGICAL ACTIVITY OF LATERAL VESTIBULAR NEURONS IN THE ALERT CAT. H. Reisine, A. Strassman and S.M. Highstein. Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461.

Cats were implanted with electrodes for electric pulse stimulation in the IIIrd nucleus, on the VIth nerve, and over the bony ampulla of the horizontal semicircular canal (S.C.C.). Cats' heads were fixed to a rotating table (sinusoidal motion), eye movements monitored with E.O.G. electrodes and head velocity and position were also recorded. Glass microelectrodes were inserted into the brainstem of alert cats through an implanted chamber.

Some neurons recorded 2-3mm lateral to the VIth nucleus were activated antidromically from the IIIrd nucleus (ANTI.) and monosynaptically from the S.C.C. These neurons encode a head velocity signal (Type I, c.f. Reisine & Highstein, Brain Res. 1979). These same neurons also encode eye position with an on-direction correlated with activation of the ipsilateral medial rectus extraocular muscle (MR). Other neurons were ANTI., but disynaptically activated from the S.C.C. These neurons did not encode head velocity but encoded eye position with an on-direction as above. The majority of neurons were poly- or disynaptically activated from the S.C.C., were not ANTI., encoded Type II head velocity signals and were not related to eye position.

We conclude that some neurons in the lateral vestibular area projecting to the IIIrd nucleus are driven monosynaptically from the ipsilateral labyrinth, and encode a mixture of Type I head velocity and horizontal eye position signals. These neurons are presumed to be ventral lateral vestibular neurons projecting via the ascending tract of Deiters' to the MR. Signals carried over this pathway may account for the remaining V.O.R. after MLF lesion. Supported by NIH EY-01670, NIH K04-EY0003, NIH NS-07512, and NIH 1F32-NS-06019.

237.9 VESTIBULAR STIMULATION ALTERS THE NEURAL CONTROL OF PRIMATE FOVEAL PURSUIT IN THE FINAL 'COMMON' PATHWAY.

R. Eckmiller. Div. of Biocybernetics, University of Düsseldorf, D-4000 Düsseldorf, West Germany.

It was recently shown that during foveal pursuit in Java monkeys the velocity component ($R\times\dot{\theta}$) of most oculomotor motoneurons is different in the agonist versus antagonist phase(Eckmiller and Mackeben, Pflügers Arch.377:15,1978). In the present study, single unit activity in the III. or VI.nerve nuclei, as well as eye movements(EOG), were recorded while the trained monkey pursued a small light spot(4 - 8 min.of arc in diameter) under three conditions: a) light spot moved horizontally on a screen; monkey head stationary. b) light spot stationary; primate chair rotated around vertical axis. c) light spot stationary; primate chair moved on a slide track parallel to the screen.

Quantitative analysis of the impulse rate time course of these neurons(with features characteristic of motoneurons) revealed: 1. A few neurons had exactly the same $R\times\dot{\theta}$ for agonist and antagonist phase, not only during condition a), but also during the other conditions(like monitors of eye movements). 2. Many neurons having different $R\times\dot{\theta}$ for agonist versus antagonist phase under condition a) exhibited another $R\times\dot{\theta}$ (without agonist-antagonist phase differences) under conditions b) and c). Further analysis of this class of neurons suggests that under condition a) they receive a velocity input only in one phase(agonist or antagonist). This velocity input could be provided by a newly discovered class of pre-motor neurons which are correlated with eye velocity in one direction during pursuit under condition a) but not b) (Eckmiller and Mackeben,Brain Res.184:210,1980).

Differences in $R\times\dot{\theta}$ for a given motoneuron during condition b)(semicircular canal stimulation) and condition c)(otolith organ stimulation) will be discussed.

One interesting conclusion is: although the visual stimulation is almost identical under all three conditions, the ocurrence of additional vestibular stimulation(b) and c)) leads to significant changes in the neural activity of most oculomotor motoneurons. This suggests that the phylogenetically oldest oculomotor subsystem, the VOR, dominates the youngest subsystem, i.e. the foveal pursuit system.

237.10 SMOOTH PURSUIT EYE MOVEMENTS WITH THE SACCADIC SYSTEM RENDERED INEFFECTIVE. Harry J. Wyatt and Jordan Pola. State College of Optometry, State University of New York, New York, NY 10010.

It is our contention that not only target velocity, but also target offset from the fovea can elicit smooth pursuit eye movements. This view is based on experiments using the "open-loop" pursuit system (Vision Res. 20(6)). However, under normal (closed-loop) circumstances, it is difficult to observe pursuit responses to target offset, since saccadic eye movements quickly eliminate the offset. Therefore, we have developed a technique of "saccadic stabilization" -- that is, of defeating attempts by the saccadic system to achieve foveation. The basis for this technique is the detection of a saccade, and the consequent jumping of the target by an amount equal to saccade length, so that target offset is the same after as before the saccade.

When "saccadic stabilization" is used, subjects can achieve fixation of a stationary eccentric target by means of slow eye movements. We have also used "saccadic stabilization" when the stimulus is ramp target motion -- i.e., constant-velocity motion with sudden onset. In response to ordinary ramp targets, Robinson (1965) noted that subjects often make a saccade to reduce target offset, followed by a "catch-up" pursuit to eliminate any residual offset. (The catch-up pursuit is faster than the target motion.) With a "saccade-stabilized" ramp target, the saccadic attempt to reduce offset is ineffectual, and the post-saccadic offset of the target is greater than it would be for an ordinary ramp target. The post-saccadic offset can be further exaggerated by introducing target jumps that are larger than, instead of equal to, saccade length. This type of target elicits catch-up pursuit movements that are faster and more prolonged than is the case for the usual unstabilized ramp targets. These findings add support to the view that target offset is an important stimulus for the smooth pursuit eye movement system.

238.1 THE INFLUENCE OF THE PERIVENTRICULAR TISSUE OF THE ANTEROVENTRAL THIRD VENTRICLE (AV3V) ON THE RELEASE OF VASOPRESSIN (VP). A. K. Johnson, S. L. Bealer, J. R. McNeil, J. Schoun, & J. Möhring*. Department of Psychology, University of Iowa, Iowa City, IA 52242 and Merrell International Research Center, Strasbourg, France.

Small lesions that destroy the tissue surrounding the AV3V produce marked disruptions in body fluid balance. The acute effects of AV3V lesions are adipsia and impaired antidiuretic responses (Johnson & Buggy, Am. J. Physiol., 234, R122, 1978). Although animals with lesions may regain ad lib drinking and survive, they manifest signs of disrupted controls of water intake and retention. Chronically, drinking responses to systemic angiotensin II (AII) and hypertonic saline (HTS) treatment are significantly reduced (Buggy & Johnson, Am. J. Physiol., 233, R44, 1977) and antidiuretic responses to intracranial injections of AII and HTS are blunted (Johnson, Hoffman, & Buggy, Br. Res., 157, 161, 1978). The impaired antidiuretic responses in both the acute and chronic post-lesion states suggest that VP release may be impaired by AV3V lesions. The present studies investigated this hypothesis.

In the first experiment rats received either sham (SL) or AV3V lesions (AV3VX). One-half of the SL animals (SL-W) and all of the rats with AV3VX received water and food post surgery; the second half of the SL group (SL-NW) had only food. The next day rats were decapitated and trunk blood, the posterior pituitary (PP) and punches of the supraoptic nuclei (SON) were collected. As usual, AV3V destruction produced adipsia. Both hematocrit and plasma osmolality were significantly increased in the AV3VX and in SL-NW as compared to SL-W. However, plasma VP was elevated only in the SL-NW. There was no difference in plasma VP levels of SL-W or AV3VX. There were no differences among groups in PP and SON VP content.

In a second experiment rats were divided into two groups. One group received AV3VX and the second SL. Several weeks post-lesion and after ad lib drinking had recovered, SL and AV3VX were randomly assigned to one of four groups to receive s.c. injections (2 ml/100g body weight) of saline in concentrations of .15M, .3M, .45M, and .6M. One-half hour after the injection trunk blood was collected. The results indicated that HTS systematically increased the levels of circulating VP. However, this was not the case for AV3VX rats where VP levels were not significantly elevated. The results from experiments with animals in acute and chronic post-lesion states show that the integrity of the AV3V is necessary for the normal control of VP to systemic dehydration. Furthermore, the results from the first experiment suggest that this impairment occurs even when VP is present in the hypothalamo-hypophyseal system. (USPHS NIH HLP-14388 & 1 RO1-H124102; NIMH 1-KO2-MH00064)

238.2 FURTHER STUDIES ON THE ROLE OF ANGIOTENSIN IN THE OSMOTIC CONTROL OF VASOPRESSIN RELEASE BY THE ORGAN CULTURED RAT HYPOTHALAMO-NEUROHYPOPHYSEAL SYSTEM. Celia D. Sladek, Depts. Neurology and Anatomy, Univ. Rochester, Rochester, NY 14642.

Physiological increases in osmolality achieved by adding either NaCl or mannitol stimulate VP release by organ cultured hypothalamo-neurohypophyseal explants from rats (Endocrin. 101:1834, 1977). This response can be blocked by the angiotensin (AII) competitive antagonist, saralasin (Endocrin. 106:173, 1980). This observation suggests that AII may either mediate or modulate osmotically stimulated VP release by HNS explants, and also suggests that AII is generated in the culture system. These possibilites were evaluated using the converting enzyme inhibitor, SQ14,255.

Converting enzyme activity in HNS cultures was demonstrated in experiments evaluating the effectiveness of AI as a stimulus for VP release. AI (10^{-5}M) significantly increased VP release to 189 ± 31% of control release ($p < .005$) however, it was less potent than AII (AII, 10^{-5}M, yields a 390 ± 85% increase). The response to AI was blocked by the simultaneous addition of SQ14,255 (10^{-5}M) suggesting that AI must be converted to AII in order to stimulate VP release and that this conversion takes place in the culture system.

The role of culture system-generated AII in the osmotic stimulation of VP release was evaluated by assessing the osmotic response of explants exposed to SQ14,255 for various periods prior to the application of the osmotic stimulus. SQ14,255 (10^{-5}M) was added either 24 hours prior, 4 hours prior, or simultaneously with sufficient NaCl to increase the culture medium osmolality from 295 to 315 mosmol/kg H_2O. There was a significant increase in VP release by the explants exposed simultaneously to the osmotic stimulus and SQ14,255, but the explants with prior exposure to the converting enzyme inhibitor did not show a significant response to the osmotic stimulus. They did respond to a comparable osmotic stimulus on the subsequent day in culture following a 24 hour incubation in the absence of SQ14,255. Since SQ14,255 and saralasin do not alter unstimulated VP release, these observations suggest that AII is being generated in the culture system in amounts which potentiate the osmotic response, but which alone are insufficient to stimulate VP release. Since the culture medium contains fetal calf serum (20%), it is possible that some of the factors necessary for AII generation are furnished by the culture medium. The ability of AII to potentiate osmotic stimuli corresponds to observations in vivo of AII potentiation of drinking and VP release in response to osmotic stimuli.

238.3 NALOXONE AND CORTICOSTERONE POTENTIATE RELEASE OF VASOPRESSIN TO HEMORRHAGE IN CONSCIOUS RATS. A.J. Baertschi*, M.J. Wicki* and M. Friedli* (SPON: B. Gähwiler). Dept. of Biology, University of Geneva, 1211 Geneva 4, Switzerland.

To test the hypothesis that endogenous opiates may be involved in blood pressure control and neurohypophysial hormone release, conscious rats with carotid catheters were subjected to a 1 ml/min hemorrhage (H) for 4 min and following a 6 min interval again for 2 min. Three blood samples (A,B,C) of 2 ml were collected and analyzed for plasma vasopressin (AVP) by a specific RIA, and arterial blood pressures were monitored before (Bef) and after (Aft) H in 4 groups of 5-8 rats (250-300g): CONTR=controls; NALOX=10 µg naloxone 30 min before H; CS 5'=10 µg corticosterone 5 min before H; CS 2h=10 µg corticosterone 2 hours before H; treatments were all given intra-arterially. Results are shown in Table:

GROUP	Mean pg AVP/ml plasma ± SE			Mean pressure, mm Hg, ± SE			
	A	B	C	Bef A	Aft B	Bef C	Aft C
CONTR	4.0±0.6	10.8±4.2	20± 5	111±4	106± 4	104± 3	46±6
NALOX	11.2±3.3	33.8±8.7	161±47	100±6	60±12	67±11	35±7
CS 5'	8.8±3.0	17.5±8.7	196±66	125±4	57±16	83±17	48±5
CS 2h	2.6±0.1	6.2±1.6	31±14	117±4	100± 4	92± 7	43±3

Thus AVP release to H was potentiated 7-fold by naloxone and acutely injected corticosterone. Plasma AVP was related to the integrated blood pressure decrease (IPD) by: $AVP = AVP' \cdot \exp(b \cdot IPD)$. For the NALOX and CS 5' groups combined, r=0.67 and AVP'=15.6 pg/ml. For the control and CS 2h groups combined, r=0.59 and AVP'= 4.5 pg/ml. The b factor was not significantly different ($p>0.4$) for these groups, demonstrating a similar blood pressure dependence of AVP release. However, AVP' was significantly ($p<0.005$) larger for the combined NALOX and CS 5' groups. The slope of the linear regression curve was two times larger ($p<0.01$) for the combined NALOX and CS 5' groups (r=0.80) than for the control and CS 2h groups (r=0.62). Thus even by taking into account the blood pressure effects, naloxone and acutely injected corticosterone potentiate AVP release to H by 350%. The results suggest that endogenous opiates participate in short-term regulation of arterial blood pressure and AVP release. The similarity of action between naloxone and acutely injected corticosterone may indicate that corticosterone transiently inhibits the release and/or inhibitory effect of endogenous opiates on the hypothalamo-neurohypophysial system. The site(s) of action of endogenous opiates, perhaps at the level of the hypothalamus or hypothalamo-hypophysial exons, remains to be investigated.

238.6 CONCENTRATIONS OF DOPAMINE IN PITUITARY STALK PLASMA AND OF PROLACTIN IN SYSTEMIC PLASMA IN RATS GIVEN 5-HYDROXYTRYPTAMINE. N. S. Pilotte and J. C. Porter. Dept. of Ob-Gyn and Physiology, Univ. of Texas Health Sci. Ctr., Dallas, TX 75235.

The release of prolactin (PRL) from the pituitary gland is enhanced after the administration of 5-hydroxytryptamine (5HT) to rats. We tested the hypothesis that 5HT augments the secretion of PRL by modifying the release of dopamine (DA) from the hypothalamus into hypophysial portal blood by measuring the concentration of DA in the pituitary stalk plasma of male rats after the intracerebroventricular administration of 5HT or its solvent vehicle. A cannula was implanted into the lateral ventricle of each rat 5-7 days before use. The animals were anesthetized with urethane, and pituitary stalk blood was collected for 1 hr after the injection of 0.5 μg or 5 μg 5HT creatinine sulfate (free base) in 10 μl phosphate-buffered saline (PBS) or 10 μl PBS. DA was measured in acidified extracts of plasma using a radioenzymatic procedure. The concentration of DA was 0.80 ± 0.18 ng/ml (mean ± SE), 0.32 ± 0.06 ng/ml, and 0.176 ± 0.04 ng/ml in the pituitary stalk plasma of rats given PBS, 0.5 μg 5HT, and 5 μg 5HT, respectively. The concentrations of PRL in another group of similarly treated animals did not change 10 min after injection of the solvent vehicle (26 ± 4 ng/ml), but increased at least 10-fold 10 min after the injection of 5 μg 5HT (from 25 ± 5 to 347 ± 19 ng/ml). The administration of 0.5 μg 5HT was followed by a 4-fold increase in the peripheral concentration of PRL (from 30 ± 4 to 169 ± 32 ng/ml). Two additional groups of male rats were used to test the hypothesis that the replacement of DA in the portal plasma would be sufficient to block the effect of serotonin on PRL release. Polyethylene cannulas were placed in the femoral artery and in the right atrium of the heart via the right jugular vein. A solution of DA in 5% glucose or 5% glucose alone was infused into the jugular cannula for 45 min. Blood withdrawn through the femoral cannula was replaced with heparinized 0.15 M NaCl at 15-min intervals beginning 15 min before the commencement of the infusion. Fifteen min after the initiation of the DA or glucose infusion, 5 μg 5HT was injected into the lateral ventricle of each rat. The concentration of plasma PRL was increased from 68 ± 15 ng/ml to 723 ± 149 ng/ml in rats infused with glucose and from 81 ± 20 ng/ml to 460 ± 77 ng/ml in rats infused with DA. The concentration of DA in the peripheral serum was 2.54 ± 0.29 ng/ml or 0.08 ± 0.03 ng/ml 15 min after the initiation of the DA or glucose infusions, respectively. These results are suggestive that 5HT modulates the secretion of PRL (1) through a direct action on the release of DA into the pituitary stalk blood and (2) through a separate mechanism that may involve a PRL releasing factor.

238.7 THE DISTRIBUTION OF LHRH FIBERS FOLLOWING SAGITTAL OR CORONAL KNIFE CUTS. J.C.King, C.W.Scouten, A.A.Gerall and F.L.Snavely*. Dept. of Anatomy, Tufts Univ.Sch. of Med., Boston, Ma 02111; Dept. of Psychol., MUN, St. John's Newfoundland, A1B3X9; Dept. of Psychol., Tulane Univ., New Orleans, La. 70118. Knife cuts were made in adult female rats in: 1)sagittal plane 1mm lateral to the midline from the preoptic area extending 2mm caudally; 2)coronal plane just caudal to the preoptic area ± 1mm across the midline; and 3)coronal plane rostral to the arcuate nucleus ± 1mm across the midline. Smears were taken to assess vaginal cyclicity following the knife cuts. Prior to perfusion with Bouin's fixative, females were ovariectomized and given 3 daily injections of 6.6ug estradiol benzoate i.m. Fifty micron vibratome sections were incubated with LHRH antisera, Arimura's #743, Jackson's #29 or antisera absorbed with LHRH and processed according to the PAP technique. The only group of animals demonstrating persistent vaginal cornification were those with a coronal cut caudal to the preoptic area (2); the other groups demonstrated some irregularities but were ovulating. In control animals, LHRH fibers extended in horizontal sections from the rostral preoptic area to the median eminence (ME) in both a direct midline path in the rostral tuberoinfundibular pathway and in close association with ventricular elements to the ME and a curvilinear pathway diverging from the midline rostrally to enter the region of the medial forebrain bundle converging caudally to enter the ME from a lateral position. Sagittal cuts did not affect the midline pathway and often only transected a small proportion of the diffuse laterally directed fibers thus having a minimal effect on the number of fibers reaching the ME. Coronal cuts at the level of the rostral arcuate nucleus did not disturb lateral fibers and often did not extend basally to disturb the majority of midline fibers. The only cut to induce persistent vaginal estrus, the coronal cut caudal to the preoptic area, disturbed both the lateral fibers as they were diverging from the midline and basal midline fibers. Although there were fibers remaining in the ME after this coronal cut, these were evidently not adequate to induce ovulation. This study was a replication of identical knife cuts in which the LHRH system was studied in paraffin sections with similar results. This work was supported by NIH grant HD 14092-01 to J.C.K.; HD00867-15 to A.A.G. and MH 28440 to C.W.M.

238.8 Gonadotropin-Releasing Hormone (GnRH): Distribution in Human Hypothalamic Nuclei. M.J. Kubek, J.F. Wilber*, and J.M. George*. Dept. of Anatomy, Indiana Univ. Sch. Med., Indianapolis, IN 46223; Depts. of Medicine, L.S.U. Med. Ctr., New Orleans, LA 70112; and Ohio State U. Sch. Med., Columbus, OH 43210.

It is well established that the hypothalamus occupies a central role in the regulation of gonadotropin secretion. Radioimmunoassay (RIA) studies of GnRH activity in human hypothalamic tissue blocks previously have revealed a rather generalized distribution of GnRH. However, precise localization of GnRH within specific human hypothalamic nuclei is needed in order to define neuroendocrine and potential non-endocrine roles of GnRH in man. To examine this problem, the hypothalamus and infundibular stalk of 8 human brains obtained at autopsy were dissected and frozen. Mean time between death and tissue processing was 8.96 hrs. Serial alternating 100 um and 300 um sections were cut from hypothalamic blocks in the frontal plane and serial "micropunch" samples were extirpated from sections with 1000 um diameter stainless steel canulae. Pooled samples were homogenized in 0.1N HCl and sonicated. Aliquots were taken for protein determinations, and samples were then lyophilized and eluted in neutral buffer for GnRH determinations by specific and sensitive RIA. GnRH immunoreactivity was quantitated in all structures examined. Highest concentrations (ng/mg protein ± SE) were localized to the infundibular stalk (0.878 ± .514) and median eminence area (0.343 ± .231) as well as the arcuate nucleus (0.222 ± .091). Somewhat lower levels were found in the supraoptic (0.145 ± .082) and paraventricular nuclei (0.115 ± .039). Lowest GnRH concentrations were observed in the mammillary complex (0.038 ± .022), posterior (0.010 ± .004) and anterior (0.008 ± .004) nuclei. Potential instability of GnRH in intact tissues were assessed in representative structures of the rat under conditions simulating human postmortem variables of time and temperature. GnRH activity in both hypothalamus and cortex was found to be stable for 16 hrs. at 4°C. Conclusions: GnRH is localized in man to those hypothalamic loci which have been implicated in gonadotropin regulation experimentally (stalk-median eminence, and arcuate nuclei). The variations in concentrations of GnRH found in each region cannot be attributed to postmortem autolysis. The presence of GnRH in additional hypothalamic areas (mammillary complex, posterior nuclei, supraoptic and paraventricular nuclei) suggests that GnRH may subserve other hypothalamic functions as well in the role of a peptide neurotransmitter or neuromodulator. (Supported in part by NIH Grants AM-106699 and AM-14997 and the V.A., Columbus, OH).

238.9 EFFECTS OF ARGININE VASOTOCIN AND VASOPRESSIN ON THE LUTEINIZING HORMONE RELEASING HORMONE-INDUCED RELEASE OF LUTEINIZING HORMONE IN THE RHESUS MONKEY. L. Y. Johnson, R. H. Asch, R. J. Reiter and M. K. Vaughan. Dept. of Anatomy, The Univ. of Texas Health Science Center at San Antonio, San Antonio, TX 78284.

Arginine vasotocin (AVT), a nonapeptide, has been tentatively identified in the human fetal neurohypophysis and pineal gland. The ability of pretreatment with AVT or arginine vasopressin (AVP), a neurohypophyseal hormone similar in structure to AVT, to alter the hormonal response to a single injection of luteinizing hormone-releasing hormone (LRH) was investigated in the monkey.

Four adult rhesus monkeys (6-8 kg) which had been bilaterally salpingoophorectomized at least 9 months prior to the experiment were maintained in an LD 14:10 lighting cycle. At 0900h, monkeys received a 0.5 ml injection of either AVT (12µg), AVP (12µg) or vehicle (0.5% bovine serum albumin in Ringer's lactate solution). Blood was drawn immediately prior to drug administration (0m) and at 10 and 20m. At 60m, blood was sampled immediately prior to the iv injection of LRH (150µg) in 0.5 ml vehicle. Additional blood samples were obtained at 70, 80, 90, 120 and 180m. Blood samples were drawn from and drugs administered via the femoral or saphenous veins after sedation with ketamine hydrochloride (7-10 mg/kg, im); serum was assayed for rhesus luteinizing hormone (LH) by radioimmunoassay. Each monkey received all three treatments with studies being separated by at least 7 days.

In the controls, an injection of vehicle at 0m was followed by no significant alteration of LH levels for 60m; LRH administration at 60m resulted in significantly elevated LH titers at 70 (3248±252 ng/ml), 80 (2587±303 ng/ml), 90 (2332±370 ng/ml) and 120m (2218±406 ng/ml) relative to the value at 60m (1411±202 ng/ml) ($p<0.001$, $p<0.01$, $p<0.02$ and $p<0.05$, respectively).

Serum LH values after AVT or AVP injection did not vary significantly from those in control studies at 0, 10, 20 or 60m. However, peptide administration did alter the serum LH response to LRH treatment. LH titers were significantly lower after AVT treatment relative to levels resulting from vehicle injection at 70m (1768±116 ng/ml vs. 3248±252 ng/ml, $p<0.01$); after AVP injection serum levels were significantly lower than those in control studies at 70 (1246±241 ng/ml vs. 3248±252 ng/ml, $p<0.001$) and 80m (1450±231 ng/ml vs. 2587±303 ng/ml, $p<0.05$). After AVT or AVP treatment, LRH injection produced no significant rise in serum LH relative to the preinjection 60m value.

The neuropeptides AVT and AVP appear to have the ability to alter the action of LRH at the level of the anterior pituitary and could be possible physiological modulators of LH release in the monkey. 238.10 EFFECTS OF RAPHE NUCLEI LESIONS ON PROLACTIN SECRETION IN MALE RATS. D. Eljarmak*, G. Charpenet*, J.C. Jéquier* and R. Collu. Neuroendocrine Research Lab., Pediat. Res. Ctr., Ste-Justine Hosp. and Univ. of Montreal, Montreal, Que. H3T 1C5.

Brain serotonin (SER) appears to play a major role in the control of prolactin (PRL) secretion at least in rats. PRL release induced by stress, pentobarbital (PB) anesthesia and the opiate peptide ß-endorphin (END) has been reported to be regulated, at least partly, by serotonergic neuronal pathways. Major serotonergic inputs to mammalian forebrain originate from cell bodies located in dorsal and medial raphe nuclei of the mesencephalon. Several experiments were performed in adult (240-260 g), male Sprague-Dawley rats in order to verify whether either one or both raphe nuclei might be involved in basal, stress-, PB- or END-induced PRL release. In addition, since thyrotropin-releasing hormone (TRH) has been found to antagonize PB- and facilitate END-induced PRL release (Taché et al., Eur. J. Pharmacol. 45: 369, 1977; Taché et al., Life Sci. 21: 841, 1977) through a central monoaminergic mechanism, the role of raphe nuclei in these extrapituitary effects of TRH has been explored. For this purpose, radiofrequency lesions were made with a stainless steel electrode either in the dorsal or medial raphe nuclei under PB anesthesia. At the same time the rats were implanted with a chronic cannula in the right lateral brain ventricle, and with a permanent silastic catheter in the right atrium for blood sampling. Sham lesions were performed in some rats by simply lowering the electrode into the mesencephalon. Groups of rats either sham operated (S), lesioned in the dorsal (LD) or the medial (LM) raphe nuclei were either sampled every 15 min for 3h30 min without anesthesia, for determination of baseline plasma PRL values by radioimmunoassay, or submitted to various treatments: immobilization stress for 30 min; PB (50 mg/kg, ip) and saline (10 µl/rat, intraventricularly), PB and TRH (10 µg/rat, ivt); END (10 µg/rat, ivt) END and TRH. Blood was collected every 15 min for 120 min for PRL determination. At the end of the experiment the animals were killed by decapitation and the brains examined for localization and extent of the lesion. Data were statistically evaluated by factorial analysis of variance. The results obtained indicate that: 1) baseline values of PRL are not influenced by raphe nuclei lesions; 2) the rise of PRL values induced by immobilization stress is suppressed in LM rats; 3) the PB-induced PRL secretion is enhanced in LD rats, blocked by TRH in S but not in LD or LM rats; 4) the END-induced PRL secretion is greatly enhanced in LD rats, potentiated by TRH in S and ever more in LD but not in LM rats. These results indicate that raphe nuclei may intervene in induced PRL secretion either in a facilitatory (medial) or inhibitory (dorsal) role.

238.11 IN VIVO AUTOREGULATION OF RAT ADENOHYPOPHYSEAL THYROTROPIN-RELEASING HORMONE-RECEPTOR. A. Banerji* and C. Prasad. Section of Endocrinology, Department of Medicine, LSU Medical Center, New Orleans, LA. 70112.

Autoregulation of membrane receptor concentration appears to be one mechanism of target cell desensitization. To see if the adenohypophyseal thyrotropin-releasing hormone (TRH)-receptor undergoes autoregulation in vivo, we have studied the down-regulation of TRH-receptor in this tissue by TRH. Rats (male Sprague-Dawley, 200-300g) were treated subcutaneously (s/c) with 100 µg TRH or saline (twice daily) for 0 to 4 days. TRH-receptor concentration was determined as described elsewhere (Endocrinology 100: 1496, 1977) except that the homogenization buffer also contained 250 mM sucrose. TRH treatment led to a time dependent decrease in the TRH-receptor number (50 and 80% decrease at day 1 and 3 respectively). This decrease was not due to the receptor occupancy because the half-life for dissociation of TRH binding to pituitary membranes is < 10 minutes while the decrease in the receptor number persisted for at least one week after termination of TRH treatment. Scatchard analysis using ligand concentration of 4×10^{-8}M to 2×10^{-7}M showed a significant decrease in both the equilibrium dissociation constant (K_D) and the maximum binding capacity (B_{max}) following TRH treatment for 3 days (see table below).

Treatment	K_D (nM)	B_{max} (fmole/mg protein)
Saline	26.5	60.2
TRH	10.0	15.2

Since TRH treatment increases both thyrotropin (TSH) and triiodothyronine (T_3), we have studied the possible role of these hormones in the modulation of TRH-receptor in vivo. In euthyroid animals neither TSH nor T_3 treatments (500 µg/day for 5 days, s/c) had any effect on the TRH-receptor number (fmole TRH bound/mg protein, control = 51.2, TSH-treated = 51.3, and T_3-treated = 55.0). In thyroidectomized rats, like euthyroid, TRH was effective in reducing its receptor number.

These data show that TRH regulates the number of its own receptor in vivo. This regulatory role of TRH is not associated with its hypophysiotropic action and therefore independent of TSH and T_3 release.

238.12 REDUCTION IN CELL FIRING INDUCED BY OPIOIDS IN HYPOTHALAMIC SLICES. M. Mühlethaler* and J.J. Dreifuss. Dept. Physiol., Univ. of Geneva Med. Sch., Geneva, Switzerland.

Endogenous opiates have been implicated in a growing number of nervous mechanisms, including the control of pituitary hormone secretion. High amounts of opiate receptors and of enkephalin are found in the basal hypothalamus, including the paraventricular nucleus (PVN). In order to ascertain whether PVN neurones possess opiate receptors and could therefore respond to locally released enkephalins, we have bath-applied stable Met-enkephalin analogues while recording the firing of PVN neurones in coronal slices prepared from the hypothalamus of adult rats.

The two analogues FK 33-824 and FW 34-569 were tested on 26 PVN neurones in 23 slices. The cells displayed stable patterns of spontaneous activity with frequencies ranging from 1-20 Hz. Enkephalins inhibited the firing of 19 cells; 7 were unaffected, although they could be excited by glutamate (5.10^{-4} M) and were inhibited by an increase in external Mg concentration. The enkephalin effect was rapid in onset and reversible. No difference was noted when assessing the effect on phasic, beating and random cells or when comparing the two analogues. Concentrations of 10^{-8} M were usually effective and a 50% inhibition was seen at about 5.10^{-7} M. In 6 cells the enkephalin effect was tested for reversibility by the opiate antagonist, naloxone. In 4, the reduction in cell firing induced by 10^{-7} M enkephalin was completely reversed by 10^{-6} M naloxone. In one cell, the antagonism was only partial and in another, naloxone had no effect. Morphine, 10^{-6} to 10^{-4} M, was tried on 12 cells; seven were reversibly inhibited.

It has been recently shown that vasopressin and oxytocin release are reduced by exogenous opiates acting on the neurohypophysial secretory axons. Our results suggest that, in addition, opiates could also regulate neurohypophysial hormone release by an effect exerted on or near the hypothalamic perikarya.

239.1 ANIMAL ACTIVITY MONITOR FOR CHRONIC DRUG STUDIES. K. A. Stauderman,* D. M. Stoff and R. J. Wyatt (SPON: F. Vargas). Laboratory of Clinical Psychopharmacology, NIMH, St. Elizabeths Hospital, Washington, D.C. 20032.

Animal models of human movement and psychiatric disorders are based almost exclusively on changes caused by CNS stimulants on stereotyped and locomotor behaviors. However, the conditions and techniques of measurement to study motor behavior impose certain limitations: (1) preclude continuous and simultaneous measurement of different motor responses under chronic conditions, (2) relatively insensitive to progressive changes in spontaneous behavior patterns of normal and drug-treated animals, and (3) require separate observational methods and intrusive instruments to distinguish differences in response topography among CNS stimulants acting through different mechanisms.

We have developed a new computerized technique (using capacitance sensing fields) for the longitudinal measurement of motor activity in the animal's laboratory/residential environment. At a very high resolution rate and wide range of sensitivities this technique is able to continuously monitor rat behavior during chronic drug infusion. It tracks the path of movement of the animal or sets threshold limits to detect specific behavioral events (e.g., rearing, circling, gross movements) in both temporal and spatial dimensions through the use of computer programs for behavioral algorithms. This technique monitors behavior patterns around the clock for weeks or months, and traces the locomotor history of the rat by quantifying the various responses and ultradian and circadian changes in activity.

In this paper we (1) describe the technique, (2) present data on entrained and free-running activity cycles in normal rats (Fig. 1) and with chronic treatment of haloperidol or amphetamine, and (3) demonstrate different response profiles for indirect and direct dopamine agonists, amphetamine and apomorphine.

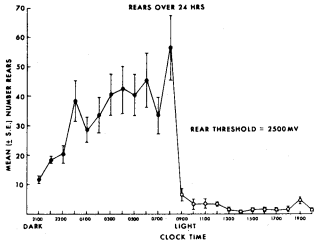

FIG. 1

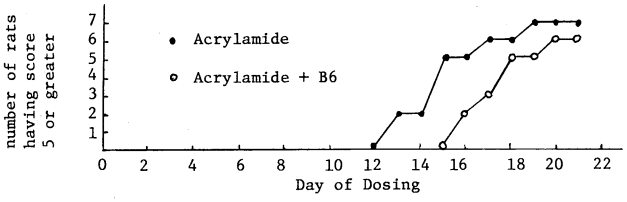
239.2 VITAMIN B6 PROTECTION AGAINST ACRYLAMIDE NEUROTOXICITY. A.L. Loeb* and R.J. Anderson. Dept. Pharmacol., George Washington Univ., Washington, D.C. 20037.

The effect of vitamin B6 supplementation on the development and severity of chronic acrylamide neurotoxicity in rats was examined. Thirty rats divided into 4 groups were dosed daily for 21 days IP with: (1) saline (n=8); (2) B6 (5 mg) (n=8); (3) acrylamide (30 mg/kg) (n=7); and (4) acrylamide (30 mg/kg) + B6 (5 mg) (n=7). Development and severity of neurotoxicity were quantified by: (1) performance on an inclined screen using a quantal 7-point scoring system and (2) measurement of hind limb footspread upon landing from a 30 cm height. Development of motor dysfunction on the inclined screen was delayed and less severe in rats receiving acrylamide + B6 compared to those receiving acrylamide alone. Acrylamide only treated animals first showed toxicity on day 9 (score = 3) and severe toxicity (score = 5) on day 13, compared with day 11 and day 16 respectively in the acrylamide + B6 group. The figure below shows the number of rats with a score of 5 or greater as a function of time with chronic dosing. At the end of the study, all the acrylamide only treated animals, whereas 4 of the 7 rats in the acrylamide + B6 group, had scores of 6 or 7. Footspread was increased over controls in both acrylamide only and acrylamide + B6 groups by day 11 ($p < 0.05$). B6 did not affect the degree of footspread increase between the acrylamide groups. Weight loss was seen in both groups receiving acrylamide 48 hours after the first dose and continued to decrease. Water intake did not decrease until after day 12 and thus probably was not responsible for the early weight loss. The saline and B6 only groups gained weight over the entire experimental period.

In conclusion, B6 was shown to delay the onset and severity of acrylamide neurotoxicity in rats as measured by the inclined screen test. This suggests that acrylamide toxicity may be caused by an interaction of acrylamide with systems utilizing B6 as a cofactor or that acrylamide may be depleting nutritional factors, which if partly replaced by B6 treatment, slow the progression of neurotoxicity. (Supported by NIH grant #ES01951.)



239.3 EFFECTS OF ACUTE LITHIUM ADMINISTRATION ON LOCAL CEREBRAL GLUCOSE UTILIZATION IN THE RAT. S. Suda*, M. Miyaoka*, C. Kennedy, and L. Sokoloff. Laboratory of Cerebral Metabolism, NIMH, Bethesda, MD 20205.

Lithium salts have been reported to alter carbohydrate metabolism of brain in vitro, in particular to stimulate glucose utilization (Mickel et al., Biochem. Pharmacol. 27:799, 1977). The close coupling of energy metabolism and functional activity in brain suggested the possibility that such stimulation might be related to the mechanism of lithium's pharmacologic actions. To examine this question we have employed the [^{14}C]deoxyglucose method to measure local rates of cerebral glucose utilization in vivo. Normal male adult Sprague-Dawley rats were injected with 7 mmoles/kg of lithium chloride intraperitoneally. Three, 14 and 22 hours later, [^{14}C]deoxyglucose was administered as a pulse intravenously and followed by the procedure for measuring local cerebral glucose utilization as previously described. Local cerebral glucose was measured by the [^{14}C]deoxyglucose method in four animals at each of these post-injection times, and the values were compared with those obtained in an equal number of control animals which received 7 mmoles/kg of sodium chloride intraperitoneally. At 3 hours lithium was found to induce sluggish responses to stimuli, a reduction in spontaneous activity, and a moderate metabolic acidosis (arterial pH, 7.30). In these animals there was a widespread reduction in rates of cerebral glucose utilization which ranged from 21% to 37% in 18 out of 35 structures. A weighted average rate for the brain as a whole was 21% below that of control animals ($p < 0.05$). In animals in which measurements were made at 14 and 22 hours after lithium administration no behavioral depression was observed, nor was there evidence of acidosis (arterial pH 7.36 and 7.39 respectively). Although six structures in both groups of animals exhibited rates slightly but statistically significantly below those of control animals, the weighted averages for the brain as a whole were unchanged from controls. Previous studies have shown that lithium reaches its maximal concentration in brain about 22 hours following intravenous administration. In our studies at 22 hours after intraperitoneal injection no structure exhibited an augmented rate of glucose utilization. Thus, our results are in contrast to in vitro observations. The marked reduction in cerebral glucose utilization three hours after lithium administration occurred in the presence of a metabolic acidosis and is in keeping with similar reductions in local cerebral metabolic rates found in our laboratory during acidosis induced with ammonium chloride. The depressant action of lithium following acute administration, therefore, appears to be non-specific.

239.4 **ACTION OF LITHIUM CHLORIDE ON MOTOR COORDINATION IN THE MURICIDAL RAT.** **Patricia A. Broderick, O.P.† and Vincent de Paul Lynch*. St. John's Univ., Jamaica, N.Y. 11439.**

The history of lithium usage in psychiatry is well established (Schou, 1959). Yet, the role of motor effects in delineating the behavioral actions of lithium are not conclusive. We found a significant increase in the motor ability of isolated, male, Long Evans, muricidal (mouse killing) rats (300-400gms) as tested by standard rotarod apparatus. These effects were observed after acute intraperitoneal administration of lithium chloride, 1.0, 2.0 and 4.0 meq/kg, and after intraperitoneal lithium chloride administration, 0.5, 1.0 and 2.0 meq/kg††, for seven days, daily. Significance levels, which were determined statistically by paired student t test, were p<0. 05 and above. Corresponding plasma lithium was quantitated (Perkin Elmer, 360). Both rotarod testing and plasma lithium determinations were done one hour after acute injection. During chronic studies, testing was carried out 24 hours after final injection. Other lithium dosage regimens, both acute and chronic, did not significantly increase motor coordination. These results are of interest because these isolated, muricidal "aberrant" rats are hyperactive and have notable prehensile strength. These features are dampened and motor coordination is enhanced by lithium chloride. Lithium modified locomotor response to methamphetamine (Furukawa et al., 1975); decreased locomotor activity in hyperthyroid rats (Rastogi and Singhal, 1977) and decreased locomotor activity in albino mice (unpublished observation). Further research will elucidate whether this increase in motor ability is dependent on physiological or environmental conditions. It will also clarify strain, intrastrain or species differences. Muricidal behavior is used as a pragmatic model for the identification of antidepressant drugs (Horovitz et al., 1966). Perhaps, an aberrant animal model might be more applicable to clinical situations. Perhaps, too, such a model might be more applicable to the relationship between motor effects and behavior in the clinic.

239.5 CHLORPROMAZINE AND BRAIN-STIMULATION REWARD: POTENTIATION OF EFFECTS BY NALOXONE. Ralph U. Esposito, William Perry* and Conan Kornetsky (SPON: J.H. Mendelson). Laboratory of Behavioral Pharmacology, Boston University School of Medicine, 80 E. Concord St., Boston, MA 02118.

Rats were implanted with electrodes aimed at either the medial forebrain bundle or the ventral tegmentum, and intracranial self-stimulation thresholds were determined by means of a modification of the classical psychophysical method of limits. Chlorpromazine (CPZ) (.25-2.0 mg/kg, i.p.) produced dose-dependent threshold increases, while naloxone (NAX) (4 mg/kg, i.p.) was devoid of effect. However, NAX administered concurrently with CPZ produced substantial potentiation of the threshold increases. In addition, behavioral "seizures" (i.e., body tremors, twitching, head bobbing and rhythmic exophthalmos, gnawing and chewing) were observed when NAX was combined with the higher doses of CPZ. These results are discussed within the context of a catecholamine-enkephalinergic involvement in the regulation of central reward processes.

239.6 INTRACRANIAL SELF-ADMINISTRATION OF ACETALDEHYDE BY SPRAGUE-DAWLEY RATS. B.R. Smith* (SPON: Z.W. Brown). Center for Research on Drug Dependence, Concordia University, Montreal, Quebec, Canada H3G 1M8.

It has been demonstrated that rats will self-administer acetaldehyde directly into the brain and it was suggested that acetaldehyde may mediate some of the psychopharmacological effects of ethanol. However, this finding was reported only in Wistar rats and it may be specific to the strain used. The present paper reports on preliminary data examining the rate of self-administration of acetaldehyde in Sprague-Dawley rats. Naive rats were placed in operant chambers for 10 consecutive days during which they could lever press for acetaldehyde (.5% v/v) or Ringer's solution. These compounds were delivered directly into the left lateral ventricle via a chronically implanted cannula. Analysis of the data revealed that from day 4, animals receiving acetaldehyde lever pressed at higher rates than control animals receiving Ringer's solution. It is interesting to note that in previous studies the lowest dose which would be self-administered by Wistars was 1% v/v, yet, in this experiment Sprague-Dawleys self-administered at half this dose. This resembles the differences in each strain's preference for ethanol as Wistars have been shown to drink higher quantities of ethanol than Sprague-Dawleys. This data may support other research which suggests that acetaldehyde may be involved in ethanol consumption in rats.

239.7 THE EFFECTS OF ENVIRONMENTAL TEMPERATURE AND ATMOSPHERIC PRESSURE ON ETHANOL NARCOSIS IN MICE. R.L. Alkana and R.D. Malcolm. School of Pharmacy, University of Southern California, Los Angeles, CA. 90033

Recent studies show that hyperbaric helium-oxygen (He-Ox) environments from 4-12 atmospheres absolute (ATA) antagonize ethanol narcosis (3.2-4.0 g/kg) in a pressure and dose related manner. Experiments using hyperbaric chambers heated to 30°C demonstrated that the antagonism from hyperbaric He-Ox was not due to the hypothermic effects of helium. Interestingly, the 1 ATA air control mice slept significantly longer in the 30°C environment than controls kept at room temperature (21-25°C). Two experiments are presented here which further investigated the relationship between ethanol sleep-time, environmental temperature and atmospheric pressure. The first experiment tested the effect of ethanol and hyperbaric He-Ox on sleep-time, wake-up blood ethanol (BEC) and brain ethanol (BrEC) concentrations under temperature conditions of 33.5°C (air) and 34.5°C (He-Ox) which eliminated the hypothermic effects of ethanol and helium. Drug-naive, male C57 mice were injected i.p. with 3.6 g/kg ethanol (20%w/v). Upon loss of their righting reflex, mice were placed in a hyperbaric chamber. Atmospheric pressure was taken to 1 ATA air or to 1,6, 8,10 or 12 ATA He-Ox. During He-Ox treatments, the chambers were kept at 34.5°C by immersion in a water bath. Air controls were kept at room temperature or 33.5°C. Rectal temperatures were monitored in separate groups of animals exposed to the same treatments and conditions. Upon wake-up, the chamber was rapidly decompressed. Blood and brain samples were taken for later gas chromatographic ethanol analysis. Hyperbaric He-Ox significantly reduced sleep-time and increased wake-up BECs and BrECs at 8,10 and 12 ATA in non-hypothermic mice (t-test). Sleep-time was significantly increased and wake-up BrEcs decreased in non-hypothermic versus hypothermic 1 ATA air controls. The second experiment investigated the effect of a range of temperature environments on rectal temperature, sleep-time and wake-up BECs and BrECs in 1 ATA air. Mice were injected with 3.6 g/kg ethanol and placed on sleep racks at room temperature (22-26°C) or at 12,14,16,30,34 or 37°C. The results suggest that sleep-time and wake-up BrECs vary in a statistically significant, temperature related manner (supported in part by NIAAA Grant AA-03972, NIH BRSG RR-05792 and the USC Pharmacy Alumni Association).

239.8 Effects of Lisuride on the behavior of cats: Implications for the limb flick model of drug-induced hallucinogenesis. James L. Marini*, Michael H. Sheard, Barry L. Jacobs and Michael E. Trulson, Dept. of Psychiat., Yale Univ. Sch. Med., New Haven, CT 06508 and Prog. Neurosci., Dept. Psychol., Princeton Univ., Princeton, NJ 08544.

Lisuride is a non-hallucinogenic ergoline derivative which is structurally similar to d-lysergic acid diethylamide (LSD), and, like LSD, reduces brain serotonin turnover (e.g., Nature 272: 278-280, 1978) and has a powerful depressant action on 5HT-containing raphe neurons (Life Sci. 24: 1289-1298, 1979). Indeed, lisuride is 5-10 times as potent as LSD in depressing raphe neuronal activity. Given the potency of lisuride on the 5HT system, we tested its behavioral effects in cats. Previous studies showed that hallucinogenic drugs which depress the central 5HT system elicit specific behaviors such as limb flicking and abortive grooming in cats (Comm. Psychopharm. 1: 243-253, 1977). Adult male and female cats were given saline or lisuride hydrogen maleate (6.25, 12.5, 25, 50 and 100 ug/kg, ip) and then observed for one hr by a rater blind to dose. Lisuride produced a dose-dependent increase in the rate of limb flicking, from a near-zero saline baseline to a maximum of 16/hr at a dose of 50 ug/kg. The limb flick rate was less (9/hr) at the 100 ug/kg dose. Abortive grooming showed a similar response: From a saline baseline of 0, there was a dose-dependent increase to a maximum of 7/hr at 50 ug/kg, and a decrease to 6/hr at 100 ug/kg. Grooming was also similar: From a saline baseline of 17/hr, there was a dose-dependent increase to a maximum of 47/hr at 50 ug/kg, and a decrease to 34/hr at the 100 ug/kg dose. A time-course study with the most effective dose (50 ug/kg) revealed that the frequencies of the behaviors reached a maximum during the first 2 hrs post-injection, declined rapidly, and were comparable to saline frequencies by 6 hrs post-injection. To determine whether tolerance develops to its repeated administration, lisuride (50 ug/kg) was administered to cats, followed by a test dose of 50 ug/kg at 6, 24 or 72 hrs after the initial dose. These studies revealed no significant tolerance effect. Finally, to test for cross tolerance with LSD, additional cats received an initial dose of 50 ug/kg of either LSD or lisuride, followed by a 50 ug/kg dose of lisuride or LSD 24 hrs later. These studies revealed no significant cross tolerance. The present data question the validity of the limb flick model for hallucinogenesis, since lisuride is very effective in eliciting limb flicks, but is not hallucinogenic in man. The model can be revised to include the condition that LSD-like tolerance must develop to repeated drug administration, since all hallucinogens tested produce a dramatic tolerance effect on limb flicks, while lisuride does not.

239.9 RX 336-M AND ACTH (1-24): STIMULANTS OF GROOMING AND SHAKING IN RATS. D.E. Gmerek* and A. Cowan (SPON: J.J. O'Neill). Dept. of Pharmacology, Temple Univ. Sch. of Med., Philadelphia, PA 19140.

RX 336-M (7,8-dihydro-5',6'-dimethylcyclohex-5'-eno-1',2', 8',14 codeinone) induces a remarkable, dose-related behavioral syndrome of excessive grooming and 'wet-dog' shakes (WDS) when administered peripherally (1.5-12 mg/kg), but not centrally, to rats. In the present work, we have studied the pharmacological bases of the excessive grooming induced by both RX 336-M and ACTH (1-24), the reference compound that causes excessive grooming when given icv to rats (Gispen et al, Life Sci. 17:645, 1975)[b]. Note that, in our hands, ACTH (1-24) (3-12 µg, icv) elicits WDS in male Sprague-Dawley rats (200-220 g) in addition to the excessive grooming.

We used groups of 8 male, S.D. albino rats (120-140 g); during test sessions they were housed individually in Plexiglas observation boxes (22 cm long; 18 cm wide; 25 cm high). The standard doses of RX 336-M and ACTH (1-24) were 6 mg/kg, i.p. and 3 µg (in 3 µl) icv, respectively. Grooming was monitored for 5 sec every 15 sec over 30 min with the help of a computer. Scoring started immediately after the injection of RX 336-M and 15 min after the administration of ACTH (1-24).

When rats were pretreated (at -15 min) with either haloperidol (0.25-1 mg/kg, s.c.) or morphine (0.3-3 mg/kg, s.c. or 1-10 µg, icv), the excessive grooming associated with both RX 336-M and ACTH (1-24) was attenuated in a dose-related manner. Naloxone (1-10 mg/kg, s.c. at -15 min) had no marked influence on RX 336-M - induced grooming. Interestingly, Gispen and Wiegent (Neurosci. Lett. 2: 159, 1976)[a] have reported that naloxone (1 mg/kg, s.c.) attenuates the excessive grooming elicited by ACTH (1-24).

Tolerance developed to excessive grooming after twice-daily injections (at 0900 h and 1800 h) of RX 336-M (6 mg/kg, i.p.) for 7 days. There was no cross-tolerance to ACTH (1-24) in the RX 336-M - tolerant rats.

Comparative data for RX 336-M and ACTH (1-24) are summarized in the Table.

	RX 336-M	ACTH (1-24)
Active route	peripheral	central
'Wet-dog' shakes	+	+
Excessive grooming	+	+
Antag. by haloperidol	+	+
Antag. by morphine	+	+
Antag. by naloxone	-	+ (a)
Antag. by adrenalectomy	-	- (b)
Tolerance	+	+ (?) (c)
Cross-tolerance		-

(c) Jolles et al, Neurosci. Lett. 9: 261, 78

Excessive grooming may be a way whereby a rat's state of arousal [raised by RX 336-M and ACTH (1-24)] is lowered and homeostasis is maintained. If so, then there are at least two pathways that can be triggered to cause the phenomenon of excessive grooming.

Supported by BSRG SO7 RR05417 from Div. of Res. Resources, NIH.

239.10 EFFECTS OF APOMORPHINE ON SELF STIMULATION (SS) RESPONDING: DOES THE DRUG MIMIC THE CURRENT? Nancy J. Leith. Dept. Pharmacol., Vanderbilt Med. Sch., Nashville, TN 37232

A substantial body of data implicates DA as important in mediating (SS) responding (see Wise, Brain Res., 1978, p. 215; Fibiger, Ann. Rev. Pharmacol. Toxicol., 1978, p. 37 for reviews). However, when apomorphine, a direct DA receptor agonist, is administered to SS animals, there is sometimes an increase and sometimes a decrease in responding reported (Wauquier & Niemegers, Psychopharm., 1973, p. 163; Broekkamp & Van Rossum, Psychopharm., 1974, p. 71), presumably because the direct receptor activation disrupts the contingency relationship between the animal's behavior and the reward produced. The present study evaluated the effects of the drug at a variety of current intensities since it was postulated that at threshold current values, the addition of low doses of the drug should produce receptor activation normally associated with suprathreshold intensities and consequently be reflected as increased responding. Animals with electrodes implanted in the MFB were repeatedly tested at 15 current intensities throughout a 30 min session. During the 1st 15 minutes, baseline responding was assessed. Then various doses of apomorphine (0.02 - 0.2 mg/kg) were injected and 5 minutes later testing was resumed for an additional 15 min. At the lowest dose, there was a significant elevation of the reward threshold in all animals presumably reflecting the stimulation of presynaptic receptors which predominates at this low dose and results in an inhibition of the firing of the DA neuron. As the dose was increased the effect shifted to a flattening of the response rate-current intensity function. That is responding was decreased at the high intensities and increased at the low, as though the animal was responding independent of the current. However, if the current was reduced to zero, the animals showed a typical extinction pattern of responding. If, on the other hand, there was current available at the first step of the 15 step sequence, the animal would respond and then persist throughout the remaining 14 steps without current. Thus, these data clearly indicate an interaction of apomorphine with the stimulating current and suggest that apomorphine may be mimicking only one aspect of the stimulation--perhaps the rewarding but not the priming or motivating.

239.11 PLASMA LEVELS OF TRICYCLIC ANTIDEPRESSANTS IN PANIC DISORDER. D.R. Sweeney, M.S. Gold, A.L.C. Pottash and D. Martin*. (SPON: Carl Boast) CIBA-GEIGY Pharmaceutical Corp., Summit, NJ 07901 Research Facilities, Fair Oaks Hospital, Summit, NJ 07901.

Spontaneous panic attacks associated with agoraphobia have been noted to respond to treatment with antidepressants such as imipramine or phenelzine. Some individuals with panic disorder respond to doses of tricyclic antidepressants that are much smaller than the typical doses employed to treat depressive disorders. Either of these patients achieve relatively high plasma levels of tricyclic antidepressants (TCA) despite the small doses employed or the plasma levels achieved correspond to the low dosages, thereby implying that the neurochemical mechanisms of response are different in these patients with panic disorder than those with depressive disorder.

Five female patients with the DSM III diagnosis of agoraphobia with panic attacks were studied. After three weeks on a fixed low dose of imipramine (10-30 mg/day) all patients had experienced a significant alleviation and the frequency and intensity of panic attacks. Plasma levels of imipramine + desipramine were assayed at 800 h on $\geq$ weekly basis by the HPLC method of Martin (Neurosci. Abstr. 5:409, 1979). All patients demonstrated a significant decrease from pretreatment behavior and self-ratings at $\geq$ 21 days. At the time of clinical response all of the plasma TCA levels corresponded to the drug dosages, i.e., they were significantly lower than those defining the typical therapeutic range for depressed patients.

This finding, along with the finding that patients with panic disorder tend to have a positive response to imipramine within the first several days, implies that the psychobiological mechanism underlying panic disorder are different than those underlying depression. A possible mechanism which may explain this difference is a TCA-induced decrease in noradrenergic locus coeruleus activity by stimulation of inhibitory autoreceptors or another mechanism. This noradrenergic inhibition hypothesis for the therapeutic efficacy of TCA in panic states is also supported by the efficacy of clonidine in naturally-occurring and spontaneous panic (Gold, et. al, Biomedicine 30:1-4, 1979), the phenomenological similarities between opiate withdrawal and panic states, and other human and primate data. A noradrenergic hyperactivity hypothesis for panic will be discussed.

240.1 AUTORADIOGRAPHIC LOCALIZATION OF SITES OF OCTOPAMINE SYNTHESIS IN LIMULUS VENTRAL EYE. B-A Battelle* and S.C. Chamberlain* (SPON: H.H. Hess) LVR, National Eye Institute, NIH, Bethesda, MD and Institute for Sensory Research, Syracuse University, Syracuse,NY.

Ventral eyes of Limulus polyphemus appear to contain two neuronal elements: photoreceptor cells with their axons and small fibers, believed to be efferents, which contain dense-core granules and ramify extensively to surround photoreceptor cell bodies. Biochemical studies have shown that the biogenic amine octopamine is specifically associated with a photoreceptor cell body-rich fraction (P-fraction) of ventral eyes. P-fractions contain an average 2.9±0.55 times more endogenous octopamine and synthesize 7.4±1.6 times more octopamine from tyramine than nerve-rich fractions. Autoradiographic studies have been carried out to determine whether it is the photoreceptor cells themselves or the surrounding efferents which synthesize and accumulate octopamine.

Ventral eyes were incubated overnight *in vitro* in saline containing a low concentration of ^{3}H-tyramine (6×10^{-8}M), then fixed, embedded in plastic and cut in 2μm sections. The ^{3}H-octopamine present in ventral eyes incubated under these conditions accounted for 37% of radioactivity in the preparation as a whole and 58% of radioactivity in the P-fraction. Autoradiographic analysis showed silver grains concentrated over a few small (1-2 μm) fibers in the optic nerve, in punctate clusters located close around the periphery of photoreceptor cell bodies and occasionally within glial folds that penetrate photoreceptor cell bodies. This pattern of labeling is reminiscent of the distribution of efferent fibers in the ventral eyes. Only background levels of silver grains were present over photoreceptor cell bodies and the large photoreceptor cell axons. On the basis of these results we suggest that octopamine in Limulus ventral eyes is associated with efferent fibers and not with the photoreceptor cells themselves. Attempts to verify this hypothesis at the ultrastructural level are in progress. We are also using the autoradiographic localization of sites of octopamine synthesis and accumulation to search for the cell bodies of efferent fibers within the Limulus protocerebrum.

240.2 ERGOT ALKALOIDS ANTAGONIZE DOPAMINE INHIBITION OF BURST-FIRING IN CELL R 15 OF APLYSIA CALIFORNICA. Sidney M. Gospe, Jr., and Wilkie A. Wilson, Jr., Department of Pharmacology, Duke University Medical Center, and Epilepsy Center, V.A. Medical Center, Durham, NC 27710.

Dopamine (DA) inhibits burst-firing in cell R 15 by reducing inward currents associated with bursting. This effect can be seen as a reduction of the region of negative slope conductance (NSC) in the current-voltage (I-V) relationship curve generated under voltage clamp conditions. Using bath application of DA (50-500 μM) we have established a dose-response relationship for this process. We have previously reported that several phenethylamines (e.g. (-) NE, (+) NE, epinine, (-) phenylephrine) have full agonist activity in the same concentration range as DA. The effects of these agonists are not blocked by neuroleptics and adrenergic blocking agents.

Ergot alkaloids do, however, antagonize DA inhibition of burst-firing. Ergotamine, methysergide, LSD, dihydroergotamine, and dihydroergocryptine antagonize DA action in a noncompetitive manner. The DA dose-response curve is shifted to the right and the maximum effect is reduced. This antagonism develops slowly, and the response to a test dose of DA may continue to decrease even after four hours of exposure to the ergot.

Ergonovine and methylergonovine antagonize DA in a different manner. These ergot drugs are partial agonists, and over the course of a three hour exposure their agonist effect decays. Upon initial application, these drugs reduce the region of NSC in the I-V curve, but the maximum effect produced by these ergots is less than the maximum DA effect. As the length of exposure to the ergot is increased, its partial agonist effect decays and antagonism to DA develops.

These data are supported by a previous study showing that ergonovine and methylergonovine are specific antagonists for inhibitory DA receptors on molluscan neurons. In certain cells of Aplysia (Ascher, J. Physiol. 225:173, 1972) a direct membrane hyperpolarization has been observed to accompany this DA antagonism. Ergonovine and methylergonovine may be partial agonists at these neurons as well as at R 15.

240.3 THE ACTION OF PROCTOLIN, A PEPTIDE, ON A LOBSTER MUSCLE. T. L. Schwarz*, R. Harris-Warrick, S. Glusman, M. Goy*, and E. A. Kravitz. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115.

Proctolin, a neuropeptide first isolated from insects (Brown & Starratt, 1975), causes sustained contractions of the opener muscle of the dactyl of the lobster (Homarus americanus) walking leg at concentrations as low as 10^{-10}M. Higher doses (5×10^{-8}M) cause larger contractures that persist for up to an hour after the peptide is washed from the bath. Proctolin appears to act directly on the muscle. Intracellular recordings were made in individual muscle fibers while stimulating the single excitatory and inhibitory axons that innervate the muscle. No presynaptic action of proctolin was found; excitatory and inhibitory junctional potential sizes and the frequency of spontaneous miniature excitatory junctional potentials are unaffected by proctolin.

We have begun to study the mechanism of proctolin action on the muscle and have found that extracellular Ca^{++} and the level of the membrane potential are both important. In a Ca^{++}-free medium, proctolin fails to evoke a response and Ca^{++} blockers (20mM Co^{++} or 5mM Mn^{++}) will prevent a contracture. The peptide elicits the contracture without significantly depolarizing the muscle; no more than a 1mV depolarization is seen, at concentrations of proctolin up to 10^{-7}M. The proctolin-induced contracture, however, can be abolished by hyperpolarizing preparations with low K^{+} (12mM) or GABA (10^{-5}M). These observations suggest that the peptide's action involves a voltage sensitive component, perhaps the Ca^{++} channel itself (see also Glusman, Moore & Kravitz, these proceedings, 1980).

Proctolin is probably not the transmitter of the excitatory nerve that innervates this preparation. Unlike the excitatory transmitter, the peptide-induced contracture is long lasting and is accompanied by neither a depolarization nor a desensitization to the excitatory transmitter. Proctolin, or a proctolin-like substance, may be functioning as a neurohormone in lobsters.

Clearly, a complex control system exists superimposed on the excitatory and inhibitory nerves that govern the activity of the opener muscle. Serotonin and octopamine circulate in the lobster haemolymph and act on the opener muscle in a manner resembling that of proctolin. Dopamine, also found in lobsters, relaxes the muscle. Thus, proctolin is the fourth agent found to have long lasting effects on this preparation.

Supported by NIH grants NS-07848, NS-02253 and NS-07112 and fellowships from the Muscular Dystrophy Association.

240.4 THE MODULATORY ACTION OF SEROTONIN AT LOBSTER NEUROMUSCULAR JUNCTIONS. S. Glusman, J. W. Moore and E. A. Kravitz. Harvard Med. Sch., Boston, MA 02115 and Duke Univ., Durham, N.C. 27710.

Serotonin seems to function, at least in part, as a circulating neurohormone in lobsters. At exoskeletal muscles, serotonin is reported to increase the release of the excitatory transmitter compound, and to cause a contracture of the muscle (Dudel, 1965; Battelle & Kravitz, 1978). In this communication we discuss ionic mechanisms which may underlie the serotonin induced increase in contractility of exoskeletal muscles. Furthermore, we show that serotonin enhances the effectiveness of inhibitory as well as excitatory neurotransmission.

Serotonin (2×10^{-7}M), applied to the opener muscle of the dactyl of the walking leg, induces a prolonged contracture, a small depolarization of muscle membrane potential (1-2 mv), a slight increase in muscle fiber input resistance (10-15%), and the appearance of large propagating action potentials in muscle fibers where none were seen before. A voltage clamp analysis was performed to study these effects further. We were able to demonstrate the existence of the following currents in these muscle fibers: 1) a voltage dependent inward Ca^{++} current (blocked by Co^{++}); 2) a voltage dependent outward current [blocked by tetraethylammonium (TEA)]; 3) an outward current dependent on the inward Ca^{++} current; 4) a residual voltage dependent outward current that remains in the presence of TEA (100mM) and Co^{++} (30mM). With serotonin treatment there is a marked increase in the inward Ca^{++} current while the TEA sensitive and the residual outward currents are unaffected. The same results were obtained if the Ca^{++} in the bathing medium was replaced with Sr^{++} or Ba^{++}, both of which pass through the Ca^{++} channel but do not appear to activate the Ca^{++} sensitive outward conductance. We have not yet tested whether serotonin affects the outward current dependent on Ca^{++} entry as well. However, the demonstration that serotonin enhances Ca^{++} entry through Ca^{++} channels could account for the appearance of action potentials in these muscle fibers.

In a second series of experiments the effects of serotonin on inhibitory junctional potentials (IJPs) and inhibitory junctional currents (IJCs) were measured at different levels of membrane potential. Serotonin caused a 2-3 fold increase in the size of both IJPs and IJCs without changes in the level of the equilibrium potential for inhibition. At present we are examining whether this is a pre- or postsynaptic action of serotonin. Serotonin thus elevates the level of activity of all the components of this neuromuscular preparation. Supported by NIH grant #NS-07848.

240.5 A NEUROACTIVE FACTOR FROM THE LOBSTER SINUS GLAND MODULATES THE SPONTANEOUS ACTIVITY OF IDENTIFIED NEURAL NETWORKS. Jorge R. Mancillas*, S. Leff* and A. Selverston (SPON: T. Melnechuk)

The sinus gland, a neurohemal organ located in the eyestalk of decapod crustaceans, is known to contain a variety of hormones. We report the existence, in extracts of the lobster sinus gland, of a neuroactive substance(s) that can modulate the activity of two identified neuronal pools in the lobster and crayfish.

Sinus glands were removed from the eyestalks of spiny lobsters and boiled at 90°C for 5 min. The tissue was homogenized, treated with chloroform and acetone, and centrifuged. The supernatant (crude extract) was stored at -70°C. The crude extract was tested for its effect on the spontaneous rhythmic activity of the stomatogastric nervous system, which was prepared for recording as described previously (Mulloney and Selverston, J. Comp. Physiol. 91:1, 1974). Different concentrations of extract were applied to the whole, non-desheathed ganglion, which was isolated from the rest of the preparation by a small vaseline pool. The main effect observed was a disruption of the coordinated rhythmic output of both the pyloric and gastric subsystems, and eventually, a cessation of the spontaneous firing of action potentials by all units monitored. An exception were some PY units, which went into a tonic firing pattern. The crude extract was also assayed on the slow flexor motoneurons of the lobster abdominal ganglia. The spontaneous tonic firing pattern was monitored and found to be consistently reduced upon application of the extract. The intensity and duration of the response was proportional to the concentration and length of exposure. The same effects were obtained when the crude extract was applied to the stomatogastric and slow flexor motoneuron system of the crayfish (Procambarus Clarkii).

A preliminary analysis of the molecular characteristics of the neuroactive substance(s) was undertaken. The crude extract was subjected to gel filtration using Sephadex G-25 columns. Using the systems mentioned as an assay, the inhibitory activity was recovered in a narrow band eluting with a Ve/Vt of 0.92 (±0.04). A crude MW estimate based on that observation yields an approximate figure of 1200. The activity is thermostable, surviving temperatures as low as -70°C and as high as 110°C. The sensitivity of the neuroactive factor to proteolytic enzymes is currently under investigation.

Some of the properties of this neuroactive factor are similar to those of Neurodepressing Hormone (NDH). NDH is a peptide neurohormone isolated from the crayfish sinus gland that has been postulated as a mediator of circadian rhythmicity in crustaceans (Huberman et al., Eur. J. Biochem 99:203 1979). Further studies are in progress to establish the identity of the neuroactive substance(s) from the lobster sinus gland and its mechanism of action. -Supported by NSF grant BNS 79-29182.

240.6 DOPAMINE AND SEROTONIN AS PUTATIVE NEUROTRANSMITTERS IN THE OPALINE GLAND OF APLYSIA CALIFORNICA. S.H. Tritt*, M. Zigmond and J.H. Byrne Depts. of Biological Sciences and Physiology, University of Pittsburgh, Pittsburgh, PA 15261.

We have previously identified three motor neurons which mediate the contraction of the opaline gland (Tritt and Byrne, 1980). In order to further characterize the motor component of this behavior we have attempted to identify the neurotransmitter released by the motor neurons. Neurotransmitters were screened for their effect on opaline gland contraction by infusing the substances into the gland via an arterial cannula. Infusion of 0.2-0.5 ml of glycine, GABA, glutamate, histamine or octopamine at concentrations of 10^{-4}M was without effect. In contrast, infusion of dopamine at concentrations as low as 10^{-6}M produced gland contractions similar to the response obtained by firing the opaline gland motor neurons or by electrical stimulation of nerve P5 in which the motor neurons send their axons. The size of the gland response, as measured by the change in pressure within the gland, was increased by raising the dopamine concentration from 10^{-6}M to 10^{-3}M. The response to dopamine could be blocked by infusing a mixture of dopamine and the dopamine antagonist fluphenazine. Infusion of fluphenazine alone also produced a graded block of neurally mediated gland contraction over a concentration range of 10^{-4} to 10^{-3}M. The block was reversed by washing out the fluphenazine. In contrast to the effects of fluphenazine, curare and hexamethonium at the same concentrations had no effect on either the dopamine response or the contraction of the gland elicited by stimulation of nerve P5. These results suggest that dopamine is involved in mediating opaline gland contraction and may be the neurotransmitter released by the identified motor neurons. Infusion of the ACh at concentrations between 10^{-6}M and 10^{-3}M caused a graded decrease in gland pressure, however, no neural pathways have so far been identified which mediate a gland response similar to this pharmacologic effect.

We have also obtained evidence that serotonin may play a role in the motor component of opaline secretion. Infusion of serotonin at concentrations greater than 10^{-5}M produced no detectable gland response, however, it enhanced subsequent gland contractions elicited by either dopamine infusion or stimulation of neural pathways. Even after washing out the transmitter, the size of the gland contraction remained greater than control for over 10 min. This modulation of the opaline gland contraction by serotonin may be similar to the serotonergic modulation of buccal muscle in Aplysia (Weiss et al., 1978).

The opaline motor neurons are large (250 μm) and readily identifiable, and may thus serve as a model system to study dopamine metabolism and axonal transport in a single identified neuron with a known behavioral function. Supported by NIH grants NS 00200 and NS 13511.

240.7 THE EFFECTS OF CHOLINE ON A CHOLINERGIC SYNAPSE. Susan R. Feinstein* and Alan Gelperin. Dept. Biology, Princeton University, Princeton, New Jersey 08544.

An important determinant of acetylcholine synthesis is the level of choline in the blood. Cholinergic neurons possess a specialized high affinity uptake system that transports choline from the extracellular fluid into the axons and nerve terminals where it is converted to acetylcholine. As circulating levels of choline vary, choline and acetylcholine stores in the neuron may fluctuate, and the acetylcholine output at the synapse may change. In order to study the dependence of transmitter output on changes in transmitter stores, we used the cholinergic synapse between the salivary burster neuron and the salivary duct muscle in the slug, Limax maximus.

The salivary burster (SB) is an autoactive motoneuron located in the buccal ganglion. Its axon traverses the salivary nerve to innervate the salivary duct musculature. Each SB spike is followed by a junction potential (JP) recorded from the salivary duct. The amplitude of these JPs was used as a measure of the amount of transmitter released by the SB. If transmitter output increases with elevated transmitter stores, then an increase in the amplitude of JPs recorded from the salivary duct should be seen.

When acetylcholine levels in the SB were elevated by incubation of the buccal ganglia and attached salivary ducts in choline-enriched saline, the amplitude of JPs increased. Changing the choline concentration from 5 to 15μM increased JP size by 69%. This effect of choline occured only after several hours and persisted for at least one hour after choline was removed from the bath. Hemicholinium-3, an inhibitor of the high affinity uptake process for choline, blocked the effect of choline on JP amplitude.

The increase in JP amplitude seen in the presence of choline is not due to a direct effect of choline on the muscle. The increase occurs only after several hours, persists even after choline is removed from the bath, and is blocked by the choline uptake inhibitor, hemicholinium-3. More likely, choline in the bath is taken up by the axon and nerve terminals of the SB where it is converted to acetylcholine. As acetylcholine stores in the cell grow, transmitter output also increases. A change as small as 10μM in choline concentration in the slug's haemolymph could affect transmitter levels in the SB and the amount of transmitter released at the synapse.

Supported by NSF Graduate Fellowship (S.R.F.) and NIH grant MH15698 (A.G.).

240.8 MODULATION OF ARTERIAL MUSCLE CONTRACTION BY GLYCINE AND NEURON R14 IN APLYSIA. D.J. McAdoo, M. Sawada*, J.E. Blankenship and C.H. Price. Marine Biomedical Institute, Univ. of Texas Medical Branch, Galveston, TX. 77550.

We here report that exogenous glycine and electrical activity in neuron R14 both enhance the contractility of muscle in the wall of the anterior aorta of the gastropod Aplysia. We have previously shown that Aplysia neurons R3-R14 have high glycine concentrations, a glycine uptake system, a glycine axonal transport system and that glycine is associated with characteristic vesicles in those neurons. Their morphology indicates that R3-R14 innervate circulatory vessel musculature. Simultaneous recording from the soma of R14 and a varicosity in a branch of R14 in the aorta muscle confirmed the innervation of the muscle by R14. The parietovisceral ganglion, the innervated section of the anterior aorta, and the vulvar nerve connecting them were dissected from the animal as a unit. R14 was stimulated to fire with histidine or an intracellular electrode. Intracellular records were obtained from R14 and the muscle fibers while simultaneously recording muscle tension with a strain gage. Neither firing of R14 nor exogenous glycine resulted in any electrophysiological effect on the muscle or on junctional potentials produced in muscle fibers by identified motoneurons (Blankenship et al., abstract, this meeting). However, both bath applied glycine and firing of R14 enhanced muscle contractions induced by stimulation of the vulvar nerve or application of 5-HT. Thus glycine appears to modulate Aplysia muscle contraction. Alanine, serine, taurine and histidine were without effect. Glycine has now met the "identity of action" criterion for establishing that it is utilized by R14 as a neurochemical messenger. Release must yet be demonstrated. Supported by NS 13311, NSF-PCM 79 12175, and NS 11255.

240.9 IDENTIFIED PEPTIDERGIC NEURONS ACTIVATE THE FEEDING MOTOR PROGRAM IN TRITONIA. P.E. Lloyd* and A.O.D. Willows. Dept. of Zoology and Friday Harbor Lab., Univ. of Washington, Seattle, WA 98195.

In the gastropod, Tritonia, the paired buccal ganglia are largely responsible for generating the feeding motor program. Each ganglion contains a large dorsal white cell (LDWC). These neurons have been shown to contain a bioactive peptide, termed small cardioactive peptide (SCP). The LDWCs have been shown to modulate the spontaneous activity of the gut (Lloyd, P.E., Soc. Neurosci. Abst. 5, 248).

In addition to the peripheral responses, intracellular stimulation of the LDWCs also caused a change in the patterned output of the feeding motor neurons located in the buccal ganglia. If a motor neuron demonstrated ongoing patterned activity, LDWC stimulation caused an increase in both the frequency and intensity of bursting. In those preparations that were not active, LDWC stimulation often produced patterned activity. This activation of the feeding motor program occurred when the LDWCs were stimulated to produce a pattern of bursting activity similar to that observed for these neurons in semi-intact 'feeding' preparations. This suggests that the central actions of the LDWCs described above are physiological, There was no evidence for direct synaptic interactions between LDWCs and motor neurons. Indeed, even when the LDWCs were stimulated to fire at high frequency for long durations, the responses observed in the motor neurons varied considerably in latency and intensity. Thus, the LDWCs do not play a 'command' role, but rather appear to be involved in more subtle modulation of the feeding motor program.

The bioactive peptide (SCP) was derived by either gel filtration of isolated LDWC somata, or sequential gel filtration, ion exchange, and aromatic affinity chromatography of whole ganglia. The application of this peptide to isolated buccal ganglia produced responses in motor neurons similar to those observed during LDWC stimulation. The threshold for these effects was the peptide content of 0.01 LDWC/µl. These responses were abolished by previous incubation of the applied samples with trypsin or Pronase.

Thus the LDWCs provide a model system in which an identified peptidergic neuron modulates both peripherally and centrally an animal's behavior. (Supported by NSF BNS-7906280)

240.10 PROTEIN KINASE INHIBITOR:EFFECTS ON PROTEIN PHOSPHORYLATION AND PHYSIOLOGICAL RESPONSES TO NEUROTRANSMITTERS IN APLYSIA NERVOUS SYSTEM. W.B.Adams and I.B. Levitan, Friedrich Miescher-Institut, POB 273, 4002 Basel, Switzerl

Protein kinase inhibitor (PKI) purified from rabbit skeletal muscle (Demaille, Peters & Fischer, Biochemistry 16 (1977) 3080-3086) was tested for its ability to modulate protein phosphorylation in Aplysia nervous system. In homogenates of Aplysia ganglia, PKI had no effect on basal incorporation of ^{32}P from γ-[^{32}P]ATP into Aplysia proteins, but completely inhibited cyclic AMP-dependent phosphorylation. This is similar to the effect of PKI in mammalian systems. To test the hypothesis that protein phosphorylation might mediate certain physiological responses, we injected PKI into Aplysia neuron R15, to give estimated intracellular concentrations between 50 and 300 µg/ml (5 to 30 µM). Three responses were examined: 1) a serotonin-induced increase in K^+ conductance which is mediated by cyclic AMP (Drummond, Benson & Levitan, PNAS (1980) in press); 2) a dopamine-induced decrease in inward ion conductance (Wilson & Wachtel, Science 202 (1978) 772-775) which does not appear to involve cyclic AMP; and 3) a long-lasting synaptic inhibition consisting of an increase in K^+ conductance together with a decrease in inward ion conductance (Adams, Parnas & Levitan, J. Neurophysiol. (1980) in press). In one experiment PKI completely inhibited the K^+ conductance increase produced by serotonin and had no effect on the response to dopamine. The response of the cell to serotonin returned to normal by 7 hours after injection. In other experiments PKI partially inhibited the response of R15 to serotonin and had little effect on the response to dopamine. In addition, PKI injection partially inhibited the K^+ conductance increase, but had little effect on the decrease in inward ion conductance, produced by synaptic stimulation. The results are consistent with the possibility that protein phosphorylation plays a role in the cyclic AMP mediated K^+ conductance increase evoked by serotonin.

We are grateful to Dr. E. Fischer for his generous gift of homogeneous PKI.

240.11 IDENTIFICATION OF GIANT PEPTIDERGIC (PROCTOLIN CONTAINING?)NEURONS IN INSECTS. M. O'Shea* and M. Adams* (SPON: A. Heller). Dept. of Pharmacol., Physiol., Univ. Chicago, Illinois, 60637 and Abteilung Huber, MPIV, Seewiesen, W. Germany.

In addition to revealing monoamine-containing dorsal mid-line neurons, the dye Neutral Red also stains a single, lateral pair of giant cell bodies in each thoracic and abdominal ganglion of several insect species (locusts, grasshoppers, crickets and cockroaches). These lateral somata are visible as white cells when live, unstained ganglia are illuminated against a dark background. We have identified the lateral Neutral Red staining somata as a system of homologous, segmentally organized, giant peptidergic neurons and we call them the Lateral Giant Peptide Neurons (LGPNs). They are accessible to functional studies by intracellular techniques (Adams & O'Shea, this volume) and can be readily isolated for single-cell biochemistry and assay of cell content.

A remarkable component of the soma is an enormous vacuole-like inclusion which forms a complex network of invaginations throughout the cell body. The cytoplasm is extremely granular when viewed with light microscopy. Ultrastructural studies show a high density of large osmiophilic granules. These granules and associated Golgi apparatus are seen bordering the vacuole. The giant vacuole is a most singular structure and we speculate it is a storage structure for the LGPN's transmitter.

Following dissection and isolation of the LGPN's soma, the soluble content is extracted in 2N acetic acid, lyophilized and then redissolved in buffer for assay of biological activity and biochemical nature. In tests for biological activity, the cell body extract is applied to a group of locust striated muscle fibers which show a myogenic, heart-like rhythm of contractions. The extract causes a marked increase in the frequency of contraction. This physiological action of the extract resembles that of Proctolin, a pentapeptide isolated from cockroach CNS. Biological activity is lost when extract or proctolin is preincubated with peptidase enzymes (Protease and Pronase). Enzymes like trypsin for example, which do not affect proctolin, do not reduce the biological activity of the LGPN extract either. This and preliminary results of high pressure liquid chromatography analysis are consistent with the idea that proctolin or a similar peptide is the active soluble component in the LGPN cell bodies. Currently we are investigating the physiology and function of the LGPN's (Adams and O'Shea, this volume) and attempting further to characterize the transmitter by immunological and chromatographic techniques. Purification of the biologically active component(s) of the cell body will enable us more precisely to characterize the transmitter(s) of the LGPNs.

240.12 ANATOMY, ELECTROPHYSIOLOGY AND FUNCTION OF AN IDENTIFIED PEPTIDERGIC NEURON IN INSECTS. M. Adams* and M. O'Shea* (SPON: J.W. Crayton). Abt. Huber, MPIV, Seewiesen, W. Germany and Dept. of Pharmacol., Physiol., Univ. Chicago, Illinois, 60637.

The abdominal and thoracic ganglia of crickets, cockroaches and grasshoppers each contain a single pair of giant lateral peptidergic neurons. We call the cells the Lateral Giant Peptide Neurons (LGPNs). They have been individually characterized by intracellular recording and dye injection techniques and are shown to form a system of serially homologous identified neurons. The somata of the LGPNs are visible in dark-field illuminated ganglia and analysis of their content has demonstrated the presence of a biologically active peptide, possibly proctolin (O'Shea and Adams, this volume). Intracellular injection of the LGPN's soma with Lucifer yellow, cobalt and horseradish peroxidase (HRP) have revealed the following anatomical features. The cell body gives rise to a single primary neurite which enters the neuropile, crosses the midline and forms a major axon which descends in the contralateral nerve cord to the next ganglion. This axon leaves the CNS via the first segmental nerve of that ganglion and passes dorsally to end at or near the myocardium. Arborizations from the primary neurite are extensive and occurs in both the neuropile and in axon tracts. The anatomy of the neuropile arborizations are typical of output or presynaptic terminations and suggests that the LGPN has widespread effects within the CNS. Arborizations also make contact with axons of sensory neurons and intersegmental interneurons contained in discrete fiber tracts. Long finger-like processes extend at least 100µm into the ascending and descending intersegmental connectives and there they interdigitate between axons of intersegmental neurons. The function of this most unusual association with axons is currently being investigated.

The LGPN soma supports overshooting, long duration action potentials, a feature untypical of insect motoneurons and interneurons. A steady volley of EPSP is shared by members of a pair of LGPNs and by LGPNs in different ganglia. Both ascending and descending interneurons contribute to the common presynaptic input. The pattern of inputs suggest that the LGPNs are activated together as a functional unit, and is suggestive of an arousal or modulatory role. We are currently investigating the function peripherally and in the CNS. Preliminary results show that the LGPNs increase the amplitude of the heartbeat an effect which is consistent with a role in general arousal. Furthermore, the effect of LGPN stimulation on the heart is similar to the effect of bath applied proctolin, the pentapeptide which we suspect may be the neurotransmitter.

240.13 EFFECTS OF TEMPERATURE ACCLIMATION ON SEROTONIN INDUCED CILIO-EXCITATION OF THE LATERAL CILIATED GILL EPITHELIUM OF MYTILUS EDULIS. Edward J. Catapane, Joyleen A. Thomas*, George B. Stefano and Denis F. Paul* Division of Natural Sciences, Medgar Evers College, C.U.N.Y., Brooklyn, N.Y. 11229.

Lateral ciliary activity of the gill of the bivalve mollusc Mytilus edulis is controlled in part by excitatory serotonergic fibers of the branchial nerve which originates in the CNS and innervates the gill epithelium. In nature and in the lab the ciliary activity of the lateral cells is modified by the temperature of the water in which the animals are placed. Warmer temperatures increase the activity. In order to determine the site of this effect of temperature the following study was performed. Animals were maintained for 2 months at 6°C or 18°C under otherwise identical conditions prior to studying ciliary activity. Other sets of animals were maintained in flowing sea water at ambient temperatures of 20 - 25°C at MBL, Woods Hole, Ma. and their ciliary activity measured at different temperatures. Ciliary activity from sections of isolated-denervated gills were studied for their response to the superfusion of serotonin at different bath temperatures by stroboscopic microscopy. The study illustrated that the ciliated cells displayed a temperature dependent activity, that the site of the temperature sensitive mechanism was in the gill, presumedly within the lateral cells themselves, and that prolonged temperature changes of 2 months, but not short-term changes of 5 hours resulted in temperature acclimation of this response. The effects of temperature may be due in part to changes in the affinity or number of postjunctional serotonin receptors in the lateral cells.

This work was supported in part by grants 5T32GM07 6041 from the MARC Program of NIGMS, 1S06RR08171 from DRR and NIMH and by a STEPS Fellowship from MBL, Woods Hole, Ma. to EJC.

241.1 EFFECTS OF DROSOPHILA PHOTORECEPTOR MUTATIONS ON THE CIRCADIAN ACTIVITY RHYTHM. Ronald J. Konopka. Biol. Div., California Institute of Technology, Pasadena, CA 91125.

Locomotor activity rhythms of adults of the following Drosophila strains were determined by means of an infrared actigraph: Canton-S and Oregon-R wild types, ocelliless, which lacks the three ocelli, sine oculis, a mutant which lacks the compound eyes, ocelli, and at least the first optic lobe, and norp A (allele p12), a mutant which has eyes but whose receptor potential measured by the electroretinogram is greatly reduced.

The activity rhythm of wild type flies in a light-dark cycle is usually bimodal, with morning and evening peaks. Ocelliless flies also have a bimodal activity rhythm, but sine oculis flies have a prominent evening peak and a poor or absent morning peak. The activity rhythm in constant temperature and constant infrared is usually unimodal, with the peak deriving from the evening peak expressed in a light-dark cycle. Flies carrying either the ocelliless or sine oculis mutation have an activity rhythm that persists in constant conditions. The circadian pacemaker of sine oculis flies can be reset by light pulses to the same extent as wild type. Thus the Drosophila circadian pacemaker possesses an extra-retinal photoreceptor.

Constant dim white light lengthens the period of the circadian pacemaker relative to that in constant infrared. The lengthening produced in the norp A mutant is similar to that produced in the Oregon-R wild type. Therefore, the lengthening effect of light on the activity rhythm is apparently not mediated by the retinula cells in the compound eye.

241.2 A CIRCADIAN RHYTHM RECORDED IN THE ISOLATED EYE OF BURSATELLA. G.D. Block and M.H. Roberts, Department of Biology, University of Virginia, Charlottesville, Virginia 22903.

The eyes of two marine molluscs, Aplysia californica and Navanax inermis, express circadian rhythms in the frequency of optic nerve potentials (Jacklet, Science, 164: 562, 1969; Eskin & Harbombe, Comp. Biochem. Physiol., 57: 443, 1977). In Aplysia the role of the eye in controlling locomotor behavior has been explored and it appears that the ocular pacemakers are involved in timing the locomotor rhythm (Strumwasser, Physiologist, 16: 9, 1973; Lickey et al., J. Comp. Physiol., 118: 121, 1977).

We currently report that Bursatella leachi plei, an anaspid opisthobranch, also possesses an ocular circadian pacemaker which will free run in vitro for several cycles. Similar to Aplysia, Bursatella eyes respond to illumination with compound action potentials which also occur spontaneously in darkness and express a circadian rhythm in their ongoing frequency. This ocular rhythm differs from the Aplysia rhythm in several respects: 1) The mean peak frequency of impulses on the first day in vitro is 96 (S.D.=36) for Bursatella compared with 247 (S.D.=61) for Aplysia eyes. 2) Unlike the circadian waveform of Aplysia eyes which contains a characteristic hump on the falling phase, the Bursatella waveform shows both a rapid rise and fall from peak values. 3) Evaluated simultaneously, the average free running period of Bursatella eyes in artificial seawater is 21.2 hr (S.D.=.6) compared to 24.3 hr (S.D.=.9) for Aplysia eyes. 4) The steady-state phase angle for entrainment differs by 4 hr from Aplysia, with Bursatella eyes showing activity peaks in the late subjective night.

We have also investigated the role of the eyes in controlling the locomotor rhythm. On L:D,12:12 Bursatella, like Aplysia, are diurnal with locomotor activity beginning near dawn. When the photoperiod is shortened (L:D, 9:15), locomotor onsets anticipate dawn by 1-2 hours. Following eye removal, locomotor movements continue to anticipate light onset with only minor changes in locomotor patterning. This is in contrast to Aplysia where there is a marked loss of anticipatory locomotor behavior following eye removal (Lickey et al., Photochem. & Photobiol., 23: 253, 1976).

Apparently the ocular pacemakers in Bursatella do not play a prominent role in timing locomotor activity when light cycles are present. We are currently investigating the role of the ocular pacemakers during free runs in continual darkness. NS15264.

241.3 PHASE RELATIONS BETWEEN THE CIRCADIAN EYE RHYTHMS AND THE LOCOMOTOR RHYTHM IN APLYSIA WITH ONE OR BOTH OPTIC NERVES CUT. M. E. Lickey, D. J. Hudson* and S. O. Hiaasen*. Dept. of Psychology, Univ. of Ore., Eugene, OR 97403.

The Aplysia eye shows a circadian rhythm of neural activity in vitro, and locomotor activity has a circadian rhythm in the whole animal. We have conducted experiments to determine the phase relation between these 2 rhythms and to determine if the optic nerve mediates coupling between them. METHODS: After entraining Aplysia to LD 12:12 we cut either one (1-X group) or both (2-X group) optic nerves. Control animals were left intact. Two to four days after surgery we released the animals into constant conditions (DD, either constant darkness or very dim constant light) and recorded their locomotor rhythms on an actograph. After 14 or more days in DD we removed the eyes and recorded their rhythms in vitro in constant darkness. RESULTS: (1) Intact animals' locomotor rhythms varied from vigorously rhythmic to nearly arrhythmic. Their eyes were nearly always found to be strongly rhythmic, but in many cases they were quite out of phase with each other. In animals that showed strong locomotor rhythms the eyes were nearly always synchronized and the rising phase of the eye rhythms corresponded to the onset of locomotion. In animals with weak locomotor rhythms the eyes were often, though not always, out of phase. (2) 1-X animals' locomotor and eye rhythms were comparable to the intact controls. In some animals, however, there was a strong locomotor rhythm even though the eyes were out of phase. In such cases the rising phase of the intact eye's rhythm nearly always corresponded to the onset of the locomotor rhythm; the cut eye's phase was not correlated with locomotor phase. (3) In most 2-X animals, locomotion was arrhythmic or nearly so, even though both eyes were nearly always rhythmic and often in phase. DISCUSSION: Coupling between the eyes and locomotion is obviously mediated by neural activity in the optic nerve. Our results give no evidence that ocular hormones are involved as suggested by the morphology of the eye(Jacklet et al., 1972) and the occurrence of calcium dependent peptide release from the eye in vitro (Harf et al., 1976; Strumwasser et al., 1979). It is also apparent that strong locomotor rhythmicity depends on proper internal synchronization of multiple oscillators and that behavioral arrhythmicity, when it occurs in intact animals, may often be due to internal desynchronization. Since there is a phase lock between the eye rhythms and the locomotor rhythm in animals with strong behavioral freerunning, the period of the locomotor rhythm is a good estimate of the period of the eye rhythm in situ. Our results on the relation between locomotor phase and eye phase agree with the results of Block (1979). (Supported by PHS NS 12374 and NSF 77-28251)

241.4 CEREBRO-PEDAL CONNECTIVES: CRITICAL PATHWAYS IN THE APLYSIA CIRCADIAN SYSTEM. M.H. Roberts and G.D. Block, Department of Biology, University of Virginia, Charlottesville, Virginia 22903.

Aplysia express a circadian rhythm in locomotor behavior (Strumwasser, In: The Neurosciences: An Intensive Study Program, p. 516, 1967). When exposed to light cycles (Light:Dark, 12hr:12hr), they are predominantly diurnal and begin locomotor activity near dawn. On shorter photoperiods (L:D, 9:15), locomotor movements typically "anticipate" the onset of light by several hours. When the eyes are surgically removed, anticipatory activity ceases. This, along with the fact that the eyes contain circadian oscillators (Jacklet, Science 164: 562, 1969) has led to the hypothesis that the ocular pacemakers are responsible for timing pre-dawn locomotor activity (Strumwasser, Physiologist 16: 9, 1973); Lickey et al., J. Comp. Physiol. 118: 121, 1977). An attempt was made to identify central pathways by which phase information travels from the ocular oscillators to the pedal ganglia, whose nerves serve the foot. Aplysia were placed in locomotor monitors and exposed to light cycles (L:D, 9:15) in order to confirm the presence of a clear locomotor rhythm. Following this, animals were removed from their tanks and the cerebro-pleural (n=8) or cerebro-pedal (n=17) connectives were bilaterally severed. After recovery from surgery, the Aplysia were returned to their monitors (L:D, 9:15) and locomotor activity was evaluated.

The results indicate that only the cerebro-pedal connectives are critical pathways in the circadian system. Bilateral section of the cerebro-pleural connectives resulted in only minor changes in locomotor patterning: anticipatory activity was not affected. In contrast, bilateral section of the cerebro-pedal connectives resulted in two reproducible effects. First, locomotor activity was markedly reduced from average pre-operative levels. This value however, was still above night time levels observed pre-operatively. Secondly, the animals failed to respond to light and locomotor behavior appeared arrythmic. These results lead us to believe that the cerebro-pedal pathways not only carry phase information from the ocular oscillators, but also carry signals from extraocular photoreceptors, which are capable of maintaining a diurnal locomotor rhythm in eyeless Aplysia (Block and Lickey, J. Comp. Physiol. 84: 367, 1974).

Whether phase information from the extraocular and ocular systems is carried separately in the cerebro-pedal pathways or first integrated in the cerebral ganglion is currently being investigated. NS15264.

241.5 LITHIUM INCREASES THE PERIOD OF A NEURONAL CIRCADIAN OSCILLATOR. Felix Strumwasser and Daniel P. Viele.* Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Halberg (1968) has suggested that circular manic-depressive cycles in patients, with severe mood disorders, could occur from a beat frequency resulting from the interaction of two endogenous oscillators only one of which remains entrained to the environment while the other free-runs.

Lithium is the present treatment of choice for patients with manic-depressive symptoms. The mechanisms of action of Li on the nervous system remain unclear but there is accumulating evidence that one of its important actions is on the circadian oscillator system. Manic-depressive patients turn out to have a fast circadian clock as evidenced by measurements of their sleep-waking or body temperature cycle (Pflug et al., 1976; Kripke et al., 1978) and Li appears to delay the circadian sleep rhythm of normal subjects in a normal social environment (Kripke et al., 1979).

We have investigated the effects of sustained Li on the free-running period of a neuronal circadian oscillator system in the eye of the opisthobranch mollusc, Aplysia. This preparation is an ideal model system because Li effects can be measured on the isolated eye without the complication of coupling factors and other oscillators present in the totally intact animal. The circadian rhythm is continuously recorded in darkness by monitoring the output of the optic nerve. The spikes in the optic nerve are compound action potentials (CAPs) due to synchronization of the output neurons located in the eye. In an artificial sea water medium (mM: NaCl, 465; KCl, 10.4; $MgSO_4$, 28; $MgCl_2$, 27; $CaCl_2$, 11; $NaHCO_3$, 13; HEPES, 15; glucose, 5) the period (τ) of the CAP frequency rhythm is 24.1 hours as measured over 4 to 6 cycles. When Li is substituted for Na we observe minimal effects on τ at 10 mM but remarkable lengthening of τ ($\sim$28 hours) at 30 mM. Reduction of Na (replacement by Mg) does not significantly alter τ. This is the first demonstration that Li has direct effects on τ of a neuronal circadian oscillator system studied in vitro and that it does slow the circadian clock as has been suggested from work on intact animals and plants (Engelman, 1973; Kripke and Wyborney, 1980). [Supported by NIH grant, NS 07071].

241.6 MAXIMUM ENTROPY SPECTRAL ANALYSIS OF JELLYFISH SWIMMING BEHAVIOR. J. L. Leonard. Dept. of Zoology, University of Wisconsin-Madison, 53706 and Friday Harbor Laboratories, Friday Harbor, Washington 98250.

A new technique (maximum entropy spectral analysis) for detecting rhythms in time-series data has been used to describe complex temporal patterns of swimming behavior in a hydrozoan jellyfish. This technique (MESA) is superior to more conventional methods of spectral analysis, such as the Fast Fourier Transform, in several respects (Childers, D. Modern Spectrum Analysis. IEEE Press, 1978). MESA is mathematically equivalent to fitting a n^{th} order Markov process to the data by the maximum likelihood procedure (Van den Bos, A. IEEE Trans. Inform. Theory vol. IT-17, 1971). MESA has two important advantages for biological work. The first is that it makes fewer assumptions about the data than does the FFT. This makes MESA more appropriate than the FFT for descriptive work. The second advantage is that MESA provides better resolution at the low frequency end of the power spectrum than does the FFT. This means that for the same length of data MESA will allow detection of low-frequency rhythms that would not be detectable with the FFT.

MESA was found to eliminate ambiguity present in FFT spectra as to which data records showed rhythms. The improved resolution at the low frequency end of the power spectra obtained by using MESA resulted in two important findings:

1. The swimming behavior of some animals showed more than one rhythm within a data record.
2. Much of the variability in the swimming behavior of an individual jellyfish is due to switching between rhythms of different frequency.

241.7 ABERRATIONS OF CIRCADIAN RHYTHMS OF BODY TEMPERATURE IN RATS WITH MEDIAL PREOPTIC LESIONS. Joseph Liran*, Evelyn Satinoff and Ronald M. Clapman*. Psychology Department, University of Illinois, Champaign, IL. 61820.

Evidence suggests that after lesions in the suprachiasmatic nucleus of the hypothalamus the circadian rhythm of body temperature (Tb) may be abolished, although the daily amplitude of the rhythm remains the same or is attenuated. We report here that lesions in the medial preoptic area (MPO), the area of the brain concerned with Tb regulation, produces severe aberrations in several aspects of the circadian rhythm of Tb.

Male rats were maintained at an ambient temperature (Ta) of 25°C in a 12:12 light:dark cycle with food and water available ad libitum. Lesions of the MPO were made through previously implanted stainless steel electrodes (2mA anodal current, 10-20 sec) in unanesthetized animals. Within 4 days the rats were tested for their ability to maintain normal Tb at a Ta of 5°C. Those that were deficient were implanted intraperitoneally with a miniature temperature transmitter and returned to their cages. Tb's were recorded every 5 min for several months.

Normal rats' Tb's fluctuated between 36.1 and 37.9°C with a mean daily Tb of 37.0 $\pm$ .06°C.(n=5). Rats with MPO lesions showed two major types of abnormalities. 1. Exaggerated amplitude of the rhythm. Tb of these rats (n=5) fluctuated between 36.0 and 41.5°C with a mean daily Tb of 38.8 $\pm$ .03°C. As the animals recovered the troughs remained essentially the same and the peaks became gradually lower although to date, four months postoperatively in several of the rats, no animal has returned to normal. 2. Exaggerated amplitudes of ultradian and the appearance of supradian components in some rats (n=3). Peaks and troughs of Tb declined successively over 4-5 days, often reaching lows of 31-33°C before drifting up again.

We interpret these results in terms of mutually inhibitory and facilitatory components of the daily Tb rhythm that together contribute to normal, small amplitude circadian oscillations. If some of the inhibitory components are preferentially damaged by MPO lesions, the resultant excessive influence of the less damaged components result in exaggerated swings of Tb and the emergence of noncircadian contributions to the overall fluctuations of Tb.

241.8 DIURNAL CHANGES IN EFFECTS OF HALOPERIDOL IN RAT. A. Campbell,* M. Herschel,* J. R. Madsen,* R. J. Baldessarini. Mailman Research Center, Harvard Medical School, McLean/Massachusetts General Hospital, Belmont, MA 02178.

To investigate diurnal variations in the behavioral effects of haloperidol, electronically monitored locomotion, catelepsy and ptosis were measured at 4h intervals over 24-h periods in rats kept under a controlled 12-h light-dark cycle (lights on, 7 a.m.). Following administration of haloperidol (1 mg/kg, i.p.) the cataleptic response was maximal at 4 p.m. and minimal at 4 a.m. The sedative responses (ptosis and inhibition of motor activity) showed a similar peak and nadir, or just the opposite of the normal diurnal pattern of spontaneous activity. After one month of reversed lighting conditions, during which time continuous electronic monitoring showed a complete reversal of day-night variations in spontaneous activity, the timing of the peak and nadir of the cataleptic response was unchanged while the sedative responses underwent a phase-shift of about 4 hours.

In addition, preliminary assays of haloperidol levels in the rat brain after injections of haloperidol (using a radioreceptor assay) also suggested the presence of corresponding diurnal variation, with levels showing a peak corresponding to the maximal cataleptic responses.

These results suggest that the cyclic cataleptic response to haloperidol is an endogenous rhythm, persistent even after the lighting changes that reversed the spontaneous activity and altered the peaks of haloperidol-induced sedation.

241.9 CHOLINERGIC STIMULATION OF PONTINE BRAINSTEM CELLS BY MINI-PUMP INFUSION AUGMENTS PARADOXICAL SLEEP FOR FIVE DAYS. P. Shiromani and W. Fishbein. Psychobiology Lab., Dept. of Psychology, The City College, CUNY, New York, N.Y. 10031.

In 1961, Jouvet (In P.G. Waser (Ed), Cholinergic Mechanisms, Raven, 1975) proposed that paradoxical sleep (PS) could depend upon brainstem cholinergic mechanisms. Much converging evidence has favored this hypothesis. Local injection of cholinergic agonists in the dorsolateral part of the pontine reticular formation trigger PS and antagonists inhibit it. Other research implicates the same cholinergic mechanisms in affective psychopathological (Sitaram et al., Science, 208, 200-1, 1980), and memory disorders (Wurtman, Trends in Neurosci., 3, VII-X, 1980). Such links imply the need to chart long-term sleep-wake alterations induced by cholinergic agonists and antagonists. In the present work we employ the implantable Alzet mini-pump to infuse drugs at a controlled rate (1 ul/hr) over 7 days.

Nine rats are implanted with chronic indwelling EEG and EMG electrodes, and a cannula in the gigantocellular tegmental field (FTG) (carbachol, n=3, .5 ug/hr; scopolamine, n=2, 9 ug/hr) or the nucleus reticularis pontis caudalis (RPC) (carbachol, n=4, .5 ug/hr). A 24 hr baseline recording is obtained one week later. The pump is then implanted and 9 days of continuous recordings follow (7 days drug, 2 days post-drug). One week after the pump is exhausted a 24 hr post-experimental record is obtained. All results are compared to pooled baseline data. The drugs are effective during the first 5 days of pump operation. In the FTG, the major increase in PS is in the night cycle (PM) (FTG=+93%, RPC=+50%). During the day cycle (AM), the FTG and RPC show similar increases (FTG=+18%, RPC=+19%). Scopolamine induces a 41% decrease in the day and no change in the night cycle. No change in slow wave sleep in any drug condition is observed. The change in PS is due to alteration in PS frequency, without any change in mean duration of PS periods. The augmenting effects of carbachol are seen only during the PM cycle (normally awake) and not in the AM cycle. This suggests that during the AM cycle, carbachol does not alter PS mechanisms beyond already existing, genetically programmed, peak levels. Conversely, scopolamine depresses PS levels in the AM but has no effect during the PM cycle.

The experiment supports the view that (1) PS is modulated by brainstem cholinergic mechanisms, and (2) PS can be neuropharmacologically augmented for a considerable time period. Indeed, this study is the first of its kind to show such a protracted augmentation.

241.10 STRUCTURE AND FUNCTION OF SUPRACHIASMATIC NUCLEI (SCN) IN HUMAN AND NON-HUMAN PRIMATES. M.C. Moore-Ede, R. Lydic, C.A. Czeisler, C.A. Fuller and H.E. Albers*. Department of Physiology, Harvard Medical School, Boston, MA 02115.

In rodents, the SCN of the hypothalamus have been demonstrated to act as a key pacemaker of the circadian timing system. Entrainment by the 24 hr light-dark (LD) cycle is mediated via a direct retinohypothalamic tract (RHT). We have extended studies of SCN structure and function to primates including man. In the New World primate, the squirrel monkey (*Saimiri sciureus*), the SCN are located on either side of the tip of the optic recess of ventricle III and have a complex three-dimensional structure with distinct anterior and posterior poles (Lydic and Moore-Ede, *Neurosci. Letts.*, In Press, 1980). Retrograde transport studies demonstrate an RHT innervating the caudal SCN of squirrel monkeys. With the broadening of the base of ventricle III in an Old World primate, the rhesus monkey (*Macaca mulatta*), the SCN are more laterally placed and comprise a more diffuse neuronal cluster. The chimpanzee (*Pan troglodytes*) also possesses a diffusely organized and more laterally placed SCN, innervated by an RHT (Tigges, J. *et al., J. Comp. Neur. 172:* 367, 1977). In human fetal, child and adult brains we found a neuronal cluster homologous to SCN bordering ventricle III. However in human brains SCN were still more laterally placed and more diffusely organized than in non-human primates (Lydic *et al., Sleep*, In Press, 1980). Although current retrograde transport techniques for demonstrating RHT are not applicable to human studies, LD cycles can entrain humans.

Physiological studies of human subjects isolated from time cues (Czeisler *et al., Sleep Res.*, In Press, 1980) demonstrate that the circadian sleep-wake cycle is generated by a separate pacemaker from the body temperature rhythm, because these two rhythms can show distinctly different free-running periods. To determine if the SCN in primates are responsible for both the rest-activity and temperature rhythms, we have placed total bilateral SCN lesions in squirrel monkeys. These lesions result in complete loss of circadian rhythmicity in the rest-activity, feeding and drinking rhythms, but a clear body temperature rhythm persists as confirmed by spectral analysis. We conclude that while the SCN acts as the pacemaker of the rest-activity cycle in primates, a separate oscillator, located outside the SCN, generates the body temperature rhythm.

241.11 LIGHT-DARK CYCLE ENTRAINMENT OF THE PERSISTING CIRCADIAN RHYTHM OF CORE BODY TEMPERATURE IN SCN-LESIONED PRIMATES. Albers, H.E.*, Lydic, R. and Moore-Ede, M.C. (SPON: A.A. Gerall.) Dept. of Physiology, Harvard Medical School, Boston, MA 02115.

The suprachiasmatic nuclei of the hypothalamus (SCN) are an important pacemaker in the mammalian circadian system, generating the circadian rhythms of feeding, drinking and locomotor activity. Entrainment of these rhythms to the environmental light-dark (LD) cycle appears to be mediated via the retinohypothalamic tract (RHT), a direct projection from the retina to the SCN. The existence of a second circadian pacemaker has been confirmed by the persistence of the free-running circadian rhythm of core body temperature in SCN-lesioned monkeys (Moore-Ede *et al., Neurosci. Abstr.*, 1980).

To determine whether this second circadian pacemaker can be entrained to LD cycles, in the absence of the SCN-RHT complex, SCN-lesioned adult male squirrel monkeys were studied under LD 12:12 (period {T}=24 hr). These animals were prepared with bilateral radio frequency lesions (60°C; 1 min duration) stereotaxically placed in the SCN under x-ray visualization. SCN-lesioned monkeys displayed no significant circadian periodicity in drinking patterns in constant illumination. Following at least 2 wks of exposure to LD 12:12, each animal, previously trained to accept chair restraint, was placed in a metabolism chair, with a rectal probe to measure core body temperature.

A robust 24-hr rhythm of core body temperature was observed in all animals, which anticipated lights-on and remained elevated throughout the 12 hr light phase. To verify entrainment of the temperature rhythm to light-dark cycles in SCN-lesioned animals, a LD 1:22 cycle (T=23 hrs) was then imposed. The temperature rhythm rapidly adopted a 23 hr period as confirmed by sequential acrophase fits and spectral analyses in both SCN-lesioned and control animals. Again the initial rise in temperature anticipated lights-on but remained elevated for several hrs after the daily 1 hr light pulse.

We conclude that the circadian rhythm of core body temperature is not generated by the SCN. Furthermore, the SCN are not essential for entrainment of the pacemaker responsible for this temperature rhythm.

242.1 SPINAL CORD INFARCTION: A NEW APPROACH IN THE EXPERIMENTAL INVESTIGATION OF STROKE. J.A. Zivin, U. DeGirolami*. Department of Neurology, University of Massachusetts Medical Center, Worcester, Massachusetts 01605.

A major obstacle to the experimental investigation of stroke has been the lack of a reproducible model of focal ischemia. To overcome this problem we have developed a method which employs infarction of the rabbit spinal cord. We believe it is reasonable to assume that the changes that occur in the spinal cord are qualatatively similar to the changes that occur in most regions of the brain during ischemia. We have found that it is possible to produce focal ischemia in 100% of the animals in a very stereotyped anatomical distribution and the lesion can be produced while the animal is fully conscious. Therefore, this model is ideally suited for biochemical and morphological correlative studies.

Snare ligatures were placed around the abdominal aortas of rabbits below the renal arteries and after recovery from anesthesia the aortas were occluded for varying periods of up to one hour. The ligatures were then removed. In 48 animals, the average time to produce any clinical signs of neurological dysfunction was 20.6 $\pm$ 2.5 min. (mean $\pm$ s.e.). The average time to produce complete paraplegia as 32.9 $\pm$ 1.8 min. Microscopic examination one week after the insult showed gray matter damage in all animals that had signs of clinical deficits but no abnormalities were observed in the rabbits that regained normal neurological function.

We believe this method is the most reproducible CNS focal ischemia model yet devised.

This study is supported in part by NIH Grants NS00456 and NS15827.

242.2 CHANGES IN RELATIVE TISSUE OXYGEN CONSUMPTION, TISSUE OXYGEN CONTENT AND BLOOD FLOW AFTER SPINAL CORD INJURY. N. Hayashi*, J. C. de la Torre, B. A. Green. Dept. of Neurosurgery, Univ. of Miami, Sch. of Med., Miami, FL 33101.

We have previously reported gray and white matter local spinal cord blood flow (lSCBF) in the rat using a multiple micro-electrode hydrogen washout technique (Hayashi et al. Neurology 30, 406, 1980). In the present study, lSCBF, tissue oxygen content (TOC) and relative tissue oxygen consumption (RTOC) were measured simultaneously using the micro-electrode technique before and after 100 g/cm force spinal cord compression injury. This corresponds to a moderately severe injury resulting in permanent paralysis of the animal.

Male Sprague-Dawley rats underwent laminectomy from T_{10}-L_1 and microelectrodes were inserted in gray and white matter in the following regions: i) at the lesion site; ii) proximal to the lesion site; and iii) distal to the lesion site.

The placement of the distal and proximal recording electrodes extended to about 2 spinal cord segments away from the lesion site.

Results show that at the lesion site lSCBF in gray matter gradually decreased but, RTOC was found to fall faster than lSCBF and did not recover for 4 hours. TOC was slightly increased during the first hour after injury, but began to decrease during the next 3 hours.

In the regions proximal to the injury site, the pattern of lSCBF reduction resembled that seen at the injury site but was less pronounced. Similarly, RTOC initially decreased 30 min after injury but then, gradually increased for the next 3 hours even as lSCBF decreased. One hour after injury this dissociation of blood flow and RTOC value was found highest at the proximal site, while TOC levels showed lower than normal levels.

Distal to the lesion site, lSCBF and RTOC were less decreased than at the site of injury.

These results suggest that inside the immediate perimeter of the lesion site, distortion of the neuronal tissue may be the most critical factor in the eventual pathophysiology that develops after trauma. However, outside the lesion site, particularly in the proximal region, blood flow and metabolic factors (such as RTOC) are probably more important in accounting for the secondary changes seen after cord injury.

242.3 SUPERSENSITIVITY TO 5-HT AFTER SPINAL CORD TRANSSECTION IN THE RAT. H. Barbeau and P. Bédard. Lab. de neurobiologie, Univ. Laval, Québec, Canada, G1K 7P4.

After spinal cord transsection in the rat, the level of spontaneous EMG activity in response to 5-hydroxytryptophan (5-HTP) measured in the extensor muscles of the hinblimbs increases with the time elapsed after the section. The response is maximal 20 to 30 days after transsection. It is blocked completely by cyproheptadine 10 mg/kg and does not appear to be affected by drugs acting on other neurotransmitters.

In parallel, during the same period of 20 to 30 days there is a ten fold increase in the strength of the nociceptive flexor reflex elicited by an electric stimulation of the paw (duration 3 ms, frequency 10 Hz, intensity 2 MA). The tension of the nociceptive reflex is measured in grams with the help of a transducer. In another set of experiments, 5-7 dihydroxytryptamine (5-7DHT) 200 mg was injected into the left cerebral ventricle. All animals were pretreated with desipramine 65 mg/kg. Twenty days after the injection of this neurotoxin all animals underwent a spinal cord transsection. The day after the transsection they were tested for spontaneous EMG activity in the hindlimbs in response to 100 mg/kg of 5-HTP and for nociceptive response after stimulation of the paw. The level of spontaneous EMG activity in response to 5-HTP is much higher than in acutely spinalized rats not pretreated with 5-7DHT and of the same order as in chronic spinal rats. On the contrary the nociceptive reflexes remained similar to those obtained in acute spinal rats untreated with 5-7DHT. Our results suggest that lumbar motoneurones in the rat become supersensitive to 5-HT after treatment with a neurotoxin. The same probably occurs after section of the descending 5-HT pathways in chronically spinalized animals. On the other hand, treatement with 5-7DHT does not appear to increase the sensitivity of lumbar neuron to noniceptive stimuli. The same reflexes are however increased in chronically spinalized rats. In the latter situation we must therefore infer that two mechanisms probably coexist namely a certain degree of supersensitivity of the 5-HT receptors which is specific to that neurotransmitter and second a certain degree of increased responsiveness of the lumbar neurons due to other mechanisms possibibly disinhibition or synaptic rearrangement.

242.4 THERAPEUTIC DIALYSIS OF CEREBROSPINAL FLUID BY EPIDURAL COOLING IN SPINAL CORD INJURIES. C. Romero-Sierra, R. Ethier*, R.N. Henriksen* and R.B. Marina*. Queen's University, Kingston, Ontario, Canada K7L 3N6.

Paraplegias of traumatic origin may be classified in primary and secondary. It is accepted knowledge that secondary traumatic paraplegia (S.T.P.) is due to an autodestructive process.

Of the various factors suggested as causal agents in the secondary process, none of them alone or combined gives a complete picture. Furthermore, different authors have published results supporting or contradicting the therapeutic effects of durotomy alone or associated with exposed spinal cord with a solution at normal temperature or by irrigation with a cold solution. It appears that, while decompression and open dialysis might be beneficial, the surgical trauma over the injured region is detrimental.

A method of local epidural spinal cord cooling has been developed and found very successful in the treatment of S.T.P. With this method no surgical injury or damage is imposed on the dura, cerebrospinal fluid (C.S.F.) or spinal cord. Furthermore, several of the beneficial effects attributed to hypothermia in a traumatized area are evident, e.g., reduction in metabolic demands, edema, swelling, vasospasm and blood pressure.

Aware of the benefits that dialysis may have in S.T.P., as well as of the very good results obtainable with local epidural spinal cord cooling, it was hypothesized that this method of hypothermia may in some way trigger C.S.F. dialysis. Based on this hypothesis, a model approximating the behaviour of the C.S.F. was developed for the situation in which a cold source is applied to the dura.

Using dimensionless analysis techniques, it was shown that the C.S.F. under the cooled region of the dura experiences convective motion, even in adverse situations where the spinal cord has swollen. In the steady state, the moving fluid forms into several Bénard cells directly under the cold source.

The steady state temperature distribution within the C.S.F., when the cold probe is applied, was then solved for. Further, a mathematical expression describing the axial flow field of the C.S.F. when fluid formation is just beginning, was derived from the approximate equations of motion. This expression indicates that there will initially be effective axial fluid transport near the cold source. This fact, along with the knowledge that steady state convection will occur, allows us to conclude that the cold source in local epidural cooling is an effective mechanism for generating C.S.F. flow.

242.5 MONOAMINE METABOLITE CONCENTRATIONS IN SPINAL GRAY AND WHITE MATTER, PLASMA, AND CISTERNAL CSF SUBSEQUENT TO THORACIC (T_5) CONTUSION OF EXPOSED CAT SPINAL CORD. Robert H. Roth, Donald Kay Riker, Dean Lohse* and William F. Collins, Jr. Depts. Pharmacology, Psychiatry and Neurosurgery, Yale Univ. Sch. Med., New Haven, CT 06510.

Monoamines present in spinal tissues as neurotransmitters or blood-borne hormones could be vasoactive when released from tissue by spinal injury or taken up at the injured site. For example, the presence of vasoconstrictive amines at the site of injury could cause local spreading ischemia and a worsened prognosis. We examined the distribution and spread of dopamine (homovanillic acid, HVA) and serotonin (5-hydroxyindoleacetic acid, 5-HIAA) metabolites by gas chromatography-mass spectrometry in cat gray and white matter after contusion of T_5. Following anesthesia and laminectomy a reproducible paraplegia-producing blow (500 g/cm) was delivered to the dorsal surface of T_5 and corroborated by transient hypertension. Cisternal CSF (cCSF) and venuous plasma samples were taken from in-dwelling catheters just before and 1, 2 and 3 hours after injury. Cats were sacrificed by pentobarbital overdose at 3 hours post-injury. The spinal cord was removed rapidly and transferred to dry ice. Frozen segments T_4, T_5, T_6, and T_{12} were dissected and gray matter punched out with a 15 g blunt needle.

Increases in HVA and 5-HIAA did not occur in any white matter surrounding the site of injury (N=5; -4 to -27%) compared to sham-operated cats run in parallel. Significant changes in HVA (-44%) and 5-HIAA (-25%) in gray matter occurred at T_5 but not in T_4 or T_6. These data support the hypothesis that local catabolism may be altered by cellular injury but no evidence for significant spread of dopamine or serotonin into surrounding tissue was obtained.

Plasma HVA (r=.49) and dihydroxyphenylacetic acid (DOPAC, r= .86) were correlated with cCSF levels of HVA and DOPAC, respectively; plasma 5-HIAA did not correlate with cCSF values. In control cats cCSF HVA consistently increased from 100 ng/ml to a plateau of 160 ng/ml at +1 hr. Three of four injured cats had a dramatic rise in HVA 1-3 hrs after trauma (200-300 ng/ml). cCSF 5-HIAA showed a similar but more variable pattern. Only 2 of 5 injured cats reflected these changes by increases in plasma metabolites. These results suggest that increased central dopamine and serotonin metabolism follows within 2 hrs of spinal injury. Clearly increased levels of HVA and 5-HIAA in CSF within 2-4 hrs of injury might be predictive of significant spinal injury. (Supported in part by a grant from USPHS, NS-10174).

242.6 THE EFFECT OF DURATION OF COMPRESSION IN ACUTE SPINAL CORD TRAUMA. A.C.Nacimiento,H.-D.Herrmann* and F.Loew* Dept.of Physiology I and Dept. of Neurosurgery, Saarland University, School of Medicine, 6650 Homburg FRG

Time course and intensity of functional losses developing acutely in a suddenly compressed L7 segment in cat under experimental conditions previously described (Soc.f.Neurosci. 1978,4,1828; ibid 1979,5,2455) are clearly influenced by the duration of compression. Polysynaptic reflex discharges (PRD) and conduction through the injured segment before, during and for 5 hrs following injury. Pathophysiological changes develop along a regular pattern in which three postraumatic phases can be discerned as a function of time: an early one, within 1-5 min after compression, followed by an intermediate one for the next 5-10 min and a late phase, generally lasting until termination of the experiment. A compression of 3 mm was maintained in 3 experimental series for 50 msec, 500 msec and 1 sec, respectively. The pattern for a duration of 50 msec was as follows: within 1 min there was a sharp decrease in PRD of about 60 % and conduction block through the injured region. The following intermediate phase was characterized by stabilization of the reduced PRD and by a partial, progressive recovery of conduction. The late phase showed no further major changes neither in recovery nor in severity in the reduced PRD, whereas conduction recovered to about 40 % of the control values. With a duration of 500 msec all changes greatly increased in severity: PRD fell by 80-90 % and conduction was totally blocked within 1 min following compression. The intermediate phase showed very little recovery of PRD and none in conduction. In the last period, reflex activity remained very low and conduction returned at the most to about 10-15 % of pre-injury level. A compression lasting 1 sec produced changes which were not significantly different from those observed at 500 msec. It is concluded that (a) functional changes occurring very early after compression do contribute to the setting of the subsequent pattern of functional recovery and (b) no further increment in severity of functional losses occurs upon reaching a duration of compression with "threshold" qualities in terms of plasticity of recovery.

242.7 EFFECTS OF METHYLPREDNISOLONE ON INJURED SPINAL CORD MICROVASCULAR PERFUSION & METABOLISM. D.K. Anderson, E.D. Means, T.R. Waters* & C.J. Spears*. VA Medical Center, Cincinnati, OH. 45220.

We have demonstrated (Neurosci. Absts. 7:519, 1979) the efficacy of prolonged, high dose methylprednisolone (MP) treatment in enhancing neurologic recovery & reducing the degree of tissue damage in experimentally injured feline spinal cords(SC). The purpose of this study was to determine the effect of MP on SC microvascular perfusion (MVP), carbohydrate & energy metabolism. For this study a total of 53 female mongrel cats, ranging in wt from 2.6 to 4.1kg were anesthetized with Na pentobarbital (30mg/kg i.p) immobilized in a stereotaxic frame & a 1 segment laminectomy was performed at L_2. To study SC MVP, cats were sacrificed at 8hrs by intracardiac perfusion of 10% formalin succeeded by a mixture of colloidal carbon & gelatin following either laminectomy only (n= 4), SC compression (SCC) with a 170gm wt/5 min (n=4) or SCC plus 30mg/kg MP i.v. 1hr postinjury (n=4). The number of colloidal carbon filled vessels were counted in gray & white matter using an eye piece reticule in a photomicroscope at 20 or 40X on the H&E stained sections. Concentrations of carbohydrate & energy metabolites were measured in SC tissue frozen in situ with liquid nitrogen at 8 (n=5) and 24 (n=6) hrs following SCC (170gm/5min) or at 8 (n=10) & 24 (n=6) hrs following SCC plus 30mg/kg MP i.v. 1hr postinjury. Controls for this study were 14 laminectomized but uninjured cats. Frozen SC segments were extracted in $HClO_4$ & analyzed for ATP, ADP, AMP, P-creatine, glu, lact & pyr using the enzymatic fluorometric methods of Lowery & Passonneau. Control SC's averaged 231 & 57 filled vessels/mm^2 of gray & white matter, respectively. Injured, untreated SC's averaged 60 & 14 vessels/mm^2 & MP treated SC's averaged 191 & 39 vessels/mm^2. In both injured treated & untreated SC's at both 8 & 24hrs, levels of ATP, ADP, AMP & P-creatine were significantly subnormal, whereas lact levels were significantly elevated. However, there were no differences in the levels of these metabolites in SC's from injured untreated & MP treated cats at either 8 or 24hrs. The only metabolite differences in the SC's of untreated vs MP treated cats were higher glu levels in the treated cats & higher pyr levels in the untreated cats at 8hr. Our data demonstrates preservation of SC MVP at 8hrs postinjury in MP treated cats perhaps due to the anti-edemic action of MP and/or some as yet unidentified direct vascular effect(s) of this steroid. However, this maintenance of MVP was not reflected in a concommittant recovery of energy metabolites in the SC's of MP treated cats at 8 or 24 hrs. Perhaps preservation of MVP occurred primarily in nonnutrient vessels or MP treatment depressed SC carbohydrate metabolism for the 24hr postinjury period. Additional studies are required to determine the basis for MP protection of the feline SC from SCC. (Supported in part by the VA & the Upjohn Corporation.)

242.8 MORPHOMETRIC STUDY OF SPINAL CORD BLOOD VESSELS IN NORMAL AND CONTUSED FELINE SPINAL CORD. E.D. Means, D.K. Anderson, L. Kalaf* & T.R. Waters* VA Medical Center, Cincinnati, Ohio 45220.

Ischemia appears to play an important role in the pathogenesis of paraplegia following experimental spinal cord injury. The proposed effects of trauma on the spinal cord vasculature include thrombosis, rupture with hemorrhage, spasm & extrinsic pressure on the microcirculation by surrounding edema. To test the hypothesis that extrinsic pressure leads to compression of spinal cord blood vessels following blunt injury, the diameters of the vessels in gray matter were calculated on the normal feline spinal cord (n=4) & at 8 (n=4) & 24 (n=4) hours following compression injury.

The cats were immobilized in a stereotaxic frame following anesthesia with sodium pentobarbital (30mg/kg). The spinal cord was compressed using a 170gm weight for 5 minutes following a one segment laminectomy at the L_2 level. At 8 & 24 hours following injury the animals were sacrificed by intraortic perfusion fixation using a combination of paraformaldehyde-gluteraldehyde. The T_5, L_2 & L_5 segments of the spinal cord were removed in normal animals or the injured segment (usually L_2) in the experimental group. The spinal cord was divided into 2-3mm transverse segments & then processed for electron microscopy. The diameter distribution of spinal cord blood vessels in gray matter was calculated from 1μ toluidine blue stained transverse sections using a Leitz camera lucida attachment adapted to a Nikon photomicroscope. A MOP-3 Kontron (Zeiss) semiautomatic image analyzer interfaced with a PDP-12 computer produced a histogram plot of vessel diameters. In injured animals, histogram plots were calculated for tissue at the center of the lesion & for nonhemorrhagic-edematous tissue at the "pole" of the injury.

Histogram plots (diameter distribution) of blood vessels in normal spinal cord at T_5, L_2 & L_5 displayed a range from 2μ to 65μ with a majority of vessels in the 4-16μ range. The density & diameter distribution of vessels at the T_5, L_2, & L_5 spinal cord segments in normal cats were virtually identical (average density = 212 vessels/mm^2). Injured spinal cord at the L_2 segment through the center & the nonhemorrhagic "poles" of the lesion showed a significant increase in the number of vessels (vessels/mm^2) in the 4-8μ range while there was a decrease of 8-14μ sized vessels.

Preliminary ultrastructural & ultrastructural morphometric data suggest that venules (8-14μ) are diminished in number due to increased transmural pressure as a result of edema formation. We speculate that the post-injury increase in the number of small diameter vessels (4-8μ) is due to opening of previously closed capillary beds secondary to venular collapse & stasis. (Supported in part by the VA & the Upjohn Corporation.)

242.9 GAIT CHANGES IN CATS FOLLOWING CORTICOSPINAL TRACT LESIONS. E. Eidelberg and Jen Yu. Audie L. Murphy VA Hosp. and Depts. of Surgery and PM&R, Univ. of Texas Health Sci. Cent., San Anton. TX 78284.

Eight cats were trained to walk upon a moving treadmill. Subsequently in four of them the motor cortex was ablated bilaterally, and in the other two unilaterally. They were retested on treadmill serially after surgery. Gait analysis was carried out in all four limbs by footfall diagrams, joint angle trajectory measurements and interlimb coordination measurements, using Super 8 movie film data (54 frames per second). We found that all the animals rapidly recovered the ability to locomote, without significant loss of interlimb coordination. Joint angle studies revealed a tendency to increased duration and excursion of joint extension phases. This diminished in the course of time. The sharp and quick wrist flexion in the swing phase, which resembles part of the placing response, was not affected significantly by any of the lesions, although these lesions abolished tactile placing permanently. These results indicate that the corticospinal system does influence locomotor activity, but its role is relatively minor and can be compensated for after lesions.

242.10 ACTIVATION OF MOTOR UNITS IN MAN BY STIMULATION OF ANTERIOR AND POSTERIOR STRUCTURES OF THE SPINAL CORD. M.R. Dimitrijevic, J. Faganel*, J.A.R. Lenman* and P.C. Sharkey*. Dept. of Clinical Neurophysiology, The Institute for Rehabilitation and Research, Houston, TX 77030.

Stimulation of spinal cord structures was accomplished via epidural electrodes in 11 patients, two with the electrodes laterally, two with one electrode on the anterior aspect, and seven with both electrodes near the midline of the dorsal column. (Studies were conducted as a part of the evaluation of continuous spinal cord stimulation for modification of motor control.) Stimuli were applied at a 1 Hz rate, at a motor threshold level, in the form of 0.2 to 0.4 ms pulses, with an amplitude ranging from 6 to 15 mA. Other studies were conducted with stimulus rates up to 150 Hz. EMG responses were recorded using recessed silver-silver chloride electrodes placed 3 cm apart over the muscle belly under study, and in some instances, with a single fiber EMG electrode for estimation of the range of latency variation.

Stimuli applied through the dorsal column will evoke only localized motor responses, confined to those muscles innervated by the stimulated segment. These localized responses are unresponsive to high rates of stimulation, with the one-to-one stimulus-response ratio beginning to fail at frequencies above 10 Hz.

Stimuli to the anterior or lateral portions of the cord evoked responses both at the segmental level of stimulation, and in some cases, at caudal levels. This motor response has a shorter refractory period than does the posterior response, and is responsive to high rates of stimulation, consistent with direct activation of motor neurons.

243.1 GLUCOCORTICOID EFFECTS ON CAT LUMBOSACRAL MOTOR NEURON ACTION POTENTIAL CHARACTERISTICS. E.D. Hall Prog. in Pharmacol. Northeastern Ohio Univ. College of Medicine, Rootstown, Ohio 44272

Previous work has demonstrated that an intensive short-term glucocorticoid regimen in cats enhances certain excitatory parameters of lumbar spinal monosynaptic reflex transmission at least in part through a direct action on the Ia afferent terminals (Hall et al., J Pharmacol. Exp. Ther. 206: 361-370, 1978; Hall and Baker J. Pharmacol. Exp. Ther. 210: 112-115, 1979).

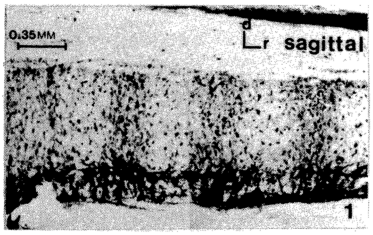
In the present study the actions of an intensive short-term methylprednisolone acetate regimen (MPA, 8 mg/kg i.m. once daily for 7 days) were examined on the characteristics of antidromically-evoked lumbosacral alpha motor neuron action potentials. All experiments were conducted in acute spinal (C-1) cats (1.8-3.5 kg). Supramaximal stimuli (0.2 msec) were applied with bipolar platinum electrodes to the proximal end of the sectioned L7 and S1 ventral roots once per sec. Glass microelectrodes (5-10 megohms) filled with 2M potassium acetate were used for recording. Data was obtained from a total of 37 antidromically activated motor neurons from 11 MPA treated cats vs. 34 cells from 12 untreated animals. Cells with resting potentials less than 50mV were discarded.

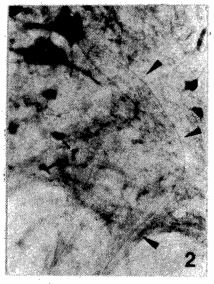
As a result of the 7 day MPA pretreatment the mean resting membrane potential was 4.2 mV more negative (-68.1) than in the untreated animals (-63.9), $p<0.002$ by t-test. Secondly, the latency from the antidromic ventral root stimulus to the beginning of conduction of the action potential through the initial axon segment was shortened from 0.67 to 0.59 msec ($p<0.03$) in the MPA treated animals. However, the conduction of the action potential through the initial segment was prolonged from 0.26 to 0.36 msec ($p<0.0002$) after MPA treatment. The only other significant change in the motor neuron action potential was a decrease in the zero overshoot of the soma-dendritic portion from 14.6 mV in the untreated neurons to 8.8 mV ($p<0.0001$) in the treated ones. This effect, however, appears to be due to the MPA-induced resting hyperpolarization since the absolute amplitude of the action potential spike was not significantly different, 78.4 mV in the untreated and 77.0 mV in the treated ($p<0.2$). The threshold and duration of the soma-dendritic spike and the after potential amplitudes were not affected by MPA.

These results demonstrate that the motor neuron is also a site of glucocorticoid action. The resting hyperpolarization, the increased myelinated axon conduction velocity and the slowed conduction through the unmyelinated initial segment undoubtedly reflect a direct glucocorticoid effect to produce a complex alteration in specific neuronal ionic conductance mechanisms. (Supported by the Amyotrophic Lateral Sclerosis Society of America and by NIMH 34111.

243.2 ALTERNATING TRANSVERSE AChE RICH AND AChE POOR BANDS IN LAMINAE VI AND VII IN THE LUMBOSACRAL CORD OF THE RAT. R. Marchand and H. Barbeau. Centre de neurobiologie, Hôpital de l'Enfant-Jésus, Québec, Qué. G1J 1Z4.

The pharmaco-histochemical method for the demonstration of acetylcholinesterase (AChE) has been applied. Ten rats were treated with di-isopropylfluorophosphate at various time intervals before sacrifice and their lumbosacral cord sectioned in either the sagittal, horizontal or transverse plane. Following this treatment AChE activity is greatly reduced in the neuropile of all regions including the dorsal horn where the activity of the enzyme is normally very diffuse. The fairly large cells of lamina I display an intense AChE activity. Lamina II is characterized by an AChE positive neuropile where tightly packed small cells displaya moderate AChE activity. Lamina III contains less densely packed neurons which display a light to moderate AChE activity in an unstained neuropile. In horizontal and sagittal sections the lateral zone of lamina VI and lamina VII show alternate AChE rich and AChE poor bands giving to this region the typical aspect seen in figure I. The AChE rich bands contain more AChE positive neurons which are predominantly orientated in the transverse plane. Long dendrites originating from the ventrolateral motor column are also present at the same level. Large AChE neurons which may correspond to the proprioneurons also occupy lamina VII. The cell bodies and processes of the neurons of the nucleus of Clark, the nucleusof the lateral funiculus and of the intermedio-lateral and medial columns also display AChE activity. In lamina IX, intensely stained large and medium sized neurons are grouped in well-defined columns inside which long dendrites are mainly orientated rostrocaudally and arranged in dendritic bundles. Some dendrites originating from the ventromedial and ventrolateral columns also converge inside laminae VIII and VII to form dendrites bundles. Other dendrites also extend dorsally along the lateral funiculus in the AChE rich bands toward the nucleus reticularis or far across the lateral funiculus. Three types of neurons may be easily identified in lamina IX. Large and medium intensely reactive cells compose most of the motor cell columns and likely correspond to the α and γ motoneurons. The third type possesses a small cell body with moderate AChE activity and occupies the ventromedial neuropile of the lamina IX near the area radiculares ventralis (fig. 2). They may possibly correspond to Renshaw cells.





243.3 DISTRIBUTION OF MONOSYNAPTIC SEGMENTAL INPUT TO CAT SPLENIUS AND BIVENTER MOTONEURONS. E. E. BRINK*, K. Jinnai*, and V. J. Wilson. Lab. of Neurophysiology, The Rockefeller University, N.Y.C. 10021.

Splenius (Sp) and biventer cervicis (Biv) are both considered single muscles but they are subdivided into compartments by tendinous inscriptions and receive innervation from several upper cervical segments (1). Do Sp and Biv motoneurons receive monosynaptic (presumably Ia) spindle input from the whole muscle or only from the compartment innervated by their axon? We have studied this problem by recording intracellularly from motoneurons in C2-C4 (with axons in C2-C4 nerves) in cats under nembutal anesthesia and stimulating branches of C1-C5 muscle nerves. Results from Sp and Biv are similar. Although the origin of monosynaptic input is restricted it does not correspond to compartments and has a rostro-caudal asymmetry. Table 1 shows the distribution of inputs judged monosynaptic to Sp motoneurons.

Muscle compartment	(1)	(1)	(2)	(3)
Nerve stimulated	C1	C2	C3	C4
segment recorded				
C2	0/4	12/12 (850)	12/12 (285)	4/9 (190)
C3	0/3	1/8 (80)	10/10 (680)	10/10 (215)
C4	0/2	1/10 (70)	2/9 (130)	11/11 (1270)

Numbers in brackets are mean EPSPs (in μV) of cases where response was present. Homonymous EPSPs were often not maximal because of antidromic firing.

Motoneurons typically receive monosynaptic EPSPs from afferents in the same nerve and from more caudal nerves. As stimulated nerves get more distant EPSP amplitude decreases and latency increases. There is usually little input from more rostral nerves except that in Biv, stimulation of the most caudal C3 branch evokes EPSPs in C4 motoneurons (6/8). In contrast to the situation in the hindlimb, therefore, motoneurons do not receive monosynaptic input from spindles scattered throughout the muscle. Instead they are influenced by change of length in regions of muscle innervated by their own axons and in more caudal regions, but only occasionally in more rostral regions. This asymmetry, whose functional meaning is not clear at this point, may be due to anatomical factors: ascending Ia collaterals may be longer than descending ones. Supported by N.I.H. grant NS02619.

243.4 RECURRENT INHIBITION OF Ia INHIBITORY INTERNEURONS AND RENSHAW CELLS DURING FICTIVE LOCOMOTION. Carol A. Pratt and Larry M. Jordan. Dept. of Physiology, Univ. of Manitoba, Winnipeg, Manitoba, Canada.

In non-moving cats, Renshaw cells (RCs) have been shown to inhibit homonymous and heteronomous motoneurons (MNs), Ia inhibitory interneurons (IaINs) projecting to antagonist MNs, and other RCs. Evidence that the recurrent inhibition of IaINs and MNs was diminished during locomotion led to the suggestion that RCs are inhibited during locomotion. It has now been shown, however, that RCs are rhythmically active during fictive locomotion (McCrea, et al., J. Neurophysiol., in press). Evidence that segmental afferents do not inhibit RC activity during normal walking was provided by the demonstration that stimulation of cut ventral roots (VRs) produced a mean reduction in rhythmic MN activity of 69% during controlled treadmill locomotion (Pratt and Jordan, J. Neurophysiol., in press). The present experiments examined whether the activity of IaINs and RCs could also be inhibited by RCs during locomotion.

The activity of IaINs and RCs was recorded during fictive locomotion in postmammillary cats which had been paralyzed with Flaxedil. Fictive locomotion was produced by stimulation of the mesencephalic locomotor region and monitored by recording rhythmic MN activity in an L6 VR filament. Recurrent inhibition was produced by stimulation of the central portion of cut ipsilateral L5-S1 VRs.

In the 6 quadriceps-coupled IaINs studied, VR stimulation resulted in a mean reduction in spontaneous IaIN activity recorded at rest of 93%. During fictive locomotion, rhythmic IaIN activity was inhibited by a mean of 35% during periods of VR stimulation. In all 6 IaINs, the difference between the initial discharge frequency (Fi) and the discharge frequency during VR stimulation (Fs) was found to be significant ($p<.05$). A positive linear relationship was found to exist between the efficacy of the recurrent inhibition of IaINs and Fi ($r=0.97$). These data, plus the finding thatdecreases in IaIN discharge during fictive locomotion tended to occur concurrently with increases in RC activity,suggest that RCs may contribute to the control of the phasing of IaIN activity during locomotion.

VR stimulation was also effective in inhibiting the rhythmic activity of RCs during fictive locomotion. The duration of RC-RC inhibition appears to be about 200 msec.

243.5 FUNCTIONAL PROPERTIES OF Ib INTERNEURONS IN SPINALIZED CATS. Corey L. Cleland, W. Zev Rymer and Frank R. Edwards*. Neuroscience Program and Depts. of Physiology and Neurology, Northwestern University Medical School, Chicago, IL 60611.

Because early investigations of spinal interneurons relied primarily on neuronal responses to electrical stimulation of muscle afferents, they did not provide any information about the interneuron's response to natural proprioceptive input. Particularly important is the inability of electrical stimulation to selectively activate golgi tendon organ and secondary spindle afferents without also activating low threshold primary spindle afferents. In order to avoid these difficulties, we have employed natural stimulation which can selectively activate Ia or Ib afferents. One of the initial goals of our study is to systematically describe the response of Ib interneurons to naturally induced activation of tendon organ receptors.

The discharge of 67 interneurons in the intermediate nucleus (depth 1.7-2.8 mm from cord dorsum) of L6-S1 has been extracellularly recorded using tungsten electrodes in decerebrate cats with spinal transection at T12. Interneurons were distinguished from tract neurons by their failure to be antidromically driven by tract stimulation at T12 and from motoneurons by their lack of response to ventral root stimulation. Interneurons were classified according to their responses to natural stimulation of muscle receptors in the lateral and medial gastrocnemius and soleus muscles. Ia interneurons were identified by their selective response to longitudinal tendon vibration at 120-200 Hz at an amplitude of 40-90 um, which specifically stimulates primary spindle afferents; Ib interneurons by their selective response to increases in isometric force induced by tetanic stimulation of either the peripheral nerve or ventral root at 8-20 Hz; secondary interneurons by their response to muscle stretch but lack of response to vibration and isometric force. Convergence from more than one major muscle afferent (i.e. Ia, Ib or II) was not observed.

Thirty-one of 67 interneurons were identified as Ib interneurons. The discharge of all Ib interneurons was substantially increased by isometric force and showed a time course which closely paralleled that of the whole muscle including small fluctuations in force. They were activated at latencies ranging from 0.7 to 8.0 ms from the incoming dorsal root volley, which corresponds to disynaptic or polysynaptic Ib input. Some of those with longer latencies to electrical stimulation showed a prolonged afterdischarge lasting in excess of 1 sec, and excitatory flexor reflex afferent (FRA) convergence from group III and IV muscle afferents.

243.6 TOPOGRAPHIC ORGANIZATION OF MONOSYNAPTIC REFLEXES IN THE CAT SPINAL CORD. Ronald C. Kramis* and Marc D. Binder (SPON: H.D. Patton). Dept. of Physiol. & Biophys., Univ. of Wash., Seattle, Washington 98195.

It has recently been shown that Ia afferents entering a given spinal segment generate larger postsynaptic population potentials in motoneurons located within that segment than in those of an adjacent segment (Lüscher, Ruenzel and Henneman, J. Neurophysiol. 43: 968-985, 1980). These results suggest that topographic factors as well as neuronal "species recognition" are important in the establishment of Ia afferent-motoneuronal connections. In the experiments reported here analogous results were obtained from comparisons of the amplitude of monosynaptic reflex discharges recorded from a ventral root when different dorsal roots were stimulated. The L_5-S_1 dorsal roots of decapitate spinal cats were placed onto separate stimulating electrodes. Potentiated, monosynaptic reflex discharges were recorded from a ventral root consequent to stimulation of each of the dorsal root filaments individually, and to stimulation of all of them together. The sequence was repeated for each ventral root filament. Subsequently, the individual dorsal and ventral root filaments were split into 2 or 3 sub-divisions, maintaining their rostral-caudal orientation and the protocol was repeated for these subdivisions. The results indicate that up to 80% of the potentiated monosynaptic reflex discharge recorded in the L_5, L_6, or L_7 ventral roots can be attributed to synaptic input entering the cord at the same segment. The S_1 ventral root is different in that it appears to receive nearly equal input from the L_7 and S_1 dorsal roots. However, for all roots including S_1, the rostral portion of a dorsal root generally exerted a greater effect on the rostral portion of the corresponding ventral root than on a caudal portion of the same ventral root. The converse was generally found for a caudal portion of the same dorsal root. These results indicate that topographic factors are prominent in the organization of spinal reflexes. 243.7 ANATOMY OF MONOSYNAPTIC CONTACTS FROM GROUP Ia AFFERENTS TO DEFINED TYPES OF EXTENSOR α MOTONEURONS IN THE CAT. R.E.Burke, M.J.Pinter*, A.Lev Tov* and M.J.O'Donovan*. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205

Horseradish peroxidase (HRP, Type VI, Sigma) was injected by iontophoresis into a functionally identified group Ia afferent (criteria: conduction velocity, stretch response, vibration sensitivity, pause during isometric muscle twitch) from one of the triceps surae heads or from plantaris, and then into 2 - 6 homonymous or synergist α motoneurons, identified as to motor unit type (see Brain Res. 160:347, 1979 for methods). Complete trajectories of Ia collaterals and motoneuron (MN) dendritic trees were reconstructed from serial sections and the numbers and spatial arrangement of presumed synaptic contacts (light microscopy only; op. cit.) onto labeled MNs noted. Although the number of complete reconstructions is thus far limited (4 cats; 4 group Ia afferents; 10 α MNs - 4 type FF, 3 type FR, 3 type S), several points can be made: (1) The number of contacts from a given afferent to a given MN (a "contact system") has varied from 3 to 30 (median 7 for 7 homonymous systems; 4 for 3 heteronymous systems). The material at hand is too limited to determine whether there are systematic differences in contact numbers or spatial positions in relation to motor unit type (see J. Physiol. 196:605, 1968). (2) Labeled contacts on a given MN can occur singly or in local groups of a few (a "contact region") but the whole contact system usually involves multiple contact regions that are widespread on different branches of a given dendrite or entirely different dendrites. (3) A given MN can receive contacts from as many as 3 adjacent collaterals from the same Ia fiber, with contact regions on dendrites both rostral and caudal to the MN cell body. (4) In only 1/10 cases were contact regions confined to the MN soma and basal dendrites; most examples have had contact regions dispersed widely at various anatomical (and presumably electrotonic) distances from the soma, including fine terminal branches. (5) Most of the studied contact systems involve profuse branching in each Ia collateral arborization and the first branch points of importance have usually been those in the base of the dorsal horn (in Rexed's laminae V - VI), where Ia collaterals first form the major branches that eventually reach the ventral horn. If failure of action potential invasion occurs at branch points in Ia collateral arborizations, this process could contribute to amplitude fluctuations seen in single-fiber Ia EPSPs. The available material confirms the hypothesis that Ia contacts are dispersed over the entire receptive surface of α MNs, although many contact systems do not appear to be confined to limited electrotonic loci as has been inferred from electrophysiological evidence.

243.8 SPATIAL DISTRIBUTION OF TRICEPS SURAE SYNERGISTIC MOTOR NUCLEI IN THE LUMBAR SPINAL CORD OF SQUIRREL MONKEY (SAIMIRI). William D. Letbetter, J. Tigges, M. Tigges, N. A. Cross*, and R. L. McBride. Department of Anatomy and Yerkes Regional Primate Research Center, Emory University, Atlanta, GA 30322.

Retrograde labeling with horseradish peroxidase (HRP) was used to identify all the motoneurons belonging to members of the triceps surae muscle complex in squirrel monkeys. The nerves to medial gastrocnemius (MG), lateral gastrocnemius (LG), and soleus (S) muscles of the ipsi- and contralateral hindlimbs in each anesthetized (Nembutal) preparation were soaked either singly or in various combinations in a 10% HRP-1.6 mg% hyaluronidase solution for 3 to 4 hours. After a 3-day survival period, the spinal cord segments L5 to S1 were serially sectioned into either 10- or 20-μ sections so that a detailed analysis of the spatial organization of the labeled motor nuclei could be made from 3-dimensional serial reconstructions.

It was established that bilateral symmetry obtains in these motor nuclei for both the number of cells labeled and their spatial distribution. The positions of MG, LG, and S motor nuclei, both relative to each other and relative to the whole triceps surae distribution, were determined to be constant from animal to animal, even though the rostro-caudal position of any one of these nuclei was seen to vary as much as one whole segment (4-5 mm) as determined by dorsal root entry zone borders. Thus, the 8.5 mm-long column of triceps cells always can be found someplace within the 13.5 mm length of spinal cord between the caudal end of S1 segment and the caudal 2 mm of L5 segment. Within the triceps column (which dorso-ventrally and medio-laterally is positioned similarly to its homologue in other species), cells of the MG and S motor nuclei are distributed coextensively in the caudalmost 5 mm of the rostro-caudal dimension. However, the S cells clearly are collected in a ventral tier of their own. The LG cells occupy the rostralmost 6 mm of the triceps column. Of the approximately 650 cells in the triceps column, 200 belong to the MG nucleus, 225 to the LG nucleus, and 225 to the S nucleus. Cell sizes ranged from approximately 20μ to 45μ ("equivalent diameters" calculated from maximum cross-sectional areas), although the major diameter value of some of the cells was as large as 70μ. The distribution of cell sizes appears to be less clearly bimodal than has been demonstrated in other species.

The clearly different distribution of the S motor nucleus in this species as compared to cat may provide a substrate for which experiments can be designed specifically to study principles governing the distribution of monosynaptic spindle afferent input to homonymous motor nuclei.

243.9 VENTRAL ROOT RECORDINGS FOLLOWING MAUTHNER CELL ACTIVATION IN AMPHIBIANS. D. Les Brown and John T. Hackett. Dept. of Physiology, Univ. of Virginia Sch. of Medicine, Charlottesville, VA 22908

The Mauthner cell (MC), its activation and the resultant rapid tail flip are well studied. Less is known about MC-motoneuron interaction. We have examined the spinal component of the rapid tail flip in *Rana catesbeiana* tadpoles *in situ*, cooled to 10° C. Animals used were characterized by hindlimb development ranging from limb bud to functional leg with degenerating tail.

Cranial nerve VIII, in particular the saccular nerve, was stimulated electrically; electrode placement was critical for producing the tail flip. Ventral root (VR) records were obtained from VR III through XIII using suction electrodes. VR records elicited by ipsilateral saccular nerve stimulation showed a small, long latency (5-10 ms) activity which correlated in time with the later phase of the contralateral VR record. The early phase of the contralateral VR record had a definite threshold, shown by its appearance with an increase in stimulus amplitude of 0.4%. The waveform was compound, showing quantal variations in its peaks in response to repeated stimulation. The latency was variable, depending on stimulus amplitude and the VR used; the shortest latency recorded was 3.5 ms. Estimation of MC conduction velocity based on simultaneous records from a pair of contralateral VR is 18 m/s, suggesting the greater part of the delay between stimulation and VR activity occurs prior to MC activation. A similar compound wave was recorded with the suction electrode attached to the ventral surface of the spinal cord distal to VR XIII. The evoked activity was distinctly different from spontaneous activity or the patterned activity associated with swimming. In addition, no muscle contraction was seen in tadpoles with intact limbs nor could electrical responses be recorded in the limb nerves. Similar experiments on an adult bullfrog showed only long latency (20 ms) activity in ipsilateral VR records.

In conclusion, we have shown all-or-none responses evoked in the contralateral spinal cord by saccular nerve stimulation. This is explained by activation of the MC. The earliest response could arise from the MC axon or from a population of cells coupled to the MC. Quantal variation in form of the response is explained by a small pool of spinal neurons which may not always reach threshold for firing. Inability to detect activity in peripheral muscles or nerves implies specificity of MC-motoneuron connectivity. These results will enable us to study MC-motoneuron interactions during metamorphosis.

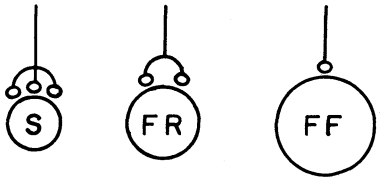
243.10 SINGLE FIBER EPSP AMPLITUDE, CELL SIZE AND MOTOR UNIT TYPE. J.W. Fleshman, G.W. Sypert and J.B. Munson. Depts. of Neuroscience and Neurosurgery, U. of Fla. Coll. of Med. and VA Med. Ctr., Gainesville, FL 32610.

EPSPs elicited in cat medial gastrocnemius (MG) motoneurons by single MG group Ia afferents were recorded using the spike-triggered averaging technique. Input resistance was determined from bridge unbalance during small current pulses. Motoneurons were then classified into motor unit types based on muscle unit responses, using a modification of the criteria of Burke et al. (J. Physiol. 234, 1973): fast twitch, fatigue-sensitive (FF), fast twitch, fatigue-resistant (FR) and slow twitch, fatigue-resistant (S). As shown in the table, single fiber EPSP amplitude decreased in the order S>FR>FF. All paired comparisons were significant ($p<.01$). When FR and S units were combined, it was found that more fatigue-resistant units (FR+S) received group Ia connections than did fatigue-sensitive units (FF) (96% vs. 87%, $p<.03$).

	FF	FR	S
EPSP amplitude (μv)	71	118	179
Input resistance (MΩ)	0.7	1.0	1.5
Conduction velocity (m/s)	101	102	86

All three unit types were found to have different input resistances (R_N), even though the conduction velocity of FF and FR units were nearly identical. To see whether R_N could account for the EPSP amplitude differences, an analysis of covariance was performed using unit type as the variate and R_N as the covariate. After adjusting for the effect of R_N, there was still a strong effect of unit type on EPSP amplitude ($F=9.20$, $p<.0001$). From these results, we propose that the density of group Ia synaptic current increases in the order FF<FR<S, and that this increase is not explained by cell size. (See also Burke and Edgerton, Exer. Sport Sci. Rev. 3, 1975).



This work was supported by the RERDS and MRS of the Veterans Administration and by grant 1 RO1 NS 15913-01.

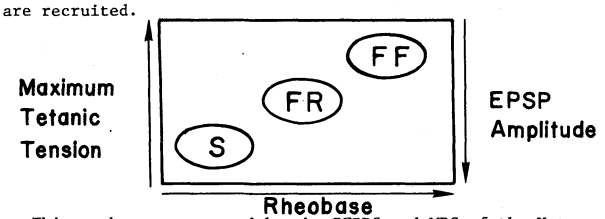
243.11 EXCITABILITY OF TYPE-IDENTIFIED MOTONEURONS. J.B. Munson, G.W. Sypert and J.W. Fleshman. Depts. of Neuroscience and Neurosurgery U. of Fla. Coll. of Med. and VA Med. Ctr., Gainesville, FL 32610.

Cat medial gastrocnemius motoneurons were impaled with micropipette electrodes. Input resistance (R_N) was determined from the bridge unbalance produced by small current pulses. Rheobase (I_{Rh}) was defined as the least current (50 ms pulse) capable of producing an action potential. EPSPs were generated by supramaximal group I stimulation of the lateral gastrocnemius-soleus (LGS) nerve. Motoneurons were identified as type S, FR, FI or FF based on the motor unit's mechanical response to intracellular stimulation, using a modification of the criteria of Burke et al. (J. Physiol. 234, 1973). Maximum tetanic tension (MTT) was determined for each motor unit.

	FF	FI	FR	S
R_N (mΩ)	0.6	0.8	0.9	1.7
I_{Rh} (na)	19.7	17.5	12.8	5.1
LGS EPSP (mv)	1.1	1.5	1.9	2.4
MTT (gm)	77	29	17	7

A very clear relation emerged between rheobase current and motor unit type. I_{Rh} was also highly correlated with R_N ($r=-.70$, $p < .0001$). However an analysis of covariance using R_N as the covariate indicated a strong relation between motor unit type and I_{Rh} (adjusted $F=10.62$, $p < .0001$), regardless of R_N.

I_{Rh} was also highly correlated with LGS EPSP amplitude ($r=-.58$, $p < .007$) and with MTT ($r=.60$, $p < .0001$). These data imply a coherent picture of motor unit recruitment by activation of group Ia synapses. Cells with the lowest rheobase thresholds (most excitable) receive the greatest group I excitation and generate the smallest tetanic tensions. Across the motor unit population, as synaptic drive is increased, motor units with higher rheobase thresholds and greater tetanic tensions are recruited.



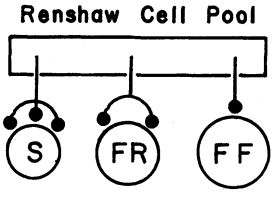
This work was supported by the RERDS and MRS of the Veterans Administration and by grant 1 RO1 N5 15913-01.

243.12 RECURRENT INHIBITION OF TYPE-IDENTIFIED MOTONEURONS. W.A. Friedman*, G.W. Sypert, J.B. Munson, J.W. Fleshman, Depts. of Neurosurgery and Neuroscience, U. of Fla. Coll. of Med. and VA Med. Ctr., Gainesville, FL 32610.

Cat medial gastrocnemius motoneurons were impaled with microelectrodes filled with 3M potassium acetate. Input resistance (R_N) was determined from the bridge unbalance produced by small current pulses. Recurrent IPSPs were generated antidromically, by stimulation of the lateral gastrocnemius-soleus (LGS) nerve, after dorsal rhizotomy of L_6, L_7, and S_1. Motoneurons were identified as type S, FR, FI or FF based on the motor unit's mechanical response to intracellular current injection, using a modification of the criteria of Burke et al. (J. Physiol. 234, 1973). As shown in the table, preliminary data indicate that both recurrent IPSP amplitude and input resistance decreased in the order S > (FR or FI) > FF.

	FF	FI	FR	S
IPSP Amplitude (μv)	101	388	389	1236
Input Resistance (MΩ)	.65	.89	.78	1.34

There was a 12-fold difference in IPSP amplitude between FF and S units, whereas the difference in R_N was approximately 2-fold. An analysis of covariance, with unit type as the variate and R_N as the covariate, was performed. After adjusting for the effect of R_N, there was still a strong effect of unit type on recurrent IPSP amplitude ($F=25.9$, $p < .0001$). These results indicate that the density of recurrent inhibitory synapses increases in the order FF < (FR or FI) < S. This conclusion is in agreement with earlier physiological studies indicating more powerful recurrent inhibition on tonic, as opposed to phasic alpha motoneurons (Kuno, J. Physiol. 149, 1959).



This work was supported by the RERDS and MRS of the Veterans Administration and by grants 1 RO1 NS 15913-01 and 1 F32 NS 06279-01.

243.13 INTERLIMB COORDINATION DURING IN-PHASE STEPPING IN THE CAT, AND TRANSITIONS BETWEEN ALTERNATE AND IN-PHASE. A. W. English* (SPON: R. Fricke) Dept. Anatomy, Emory Univ., Atlanta, GA 30322.

The coordination of step cycles of all four limbs during in-phase stepping and during transitions between alternate and in-phase was studied in 12 adult cats, during repeated overground stepping trials. The temporal spacing of step cycles of the different limbs was determined from analysis of electromyographic activity of single-joint extensor muscles of each limb. Patterns of coordination of the different limbs were established on the basis of the frequency with which the phase separating step cycles was encountered. For the analysis of in-phase stepping, only steps in which the phasing of hindlimb step cycles was closer to true in-phase coupling (0^0) than to alternation (180^0), and where similar phase relationships were present in both the preceeding and succeeding steps were analyzed. Distinct patterns of coordination of step cycles of the two forelimbs and of the forelimbs and hindlimbs were noted under these steady-state phase conditions. Forelimb step cycles were coordinated ca. 90^0 out of phase. Step cycles of the ipsilateral forelimb and hindlimb are coordinated about trotting (180^0), diagonal couplet ($\pm 120^0$) or lateral couplet ($\pm 60^0$) forms of coordination. Transitions between alternate and in-phase stepping were studied by analysis of the phase relationships of step cycles of the different limbs during consecutive steps in which a transition between the two main forms of hindlimb-hindlimb coordination occurred. Phasing of the step cycles of the two hindlimbs, the two forelimbs and of the ipsilateral forelimb and hindlimb all were observed to undergo a shift from one pattern to another during such transitions. Abrupt changes between alternate and in-phase patterns were encountered considerably less frequently. It is concluded that the step cycles of the four limbs are coordinated during in-phase stepping in the cat according to a few basic patterns. Phase angles are clearly grouped about a few preferred patterns. However, the variability about these patterns makes their association with any simple neural circuitry rather speculative. The graded transition between alternate and in-phase stepping is consistent with the notion that such transitions are dependent upon the particular phase relationships of the different limbs at the onset and termination of the transition and that they are not merely abrupt shifts from one motor program to another.

Supported by grant # 1R01 NS15452-01 from the USPHS.

243.14 RELATION BETWEEN SHAPES OF POST-SYNAPTIC POTENTIALS AND CROSS-CORRELOGRAM PEAKS IN CAT MOTONEURONS E.E. Fetz and B.G. Gustafsson*. Dept of Physiol, Univ of Göteborg, Göteborg, Sweden

The effect of postsynaptic potentials on the firing probability of active motoneurons was investigated to determine the relation between the time course of the PSP's and the shape of the resulting cross-correlogram peaks. Several possible relations between EPSP and correlogram shapes have been proposed on theoretical grounds: that the correlogram peak resembles the EPSP itself[1], or its temporal derivitive[2], or some combination of the two[3]. To investigate this relation empirically, we evoked EPSP's and IPSP's in cat lumbar motoneurons by electrical stimulation of peripheral nerve filaments—first leaving the motoneuron quiescent, to document the average PSP shape, and then making the motoneuron fire repetitively with intracellular current injection, to document the post-stimulus time histogram (PSTH) of motoneuron action potentials (i.e., the cross-correlogram between stimulus and spike trains). As illustrated below, EPSP's produced briefer correlogram peaks, typically occurring near the summit of the EPSP. On the average, the PSTH peak began about .53 ms. after onset of the EPSP (n=44). The EPSP's studied ranged in amplitude from .15 - 5 mV. (mean ± S.D. = 0.93 ± 0.74 mV.); the larger EPSP's produced larger and narrower correlogram peaks. The temporal derivative of each EPSP was calculated and its positive component (corresponding to the EPSP rise) was compared with the correlogram peak. In most cases the correlogram peaks resembled the EPSP derivatives, but were displaced by a mean temporal delay of .65 ± .26 ms. The half-widths of the correlogram peaks (.53 ± .37 ms) correlated positively with the half-widths of the EPSP derivatives (.60 ±.25 ms). Following the correlogram peak was a compensatory trough, representing the spikes whose occurrence had been advanced by the EPSP; this trough coincided with the decay (i.e., negative slope) of the EPSP. IPSP's also produced correlogram features which qualitatively resembled their temporal derivatives: a drop in firing probability with the rise and peak of the IPSP, followed by a compensatory increase during their decay. Preliminary results with unitary EPSP's, using spike-triggered averaging from single muscle afferents, suggest a similar relation, although appreciable synaptic noise may broaden the correlogram peaks.

243.15 INTERACTIONS BETWEEN A CENTRAL MOTOR PROGRAM AND SENSORY INPUT IN BULLFROG TADPOLES. Donald J. Stehouwer* and Paul B. Farel (SPON: R.A. King) Dept. Physiol., Sch. Med., Univ. N. Carolina, Chapel Hill, NC 27514.

Spinal motoneurons of the in vitro nervous system of bullfrog larvae exhibit spontaneous episodes of patterned burst discharges which have been shown to underlie swimming. Although the CNS produces the pattern autonomously, the rostrocaudal delay in motoneuronal activation occurring in the normal animal appears to arise from an interaction between the CNS and peripheral influences arriving via the dorsal roots (Stehouwer and Farel, Brain Res., in press).

The present study demonstrates that there are phasic inputs related to tail movements, that dorsal root volleys initiate and modify episodes of patterned burst activity, and that the central motor program regulates transmission from primary afferent terminals.

In the first experiments, the central nervous system was completely removed, leaving long distal stumps of the spinal roots projecting into the vacant vertebral canal. Records were obtained from the dorsal stumps while the tail was manipulated. Rapid oscillation of the tadpole's tail with a pair of forceps or jets of water resulted in bilateral bursts of afferent activity with each movement of the tail. Slowly moving the tail to a fixed, bent position produced afferent activity which ceased when tail movement stopped, regardless of its position. If the tail was held stationary, water jets produced only slight afferent activity. Skinning the preparation did not prevent the response to tail movement. These experiments suggest that proprioceptors in the tadpole tail respond to movement but not static position and that many but perhaps not all of the proprioceptors are found in the muscle rather than in the skin.

The next experiments were conducted in vitro using the isolated nervous system of the larva. Stimulation of the dorsal roots during spontaneous episodes of bursting was found to alter the rate of bursting, usually increasing its frequency. A stimulus presented during one of the silent periods between burst episodes often elicited a burst episode indistinguishable from spontaneous episodes. In no case was a rostrocaudal lag produced. Dorsal root terminals became depolarized at the onset of a burst episode and showed subsequent peaks of depolarization with each ventral root burst. These dorsal root potentials suggest a presynaptic regulation of transmission of movement-induced sensory activity. Supported by NSF grant BNS 24528, NIH grant NS 14899 and NIMH postdoctoral fellowship MH 07409 (DJS).

243.16 NEURONAL RESPONSES TO PASSIVE LIMB DISPLACEMENT IN THE PRECENTRAL MOTOR CORTEX (MI) AND AREA 3a OF UNANESTHETIZED MACAQUES. S. P. Wise and J. Tanji. Lab. of Neurophysiol., NIMH, Bethesda, MD 20205.

Responses to passive foot displacements were examined in 250 single units in the MI and area 3a hindlimb representations of cynomolgus monkeys conditioned to tolerate imposed dorsiflexion and plantarflexion of 20 degrees. A servo-controlled torque motor displaced a pedal attached to the monkey's foot. "Trapezoidal" foot displacements in both directions, at four ramp velocities, and to five amplitudes of maintained displacement demonstrated the direction, velocity, and position sensitivity of cortical neurons. The study employed standard transdural recording techniques with platinum-iridium electrodes. EMG activity monitored during the displacements demonstrated that position related unit activity did not depend upon changes in the tonic activity levels of hindlimb muscles. The units were also tested for responses to tactile stimuli. Those units responsive to such stimuli were termed cutaneous; those unresponsive non-cutaneous.

MI and area 3a responses fell into two categories. One group of units responded both to ramps and maintained displacements and thus resembled the muscle spindle afferent response to muscle stretch. The other group responded only to the ramp phase of passive foot movements. Most (79%) non-cutaneous units, which were concentrated in both area 3a and the rostral part of MI (MI/r), were excited either in relation to passive dorsi- or plantarflexion of the foot, but not both and therefore displayed a direction sensitivity. Cutaneous units, which were concentrated in the caudal 3-4 mm of MI and in areas 3b and 1, rarely (<10%) showed such direction sensitivity. Area 3a unit activity showed greater sensitivity to a given velocity of foot displacement than that of MI/r units and correlated better with foot velocity, as judged by the mean peak firing frequency in response to the ramps. Conversely, MI/r units showed greater sensitivity to foot position than area 3a units. The data support the hypothesis that input corresponding to velocity and position of a limb segment plays a role in cortically mediated regulation of movement and posture and that both area 3a and MI may be involved in this regulation.

The part of the hindlimb sensorimotor cortex which we consider, on electrophysiological grounds, to be area 3a is a region containing a thin internal granular layer (layer IV) which can be distinguished from the caudally adjacent koniocortex (area 3b) and the rostrally adjacent agranular neocortex (area 4).

243.17 RED NUCLEUS NEURON (RNN) DISCHARGE WITH MOVEMENT TERMINATION. Y. Shinoda*, C. Fromm*, E. V. Evarts and J. Kröller* (SPON: J. C. Eberhart). Lab. of Neurophysiology, NIMH, Bethesda, MD 20205.

RNN discharge was recorded in a monkey rewarded for maintaining a handle in one of three positions (15° pronation, neutral, 15° supination) on the basis of a visual display. A shift of the visual display triggered active 15° pronation or supination movements between these three positions. A torque motor coupled to the handle allowed variation of steady state load in each position and provided a means of delivering supinating or pronating ramp displacements to test afferent responsiveness of RNNs.

160 of 229 RNNs recorded from the magnocellular and posterior parvocellular RN showed relations with some aspect of the task, and 34 of these 160 were highly related, i.e., their frequency changed even with the very small corrective supinations or pronations (1.5° or less in amplitude) performed in this paradigm during steady holding in a given position. For most RNNs, changes in frequency failed to precede EMG changes of arm muscles discharging in advance of large, high velocity movements, with RNN discharge starting at movement onset or during movement. The typical time course of RNN discharge (observed for 24 of the 34 highly related units) during the 15° movements was a gradual build-up of activity with peaking near termination. In contrast to this terminal peaking of RNN discharge, the activity of the muscles usually peaked around movement onset, and early peaking was also seen for both precentral and postcentral pyramidal tract neurons (PTNs). Unlike the majority of sensorimotor cortex PTNs, RNN discharge did not vary with different levels of muscle activity in the steady state due to different steady state loads or different steady state holding positions. Another difference between RNNs and PTNs was the relatively low incidence of short-latency afferent responses to passive ramp displacements in RNNs, especially RNNs related to small active movements. Only 8 of the 34 units related to small movements had response latencies less than 50 msec, whereas 20/34 of these units had long-latency responses (>100 ms) to the passive ramp displacements.

Many RNNs failing to discharge prior to large, high velocity movements nevertheless discharged prior to small corrective movements where the starting point of the movement was already close to the terminal point. In view of the findings of previous investigators concerning the action of RN on dynamic gamma motoneurons, it seems possible that accurate termination of a movement involves an increased bias upon the dynamic gamma motoneurons, while the initial acceleration is accompanied by a relative decrease of the dependence on the velocity parameter in the agonist myotatic loop. RNN discharge patterns fit nicely with this putative role in differential regulation of reflex excitability with different phases of movement.

243,18 A "STATE PREDICTOR" MODEL TO DESCRIBE MOTOR CONTROL. Lloyd D. Partridge and Laurel A. Benton*. Univ. Tennessee, Memphis, TN 38163 & Rancho los Amigos Hosp., Downey, CA 90242.

Increasing difficulty is experienced as one attempts to incorporate a feedback model into progressively more complete representations of motor control. Most successful motor actions involve multi-muscle coordination with details which must vary with both starting and ambient conditions within and outside of the muscles. Whether we describe the effector units as pure muscles or as systems with muscle properties modified by "reflex feedback", their coordinated control was found long ago to be adjusted by both response dependent and non-response dependent sensory signals. Presumably, drives to the peripheral systems originate by action of nervous system rules on information distributed centrally following sensory input plus any new central signals. In effect, sensory signals are a continuous but imperfect report on recent states of a vaguely bounded system overlapping the individual and environment. Likewise, new central signals become a command. The rules are described as subject to modification on criteria including their success in driving desired state trajectories. From this viewpoint, to relegate proprioception to a feedback role produces a more complex description than a predictor which uses all sensory signals to directly drive motor units, a form that also easily deals with variation of the dimensions controlled. We propose that both research and current teaching will be better served by use of diagrams of a state predictor model than by continued use and development of the more complex forms needed to describe the same data, based on models of motor control which represent the peripheral elements as separable feedback systems.

244.1 EXPERIMENTAL TREATMENT OF SCHIZOPHRENIA BY HEMODIALYSIS. L.W. Brown*, H. Wagemaker, Jr.*, and R.S. Levy. Laboratory Biological Psychiatry and Depts. of Biochemistry and Psychiatry, Univ. of Louisville School of Medicine, Louisville, KY 40292.

Fifteen chronically-ill schizophrenic patients were hemodialyzed for 5 hours twice a week for 8 weeks (16 sessions). Ten patients became relatively symptom-free; two showed moderate improvement; three were not affected. We examined the dialysates to determine if removal of specific compounds could be linked to remission of symptoms in these patients. For controls we used dialysates from renal patients who were not schizophrenic. We measured creatinine, dopamine, epinephrine, norepinephrine, uric acid, and β-endorphin levels in the dialysates. There were no significant differences in the quantitative removal of these compounds by hemodialysis when schizophrenic patients and controls were compared.

We found a characteristic absorbancy peak with an early retention time when high pressure liquid chromatography was used to analyze the dialysates from some patients. Applying a dialysate sample of 10 µl with a flow rate of 2 ml per minute, the material appeared just after a met-enkephalin reference standard when eluted with an acetonitrile-phosphate solution from a C_{18} reverse phase column using a Varian high pressure liquid chromatography with the UV detector set at 210 nm. This material increased in amount in dialysates from schizophrenics as opposed to those from non-schizophrenics. The characterization of this material will be reported.

244.2 METRIZAMIDE COMPETITIVELY INHIBITS HEXOKINASE. J. M. Bertoni* and G. M. Alexander* (SPON: J. Yu). Lab. of Neurology, The University of Texas Health Science Center, San Antonio, Texas 78284.

Although it is regarded as a safe radiological contrast agent for use in the human cerebrospinal fluid, metrizamide has been increasingly associated with a variety of adverse reactions of unknown mechanism. Because it is a 2-deoxyglucose (2DG) analog, we compared the effects of metrizamide on hexokinase (HK) activity to those of 2DG and 2-amino-2-deoxyglucose (glucosamine). The initial rates of HK were determined at 30° in a reaction coupled with glucose 6 phosphate dehydrogenase (G6PDH) using (final concentration) 0.05 M Tris buffer (pH 7.6), 0.54 mM ATP, 0.58 mM nicotinamide adenine dinucleotide phosphate (NADP), 7.3 mM $MgCl_2$, and from 0 to 0.16 mM glucose. NADPH formation was then followed spectrophotometrically at 340 nm:

$$\text{GLUCOSE} + \text{ATP} \xrightarrow{\text{HK}} \text{G6P} + \text{ADP}$$

$$\text{G6P} + \text{NADP}^+ \xrightarrow{\text{G6PDH}} \text{6-PHOSPHOGLUCONATE} + \text{NADPH} + \text{H}^+$$

HK is rate limiting in this system.

The Km for glucose of HK is 0.12 mM. At 0.4, 1.0, and 2.0 mM inhibitor concentrations, the Km changes to 0.24, 0.33 and 0.78 mM for metrizamide; 0.17, 0.36 and 0.06 mM for 2DG; and 0.14, 0.23 and 0.49 for glucosamine. The Ki for each inhibitor is between 1 and 2 mM. These agents do not affect the Vmax of HK to a significant degree. 2.0 mM mannitol and metrizoic acid have no effect on either the Km for glucose or Vmax of HK. 2.0 mM metrizamide, 2DG and glucosamine have no effect on the Vmax or Km for glucose of G6PDH. 2DG is an effective substrate in this system, although the maximal rate of NADPH formation with 2DG is less than that with glucose. We conclude that metrizamide is a competitive inhibitor of HK by virtue of its similarity to 2DG, and that its presence in cerebrospinal fluid may be detrimental to glucose metabolism. Furthermore, the possibility that 2DG6P is metabolized through the pentose phosphate shunt has implications regarding the fate of 2DG used in quantifying metabolic rates. These studies utilizing microbial enzymes should be confirmed using enzymes purified from mammalian brain.

244.3 SELECTIVE ACTIVATION OF PIGEON nBOR WITH VERTICAL WHOLE-FIELD MOVEMENT AS REVEALED BY ^{14}C-2DG AUTORADIOGRAPHY. B.J. Frost, P. Ramm*, and B. Morgan*. Dept. of Psychology, Queen's University, Kingston, Ontario, Canada, K7L 3N6.

Anatomical evidence shows that the nucleus of the basal optic root (nBOR) in pigeons receives input directly from displaced ganglion cells and projects to the oculomotor complex and vestibulocerebellum (Brecha and Karten, 1979, Brecha, Karten, and Hunt, in press). Recent physiological investigations have shown that cells in this nucleus in pigeons (Morgan and Frost, 1979) and chickens (Burns and Wallman, 1979) and in the medial terminal nucleus in rabbits (Simpson, Soodak and Hess, 1979) have very large receptive fields and in general prefer large textured patterns moved slowly in upward directions.

In this experiment lightly anesthetized pigeons viewed a multifaceted tangent screen that allowed their right monocular visual field to be completely filled with a random noise pattern. The left eye was occluded. After injection of 25 µci of ^{14}2-2DG the pattern was moved at 2° sec^{-1} in either an upward or downward direction. Autoradiographs of coronal sections in the region of nBOR reveal marked increases in density in the contralteral nBOR for birds receiving upward movement. Downward movement produced only slight increases in density. The increased density produced by upward movement was not found throughout the entire nBOR but was confined to a medial and ventral band. The slight increases in density produced by downward movement were somewhat more diffuse with a tendency to be more laterally located. These results complement and confirm electrophysiological findings which suggest nBOR processes vertical pursuit slip required for optokinetic stabilization.

244.4 RABBIT NICTITATING MEMBRANE CONDITIONING STUDIED WITH ^{14}C 2-DEOXYGLUCOSE. L. Sargent Jones and J.F. Disterhoft. Department of Anatomy, Northwestern Univ. Med. Sch., Chicago, IL., 60611.

The ^{14}C 2-DG method can be used to study the rabbit auditory pathway (Jones and Disterhoft, Neurosci. Abst., 5, 1979, 23). The present study examined brain regions in rabbit thought to be involved in tone signalled nictitating membrane (NM) conditioning with this technique.

The 5 groups were conditioned, pseudoconditioned, tone alone, shock alone, unstimulated control. Four conditioned Ss received 2 days of a training paradigm which paired a 400 msec, 2 KHz, 80 dB tone with a 7 V shock delivered at the 250th msec of the tone. The shock pulse produced the NM reflex and a blink attempt but did not elicit any other overt behavioral response. One trial was given per min at ITIs between 20 and 100 sec; 100 trials were presented per session. The Ss showed conditioned responses about the 130th trial and were overtrained by 200 trials. On day 3 Ss were primed with 20 trials and then injected i.v. with the 2-DG. After 45 trials the Ss were decapitated and the brains processed. Four pseudoconditioned Ss received unpaired random tones and shocks; 3 tone alone and 4 shock alone Ss received just tones or shocks; 3 controls neither.

X-rays from all 18 rabbits were similar on inspection. Structures from all Ss were analyzed by scanning densitometry to see if density differences existed. No statistically significant differences were present between brain regions. The right inferior colliculus (IC), the left dorsal cochlear nucleus and the left medial nucleus of the trapezoid body had the highest density; the VIIth nucleus was lower; and the VIth, IIIrd, the primary sensory portion of the Vth nucleus on the left and the right dentate gyrus of the hippocampus had the lowest density. Failure to show differences led to the densitometric analysis of data reported previously (Jones and Disterhoft, '79). These rabbits had received a 50 msec tone once per sec for 45 min. Data from the right IC of this group was significantly different from that of the present work. Once per sec Ss showed an average increase of 50% in right IC density over any group in the learning study.

The lack of a measurable change in the overall pattern of 2-DG uptake after NM conditioning appears to be due to the fact that one trial per min in this paradigm is not sufficiently perturbing to induce significant changes above the normal metabolic levels as measured by scanning microdensitometry.

244.5 DIRECT APPLICATION OF DOPAMINE TO RAT STRIATUM DECREASES GLUCOSE UTILIZATION IN THE STRIATUM AND RELATED STRUCTURES. Lucy L. Brown and Leslie I. Wolfson*. Dept. of Neurology, Albert Einstein College of Medicine, Bronx, New York 10461.

Tracer amounts of ^{14}C deoxyglucose (DG) were used to quantify glucose utilization (GU) in rats by the autoradiographic method of Sokoloff et al. (1977). Ten days after placement of intrastriatal cannulae, 21 rats were tested for behavioral effects of intrastriatal dopamine (DA) (50 ug DA HCl in 0.5 ul of a 0.1% solution of ascorbic acid in Ringer's; pretreatment: 50 mg/kg pargyline, 30 min before DA). All rats showed a contralateral body twist or active contralateral turning after DA injection. At least two days later, the rats were partially restrained and given an IV bolus (0.5 cc) of DG (50 uCi) at variable intervals (10 to 80 min) after an intrastriatal injection of DA (N = 16) or of the vehicle solution alone (N = 5). Forty-five min after DG injection, rats were decapitated and brains were prepared for autoradiographic study. The results showed that, with only one exception, DA caused a decrease in striatal GU which varied in area and in magnitude among animals, probably because (a) the amount of DA effectively delivered varied, and (b) some cannulae were placed at the very edge of the striatum. Four of five animals injected with DG 45 to 80 min after intrastriatal DA showed less dramatic decreases than did eleven others injected within 10 to 25 min. This effect of DA over time on GU may be significant because we also observed that the latency to turn or orient contralaterally was twenty minutes or more. A consistent decrease in GU was also seen in the ventrobasal thalamic area. A more variable change in GU was found in substantia nigra: animals with large striatal GU decreases also had a decrease in substantia nigra; animals with small striatal GU decreases had an increase in substantia nigra. None of the patterns of GU described above differentiated the active turners (N = 3) from those who maintained a contralateral body twist (N = 13). Thus, intrastriatal injections of DA which produce postural asymmetries also cause (a) a decrease in striatal GU, and (b) a consistently large GU decrease in ventrobasal thalamus. The variable effects seen in substantia nigra may not be important for the behavioral consequences of intrastriatal DA. Supported by NIH Grant NS09649.

244.6 THE METABOLIC RESPONSE TO INCREASING AMOUNTS OF EXPOSURE TO A VISUAL STIMULUS. A.W. Toga, and R.C. Collins, Dept. of Neurology, Wash. Univ. Sch. of Med., St. Louis, MO 63110

The functional organization of the rat visual system has been previously studied using ^{14}C-2-deoxyglucose autoradiography (2DG). Changes in glucose utilization reflect the intensity, the frequency of presentations and the pattern of the visual stimuli. However, little is known about the metabolic response to prolonged exposure to a stimulus.

One day prior to stimulus presentation hooded rats had one eye enucleated and femoral arterial and venous catheters inserted to allow free movement. Animals were fasted for 12 hours in the stimulus chamber. Full field photo flash was presented at 16.5/s. To study the effect of stimulus experience animals were assigned to one of 3 groups (N=3); novel, 5 hrs or 10 hrs of continuous flashing. In the novel group, animals received 60 uCi/kg of 14C-2DG at the same time the stimulus was initiated. The remaining animals received the 2DG following the assigned number of hours of experience with the stimulus continuing for the duration of the experiment. All subjects received homatropine prior to 2DG administration. Timed blood samples were drawn to determine plasma glucose and specific activity levels. Animals were sacrificed, perfuse-fixed, frozen, and brains cut for autoradiography.

Visual structures innervated by the stimulated eye compared to enucleated showed an increase glucose utilization regardless of the amount of experience. In all experimental groups, the greatest metabolic response was seen in the stimulated dorsal superior colliculus and dorsal lateral geniculate. Glucose utilization for these two structures in animals of the novel group was 1.56 ± .35 (mean ± S.D.) versus .53 ± .10 (enucleated) and 1.03 ± .38 versus .57 ± .20 μmoles/g/min. The metabolic response of the visual system was slightly depressed in animals exposed for 5 hrs compared to the novel group. Animals exposed for 10 hrs showed a bilateral increase in glucose utilization throughout brain. The ratio of stimulated/enucleated visual structures was also greatest in the 10 hr group. In addition, assymmetrical changes were noted in globus pallidus, entopeduncularis and lateral habenular nucleus.

This time-response curve indicates that glucose utilization in the visual system becomes depressed following experience with photic flash (5 hrs) but that with prolonged exposure (10 hrs) the metabolic requirements become greater.

244.7 EFFECTS OF LITHIUM TREATMENT ON MYO-INOSITOL-1-PHOSPHATE LEVELS IN SYNAPTOSOMES OF RAT CEREBRAL CORTEX. R.W. Wise*, A.L. Leavitt* and W.R. Sherman* (SPON: B.K. Hartman). Department of Psychiatry, Washington University School of Medicine, St. Louis, MO 63110.

Lithium chloride, when administered to rats, has been shown to decrease the levels of myo-inositol (Allison, J.H. and Stewart, M.A., Nature, 233:267, 1971) and to increase the levels of myo-inositol-1-phosphate (MIP) (Allison, J.H. et al, Biochem. Biophys. Res. Commun. 71:664, 1976) in cerebral cortex of the rat. Both of these effects have been shown to be blocked by atropine. We have undertaken a study to determine whether the increased levels of MIP could be localized in subcellular fractions of the cerebral cortex.

In one experiment rats weighing about 350g were given 10 meq/kg LiCl intraperitoneally 18 hours before decapitation and removal of the cerebral cortex. Cortex was homogenized in 0.32 M sucrose and subcellular fractions prepared by Ficoll density gradient centrifugation. Results show an 8.3-fold increase in MIP levels in the synaptosome fraction from lithium treated animals with respect to controls.

The effect of lithium on synaptosome preparations in vitro will be discussed.

enriched fractions	mmoles MIP/kg protein	
	lithium	control
microsomes	1.56	<0.1
myelin	<0.1	<0.1
synaptosomes	4.00	0.48
mitochondria	1.37	1.58
low speed pellet	0.96	0.32

244.8 SPECTROPHOTOMETRIC MONITORING OF CEREBRAL CYTOCHROME c OXIDASE REDOX STATES AND HEMOGLOBIN SATURATION DURING HYPOTENSIVE SHOCK. A.L. Sylvia, H.J. Proctor* and F.F. Jöbsis*. Dept. of Physiology Duke University Medical Center, Durham, NC 27710 and Dept. of Surgery, U.N.C. School of Medicine, Chapel Hill, NC 27514

It has been recognized that severe blood loss results in hypotension and tissue hypoperfusion, and when not corrected early results in irreversible cellular brain damage. In many instances, despite correction of hypoxia and hypotension, fatal cerebral dysfunction still occurs.

In the present study, quadruple beam spectrophotometry was used to continuously and simultaneously monitor changes in the reduction/oxidation (redox) level of cytochrome c oxidase (Cyt. a,a_3) and hemoglobin saturation states (HbO_2) in rat brain during the course of hypotensive shock. By taking advantage of known absorption spectra for reduced Cyt. a,a_3 (605 nm) and oxygenated hemoglobin (577 nm), it is possible to noninvasively and nondestructively measure such parameters in the central nervous system.

Animals were anesthetized, tracheotomized, and femoral arteries and veins were cannulated. The rats were ventilated using 30% O_2/70% N_2. After baseline stabilization and established normal blood gases (PaO_2 100+ mm Hg; $PaCO_2$ 35-40 mm Hg) were obtained, the animals were subjected to a controlled step-wise hemorrhagic hypotension (MABP 30 mm Hg) plus hypoxia (FiO_2 8%) for a 30 minute period. The animals were subsequently resuscitated by reinfusion of the shed blood plus equal volumes of saline and by readministration of 30% O_2/70% N_2. Monitoring was performed continuously, i.e. during shock, end shock (ES) and both at 20 and 120 minutes after shock (S+20; S+120). The data are presented as absorbance differences (O.D. units) from the originally established baseline signals. We observed that Cyt. a,a_3 became increasingly reduced and failed to re-oxidize at a time when intracerebral hemoglobin became reoxygenated and the MABP and PaO_2 were restored to clinically acceptable values.

244.9 OXIDATIVE METABOLIC ACTIVITY OF THE CEREBRAL CORTEX AFTER HEAD INJURY IN THE CAT RB Duckrow*, JC LaManna, M Rosenthal, JE Levasseur*, and JL Patterson, Jr* Department of Neurology, University of Miami School of Medicine, Miami, FL 33101 and Department of Medicine, Medical College of Virginia, Richmond, VA 23298

To assess the metabolic and vascular effects of head trauma, fluid-percussion pressure waves were transmitted to the brains of seven paralyzed and artificially ventilated cats using the technique of Sullivan (J Neurosurg 45:520,1976). Arterial blood gas tensions and pH were measured and maintained within physiological limits. Changes in the redox state of cytochrome a,a_3 and relative local blood volume were measured in situ by dual-wavelength reflection spectrophotometry of the cortical surface viewed through an acrylic cranial window implanted within the closed skull. Initial fluid-percussion impacts of 0.5 to 2.8 atmospheres peak pressure produced consistent transient oxidation of cytochrome a,a_3 and increases of cortical blood vloume. This oxidation occurred despite the presence of transient post-traumatic hypotension in some cases. Also, impact-induced alterations of vascular tone, indicated by the persistence of increased cortical blood volume, occurred independent of the presence or absence of transient hypertension in the post-traumatic period. Electroencephalographic (EEG) activity was suppressed immediately after impact and recovered in 24 to 72 seconds. Total suppression of EEG activity or persistent changes were not seen. In five animals, intracranial pressure (ICP) either decreased or stayed the same after impact. Two animals showed transient increases in ICP after trauma, but these transients resolved within 1.5 minutes. There were no persistent ICP increases over the two hour (maximum) observation period. These data demonstrate that hypoxia does not play a role in the immediate post-traumatic period in cerebral cortex and are consistent with the idea that following trauma there is increased cortical energy conservation. These data support the concept that head trauma alters the relationship of metabolism and cerebral circulation in the immediate post-trauma period. (Supported in part by Head Trauma Center Grant NS 12587, PHS grants NS 14319 and NS 14325, and a grant from the American Heart Association of Greater Miami)

244.10 COMPARATIVE EFFECTS OF ANOXIA ON EXTRACELLULAR POTASSIUM ION IN THE TURTLE AND RAT. T.J. Sick*, P. Lutz*, M. Rosenthal and J.C. LaManna. Depts. of Neurology and Marine and Atmospheric Science Univ. of Miami, Miami, FL. 33101.

To compare resistances to anoxia, extracellular potassium ion (K^+o) was measured with K^+ sensitive microelectrodes in cerebral cortex of turtles (Pseudemus Scripta) and rats. After establishing resting K^+o values, the rats and turltes were respired with 100% N_2. Brain hypoxia was determined polarographically with platinum microelectrodes and by monitoring the redox state of cytochrome a,a_3 by reflectance spectophotometry. The electrocorticogram (ECoG) was monitored continuously as an index of cerebral function. N_2 respiration in rats resulted in a fall in tissue oxygen tension and reduction of cytochrome a,a_3. These events were accompanied first by a slow elevation of K^+o from approximately 3 mM to 10-12 mM which occurred in 15-30 sec. This slow elevation was followed by a rapid rise in K^+o to 40-60 mM which lasted until N_2 was discontinued. The ECoG became isoelectric during the initial slow elevation of K^+o and remained isoelectric for 3-5 min after N_2 had been discontinued. In the turtle, respiration with 100% N_2 also resulted in a fall in tissue oxygen tension and reduction of cytochrome a,a_3 but the changes were considerably slower than those of rat. However, K^+o in turtle cortex remained at or near resting levels (4 mM) for over 3 hr. The amplitude of the ECoG was gradually reduced despite maintenance of K^+o at low levels, but the turtle brain remained excitable as demonstrated by a local negative DC shift and transient elevation of K^+o in response to direct cortical stimulation. To determine whether differences in body temperature are responsible for turtle's resistance to anoxia, rats were cooled from 37° C to 21-23° C. This resulted in moderate ECoG depression but did not prevent elevation of K^+o in response to N_2 and further depression of the ECoG.

These results suggest that there is no obligatory dependence of K^+ homeostasis upon oxidative metabolism in turtle brain in contrast to mammalian CNS. The results suggest, however, that energy demand in the turtle is reduced during anoxia but that depression of neuronal activity is not signalled by a rise in K^+o. In turtle, anoxia is signalled in another manner which results in energy conservation through depression of neuronal activity, without loss of Na-K transmembrane gradients. (Supported in part by PHS grants NS14319, NS14325 and NS06300)

244.11 TWO OPPOSITE EFFECTS ON SENSITIVITY TO INSULIN HYPOGLYCEMIC CONVULSIONS PRODUCED BY GOLD THIOGLUCOSE (GTG) TREATMENT. John Holliday*, Joan Luby*, Kathy Fish* and Mary Ann Marrazzi, Depts. Psychol. and Pharmacol. (Sch. Med.), Wayne State Univ, Detroit, Michigan 48201.

Systemically administered gold thioglucose (GTG) is well known to cause hyperphagia and a resulting obesity and to be associated with histological damage focused relatively selectively in the ventromedial (VMH)-arcuate hypothalamus. GTG lesions also alter the sensitivity to insulin hypoglycemic convulsions. Depending on the time after GTG treatment, this may be a decrease or an increase. Female CBA/J mice were treated intraperitoneally with GTG (0.8mg/g), gold thiomalate (GTM) (0.8mg/g) or saline. (GTM does not produce the selective GTG effects and is a control for non-specific gold thio-compound effects.) At 16 hours, insulin convulsions in the 3 groups were 3.8%, 65.6% and 68.8%, respectively. Similarly, at 24 hours, insulin convulsions were 0%, 25.0% and 31.3% respectively. In contrast to this decreased % convulsions, at 1 week the GTG group had increased % convulsions, 66% as compared to 0 and 6% in the GTM and saline groups. This effect can be seen for a couple of weeks after GTG before obesity becomes a significant complicating factor. Both the increased and decreased sensitivity are seen on the same population of mice tested at different times after the treatments. Blood glucose was the same in all 3 groups for both the increased and decreased % convulsions. In both cases, the difference must be in the brain's convulsive response to hypoglycemia, rather than in the degree of hypoglycemia resulting from insulin. Metrazol induced convulsions are not altered, so that the effects are not non-specific ones on stress or convulsion in general. Thus, GTG lesions seem to be affecting some control center(s) involved in the brain's functional adjustment to hypoglycemia. Moreover, the GTG lesioned glucostat seems to be the composite of 2 opposite regulatory components. Furthermore, the GTG lesion seems to be a relatively discrete brain lesion which alters a metabolic convulsion.

There is no change, however, in the convulsive response to hypoglycemia as early as 3 hours after GTG. Histological damage is visible with cresyl violet at 16 hours but not 3 hours after GTG, suggesting that the functional change does not occur prior to the visible histological damage. Concentration and hence localization of the cytotoxicity of systemically administered GTG, but not other gold thio-sugars, has been suggested to be due to binding of the glucose moiety of GTG to glucoreceptors, allowing the cytotoxicity of the gold thio-portion to be focused at that site. This hypothesis might predict an early functional deficit due to blocking by binding alone during the latency in establishing cytological damage, but this is not supported by these data. 244.12 EVIDENCE THAT ATP DEPLETION MAY LEAD TO SYNAPTIC TRANSMISSION FAILURE DURING HYPOXIA IN THE IN VITRO HIPPOCAMPAL SLICE. Tim S. Whittingham* and Peter Lipton. Dept. of Physiology, Sch. Med., Univ. of Wisconsin, Madison, WI 53706.

The relatively high levels of phosphocreatine (PCr) and ATP in brain tissue suggest that these high energy phosphate compounds (~P) may be critical for normal neural activity. Recent experiments in our laboratory have indicated that the phosphocreatine system (PCr + ADP $\rightleftharpoons$ ATP + Cr) plays an important role in prolonging normal neuronal function in anoxic conditions, probably by maintaining neuronal ATP levels for a longer period of time.

In this laboratory, using transverse (.5 mm) hippocampal slices, synaptic transmission failure is observed to begin as early as 30-45 seconds after switching from bicarbonate buffer aerated with 95% O_2-5% CO_2 to buffer equilibrated with 95% N_2-5% CO_2. Field potentials are recorded from the dentate granule cell region following bipolar stimulation of the perforant path axons. If a decrease in [ATP] is leading to the hypoxic transmission failure, then there should be a decrease in ATP prior to any observed decrease in the evoked response. Last year we reported that when whole slice ~P levels were measured, there was no significant decrease in [ATP], indicating that a decrease in [ATP] was not leading to hypoxic transmission block. We now have evidence that there is a small, critical pool of ATP whose depletion is leading to hypoxic transmission failure.

Hippocampal slices were frozen at the time of the first noticeable decrease in the evoked response (~35 sec). Earlier experiments indicated that the site of transmission failure was located in the molecular layer, a region predominantly composed of axon terminals and dendrites, which can be dissected away from the surrounding slice tissue. The ~P levels of molecular layer tissue were measured fluorimetrically as described by Lowry and Passonneau (1972). [PCr] has dropped ~32% (from the control value of 40.88±1.94 (SEM) to 27.97±1.56 at the time of first noticeable decrease) while [ATP] dropped ~20% (from 20.85±1.29 to 16.77±1.57). If the phosphocreatine system is of value in maintaining neuronal transmission due to its ATP buffering ability, then, increases in molecular layer [PCr] should result in prolonged neural function during anoxia. Slices were exposed to buffer containing 25 mM creatine for up to 3.5 hours. Over that time there was a gradual increase in [PCr] (from ~40 µMoles/mg protein to ~185 µMoles/mg protein) with no change in [ATP] (20.01±1.14 to 19.24±1.36). Over this same time period, there was a 3-4x increase in the time needed to observe the first noticeable decrease in the evoked response (from ~36 sec to ~2'0"). These experiments indicate that there may be a critical pool of ATP located in the synaptic region of the dentate gyrus, whose depletion results in synaptic transmission failure during anoxia. (USPHS grant# NS15878).

244.13 DEVELOPMENTAL CHANGES IN GLUCOSE AND GLYCOGEN CONCENTRATIONS IN BRAINS OF DBA/2J AND C57BL/6J MICE: POSSIBLE EVIDENCE FOR ENERGY RESERVES DEFICITS UNDERLYING SUSCEPTIBILITY TO AUDIOGENIC SEIZURES. Robert A. Schreiber, Dept. of Biochem., Univ. of TN. Center for the Health Sciences, Memphis, TN. 38163, USA.

During the developmental period characterized by suckling, the brain is primarily dependent of ketone-bodies derived from the dam's high-fat milk as a source of acetyl-CoA. The pups are weaned by the dam when the brain reaches near-adult size, and begins to shift to carbohydrate-derived sources of acetyl-CoA for brain functions.

The onset of susceptibility to audiogenic seizures (AGS) in genetically AGS-prone mice coincides developmentally with the above (see graph below). There may be a lag in the development of adequate immediately available energy reserves to last through a brief period of an external-stimulus-induced large energy expenditure (sec) until energy repletion processes can begin. On stimulation, CNS activity may then become disorganized, resulting in the onset of an AGS (Med. Hypot., 5, 487, 1979).

Since glucose and glycogen provide the bulk of the brain energy reserve, a developmental study was performed to measure the concentrations of these in brain tissue from DBA/2J mice (susceptible to AGS) and C57BL/6J mice (not susceptible). Mice were placed into a 6cm high by 8 cm diameter cage constructed of 1/4 in. hardware cloth for about two min. during which the cage was lifted by its wire handle a few times to the level of a Dewar flask containing liquid N_2. When the mouse showed no signs of agitation on lifting, the cage was plunged into the N_2. The mouse was then placed into a -20°C chamber, and 10 to 20 mg samples of frontal, temporal, cerebellar, and diencephalic regions were taken, weighed, extracted, and assayed for glucose, glycogen, ATP and phosphocreatine. Pooled preliminary data are shown below (N = 2 to 6 mice per age; no significant differences among areas). No difference with age have been found to date in the latter two metabolites.

244.14 INCREASED ACTIVITY OF ADENOSINE - STIMULATED ADENYL CYCLASE IN CORTEX FOLLOWING ELECTROCONVULSIVE SEIZURES (ECT). Albert Sattin. VA Hospital and Institute of Psychiatric Research, Department of Psychiatry, I.U. Medical Center, Indianapolis, IN 46223

Many psychiatrists consider ECT to be the most efficacious treatment for endogenous depressions (Amer. Psychiat. Assn. Task Force Report 14, Electroconvulsive Therapy, Sept., 1978). Although the mechanism(s) of this "auto-pharmacological" treatment remain unknown, it is believed to work through the time-dependent cumulation of individual seizure effects to an end-point (clinical recovery) that persists following cessation of treatment. Since biogenic amine function may be altered in depression, ECT-induced changes in related systems are of interest. Vetulani et al have shown (N. Schmied. Arch. Pharm. 293:109, 1976) that 8 daily ECT's produce an apparent decrease in the NE-induced accumulation of cyclic AMP (CA) in chopped limbic forebrain that persists for at least 8 days after the last ECT. Chronic tricyclic antidepressant treatment produces similar effects which have also been directly correlated with a decreased number of β-receptors in cerebral cortex (Wolfe et al, J. Pharm. Exper. Therap. 207: 446, 1978).

Male Sprague-Dawley rats, age 2 mo., were given sham ECT or ECT, 60-80 millicoulombs, daily at 9:00 a.m. x 8 days through earclip electrodes. ECT induced seizures that almost always displayed hindlimb extensions. Rats were sacrificed 2 days after the 8th ECT. Cerebral cortex was dissected free of striatum, temporal lobes and anterior frontal cortex. The remaining cortex was chopped, (0.32 mm) randomized and (ca. 100 mg/20 ml) preincubated x 50 minutes in a K-R-B buffer, 37°, then transferred to buffer containing maximal doses of NE, 10μM, adenosine, 200μM or n-ethyl-carboxamide adenosine (NECA, an enzymatically stable analogue supplied by Dr. Jan Wolff), 1.0μM. After 10 minutes, the tissue was frozen in liq. N_2. cA was assayed by the Gilman method after Dow 50 purification. Mean control values in 2 experiments were 4.6 ± 1.1 (15) and 14.3 ± 2.0 (10) p moles/mg protein. Adenosine produced a 15.3-fold increase in sham ECT tissue and a 27-fold increase in ECT tissue (76% increase, $p<0.01$, 2-tailed t-test). In a third experiment, adenosine deaminase, 1U/ml was used to reduce the adenosine background. The NE-induced increase in cA was reduced by 41% in the ECT tissue while the NECA-induced increase was augmented by 38%. The two tissues did not differ in their cA response to NE + NECA which was potentiated 3-fold. These results suggest that ECT increases the responsiveness of α-NE receptors in forebrain by augmenting the adenosine component of the response. (Sattin et al, J. Pharm. Exper. Ther. 192:22, 1975). Other adenosine receptor effects might also be augmented.

245.1 EFFECT OF TELENCEPHALIC CATECHOLAMINE DEPLETION ON FIXED INTERVAL PECKING IN PIGEONS: A MATTER OF INTERACTION. Irving Goodman, James Zacny*, Augustine Osman*, Albert Azzaro*, & Carol Donovan*. Depts. of Psychology & Neurology, West Virginia U. Morgantown, WV

Fixed interval (FI) key pecking rates are reduced and patterns are disturbed following the destruction of dopamine rich limbic or striatal structures in the pigeon forebrain (Wesp & Goodman, 1978). The present study initially attempted to determine the effects on FI responding of dopamine depletion achieved by destruction of dopamine bearing forebrain inputs, originating in nucleus tegmenti pedunculo pontinus (TPc), presumed homologue of the mammalian substantia nigra.

Intact pigeons, taught to key peck for grain reinforcement, responded on a schedule that had reinforcement delivered after the first response following a 2 min no reinforcement interval (FI-2). Following the establishment of stable response rates and patterns, birds were lesioned bilaterally in or near TPc, either by electrolysis (2mA, dc anodal current for 15 sec), 6-hydroxydopamine (6-OHDA)(8 ug/2uL saline) or pretreatment with desmethylimipramine (DMI)(15 mg/kg) followed by 6-OHDA. Control birds received 2 uL saline in TPc. Animals were run for 30 or more consecutive, daily, postoperative sessions, 30 min/session, on the FI-2 schedule. Initial analysis of postoperative performance was unimpressive; about half of the lesioned subjects showed increases and the other half decreases in response rates in comparison to preoperative performance. Subsequent assays of telencephalic levels of norepinephrine (NE) and dopamine (DA) in lesioned and control animals provided four outcome groups: (1) NE, normal/DA, normal; (2) NE,normal/DA, low; (3) NE, low/DA, normal; and (4) NE, low/DA, low. Low levels were defined as depletion greater than 25% of control level Catecholamine (CA) outcome groups were selectively associated with pecking rate changes. Individuals falling into groups (3) or (4) consistently showed increased key pecking rates from days 7 - 30. However, those in group (2) showed a marked decrease in key pecking over that same period. These data indicate that the reduction of forebrain DA provides insufficient information from which to predict decreased responding; likewise, increased responding is not always associated with a decrease in forebrain NE, since controls, which fell into group (1), were also seen to have an increase in FI responding. An interaction between NE and DA is clearly indicated. These findings in an avian species support the general view that behavioral task demands are not controlled by single neurotransmitter systems and that the analysis of multiple synaptic transmitters and modulators will be necessary to reach higher correlations between brain function and behavior.

245.2 INTRACRANIAL SELF-STIMULATION IN RELATION TO DOPAMINE TERMINALS IN THE SEPTAL AREA OF THE RAT. R. A. Prado-Alcala and R. A. Wise Physiol. Dept., Sch. Med., Natl. Univ. Mexico, Mexico 20, D. F. and Psychol. Dept., Concordia Univ., Montreal, P. Q., Canada H3G 1M8

Anatomical and pharmacological evidence implicate dopamine (DA) systems in the mechanisms of brain stimulation reward. Brain stimulation reward sites have an anatomical distribution in the ventral tegmental area which follows very closely the distribution of DA cells in that region.[1] Intracranial self-stimulation (ICSS) is obtained when electrodes are in the layer of DA cells, but not when they are in the interpeduncular nucleus or the zona reticulata, below, or the medial lemniscus, above, the nigral and ventral tegmental DA cells. The present study was designed to explore the reported correlation between ICSS sites and DA terminal fields particularly in relation to the distinct band of DA terminals on the ventro-medial aspect of the lateral septal nucleus (to which some of the tegmental DA cells project).

DA terminals in the septum are mostly restricted to a dense diagonal ribbon forming the medial border of the lateral septal nucleus throughout its anterior-posterior length. ICSS was tested above, within, and below this sheet of terminals. A moveable electrode was used to test 4-10 placements in a vertical penetration in each animal; rate of responding was assessed at currents ranging from 60 µa down in 2 µa steps to the lowest currents that would sustain responding (threshold).

ICSS did not vary in clear relation to dopaminergic terminal density as revealed by glyoxylic acid-induced fluorescence histochemistry. Self-stimulation was generally strongest in the dorsal region of the septum and was better in the area above the dopamine cells than within them. ICSS was sustained, though not as well, in the medial septal region also. Thus ICSS near the narrow band of DA terminals in the septum does not follow the close relation to DA anatomy that is seen near the cell bodies in the ventral tegmentum. It would thus appear that DA fibers to the septal area are an unlikely candidate for a brain stimulation reward substrate, although non-dopaminergic fibers from the septal area to the ventral tegmentum (conforming to the anatomy of the tegmental DA cell layer perhaps because they terminate there) remains an interesting possibility.

245.3 HYPERACTIVITY AND IMPAIRED T-MAZE PERFORMANCE AFTER LESION OF MESOLIMBIC DOPAMINE TERMINAL REGIONS. P.H. Kelly and J.J. Shih*. Department of Physiology and Biophysics, University of Southern California, School of Medicine, Los Angeles, CA. 90033.

Rats with electrolytic lesions of the nucleus accumbens and olfactory tubercle were hyperactive compared to controls when tested in photocell cages 18 days after the lesion. The hyperactivity was most marked during the nocturnal phase of the light-dark cycle. Twenty-three days postoperatively, animals were placed on a one hour per day feeding schedule. Acquisition of a position discrimination in a T-maze (five trials per day, four 45mg Noyes pellets per trial) for food reward was begun after familiarization with the maze and a spontaneous alternation test with food in both arms of the maze. During a 10-minute familiarization session with food in both arms, control and lesion groups did not differ in the number of transitions made from one portion of the maze to another. The spontaneous alternation test showed that lesion and control groups did not differ in position preference nor in their tendency to alternate entries into the two arms of the maze. During five days of acquisition training the lesion group was slower to learn the postion preference and made fewer total correct responses. After five days of no training they retained the preference as well as controls. When the rewarded arm of the T-maze was reversed, the lesion group was significantly impaired in reversing the previously learned habit. Since hyperactive children with the "minimal brain dysfunction" syndrome demonstrate learning impairments, there appear to be similiarities between this syndrome and the effects of lesions in regions of mesolimbic dopamine terminals.

245.4 ALTERED BEHAVIOR OF MACAQUES FOLLOWING DOPAMINE INJECTION INTO CAUDATE N., N. ACCUMBENS, AND SUBSTANTIA NIGRA. M.F. Dubach* and D.M. Bowden. Depts of Physical Anthropology and Psychiatry & Behavioral Sciences and Regional Primate Research Center, Univ of Washington, Seattle, WA 98195.

To investigate the neuroanatical substrate of amphetamine psychosis, a technique was devised for making repeated intracerebral (IC) injections of dopamine (DA) into discrete sites in the monkey (Macaca fascicularis). Ninety µg of DA in 0.1 µl injections were made over a period of two minutes via 33 ga needles.

Behavior of the monkey, freely moving in a 4'x4'x5' cage, was recorded on video tape for one hour following an injection of DA or vehicle. Using a digitizer as an ethological recording device, a detailed numerical account of the animal's social behavior and activity pattern was generated. The data represented a continuous tabulation of location, posture, direction of orientation, and proximity to a companion monkey, as well as behavioral activity, including handedness and object involved. The first thirty seconds of each minute were scored, and data were stored on microcomputer floppy disk. Later, computer analysis provided a breakdown of duration and frequency data for each behavior code and each period in the hour, as well as an account of locomotor rate and repetitiveness of path, turning behavior, and stereotypy of activity and posture.

Analysis of early runs in three monkeys has indicated that significant behavioral changes occur within minutes of injection; different behavioral patterns are elicited by DA administered to different sites and the pattern obtained from a given site in a given animal is consistent from test to test. Injections have been made in substantia nigra, nucleus accumbens, and two sites in the head of the caudate nucleus, one at the AP level of the anterior commissure and the other 6 mm more rostral. At least three weeks intervened between injections at a given site.

Effects included changes in oral, locomotor, exploratory, and social behavior, reminiscent of changes observed in monkeys treated peripherally with CNS stimulants. Particularly interesting were increases in social distance, decrease in grooming and being groomed, and increase in grimacing when the companion animal was nearby. Responses to IC-DA in a given site, like behavior of untreated monkeys, varied considerably from one animal to another, but using each animal as its own control, consistent repeatable drug effects have been observed for each site. The results suggest that the neostriatum, as well as mesolimbic sites, may be involved in emotional and social responses to increased stimulation of DA receptors.

245.5 SPIROPERIDOL-INDUCED ANTAGONISM OF (+)-AMPHETAMINE LETHALITY IN ADULT RATS. P.A. Burger*, J. Malles*, and L.A. Baez. Psychology Dept., Sch. of Medicine, Southern Illinois University at Carbondale, Carbondale, IL 62901.

Previous investigations in this laboratory (Baez, Kerns, & Smith, 1977) have indicated that both the behavioral and lethal actions of (+)-amphetamine sulfate can be successfully blocked by pretreatment with low doses (.25 mg/Kg) of the neuroleptic drug, spiroperidol. Those investigations raised the possibility that spiroperidol might act in a noncompetitive manner in its ability to block the behavioral effects of (+)-amphetamine , since the spiroperidol blockade was not overcome by doses of amphetamine as high as 60.0 mg/Kg. The present study further investigated this problem by exploring the nature of the spiroperidol antagonism of amphetamine lethality.

Phase I of the present study established the LD100 value for (+)-amphetamine sulfate in this laboratory. Adult male Long-Evans rats (225-300 g) housed in isolation, were injected intraperitoneally with (+)-amphetamine sulfate. Mortality counts were taken at four hours post-injection. 80 mg/Kg (+) amphetamine sulfate was found to represent an LD100 value.

Phase II explored the spiroperidol-induced antagonism of (+) amphetamine mortality. Adult male Long-Evans rats were injected subcutaneously with spiroperidol thirty minutes prior to an intraperitoneal injection of 80 mg/Kg (+)-amphetamine sulfate. Spiroperidol (.00078, .0015, .003, .006, .0125, .025, .050, .10 mg/Kg) was found to significantly reduce (+)-amphetamine mortality (χ^2= 22.1;p<.001) at four hours post-injection. A spiroperidol dose of .025 mg/Kg represented an ED100 value for the protective effect.

Phase III investigated the nature of the spiroperidol-induced protective effect. Adult male Long-Evans rats were injected subcutaneously with .025 mg/Kg spiroperidol thirty minutes prior to an intraperitoneal injection of (+)-amphetamine sulfate (40, 80, 90, 100, 120, 140, 160 mg/Kg). Because doses of (+) amphetamine greater than 100 mg/Kg were able to overcome the spiroperidol-induced protection against the lethal action of the agonist, the hypothesis of noncompetitive antagonism was not supported.

245.6 EFFECTS OF CHRONIC ANTIDEPRESSANT TREATMENT ON PASSIVE AVOIDANCE IN OLFACTORY BULBECTOMIZED RATS: IMPORTANCE OF THE TREATMENT-TEST INTERVAL. L. Noreika*, G. Pastor* and J. M. Liebman. Res. Dept., Pharmaceuticals Div., CIBA-GEIGY Corp., Summit, NJ 07901

Bilateral olfactory bulbectomy in rats markedly disrupts acquisition of a passive avoidance task. Using a step-down procedure, Van Riezen et al. (Br. J. Pharmacol. 60:521, 1978) have demonstrated that this effect can be reversed by repeated antidepressant (AD) treatment. In the present experiments, which examined this phenomenon in further detail, the interval separating the end of treatment from the passive avoidance test has been found to be crucial for the emergence of this AD-induced effect. These findings suggest that this proposed model of AD activity may reflect induced receptor sensitivity changes.

Two to three weeks after bilateral ablation (by suction, under surgical anesthesia) of the olfactory bulbs, chronic (once daily) i.p. drug treatment was initiated. At various intervals (4, 24, 48 and 72 hr) following the end of treatment, the animals were tested in a shuttlebox passive avoidance task. After completion of this test, brains were removed for visual confirmation of the ablation.

Daily AD treatment for 7 days (imipramine, 5 mg/kg; amitriptyline, 10 mg/kg; doxepin, 30 mg/kg; viloxazine, 5 mg/kg; mianserin, 20 mg/kg; bupropion, 30 mg/kg) attenuated the passive avoidance deficit in olfactory bulbectomized rats. This AD effect was most apparent in animals tested 48 and 72 hr after termination of treatment, and was absent or less consistent when testing took place 4 or 24 hr after completion of these treatments. When imipramine (5 mg/kg) was administered for 2 or 4 days, antagonism of the passive avoidance deficit was less consistent, and no effect was apparent when imipramine was given for one day. Neither haloperidol (0.1 mg/kg x 7 days) nor tranylcypromine (10 mg/kg x 7 days) had any effect at any post-treatment interval. At a high dose (5 mg/kg x 7 days), d-amphetamine reversed the deficit 48 hr after the end of treatment, but not at the 4-hr interval. A lower dose of d-amphetamine (0.5 mg/kg x 7 days) was ineffective.

The fact that the passive avoidance deficit was not reversed until 48-72 hr after repeated AD treatment suggests that an indirect process may be involved rather than a direct action of the AD. Repeated AD treatment is reported to reduce sensitivity of beta-adrenergic receptors in the brain (Nature 268:455, 1977) and to increase that of forebrain serotonin receptors (Science 202: 1303, 1978). The effects of ADs on the olfactory bulbectomy syndrome may reflect such an induced change in receptor sensitivity.

245.7 ANALYSIS OF THE MOTOR STIMULANT EFFECTS INDUCED BY INJECTION OF THE DOPAMINE AGONIST SK&F 38393 INTO THE NUCLEUS ACCUMBENS. Maryann Malesky* and Paulette E. Setler (SPON: R. Krell) Smith Kline & French Laboratories, Philadelphia, Pa. 19101.

SK&F 38393 (2,3,4,5-tetrahydro-7,8-dihydroxy-1-phenyl-1H-3-benzazepine) is a dopamine (DA) agonist having unique properties which include production of contralateral rotation in rats with unilateral lesions of the substantia nigra (SNX), activation of dopamine-sensitive adenylate cyclase, and contralateral rotation after infusion into the denervated caudate nucleus. SK&F 38393 does not stimulate prolactin secretion or produce stereotyped behavior and does not cause emesis in dogs(Setler et al., Eur. J. Pharm. 50 (4), 419-430, 1978). Freedman et al.(Br. J. Pharm. 67(3), 430-431P, 1979) have reported that bilateral injections of SK&F 38393 into the nucleus accumbens (NA) of conscious rats produce a long-lasting increase in locomotor activity. The present study was undertaken to analyze this phenomenon.

Drugs (0.5 µl) were injected bilaterally in the NA of rats through permanently implanted cannulae (A 9.5, V-0.6, L 1.5, König and Klippel, 1963) and motor activity was measured in doughnut-shaped photo-cell activity chambers.

SK&F 38393 produced a dose-related (5.0 - 25.0 µg) increase in forward directed locomotion. Stereotyped behavior was not observed. Locomotor activity reached a maximum between 2 and 3 hours and lasted longer than 5 hours. This effect was antagonized by chlorpromazine or pimozide. These data suggest that the stimulating actions of SK&F 38393 in the NA are mediated by DA receptors as originally postulated for other agents by Woodruff et al. (Brain Res. 115, 233-242, 1976).

SK&F 38393 causes contralateral rotation when injected unilaterally at low doses (0.04-5.0 µg) into the DA depleted caudate nucleus, an effect blocked by chlorpromazine but not by pimozide. Unilateral injection of SK&F 38393 into the intact caudate nucleus is without effect even at high doses (30.0 µg) (Setler et al.; Abstract 1940, SN Meeting, 1979). The data suggest that the locomotor stimulant effects of SK&F 38393 given in NA may be mediated by a dopaminergic mechanism different from that mediating the caudate effects of this DA agonist.

245.8 PRODUCTION OF CONTRALATERAL ROTATION BY INJECTION OF DOPAMINE INTO THE PARS RETICULATA OF THE SUBSTANTIA NIGRA. Joseph T. McDevitt* and Paulette E. Setler. Smith Kline & French Laboratories, Philadelphia, Pennsylvania 19101.

Rotation behavior, produced by electrical stimulation of the striatum, or by dopamine agonists in unilaterally dopamine depleted animals, was originally believed to be due to striatal dopamine receptor activation. More recently, it has been observed that numerous agents when injected into substantia nigra also cause rotation, which could in some cases be due to modulation of the nigro-striatal dopamine pathway.

We have investigated the effects of dopamine stereotaxically injected into the rostral, middle, and caudal segments of the pars reticulata of the substantia nigra (SnR) of male Charles River rats, which were pretreated for 3 hrs with tranylcypromine (1.0 mg/kg, i.p.) and anesthetized with sodium brevital (10.0 mg/kg, i.v.). Dopamine, in concentrations of 5.0, 10.0, or 20.0 µg/0.5 µl, injected into the rostral segment of SnR caused significant dose dependent contralateral rotation, lasting >2 hrs. As the SnR injection sites were moved caudally, contralateral rotation decreased, and at extremely caudal sites dopamine caused slight to moderate ipsilateral rotation.

Another complexity was introduced by the observation that only some, but not all dopamine agonists cause contralateral rotation after intranigral injection. The novel benzazepine dopamine agonist SK&F 38393-A,tested at concentrations of 2.5, 5.0, or 10.0 µg/0.5 µl, also produced contralateral rotation after injections into SnR. Apomorphine, Piribedil, and the ergot derivative lergotrile, were ineffective.

Inhibition of dopamine induced rotation by systemically administered dopamine antagonists suggested that the effect of dopamine in SnR was mediated by dopamine receptors. Dopamine induced contralateral rotation does not appear, however, to be dependent on the nigro-striatal dopamine system. Enhancement rather than antagonism of the intranigral effects of dopamine agonists was observed in animals with prior unilateral 6-hydroxydopamine lesions of the ipsilaterally treated nigra. Similar results in 6-hydroxydopamine lesioned rats have been obtained with the GABA agonist muscimol (Arnt et al., Psychopharm 62, 1979).

The results of our studies suggest that rotational behavior produced by systemic administration of some dopamine agonists may not be entirely due to activation of striatal dopamine receptors, or reflective of nigro-striatal dopamine activity, but may also reflect activation of dopamine receptors in SnR. Which system(s) is modulated by these SnR dopamine receptors remains to be determined.

245.9 EFFECTS OF AMINERGIC STIMULATION OF THE AMYGDALA ON RAT MURICIDAL BEHAVIOR. John F. Miller* and Carlton E. Lints. Department of Psychology, Northern Illinois University, DeKalb, IL 60115.

Although numerous reports have implicated brain serotonin (5HT) in the inhibition of rat muricidal behavior, one frequently quoted study (Leaf et al., 1969) suggested that norepinephrine (NE) may play a similar role within the amygdala. The results of the present experiments provide further support for this suggestion.

In experiment 1, separate groups of established mouse killers were given bilateral intracranial injections of different doses (45, 90 and 180 nmole) of either saline, 5HT, NE or the beta-adrenergic agonist isoproterenol (ISOP) aimed at the central nucleus of the amygdala. Only the 45 and 180 nmole doses of ISOP significantly elevated the kill latencies of the killer rats without significantly affecting their attack latencies. In experiment 2 the bilateral intracranial injection of 300 nmole of either ISOP or NE produced a complete and reversible block of muricide in 60-70% of the rats tested without affecting righting or placing reflexes and without producing any overt signs of motor ataxia.

The results of these experiments support previous reports of noradrenergic inhibition of rat muricidal behavior and suggest that the effect is mediated by beta-adrenergic receptors within the amygdala.

245.10 Dual role of substantia nigra dopamine neurons in mnemonic and motor functions. Ellen H.-J. Kim and Aryeh Routtenberg. Dept. of Psychiatry, MRRC, UCLA, Los Angeles, CA 90024 and Cresap Neurosci. Lab., Northwestern Univ., Evanston, Illinois 60201.

Retention of learned passive avoidance behavior can be disrupted by 5-min post-trial microinjection of either picrotoxin into substantia nigra (SN) or dopamine (DA) into neostriatum in rats (Brain Res., 113, 620, 1976; Neurosci. Abst., 2, 445, 1976). In this study, 6-OH DA, DA, or GHBA (each dissolved in 0.5 µl of physiological saline) was injected unilaterally into SN either 5-min or 22-hr post-learning. Only 6-OH DA (2 µg) injected 5-min post-learning produced a retention deficit. Delayed (22 hr) injection of 6-OH DA was ineffective. The performances on retention testing of DA (50 µg) or GHBA (75 or 100 µg) injected subjects did not differ from those of saline injected controls. Fluorescence microscopic examination of soma-dendritic DA fluorescence of ventral tegmental DA cells in a rat that received SN 6-OH DA 30 min prior to sacrifice indicated that this drug may initially have stimulated the A9 DA neurons. The A10 DA cells appeared to be minimally affected. Thus, hyperactivity of SN DA neurons (i.e., supra-normal release of DA in neostriatum and other areas of DAgic nigral projection), when induced shortly following learning, appears to interfere with the consolidation processes of memory for passive avoidance.

The present 6-OH DA injection caused no overt motoric abnormality. Nor did any of saline vehicle injections. In contrast, both DA and GHBA produced circling away from the side of injection. When DA or GHBA was injected into SN of experimentally naive rats, similar contraversive circling was observed.

In sum, 6-OH DA-induced post-learning alteration suggestive of an increase in the activity of nigroneostriatal DA neurons disrupted retention of learned passive avoidance without eliciting any motor asymmetry. On the other hand, intranigral injections of DA or GHBA that resulted in motor asymmetry did not interfere with passive avoidance retention. This indicates that the neural mechanisms underlying the two phenomena are dissociable. Finally, the fact that both DA and GHBA resulted in similar circling behavior suggests that the actions of the two drugs in SN may share a common route to produce such an asymmetric motor response. One possible route is via the down-stream action of non-DA neurons in SN that receive GABA terminals of extra-nigral origin (Neurosci.Abst. 5, 71, 1979). It is possible that DA produced a result similar to that of GHBA by mimicking dendritic DA action on GABA terminals (Brain Res., 136, 45, 1977), hence causing release of endogenous GABA in SN (Nature, 268, 652, 1977). -Supported by NIMH 25281 & NSF 20630 to A. 245.11 CONTRASTING ROLES OF STRIATAL AND ACCUMBENS DOPAMINE IN MOTOR ACTIVITY IN SQUIRREL MONKEYS. Daniel L. Jones, R. E. Dill, Roy L. Dorris* and Sherry L. Berg*. Depts. Microscopic Anatomy and Pharmacology, Baylor College of Dentistry, Dallas, Tx.

Male squirrel monkeys (10) were chronically cannulated bilaterally in the nucleus accumbens septi and head of the caudate nucleus for subsequent drug injection. In all cases drugs were injected in a volume of 2 µl, followed by 2 µl of saline 2 min later to flush the cannula. Locomotor activity was assessed by means of a photocell activity cage coupled to a Heathkit LSI-11 computer. Catalepsy was judged present if the animal remained suspended (involving the hind limbs) from a 0.25 inch dia. rod for at least 10 min.

Intra-accumbens (i.a.) injection of dopamine (DA) produced a dose-dependent locomotor stimulation following a period of depressed activity the duration of which was dose-related in a positive manner. The DA antagonist, haloperidol (0.05 mg/kg s.c.), given 30 min prior to intracranial injection, completely blocked the locomotor stimulating effects of 25 µg DA given i.a. bilaterally, but did not alter the locomotor effects of 100 µg DA i.a. The depressed phase was not affected by the haloperidol in either case. This level of haloperidol (0.05 mg/kg s.c.) produced catalepsy in 30-40 min in 5 young monkeys (600-800 g) but not in mature animals (900-1100 g). The catalepsy induced by systemic haloperidol was not altered by the i.a. DA (25-100 µg). Haloperidol (0.4 to 10 µg) injected bilaterally i.a. or intra-caudate (i.c.) was not effective in producing catalepsy. However, i.a. haloperidol (10 µg) rapidly blocked ongoing locomotor activity induced by 100 µg i.a. DA. Intra-accumben DA was more effective than i.c. DA (50 µg both sites) in producing locomotor stimulation ($P < 0.01$).

These data confirm in a primate that the i.a. injection of DA is effective in producing locomotor stimulation, while i.a. haloperidol is not effective in producing catalepsy. The caudate does not appear to be critically involved in either motor effect. Supported by NIH Grant NS-15020.

245.12 SULCAL PREFRONTAL CORTICAL SELF-STIMULATION: EFFECTS OF 6-HYDROXYDOPAMINE OR KAINIC ACID LESIONS AT THE SITE OF STIMULATION. C.R. Gerfen, R.M. Clavier, and D.H. Henkelman*. Dept. of Anatomy University of British Columbia, Vancouver, B.C. V6T 1W5

We have previously reported that sulcal cortical intracranial self-stimulation (ICSS) in rats is abolished by 6-hydroxydopamine (6-OHDA) lesions of the A-10 and A-9 dopaminergic (DA) cell systems ipsilateral to the electrode. Contralateral lesions had only a temporary attenuating effect. However, destruction of the A-10 projection to the sulcal cortex was not necessarily implicated in the attenuation of sulcal ICSS since all ascending ipsilateral DA systems were destroyed. To determine whether DA innervation of the sulcal cortex is necessary for sulcal ICSS we have injected 6-OHDA (5 ug in 2.5 ul 0.9% saline with 0.3 mg/ml ascorbic acid) into the area around sulcal stimulation sites using a combined electrode-cannula system. Using this procedure sulcal cortical ICSS was maintained at prelesion rates after the removal of the DA innervation of that cortex. Verification of the lesions was made using the glyoxylic acid technique for catecholamine (CA) histofluorescence of Lindvall and Bjorklund (1974). The procedure revealed normal CA fiber and terminal patterns in the medial prefrontal cortex, nucleus accumbens, and olfactory tubercle ipsilateral to the electrode-lesion. The sulcal cortex, which normally contains a large number of DA fibers and terminals, had only trace numbers of DA fibers around the electrode in 8 of 10 animals tested. These data suggest that DA innervation of the sulcal cortex is not essential for ICSS elicited from that cortex.

In a second study, kainic acid (4 nmoles/1 ul) was injected into the sulcal cortex in sulcal ICSS animals. 7 of 10 animals receiving this treatment stopped bar pressing for sulcal ICSS for the duration of a 21 day post lesion trial period. All 10 animals had extensive neuronal cell loss in the sulcal cortex as determined by cresyl violet staining. However, only those 3 animals that recovered to prelesion ICSS rates had surviving neural perikarya around the electrode tip. In the 7 animals that showed attenuation of sulcal ICSS after the lesions, anterograde degeneration of fibers could be traced from the sulcal cortical ICSS area to, among other areas, the ventral tegmental area (site of the A-10 DA cells) and to the substantia nigra (site of the A-9 DA cell group) with Fink-Heimer staining.

The data presented here combined with our previous report suggest that sulcal ICSS may result from the stimulation of sulcal efferent systems with the possible subsequent activation of DA neural substrates.

245.13 RELATIONSHIP BETWEEN ENDOGENOUS BRAIN TYROSINE HYDROXYLASE AND SOCIAL BEHAVIOR OF RATS. S.L. Salman, J.M. Weiss*, W.H. Bailey and T.H. Joh. Rockefeller University, and Lab. of Neurobiology, Cornell Univ. Medical College, New York, NY 10021.

In constructing animal models of psychopathology, it would seem highly desirable to develop models in which abnormal behavior could be identified and studied in a natural social context, since abnormal behavior in humans is normally identified within such a context. The well known catecholamine hypothesis identifies disturbances in noradrenergic function as a basis of behavioral depression. Therefore, we asked the question: are there differences in endogenous catecholamine activity among animals in a population which are related to social 'dominance' behavior? Using the basic colony conditions described by Ellison (Brain Res.103:81,1976), we investigated the relationship between the activity of endogenous brain tyrosine hydroxylase (TH), the rate-limiting enzyme in catecholamine biosynthesis, and the behavior of animals in a colony hierarchy.

Male hooded rats were left undisturbed for ten weeks in a large colony enclosure while they established a dominance hierarchy. Behavioral observations were then scored on various measures: boxing, wrestling, fighting,'broadsiding',etc. Animals were then sacrificed, brains dissected into hypothalamus (Hypo), substantia nigra, locus coeruleus (LC), olfactory tubercles, amygdalas, caudate n., and frontal cortex. These regions were sampled for TH activity according to the method of Joh (Reis et. al. JPET 193:775,1975). Significant correlations between TH activity and dominance rank are presented below:

Spearman Rank-Order Correlations Between TH and Dominance Rank.

	Exp. 1 (N=9)	Exp. 2 (N=8)	Exp. 3 (N=9)
LC	.84*	.88*	--+
Hypo	.84*	.45	.63*

* p<.05
\+ samples lost

There was no significant correlation between behavior and TH activity in other brain regions. These data suggest that brain noradrenergic function is related to social dominance in rats. It remains to be determined whether social dominance results in elevated TH activity, or whether high TH activity in LC produces a dominant animal. However, the latter is suggested by recent investigations (Eison et.al. Pharm.Biochem.&Beh. 7:87,1977) in which LC-lesioned animals were found to be dominated in a social environment.

245.14 NORADRENALINE AND DISCRIMINATION LEARNING: FAILURE TO SUPPORT THE ATTENTIONAL HYPOTHESIS. M. Pisa and H.C. Fibiger, Div. Neurol. Sci., Dept. Psychiat., Univ. British Columbia, Vancouver, B.C.

The hypothesis of a role of forebrain noradrenaline (NA) systems in selective attention (Mason, S.T. and Iversen, S.D., Brain Res. Rev.1:107,1979) predicts that lesions of the dorsal noradrenergic bundle should impair both learning and reversal of discrimination tasks with only one relevant dimension available, and should facilitate nonreversal shift. Results of recent studies appear to support these predictions (Mason, S.T. et al., J. Comp.Physiol.Psychol., 1980, in press).

Using either a T maze or a cross maze, vehicle injected rats and rats with bilateral injections of 6-OHDA (4 µg in 2 µl) in the dorsal bundle (DB rats)were trained in either a position, a visual or a response discrimination task. Both the visual (white vs. black) and the kinesthetic (left vs. right turn) dimensions were relevant in the position discrimination. In contrast, the visual dimension was relevant, and the kinesthetic irrelevant, in the visual discrimination, and vice-versa in the response discrimination. On reaching learning criterion, rats of the position discrimination group were trained on multiple reversals, those of the visual and the response discrimination groups were either trained on multiple reversals or shifted to response and to visual discrimination respectively. Surprisingly, no significant differences among control and DB rats were found in either acquisition,reversal, or nonreversal shift, in any of the discrimination tasks.

It has also been reported that DB rats are impaired in left-right alternation learning (Mason, S.T. et al., J. Comp. Physiol. Psychol., 1980, in press) a finding thought to support further the attentional hypothesis. To evaluate whether increasing the distinctiveness of the choice arms had a differential beneficial effect on the alternation performance of DB rats, different groups were trained to alternate in a T maze with either similar grey arms or with distinctive, white vs. black, arms. Both control and DB rats performed significantly better in the T maze with distinctive arms than in that with similar arms. Surprisingly, however, no significant differences between control and DB rats were found either in learning or in retention (two weeks after discontinuation of acquisition training) with progressively increasing delays.

Biochemistry showed that the NA concentration in the cortex of DB rats was reduced to approximately 5-10% of control values.

Thus, previous reports that dorsal bundle lesions impair visual discrimination, facilitate nonreversal shift, and impair spatial alternation could not be confirmed, and no evidence was found to support the attentional hypothesis. Procedural differences possibly responsible for the discrepancy between present and previous results remain to be specified.

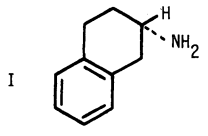
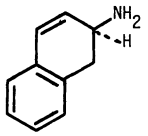
245.15 STIMULANT EFFECTS OF A NEW AMPHETAMINE ANALOGUE: 2-AMINO-1,2-DI HYDRONAPHTHALENE (2-ADN). M.B. Nichols*, G.K.W. Yim, B.A. Hathaway*, and D.E. Nichols. Depts. of Pharmacology and Toxicology and Medicinal Chemistry and Pharmacognosy, Purdue Univ., West Lafayette, IN 47907.

We have previously reported (Nichols et al., Brain Res. Bull., 2:169, 1977) that (-)-2-amino-1,2,3,4-tetrahydronaphthalene (2-AT, I) depresses spontaneous motor activity (SMA) in mice and resembles hallucinogens such as mescaline in its effects. In further extensions of this work we have now synthesized and screened 2-amino-1,2-dihydronaphthalene (2-ADN, II). Unlike 2-AT, which depressed spontaneous motor activity, 2-ADN increased



I



II

SMA. Although it was found that the (-) isomer of 2-ADN is most active, it's stereochemical configuration is opposite to that of (-)-2-AT. A parallel line bioassay indicated that racemic 2-ADN was one-fourth as potent as (+)-amphetamine in increasing SMA. 2-ADN also produces stereotypy similar to that elicited by (+)-amphetamine, indicating that it has an action on dopaminergic nigrostriatal systems. The central effects of 2-ADN were blocked by both reserpine and alpha methyl para tyrosine. Thus, the effects of 2-ADN, like that of ephedrine, may involve the release of catecholamine both from newly synthesized reserpine resistant, as well as from reserpine sensitive pools. It is intriguing that the introduction of a double bond into 2-AT should lead to a reversal in the pharmacological action. This feature may relate to a subtle structural requirement of the catecholamine uptake site. (This work was supported, in part, by Pharmacol. Toxicol. Training Grant GM-709504 (M.B.N.) and USPHS grant DA-01916).

245.16 LOWER ENDOGENOUS LEVELS OF NOREPINEPHRINE AND SEROTONIN IN THE BRAINS OF RATS FROM A GENETICALLY SEIZURE SUSCEPTIBLE STRAIN. H. E. Laird II, L. Chin*and A. L. Picchioni*. Dept. of Pharmacol. and Toxicol., Coll. of Pharmacy, Univ. of AZ., Tucson, AZ. 85721.

It has been previously demonstrated in our laboratory that genetically seizure susceptible (GS) rats have lower thresholds for convulsions due to sound, pentylenetetrazol, minimal, maximal and intracerebral electroshock than genetically seizure resistant (GR) rats (Laird and Huxtable, In: Taurine and Neurological Disorders, 1979; Duplisse et al. J. Int. Res. Comm. 1:(9),1973; Jobe, Picchioni and Chin, J. Pharmacol. Expt. Ther. 184:1-10,1973) A comparison of the endogenous levels of the inhibitory neurotransmitters, norepinephrine (NE) and serotonin (5HT) in the brains of these two strains of rats with differing seizure susceptibilities has revealed that NE and 5HT levels are lower in several areas of the brains of GS rats. Biogenic amines were estimated spectrophotoflurometrically. These results are presented below:

	NE CONTENT ng/g (+SEM)					5HT CONTENT ng/g (+SEM)				
	CH	MB	HT	PM	CB	CH	MB	HT	PM	CB
GR	430 (±30)	560 (±20)	2930 (±160)	710 (±40)	210 (±20)	730 (±40)	1070 (±50)	1950 (±130)	730 (±30)	220 (±10)
GS	270* (±10)	300* (±10)	1740* (±120)	420* (±40)	180 (±10)	600* (±20)	750* (±10)	1670 (±40)	690 (±20)	230 (±10)

* P 0.02 CH=Cerebral Hemispheres; MB=Midbrain; HT=Hypothalamus; PM=Pons-Medulla; CB=Cerebellum

Although this study does not distinguish between the relative roles of NE and 5HT in the modulation of seizure activity, it does provide data that agree with correlative studies involving drug-induced reduction of brain biogenic amine levels and changes in seizure thresholds. Furthermore, these data support the postulation that animals with lower endogenous brain biogenic amine levels have a reduced inhibitory function in the central nervous system (Scudder et al., Neuropharmacol.5:343-51,1966). In view of the differential distribution of the biogenic amines it is tempting to speculate that the low levels of NE in the CH, MB, HT,and the low levels of 5HT in the CH and MB of the GS rats are responsible for the greater seizure sensitivity of these animals.

245.17 THE EFFECT OF PERIPHERALLY ADMINISTERED SEROTONIN ON FOOD INTAKE IN THE RAT. J.D. Pollock* (SPON: D.S. Levine). Psychobiology Program, University of Pittsburgh, Pittsburgh, PA 15260.

The present experiments demonstrate a dose dependent suppression of food intake by serotonin (0.5 to 5.0 mg/kg free base) with or without the MAO inhibitor, clorgyline, 5.0 mg/kg ($p < .05$) in rats. This effect cannot be attributed to the creatinine in the serotonin creatinine sulfate complex since creatinine equal to the amount in the highest dose of serotonin creatinine had no effect. The high dose of serotonin, 5.0 mg/kg serotonin free base, particularly with clorgyline showed motor impairment as revealed by front end catalepsy. At this dose no significant impairment was observed on open field tests and back end catalepsy. Lower doses of serotonin creatinine sulfate (free base) manifest no apparent motor impairment. These results suggest that the dose dependent suppression of food intake at doses less than 5.0 mg/kg serotonin free base is not related to motor impairment. The relationship to a peripheral satiety mechanism and symptoms of the carcinoid syndrome will be discussed.

245.18 SELF-STIMULATION OF THE MEDIAL PREFRONTAL CORTEX DOES NOT INVOLVE THE MEDIAL FOREBRAIN BUNDLE. D. R. Corbett, A. Laferriere and P. Milner. (SPON: N. White). Dept. of Psych., McGill Univ., Montreal, Quebec, H3A1B1.

Intracranial self-stimulation (ICSS) has been reported from two areas of the neocortex, the medial prefrontal cortex and the sulcal prefrontal cortex (Routtenberg & Sloan, 1972). Opinion has been divided as to the neural substrates of ICSS in these two areas. Some have suggested that the ascending dopaminergic systems underlie the observed ICSS, while others have argued that descending systems from the cortex are responsible. Since both of these neural networks traverse the medial forebrain bundle (MFB) and peri-capsular regions we sought to assess their involvement in ICSS from the medial prefrontal cortex.

Each animal was implanted with a bipolar stimulating electrode in the infralimbic area (area 32) of the medial prefrontal cortex and a monopolar lesioning electrode on the far-lateral border of the MFB, ipsilateral to the stimulating electrode. The rats were then trained to lever press for brain stimulation in daily 15 min. test sessions. Once responding had stabilized, anodal electrolytic lesions (2.0 mA/10 sec.) were made via the MFB electrode. Behavioral testing resumed 24 hrs. after the MFB lesions and continued at intervals of 4, 7, 14 and 21 days post lesion.

Medial prefrontal cortex ICSS was not affected by these lesions. This finding was especially surprising because a number of the lesioned animals were hypophagic, they ceased grooming and they displayed reduced sensory-motor abilities. Histological examination of the lesions showed them to be large, extending from the fornix to the medial portions of the internal capsule and from the zona incerta to the base of the brain.

These data suggest that the ascending dopaminergic systems do not have an important modulatory role in medial prefrontal cortex ICSS, as they do at many other ICSS sites in the forebrain and midbrain. Moreover, lesions of the MFB-lateral hypothalamic area much smaller than the lesions reported here are known to eliminate or attenuate ICSS from a number of other limbic and mid- and lower brainstem sites. This observation suggests that whatever neural systems support ICSS in the medial prefrontal cortex they do not traverse the ventral diencephalon.

Thus it appears that prefrontal cortex ICSS involves very different neural systems and may therefore exhibit different characteristics than the commonly studied MFB ICSS system.

245.19 MULTIPLE SITE MONITORING OF DOPAMINE RELEASE IN FREELY MOVING RATS: BEHAVIORAL CORRELATES. John D. Salamone*, Darryl B. Neill*, Wayne S. Lindsay*, Brad Kizzort*, and J. B. Justice* (SPON: David Freides) Depts. of Psychology and Chemistry, Emory University., Atlanta, Georgia 30322

Recently several groups have utilized electrochemical techniques for in vivo monitoring of electroactive compounds in the brains of experimental animals.

We have designed and constructed a microcomputer-controlled electrochemical system for multiple-site in vivo monitoring of monoamine release in freely moving animals. The system consists of a microcomputer, A/D and D/A converter board, and a multiplexed potentiostat-amplifier. Sixteen working electrodes can be monitored, allowing near-simultaneous evaluation of monoamine release at different brain sites.

The circuitry can be used for all controlled potential electrochemical techniques. We have written software (Intel 8080 microprocessor) to perform chronoamperometry. The computer has control over the length of time the potential is applied, the time between measurements, and the number of points collected during each pulse.

We have used this sytem to monitor dopamine release in forebrain terminal areas of the nigrostriatal and mesolimbic dopaminergic systems of rats. Experimental results will be presented showing:

(1) Correlations of the chronoamperomentric signal with more conventional measures of dopamine release.

(2) The effects on the signal of systemically administered drugs which alter dopaminergic transmission with concurrent behavioral evaluation of locomotion activity and stereotypy.

(3) Correlations of the signal with both spontaneous and conditioned behaviors in non-drugged rats.

This project has been supported by grant BNS-79-06815 from the National Science Foundation.

245.20 RISE IN URINARY 5-HYDROXYINDOLEACETIC ACID (5-HIAA) ASSOCIATED WITH PRACTICE OF THE TRANSCENDENTAL MEDITATION PROGRAM. R.K. Wallace*, B. Simon*, S. Guich*, P.F. Tomlinson*, L. Petrick*, S. Beth* and K.G. Walton. Biochem. Lab., Institute of Psychophysiology, Maharishi International University, Fairfield, IA 52556.

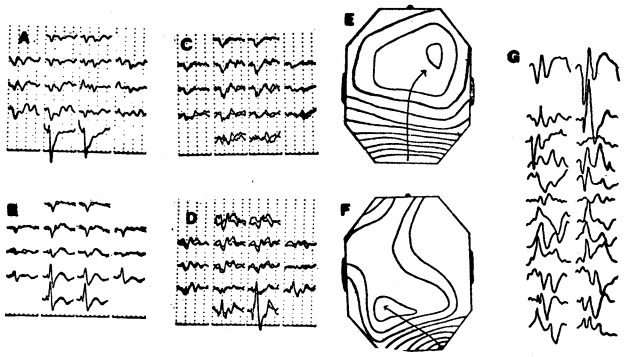
Transcendental Meditation (TM) is the name applied to an effortless mental technique for expanding the conscious mind introduced over 20 years ago by Maharishi Mahesh Yogi, a world-renowned teacher and scholar of the ancient Vedic tradition of knowledge. Maharishi has been instrumental in reviving the Vedic science of consciousness, of which the TM program, including the recently rediscovered TM-Sidhi techniques, may be considered the practical or laboratory aspect.

In the past 10 years a number of psychological, physiological and biochemical correlates of the TM practice have been identified (Scientific Research on the Transcendental Meditation Program: Collected Papers, Vols. I and II, MERU Press, 1977 and 1980). The nature of these correlates suggests that a unique behavioral state, referred to as transcendental consciousness (TC), is produced periodically during each practice session. Such periods are characterized by a large drop in respiratory rate, decreased heart rate, increased EEG coherence at all frequencies, and subjective alertness with little or no mental activity. The observed long-term effects of the TM practice, including a broad spectrum of improvements in mental and physical health, increased perceptual-motor coordination, increased creativity and enhanced enjoyment of life, appear to be related to the repeated experience of this TC state.

An increase of urinary 5-HIAA, the main metabolite of serotonin, was reported previously to be associated with the TM practice in 11 meditators (Bujatti, M. and Reiderer, P., J. Neural Transmission 39:257, 1976). We have confirmed and extended this observation using three experimental paradigms which appear to exclude the possibility that the observed rise in urinary 5-HIAA could be accounted for by normal circadian rhythms of 5-HIAA. Other researchers have reported changes in lactate, phenylalanine, prolactin, TSH, FSH, ACTH, T_4, cholesterol, cortisol and catecholamines in blood or urine, or both, which appear to be associated with practice of the TM program. Most of these substances are either produced or indirectly regulated by the pituitary. Brain monoamines, including serotonin, are known to affect pituitary secretion. Thus, while the increased 5-HIAA excretion correlated with the TM practice might reflect altered metabolism of peripheral serotonin, the hypothesis we are pursuing, namely, that the TC state involves central serotonergic and possibly other monoamine systems, seems more tenable. (Supported in part by a grant from the Rogers Foundation.)

246.1 TOPOGRAPHY OF 16 CHANNEL PATTERN SHIFT POTENTIALS (P-VERS) IN NORMAL SUBJECTS AND LEARNING DEFECTIVES. R. G. Bickford, D. G. Brunet* and M. L. Scholl*. BIK Foundation, La Jolla, CA 92037.

Studies of 70 normal subjects and 30 patients with learning defects were made from 10-20 system electrodes positioned by "electrocap". Results were computed by ACE (Automated Cerebral Electrogram) software and Mini-CEARS (BIK Systems) and DEC PDP/1140 computers. In addition these systems generated spectral bin averages, area displays, direct and integrated 16 channel averages (VER, AEP, BAER, and SER) for overall comparison. Results, normals: great variety in response in both contour and distribution was seen (A, B, C) indicating involvement of frontal lobes in processing. Patients: approximately 20% show O1-O2 voltage asymmetry greater than normals. O1-O2 integrated P-VERS allow estimation of ratios and setting of normative cut-off. Conclusions: 1) P-VERS are widely processed; 2) alpha and P-VERS generators are independent;3) a group of learning disordered patients with R/L processing problems has been delineated. Legend - 16 channel averages, linked ear reference, 350 msec. sweep, 100 stimuli binocular pattern viewing 34 min. arc checks. A, B, C, - varieties of response in normal subjects; D - response in learning defective patient; E - computer generated area display at 84 msec.; F - same display for learning defective patient 75 msec. Note line indicating direction of voltage gradient is different from E. G - display of 12 P-VERS in 12 learning defective patients O1 and O2 responses show frequent asymmetry, 350 msec. sweep.



Supported by BIK Foundation.

246.2 SIMULTANEOUS RECORDINGS OF THE AUDITORY BRAINSTEM (ABR) AND MIDDLE LATENCY RESPONSES (MLR) IN NORMAL SUBJECTS AND NEUROLOGICAL PATIENTS. N. Kraus, O. Özdamar*, L. Stein*, and D. Hier*. Siegel Institute, Michael Reese Hospital, Chicago, Illinois 60616.

Although auditory middle latency responses in man (8-50 msec, post-stimulus onset) have been shown to be generated intracranially, their source of origin is still uncertain. Recent studies suggest that these responses are cortically mediated (Picton et al, 1974). MLRs have been extensively investigated as a test of hearing (Mendel et al, 1975). As a neurological test, MLR has received little attention. This study was undertaken a) to examine the feasibility of recording these responses in a clinical setting, b) to ascertain the validity of audiological applications of MLRs using ABRs as a reference and c) to examine MLRs in patients with neurological impairments involving cortical dysfunction.

ABRs were recorded simultaneously with MLRs to assess the integrity of the auditory periphery and brainstem. Click stimuli were presented at several intensities and repetition rates. Filters were set at 3 and 2000 Hz and a 20 μsec sampling time was used. To be of clinical value, MLR recording should be applicable to uncooperative patients and individuals with whom communication is difficult. As sedation is frequently required, the effect of chloral hydrate on MLRs was examined. ABR and MLRs were obtained in normal adults with and without chloral hydrate sedation (1000 mg, p.o.). All patients received chloral hydrate. Adult patients were stroke victims with cortical lesions defined by CAT scans and behavioral evaluations. Children were language delayed, encephalitis and meningitis cases.

In normal subjects the major MLR component (P_a) was easily identified with a mean peak latency of 30 msec. The latency and amplitude of both P_a and ABR components were not significantly affected by sedation or the repetition rates employed. While the amplitude of ABR waves continued to increase with click intensity, P_a leveled off at 50-60 dB HL. ABR wave V and P_a were identifiable down to 10 dB HL. A number of patients showed normal ABRs in the absence of MLRs. This suggests that ABR wave V is a more reliable index of auditory sensitivity than MLR. Middle latency responses in pathological cases were evaluated with respect to normative data.

246.3 STUDIES ON PERIODIC AUDITORY EVOKED POTENTIALS AND 40 HZ RHYTHM INTERACTION IN THE AMYGDALA AND LIMBIC STRIATUM. C. C. Turbes, G. T. Schneider*, J. M. Simard* and R. J. Morgan. Dept. of Anatomy, Creighton University Sch. of Medicine, Omaha, NE 68178.

The interaction between the 40 Hz rhythm and auditory evoked potential (AEP) are considered in these studies. The 40 Hz rhythm is of special interest in this relationship since it is associated physiologically to respiration, alert and oriented states.

Recordings are made on free-moving cats using telemetry. Chronic electrodes are implanted in the sigmoid gyrus, amygdala and limbic striatum. The interaction of slow wave activity of these brain areas are analyzed using spectral, coherence spectral and crosscorrelation methods.

Autospectral analyses show the auditory evoked potentials and the 40 Hz activity are present in these areas of the brain. Coherence spectral estimates show the 40 Hz activity and the AEP between these brain regions are phase locked. This is shown by the per cent coherence and is a possible indication of the degree of physiological interaction between these regions of the brain.

The correlation levels of AEP between the nucleus accumbens and the amygdala ranges between 59% and 90% at 8 to 10 Hz. The associated 40 Hz activity ranges from 56% to 80%. The shortest time delays (tau), an indication of long pathway synaptic transmission, is from the nucleus accumbens to the amygdala. These are within the limits of synaptic delay and fit neuroanatomical findings.

In the case of the sigmoid gyrus and amygdala, the correlation levels range from 35% to 91% at 5 to 7 Hz. The 40 Hz activity showed correlation levels at 60% to 79%. In each case the shortest synaptic transmission was from amygdala to sigmoid gyrus.

The interactions between sigmoid gyrus and nucleus accumbens of AEP showed correlations at 76% to 90% at 12 to 14 Hz.

The 40 Hz activity showed correlation levels at 54% to 77%. The direction of shortest synaptic transmission was nucleus accumbens to sigmoid gyrus.

Where no periodic auditory stimuli are used, the average correlation levels for these frequencies are lower and show great fluctuation. This is possibly due to the changing behavior of drowziness, sleep and arousal during the absence of the stimulus.

246.4 THE EFFECTS OF SPINAL CORD INJURY ON SEPs PRODUCED BY NEURONAL INTERACTION, Richard K. Simpson, Jr., John G. Blackburn, Henry F. Martin and Sidney Katz, Dept. of Physiology, Medical University of South Carolina, Charleston, S.C. 29403.

The purpose of the present study was to determine the utility of somatic evoked potentials (SEPs) produced by neuronal interaction for spinal cord injury evaluation. Interaction between spatially separate afferent inputs was measured as alterations in SEP configuration compared to controls. In contrast to cats under choralose (Katz, S. et.al. EEG clin. Neurophysiol. 45:45-52 1978), monkeys anesthetized with N_2O were used. Stimulus intensities were sufficient to excite all nerve fibers. The conditioning stimulus (CS) was applied to the left peroneal nerve and test stimulus (TS) to the left radial nerve. CS-TS intervals were 100 msec in duration. SEPs were recorded from the primary cortical receiving area for the forelimb. Different surgical lesions were made at spinal cord level T_3-T_4.

Amplitudes of TS produced SEPs remained unchanged post lesion. CS produced SEPs were found to be dependent upon the integrity of anterolateral column pathways. Accentuated interaction was observed following dorsal column ablation. Little interaction was observed following anterolateral column ablation. Interaction was enhanced after left hemisection but diminished after right hemisection or central cord lesion. Interaction between spatially separate afferent inputs as measured by SEP alteration is a sensitive indicator of spinal cord injury. (Supported by NINDS grant P-5P81-NS-11066).

246.5 DETECTION OF SENSORY SPINAL TRACT DYSFUNCTION WITH SIGNAL DETECTION THEORY. Richard J. Schneider and Ronald Burke*. Maryland Institute for Emergency Medical Service Systems, Baltimore, Md. 21201.

A somatosensory discrimination task was established using either hair follicle or electrocutaneous stimuli. The hair follicle task required subjects to discriminate either two different frequencies or amplitudes of hair displacement on the anterior aspect of the calf. The electrocutaneous task required discrimination of two amplitudes of current pulses delivered over the sural or peroneal nerve. The paradigm was arranged to allow the relative ambiguity of the various stimuli to be manipulated. The task required the subject to push a button in response to one stimulus and to refrain from pushing in response to the complementary stimulus. In theory of signal detectability (TSD) terminology, hits and false alarms were recorded and used to construct a receiver operating curve (ROC). Normal human subjects and subjects diagnosed to have MS with spinal symptoms were tested for discriminative capacity in this paradigm. In an analogous fashion, the capacity of M. mulatta to discriminate electrocutaneous and hair follicle stimuli was compared.

The data obtained with this paradigm were described adequately by TSD. Thus, a reliable measure of discriminative capacity was obtained which was independent of response biases. Results suggest that normal subjects possess superior discriminative capacity compared to MS subjects. This result was evident irrespective of individual differences in surface hair density. Normal humans and M. mulatta demonstrated comparable discriminative capacity across several levels of task difficulty. The evidence suggested that when hair follicles were not stimulated uniquely, i.e. other receptor populations like low-threshold skin were activated, performance improved dramatically. When peripheral nerves were blocked with local anesthetic in M. mulatta discriminative acuity decreased to hair follicle and electrocutaneous stimuli. Following dorsal funiculus section discriminative capacity to hair follicle stimuli was diminished in these subjects but electrocutaneous capacity did not show the same effect.

These data support the conclusion that this paradigm together with TSD may be used to differentiate normal and MS subjects. Further, hair follicle stimulation preferentially assesses dorsal funiculus function while electrocutaneous stimulation is less specific. While these results were not dependent on receptor density, it was necessary to stimulate hair follicle receptors uniquely to obtain high resolution results.

Supported by Research Grant RG-1207-A-1 from the National Multiple Sclerosis Society.

246.6 THE EFFECTS OF SPINAL CORD LESIONS ON THE SOMATOSENSORY EVOKED POTENTIALS IN MACACA FASCICULARIS. S. Katz, J.G. Blackburn*, H.F. Martin, and R.K. Simpson. Dept. of Physiology, Medical University of South Carolina, Charleston, S.C. 29403.

The effects of selected spinal lesions on the somatosensory evoked potential (SEP) were studied in chronic animal preparations (Macaca Fascicularis). The left and/or right posterior tibial nerves were stimulated percutaneously at .3-.2 Hz, 0.3 msec, and 3-4 mA. Recordings were taken from chronic, epidural electrodes over the leg (Cz) area in response to both unilateral and bilateral nerve stimulation. Following well-defined control recordings, the spinal cord was surgically transected. Transections included the dorsal columns, right and left hemisections, and anterolateral columns. Central cord lesions were made using an RF lesion generator. All lesions were placed at T_3-T_4. Recordings were taken at intervals ranging from one day to 10 weeks. All recordings were made under N_2O-O_2 anesthesia.

A bilateral dorsal column transection (which also included the spinocervical tracts) was followed by an attenuation of the early, primary components of the SEP with minimal alteration of the late, secondary responses. Similar responses were seen with both unilateral and bilateral nerve stimulation. Significant alterations in the late components were seen following bilateral transection of the anterolateral columns in response to both unilateral and bilateral stimulation. Left hemisections were followed by loss of the primary components with little attenuation of the late components in response to left tibial nerve stimulation. Similar results were observed with right hemisections in response to ipsilateral nerve stimulation. Bilateral nerve stimulation revealed SEPs with both early and late components. Variable alterations in all components of the SEP were seen in response to both unilateral and bilateral stimulation following central cord lesions. Some deterioration of the evoked potentials with time was observed following several of the spinal lesions. All lesions were confirmed histologically.

The results obtained support previous observations in acute preparations indicating that both the dorsal and anterolateral columns contribute to the SEP. (Supported by NINCDS Grant P-5P81-NS-11066).

246.7 ACRYLAMIDE TOXICITY: EFFECTS ON CORTICAL EVOKED POTENTIALS AND LOCOMOTOR ACTIVITY IN RATS. William K. Boyes*, R. Dana Laurie*, G.P. Cooper (SPON: R. S. Manalis). Dept. of Environmental Health, Univ. of Cincinnati, Cincinnati, OH 45267 and Health Effects Research Laboratory, U.S. Environmental Protection Agency, Cincinnati, OH 45268.

Most electrophysiological investigations of chronic acrylamide neurotoxicity have been devoted to studies of peripheral nerve despite ultrastructural evidence of significant CNS damage. In this experiment we investigated ascending sensory systems by recording somatosensory and visual evoked potentials (SEPs and VEPs) in acrylamide-poisoned rats. In addition, electrophysiological measures were correlated with a behavioral indication of intoxication by housing acrylamide treated rats in standard running wheel cages. Acrylamide monomer was given to adult male Sprague Dawley rats in drinking water at concentrations of 0, 50 or 100 ppm. Cortical evoked potentials were recorded under nembutal anesthesia from chronically implanted electrodes before, and after 1, 3, 5, 7 and 24 weeks of exposure. Running wheel activity was monitored for 2 weeks before and 12 weeks following onset of exposure. The mean weekly number of wheel revolutions turned by the 100 ppm group was significantly less than the other two groups for each week beyond the fourth week of exposure. After 5 to 6 weeks of exposure, some of the 100 ppm animals demonstrated signs of ataxia including outward splaying of the hind limbs. After 7 weeks of exposure the latency of the N1 peak of the SEP was significantly increased in the 100 ppm group. The latency of both P1 and N1 was prolonged in the 100 ppm group after 24 weeks. No effect was found on the latency of later components of the SEP. Alterations in VEP waveforms were less severe. Measurements from the 50 ppm group were not significantly different from control in either behavioral or electrophysiological experiments. The finding that the early peaks of the SEP, which are thought to arise from specific somatosensory projection fibers, were altered by acrylamide and the later peaks, thought to arise from slower nonspecific systems, were not altered, suggests that acrylamide effects ascending somatosensory fibers in a manner similar to that reported in peripheral nerves. Large, fast fibers are more sensitive to acrylamide than small, slow ones. The fact that behavioral deficits were evident well before SEP alterations indicates that either (a) the SEP, as measured, is insensitive to small amounts of nerve damage or (b) that the initial acrylamide lesions occur in systems other the ascending somatosensory systems. (Supported by the EPA, and NIEHS Grant ES00159 and the Alice B. Ryan Foundation).

246.8 ACUTE TRIETHYLTIN ALTERS VISUAL EVOKED POTENTIALS AND HIPPOCAMPAL AFTERDISCHARGES W. E. Howell and R. S. Dyer. Neurotoxicology Division, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711.

Acute exposure to triethyltin (TET) is known to produce intramyelinic vacuolization and edema (Magee et al., J. Path. Bact., 1957, 73:107), and to inhibit mitochondrial oxidative phosphorylation and coupled respiration (Stockdale et al, Eur. J. Biochem., 1970, 15:342). The visual evoked potential (VEP) and hippocampal afterdischarge (AD) were used to study the effects of TET on visual and limbic system function, respectively. Fifty male Long-Evans hooded rats were surgically implanted with a bipolar electrode in the dentate gyrus of the dorsal hippocampus and an epidural screw electrode overlying visual cortex; two frontal cortex screws were used as reference and ground electrodes. Animals were tested for 10 consecutive days using both methods (VEP and AD). On days 2-6 animals received an i.p. injection of either 0.000, 0.188, 0.375, 0.750, or 1.500 mg/kg TET bromide in saline. Pupils were dilated prior to VEP testing using a 1% atropine sulfate solution. Daily average VEPs were derived from 256 individual responses to a 10 μsec strobe flash. Immediately following the VEP test session, AD threshold stimulus intensity level was determined by stimulating the dentate gyrus with a series of 50 HZ 2 sec trains of 0.2 msec biphasic pulses at ascending current steps once per minute (AD1). Suprathreshold AD properties were determined by retesting 15 min later at a 4x threshold current (AD2). Beginning 10 min after AD2, a measure of posticta1 excitability was obtained by stimulating at 2x threshold current every 2 min until a third AD (AD3) was elicited. Animals that received 1.500 mg/kg TET exhibited significantly increased VEP peak latencies (P1, N1, P2, and N3) compared to controls; no TET-induced amplitude differences were observed. ADs recorded from animals treated with 1.500 mg/kg TET exhibited a significant increase in spike frequency during the first segment of the AD. In contrast to this apparent excitatory effect, there was an increase in severity of the post-ictal EEG depression (PID) and an increase in time required to elicit AD3. These findings indicate that excitability in the hippocampus and visual system is differentially affected by TET. The visual system findings imply altered conduction velocities but no effect upon cellular responsiveness (no amplitude changes). The AD findings imply a profound depression, measured by both the increased PID severity and longer post-AD refractory period. Failure of TET to increase AD thresholds dissociates TET-induced depression from barbiturate-induced and ethanol-induced depression, both of which increase AD thresholds.

246.9 DELTA-9 TETRAHYDROCANNABINOL SLOWS PRIMARY CORTICAL EVOKED RESPONSE TO SOMATOSENSORY STIMULATION IN CATS. D.M. Wilkison* and M.J. Hosko. Department of Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI 53226.

In an attempt to establish the relationship between the altered sensory preception induced by drugs of abuse and the neurophysiological mechanisms that are responsible for those alterations we have undertaken a study in which a series of agents commonly involved in abuse will be evaluated using modality-specific and non-specific event-related potentials. The effects of delta-9 tetrahydrocannabinol (THC) on modality-specific (primary) somatosensory stimulation in acutely prepared alpha-chloralose-anesthetized cats will be reported here. Nucleus ventralis posterolateralis of the thalamus (VPL) and the sigmoid gyri of the cortex were mapped bilaterally with recording electrodes for the location of the maximal positive-negative potential in response to contralateral radial nerve electrical stimulation. After mapping, one thalamic electrode was used to evoke a thalamocortical response, the other served to record thalamic responses to radial nerve stimulation.

THC (0.5-4.0 mg/kg) produced a dose-dependent slowing of cortical responses to radial nerve stimulation characterized by a decrease in the slope and an increase in the latency of the primary positive potential. Cortical responses evoked from the thalamus were delayed similarly. The effects of THC on the cortical evoked response to either VPL or radial nerve stimulation were dependent on the intensity of the stimulus. The 2 mg/kg dose of THC typically delayed the primary cortical response to a near maximal stimulus by 1-3 milliseconds while the response to a near threshold stimulus was markedly attenuated. In contrast to the effects on cortical responses, THC did not alter the latency of potentials evoked from VPL by radial nerve stimulation. A cannabinoid analog, dimethylheptalpuran, which is alleged to have little or no psychotropic activity while retaining the cardiovascular activity of THC delayed the cortical response approximately 1 millisecond but did not exhibit the stimulus intensity-dependent characteristic seen with THC. These data support that THC alters thalamocortical processing of primary somatosensory activity without significantly altering the thalamic response to radial nerve input. (Supported by PHS Grant #DA-01754).

246.10 CAPSAICIN MODIFIES SENSORY EVOKED POTENTIALS FROM HABENULA, ANTERIOR HYPOTHALAMUS, DORSAL RAPHE, AND SUBSTANTIA NIGRA FROM FREELY BEHAVING RATS. L. S. Rabe*, L. M. Moreno*, and N. Dafny. Depts. of Anesthesiol. and Neurobiol. and Anat., Univ. of Texas Med. Sch. at Houston, Houston, TEX., 77025

Peripheral injections of a homovanillic acid derivative, capsaicin, have been shown to cause changes in primary sensory neurons and decreases in the amount of substance P in the dorsal horn of the spinal cord of rats. The present study was designed to assess the effects of peripheral administration of capsaicin on sensory evoked responses recorded from several brain sites. Male Sprague Dawley rats were stereotaxically implanted with permanent stainless steel teflon-coated electrodes (120μm in diameter) in areas of the brain which had been shown to have high concentrations of substance P: substantia nigra (SN), habenula (HB), dorsal raphe (DR), and anterior hypothalamus (AH). Three to five days after recovery from surgery, the unrestrained, unanesthetized rats were placed in a shielded electrophysiological test chamber for recording averaged sensory evoked responses, (AER's). A set of four AER's to both acoustic and visual stimuli (32 repetitions) were taken as controls. Another set of AER's to both acoustic and visual stimuli was recorded following each injection of capsaicin (in successive doses of 5, 10, and 20 mg/kg, sc). Between stimulations spontaneous EEG-like activity was recorded from the same electrodes as the AAER's.

A dose of 5 mg of capsaicin elicited some spiking activity from HB. At the dose of 10 mg, more frequent bursting and spiking activity appeared in HB and AH. After 20 mg all four structures exhibited spike activities. The capsaicin injections in general modified sensory evoked responses in all four brain areas. The averaged acoustic evoked responses exhibited the most consistent and apparent effects of capsaicin. The recordings from the HB and the AH had significant increases in the amplitudes of N_2 and P_3 components. This increase was dose-related, in that the highest dose of capsaicin produced the greatest increase in amplitudes. However, the averaged visual evoked responses from HB and AH showed a biphasic dose-response effect of capsaicin consisting of an increase in the amplitude of the N_2 component at the lowest dose and a decrease at the two higher doses.

The results of this study show that peripherally administered capsaicin modifies sensory information transmission in the CNS and that this effect is not identical in all brain areas. The HB exhibited the greatest effects, both to acoustic and visual stimuli : the AH was somewhat less sensitive, and the DR and SN had minimal sensitivity to capsaicin.

247.1 PREPARATION OF SYNAPTOSOMES FROM THE CENTRAL NERVOUS SYSTEM OF THE HORSESHOE CRAB Limulus polyphemus. R. Sukumar*, R.F. Newkirk*, W.E. Thomas*, and J.G. Townsel. Dept. of Physiol. and Biophys., University of Illinois Medical Center, Chicago, Il. 60612.

Subcellular fractions from the central nervous system (CNS) of Limulus were separated in 0.8 M sucrose using a floatation procedure previously applied in the preparation of synaptosomes from invertebrate nervous tissue [Newkirk, et al., Brain Res. 101:103-111, 1976]. A low speed pellet (P_1) a high speed supernatant (S_2), a floating pellicle (P_2L) and a high speed pellet (P_2^2H) were isolated from a 10 per cent homogenate of Limulus CNS. These fractions were biochemically characterized. The P_2H fraction was determined to be enriched in fumarase activity, a mitochondrial marker enzyme, while the S_2 fraction was enriched with lactic dehydrogenase activity, a cytoplasmic marker. The P_2L fraction was enriched with choline acetyltransferase activity, a presumed marker of synaptosomes. Further, a marked enrichment of acetylcholine (ACh) was seen in the P_2L fraction. This fraction also took up ^{3}H-choline in the high affinity range [Maleque, et al., Biochem. Pharmacol. 28:985-990, 1979]. Greater than 80 per cent of the ^{3}H-choline taken up into this fraction was released by osmotic shock. These results are consistent with the presence of a sequestered compartment within the P_2L (i.e. synaptosomes). Ultrastructural studies of the P_2^2L fraction revealed a diverse population of membrane bound structures. Some appeared to be large featureless membrane bound sacs while others presented well organized profiles containing mitochondria and vesicles, typical of synaptosomes. These results provide evidence that the CNS of Limulus offers a reasonable source of cholinergic synaptosomes. (Supported by NIH grant HL 24140)

247.2 **ISOLATION AND CHARACTERIZATION OF GOLGI ENRICHED FRACTIONS FROM ISOLATED NEURONS OF RAT BRAIN.** **D.S. Deshmukh*, W.D. Bear* and S. Kuizon* (Spon: G.Y. Wen). Dept. Neurochem., Institute for Basic Research in Mental Retardation, Staten Island, NY 10314.**

In order to investigate the role of Golgi apparatus (GA) in the synthesis and assembly of the plasma membranes during active period of neuronal proliferation and synaptogenesis, attempts were made to isolate GA membranes from the neuronal cell enriched fraction of brains of 8 day old rats. The procedure of Farooq et al. (Brain Res. 124, 69, 1977) was adopted for the bulk preparation of neurons, with the use of trypsin and a defined orifice nozzle for dissociation of the tissue. Neurons were obtained in a fraction at the bottom of 48% sucrose. The cells suspended in 10% sucrose medium were colected by low speed centrifugation. Yield of neuronal cells was 32 x 10^6 cells/g or 5.8 mg protein/g brain. Values of DNA and RNA/DNA ratio were 6.8 pg DNA/cell and 1.6 respectively.

The cells were homogenized with the help of a Tekmar tissuemizer in a medium containing 0.5 M sucrose and the optimal concentrations of $MgCl_2$, KCl, EGTA and dextran (BBA 542, 248, 1978), and centrifuged at 5,000 x rpm for 5 min. Density-gradient centrifugation of the supernatant yielded distinct bands of the fractions at the top of 0.72M, 0.88M, 1.13M, and 1.17M sucrose. The specific activities of the Golgi-marker enzymes, N-acetyllactosaminyl synthetase (NAL-synthetase) and thiamine pyrophosphatase (TPPase) of the 0.72M and 1.13M fractions, were about 4 to 8 times enriched over those of the whole neurons. The specific activities of these enzymes (3.8 for NAL synthetase; 2.5 for TPPase) were also enriched over those of the original brain homogenates. The recoveries of the enzyme activities were 1.2% for NAL-synthetase, 26% for TPPase in the 0.72M fraction, 5.5 and 30% in the 1.13M fraction. Recovery and relative specific activities of marker enzymes for other subcellular organelles were low in two fractions. Thus, GA was found in two fractions, at the 0.5-0.72M interface, possibly enriched in GA vesicles, the second at the 0.88-1.13M interface, probably representing the GA cisternae. **This work was supported by U.S.P.H.S. grants NS14073 and NS14480 from NIH, Bethesda, MD.**

247.3 NORMAL ONTOGENESIS OF NEURO-MUSCULAR TISSUES *in vivo* and *in vitro*. CONSTITUTIVITY OF CREATINE KINASE DURING PHYSIOLOGICAL DIFFERENTIATION OF BRAIN, HEART AND SKELETAL MUSCLE AND THE EXISTENCE OF THE TERMINAL, FUSION-CAPABLE MYOBLAST. [1,3]Oscar Ramírez, [2]Efraín Mercado*, [2]Omar Hernández*, [3]John Takahashi* and [1]Margarita Hernández*. [1]Centro de Investigación del Inst.Politécnico Nal. [2]Div. Bioquímica Inv. Científica, Centro Médico Nal. del I.M.S.S. México 14, and México 7, D.F., and [3]C.V.R.I. University of California Med. Center, San Francisco, 94143. Adult tissues of higher vertebrate with high energy requirements, such as muscle and brain, contain high levels of creatine kinase (CK) *In vivo*, it has been proposed that the first abrupt increase in cytosolic brain CK is associated with neuronal multiplication at early stages and the second increase with neuronal maturation before hatching, in chick development (Ramírez et al., (1977) J. Neurochem. 28, 411).

The aims of the present study were: 1) to determine the early ontogenesis of cytosolic chick brain and limb-bud (muscle) CK activity *in ovo*, to see if such CK activity was measurable before the advent of creatine during chick embryo development; 2) to learn whether insulin might be physiologically involved in the increase of CK activity in neuro-muscular tissues *in ovo*; 3) to decide whether thigh myogenic cells of 11-12 day-old chick embryos can fuse typically in the absence of chick embryo extract (CEE) in primary culture; 4) to investigate the role that calcium and insulin play in syncytium formation and muscle CK activation in a CEE-free medium; and 5) to elucidate if chick skeletal fibro myogenic CK was also constitutive in cultures fed continuously in a creatine-free medium. The brain enzyme appeared at stage 11.5 (≃ 42 h) and increased sharply, before creatine and insulin advent *in ovo*. First detection of limb-bud CK and creatine in the whole embryo occurred at stage 24 (4.5 days) before myogenic cells can be distinguished histologically. Phosphocreatine has not been formed in the embryo before stage 28 (5 1/2 - 6 days).

In primary culture, competent (terminal) myoblasts from 11-12 day-old chick embryos could form typically aligned myotubes with 20 or more nuclei in a CEE-free medium. Typical myotube formation and CK activation depend on the conditioning of the micro-environment in creatine-free media containing from 0.3 to 1.5 mM calcium.

In early development of the chick heart, skeletal muscle and brain, CK is a constitutive enzyme regarding creatine and independent of insulin, *in vivo* and *in vitro*.

247.4 *LECTINS AS CYTOCHEMICAL PROBES FOR VISUALIZATION OF MEMBRANE* OLIGOSACCHARIDES IN HUMAN MUSCLE. S. D. J. Pena*, B. B. Gordon*, G. Karpati and S. Carpenter*. Department of Neurology and Neurosurgery, Montreal Neurological Institute, Montreal, P.Q., Canada H3A 2B4.

Biotynyl derivatives of seven plant lectins — concanavalin A (Con A), Ricin I (RCA I), wheat germ agglutinin (WGA), peanut agglutinin (PNA), soybean agglutinin (SBA), Ulex europeus agglutinin (UEA I) and Dolichos biflorus agglutinin (DBA) — were allowed to bind to cryostat sections of biopsied normal human muscle. The sections were then reacted with avidin-horseradish peroxidase conjugates and stained with 3,3'-diaminobenzidine. The most general staining was observed with Con A, RCA I and WGA which permitted strong visualization of the plasmalemma-basement membrane unit, tubular profiles in the interior of muscle fibers, blood vessels and connective tissue. PNA gave virtually no intracellular or blood vessel staining while SBA and UEA I selectively stained blood vessels. DBA was unique in providing good visualization of myonuclei. In each case, lectin staining could be blocked by appropriate sugar inhibitors. Neuraminidase treatment of the cryostat sections altered the pattern of staining of all lectins except UEA I and Con A. Staining with RCA I became stronger while that with WGA became less intense. Staining with PNA, SBA and DBA became stronger and more generalized, resembling that of RCA I. These effects of neuraminidase treatment are in conformity with the known structure of the oligosaccharide chains of membrane glycoproteins and the specificities of the lectins involved. Lectin histochemistry will certainly provide a useful new tool for the investigation of muscle disorders.
(Supported by grants from the Medical Research Council and the Muscular Dystrophy Association of Canada).

247.5 THE IMMUNOCYTOCHEMICAL LOCALIZATION OF ALCOHOL DEHYDROGENASE IN ADULT RAT CEREBRAL CORTEX. Barry Goldstein* and David S. Maxwell. Department of Anatomy, U.C.L.A., Los Angeles, California 90024

Alcohol dehydrogenase (AdH) activity in normal rat brain has been demonstrated biochemically in many laboratories. The presence of the enzyme suggests that the central nervous system can metabolize ethanol, although this capacity appears to be quite limited. This study utilizes the immunocytochemical method to determine the cellular localization of rat brain alcohol dehydrogenase in the cerebral cortex.

Antisera against alcohol dehydrogenase was obtained from rabbits that were injected with horse liver alcohol dehydrogenase. Appropriate biochemical and immunochemical studies were completed to establish the titer of the antisera and determine the cross-reactivity and specificity of the rabbit anti-alcohol dehydrogenase antibodies. These methods included spectrophotometric assays for AdH, the Ouchterlony double diffusion method, and immunotitration (enzyme-inactivation) studies.

Three immunocytochemical methods were compared, the peroxidase antiperoxidase (PAP) method, the indirect horseradish peroxidase-labeled antibody method, and the indirect fluorescein-labeled antibody method. A modified PAP method yielded the best results for both light and electron microscopy.

Neurons in the deeper layers of the cerebral cortex were the only cells that contained reaction product after staining. Cell bodies, processes and specific synapses were intensely stained. Astrocytes and oligodendrocytes did not contain any reaction product. Parallel control sections were all negative.

The light microscopic appearance of the cortical neurons displayed cell bodies with unstained nuclei and long apical processes continuing towards the surface of the brain. All areas of the cortex contained labeled neurons but the greatest density of cells was observed in the motor cortex. Electron microscopy demonstrated the reaction product in the cytoplasm of neurons and in many profiles of sectioned processes.

This study has established a means for the morphological localization of alcohol dehydrogenase in the rat cerebral cortex. This method offers an approach to study the distribution of this enzyme in different brain regions and after various experimental conditions. In addition, alcohol dehydrogenase might prove to be a useful neuronal-specific enzyme. (Supported by Grant AA03513-03 from the National Institute on Alcohol Abuse and Alcoholism.)

247.6 ULTRASTRUCTURAL LOCALIZATION OF NON-SPECIFIC ESTERASE IN NORMAL AND PATHOLOGIC HUMAN MUSCLE. V. Askanas, E.K. Worthington*, W.K. Engel and G.G. Cunningham*. Neuromuscular Diseases Section, NINCDS, NIH, Bethesda, MD 20205

Light microscopic evaluation of non-specific esterase (NSE) staining on fresh-frozen sections of abnormal human muscle is of diagnostic value. Highlighted by the NSE reaction are positively stained small, angular fibers (diagnostic of denervation), tubular aggregates, regenerating-degenerating fibers and macrophages (in inflammatory-cell reactions). In normal muscle the NSE reaction stains end-plates and distinguishes fiber types and subtypes of type-I fibers. We have developed an ultrastructural technique for NSE and studied 39 normal and pathological muscle biopsies from patients with different neuromuscular diseases. The technique of Nachlas and Seligman (J. Biol. Chemistry 151: 343, 1949) was modified for EM. Elimination of any component of the histochemical reaction prevented staining. The NSE-EM reaction was fully inhibited by phenylmethyl sulfonyl fluoride 10^{-2}M. Eserine 10^{-4}M, iso-OMPA 10^{-3}M, or BW284C51 dibromide 10^{-4}M minimally decreased (but did not abolish) the NSE-EM reaction. In both normal and abnormal muscle the reaction product of NSE-EM was localized to plasmalemma, t-tubules (but not sarcoplasmic reticulum), and mitochondrial outer > inner membrane (but not cristae, suggesting different enzymatic composition of cristae cf. inner mitochondrial membrane). In abnormal muscle, bizarrely shaped mitochondria in carnitine deficiency were highlighted by NSE including their proliferated cristae. Tubular aggregates (considered to be proliferations of sarcoplasmic reticulum, Engel, Bishop, Cunningham, J. Ultrastruct. Res. 31: 507-525, 1970) of type-II fibers were also positively stained with NSE. The dark staining of angular fibers could be only partly attributed to the denser accumulation of mitochondria per cross-sectional unit: the individual mitochondria had darker outer and inner membranes, and, especially, the myofibrils of small, angular fibers stained darker than normal, suggesting that loss of neural trophic influence changes enzymatic properties of both mitochondria and myofibrils.

Thus, under different circumstances pathologic mitochondria (outer and inner membranes and/or cristae), sarcoplasmic reticulum, and myofibrils can be stained excessively by the NSE-EM. Accordingly, ultrastructural localization of NSE may become an important tool for demonstrating enzymatic properties of different organelles in pathological muscle.

247.7 TISSUE CULTURES OF GOLDFISH BRAIN EPENDYMAL ZONE CELLS: IMMUNOHISTOCHEMICAL IDENTIFICATION OF β AND γ EPENDYMIN, NGF AND GFA CONTAINING CELLS. R. E. Majocha* and V. E. Shashoua (SPON: G. Hauser). Mailman Research Center, McLean Hospital, Harvard Medical School, Belmont, MA 02178.

In previous investigations, two proteins (β and γ Ependymins) localized in the ependymal zone of goldfish brain were found to be associated with the process of acquisition of new patterns of behavior (Shashoua, V.E., Science, 193:1264, 1976). The ependymal zone also has NGF containing cells (Benowitz, L. and Shashoua, V.E., Brain Res., 172:561, 1979). These findings have stimulated us to develop a tissue culture system for the growth and characterization of ependymal zone cells.

Excised ependymal tissue from the ventricular surface of optic tecta was used as a source for several types of cells by mild trypsinization. These were grown on polylysine-coated glass slides in Medium 199 with 10% fetal calf plus 5% calf serum in an atmosphere of 1% CO_2 in air at 22° C.

At 3-5 days after plating, the initially uniformly dispersed round undifferentiated cells begin to sprout processes and to form micro-aggregates 50-200 μm in diameter. At about 10 days multiple fiber connections develop between islets of cells. Such culture could be maintained at least 5 weeks in vitro. Immunohistochemical studies with antisera to the β and γ Ependymins, to NGF and to GFA (antiserum obtained from Drs. Bignami and Dahl) showed that each antiserum stained a different but distinct cell type within the cultures.

Cells containing β and γ sent out multiple processes which could be seen as early as 24 hours after plating. Brilliant staining varicosities were visible on the membrane surfaces and along their processes. Morphologically the cells resembled glia.

The NGF-containing cells had a fibrous appearance with maximum staining localized in their processes; cell soma were only faintly stained. GFA containing cells were similar to NGF cells morphologically. They differed, however, in their staining patterns; anti-GFA could intensely stain processes as well as cell bodies. Light microscopy studies of cresyl violet stained cultures indicate that these ependymal zone cultures also contain "neuron-like" as well as a background of fibroblast cells. These results demonstrate that the ependymal zone of goldfish contains a multiple population of cells which can be maintained in culture and that at least three types retain their in vivo capacity to produce specific proteins which can be visualized by immunohistochemical methods.

247.8 NEURON SPECIFIC ENOLASE (NSE) AND NON-NEURONAL ENOLASE (NNE) IMMUNOREACTIVITY IN PRIMARY CULTURES FROM FETAL RAT BRAIN. J.A. Weyhenmeyer*, M.K. Raizada*, P.J. Marangos, and R.E. Fellows. School of Basic Medical Science, University of Illinois, Urbana, IL 61801, Department of Physiology and Biophysics, The University of Iowa, Iowa City, IA 52242, and National Institute of Mental Health, Bethesda, MD 20205.

Recently the existence of two physiologically distinct glycolytic isoenzymes, neuron specific enolase (NSE) and non-neuronal enolase (NNE) has been reported in mammalian brain. The purpose of this investigation was to determine whether antisera to these enzymes can be used as specific neuronal and glial markers in primary cell cultures from fetal rat brain. Cells were dissociated from 20-day fetal brain with trypsin and were grown in Dulbecco's modified Eagle's medium (DME) with 10% fetal bovine serum in 35mm tissue culture dishes containing 11x22mm glass coverslips. Brain cells were used for experiments after 4, 6, 8, 10, 12 and 14 days in culture. Cells were stained by the peroxidase-anti-peroxidase method using highly specific antisera to NSE or NNE and buffered diaminobenzidine-H_2O_2. Typically, these cultures consist of phase-dark cells over a background monolayer of large flat cells of glial origin. The phase-dark cells have been characterized on the basis of morphological and physiological criteria as neurons. NSE immunoreactivity was demonstrated as dense staining limited to the neuronal cell body and processes, without staining of glial elements. NSE was also localized in varicosity-like structures along the length of neurites. Immunoreactive NNE was observed only in large, flat cells of glial origin, with no staining of neurons. A progressive increase in percentage of NSE-positive neurons was observed with increasing time in culture between 4 and 14 days. A decrease in NNE immunoreactivity of glial elements also occurred over the same time period. The observation that the number of positively stained neurons increases with time suggests that the neuronal population is capable of undergoing differentiation under the conditions of cell culture. This research is supported by NIH grants HD11184 and HL24402 to REF.

247.9 CNA-1: A NEURAL AND AVIAN SPECIFIC ANTIGEN. J.D. Redshaw* and D.J. McCallion*, (Spon.: M. Bisby). Department of Anatomy, McMaster University, Hamilton, Ontario L8S 4J9, Canada

Chicken neural antigen-1 (CNA-1), a saline soluble antigen has been isolated and purified from adult chicken brain tissue extract. The purification of CNA-1 was performed by using salt fractionation, chromatographic methods (ion exchange and gel filtration) and polyacrylamide gel electrophoresis. Each step of the purification procedure was monitored using quantitative immunoelectrophoretic techniques. A 76.9-fold purification was achieved with a 0.9% yield. The purified antigen demonstrated alpha-1 globulin mobility during immunoelectrophoresis, a molecular weight of 65,000 daltons by molecular exclusion chromatography, and two identical subunits (30,000 MW) during SDS-polyacrylamide gel electrophoresis. CNA-1 accounted for about 1.3% of the total soluble protein within the adult brain extract. By immunochemical criteria, CNA-1 was demonstrated to be both avian restricted (not present in brain extracts of mammalian species) as well as neural specific (not present in non-neural tissue extracts). The CNA-1 antigenic determinant was found to be protein in nature, since treatment with either chymotrypsin or trypsin resulted in a loss of antigenicity. Molecular weight heterogeneity of CNA-1 on molecular exclusion chromatography (> 1,500,000 and 65,000 MW) was also revealed with the use of a monospecific antiserum directed against the antigen. CNA-1 was detected as early as the seventh day of incubation in embryonic brain extracts and found to accumulate within the developing embryonic brain from Day 7 to hatching. Both neurogenesis and synaptogenesis are known to occur during this period within the chicken CNS. Prehatching (Day 20) levels were observed to be only 54.0% of adult CNA-1 levels, therefore accumulation of the antigen continues until adult levels are achieved. Immunohistochemical localization studies demonstrated CNA-1 specifically localized on neuronal plasma membranes and processes. However not all neuronal types expressed the antigenic label. Further studies are in progress to elucidate the role of CNA-1 in embryonic development and adult function.

247.10 MONOCLONAL ANTIBODIES TO THE SYNAPSE. E. Niday and R. Hawks*. Freidrich Miescher-Institut, P.O.Box 273, CH-4002 Basel, Switzerland.

We wish to identify markers specific to cell types and regions of the brain. To this end we are producing a series of monoclonal antibodies to the rat brain synaptic plasma membrane (SPM). These membranes, composed of pre- and postsynaptic components, were isolated by differential centrifugations of brain homogenates. Spleen cells from mice immunized against SPM were fused to a myeloma cell line and the hybridomas were selected according to Köhler and Milstein (Eur. J. Immunol., 6:511, 1976).

Antibody production was detected in the culture media with a peroxidase labelled sandwiching technique. Millipore filters were spotted with 1.0 µl of a 100 µg/ml solution of antigen, incubated with conditioned media containing concentrations between 3-15 µg of putative antibody, then allowed to react with commercially available peroxidase labelled rabbit anti-mouse immunoglobulin.

We can use these monoclonal antibodies to determine the distribution of specific proteins in the brain. Firstly, we can identify the specific protein antigen by separating the SPM proteins on SDS-PAGE, electrophoretically transferring the proteins onto nitrocellulose filters following the method of Towbin et al. (Towbin, H., Staehelin, T., and Gordon, J., Proc. Natl. Acad. Sci. USA, 76:4350, 1979), and reacting the "Towbin Blot" with monoclonal antibodies. Secondly, we determine the distribution of that protein in the brain by immunohistochemistry.

247.11 IMMUNOHISTOCHEMISTRY OF MONOCLONAL ANTIBODIES TO SYNAPTIC ANTIGENIC DETERMINANTS. R. S. Lasher and P. F. Erickson*. University Colorado Medical School, Denver, Co. 80262

In an attempt to develop immunologic probes for use in the analysis of the membrane components of synapses and their role in synapse formation, synaptosomes or fractions of synaptosomal membranes were used to produce antibodies in BALB/c mice. Spleen cells from these mice were fused either with P3X63-Ag8 or with P3-NSI/1-Ag4-1 myeloma cells using PEG 1000. The cells were cultured in 24-well dishes containing DME+20%FBS+HAT+50µM 2-ME. Wells containing the desired hybridomas were identified by utilizing a binding assay involving incubation of the culture medium with synaptosomes and I-125 protein A. Cells in positive wells were cloned, all of the clones were assayed, and positive clones were grown up and used to produce ascites in Pristane-primed mice.

Eight different monoclonal antibodies have been produced thus far, and light and electron microscopic immunohistochemical studies have been initiated on 5 of them (A45,A78,A105,A110,A112). Anesthetized rats were perfused through the ventricle with cold 5% paraformaldehyde in 0.15M phosphate buffer. After fixation for 3 hrs., 50 µm sections of the desired areas were cut using a Vibratome, and then were processed using a number of indirect procedures employing protein A as a linker and either anti-HRP + HRP or PAP. In one case (A78), 0.2% Triton X-100 was required in the initial incubation step. Either normal mouse serum or ascites produced by P3X63-Ag8 cells was used as a control. Sections were postfixed in 1% OsO4, stained briefly in 1% aqueous uranyl acetate, dehydrated, embedded in Epon and sectioned.

The antibodies were found to react with the following antgenic determinants (only the areas listed were examined). A45: (a) in the nuclei of neurons in the cerebellum, choroid epithelial cells and smooth muscle cells; and (b) within dendrites and to a small extent on plasma membranes of Purkinje cells. Biochemical evidence suggests that the antigenic determinant is in a carbohydrate present on a large number of glycoproteins. A78: in the presynaptic dense projections and postsynaptic density of many (all?) synapses in the cerebellum and substantia nigra. A105: mainly in postsynaptic dendritic profiles (on the plasma membrane, around microtubules and mitochondria; cerebral cortex, cerebellum, spinal cord); also in some presynaptic terminals, esp. cerebellar glomeruli, on the plasma membrane, around synaptic vesicles and mitochondria; and in neuronal soma (spinal cord). A110: in the plasma membrane and cytoplasm of climbing fibers and terminals, and associated regions of dendrites of Purkinje cells (cerebellum). A112: mainly in Purkinje cell dendrites and processes of Bergmann glial cells. Characterization of the antigenic determinants involved is underway. Supported by NINCDS grants NS-09199 and NS-13133.

247.12 SPATIAL AND TEMPORAL DISTRIBUTION OF SYNAPTIC VESICLES IN NERVE TERMINALS VIEWED WITH HIGH-VOLTAGE ELECTRON MICROSCOPY. W.D. Niles and D.O. Smith. Department of Physiology, University of Wisconsin, Madison, WI 53706.

The spatial and temporal distribution of synaptic vesicles in the terminals of the excitor axons of the crayfish walking leg were viewed with high-voltage electron microscopy. The tissue was fixed in 4% glutaraldehyde in either phosphate or cacodylate buffer. After postfixation in 1% OsO4, dehydration and embedding in Spurr, sections ranging in thickness from 0.1 to 0.5 µm were cut and stained with uranyl-magnesium acetate and Sato's lead. Synaptic terminals of the excitor axon were readily identified by their round vesicles, which fell into size groups with diameters of 40 to 70 nm and larger than 100 nm.

In nonstimulated tissue, the smaller vesicles clustered around the active zone and the larger vesicles were situated around the peripheral regions of this cluster. The entire population of vesicles was surrounded in most terminals by large, irregularly shaped mitochondria. Microtubules were seen to project from the more proximal region of the axon, to pass in close apposition to these mitochondria, and then to continue through the cluster of vesicles towards the active zone. In some preparations, vesicles were seen in contact with these structures.

Electrical stimulation of 30 impulses/s of the axon before and during fixation altered the ultrastructure of the terminals. In some cases, a filamentous network was seen to radiate from the microtubules. The axolemma overlying junctional folds was smooth in nonstimulated tissue but exhibited extensive involutions into the interior regions of the terminal following 15 min of stimulation or of incubation in physiologic saline with 20 mM K^+. After 90 min of stimulation, elongated cisternae measuring about 50 nm x 200 nm were intermingled with the synaptic vesicles.

When horseradish peroxidase (HRP) was added to the extracellular environment, uptake into the terminals was not observed in the absence of stimulation. After 15 min of stimulation (30 impulses/s), HRP appeared in the involutions and in a few synaptic vesicles located at the periphery of the vesicle cluster in the center of the terminal. After 90 min of stimulation with HRP added during the final 30 min, labeled vesicles were present throughout the cluster and apparently in contact with the mitochondria.

It is hypothesized that vesicles are recovered via the involutions and cisternae in the central region of the terminal. Then they are transported along microtubules past mitochondria, with which they may come into contact, into the cluster overlying the active zone. Supported by NIH grants NS13600 and NS00380 and the Alfred P. Sloan Foundation; W.D.N. was supported by an NIH training grant to the Neurosciences Training Program.

247.13 GROWTH CONE MOTILITY: HIGH-VOLTAGE ULTRASTRUCTURAL OBSERVATIONS OF INDIVIDUAL NEURONS WITH DOCUMENTED MOTILE HISTORIES. K. W. Tosney* and N. K. Wessells* (SPON: L. Landmesser). Biol. Dept., Stanford U., Stanford, CA 94305 and MCDB, U. Colorado, Boulder, CO 80309.

The motile activity of neurons is characterized by the extension, movement, and retraction of lamellepodia ("veils") and rodlike filopodia ("microspikes") along the leading edge of "growth cones", the tips of elongating neurites. We have filmed the motile activity of individual chick ciliary ganglion neurons and examined the same cells with high-voltage electron microscopy. Since this combination of techniques allows, for the first time, a direct correlation between the ultrastructure and the local, short-term motile history of a cell, we hoped to gain insights into the mechanisms of cell surface extension, adhesion, and turnover during cellular motility.

We find that recently extended veils contain only cortical lattice elements; microtubules and large membrane-bound organelles are absent. In contrast, sites of recent veil retraction contain strings of vesicles between the cortical lattice and the naked, complexly folded, upper membrane. In general, other large vesicle groups occur only in bulbous, retracting growth cones or in glutaraldehyde-induced artifacts ("blisters"). Areas without veil activity contain a three-dimensional microtrabecular lattice without vesicle clusters. These observations suggest that the generation of new surface area during extension of processes does not involve local populations of large vesicular elements. However, the mechanism of cell surface retrieval may transiently produce vesicles during veil retraction, or may alter membrane-cytoskeletal relationships in a manner that renders the local area highly susceptible to blistering upon fixation.

We also find differences between fixed and moving processes. Attached microspikes contain closely packed and aligned lattice elements which often extend as a small stress fiber into the body of the growth cone. In contrast, unattached microspikes have a more open, criss-cross array of lattice elements. Similarly, in actively extending veils, the lattice elements, while planar, are also criss-cross and loosely arranged. Compact trabecular arrangements generally insert into areas of apparant adhesion located proximal to the area of newest extension. These results suggest that the mechanism of cell surface extension operates through loosely packed trabecular elements, rather than through more compact trabecular arrangements. The latter are probably generated at adhesion points subsequent to extension.

247.14 A SINGLE NEURON EXPRESSES MULTIPLE FORMS OF TUBULIN. K.J. Sweadner and I. Gozes. Dept. of Neurobiology, Harvard Med. School, Boston, MA 02115 and Lab. of Neural Endocrine Regulation, MIT, Cambridge MA 02138.

Given the structural complexity of neurons in the mature brain it is of interest that a major cytoskeletal component, tubulin, has multiple molecular forms. In contrast to non-neuronal tissues, the brain has nine different molecular forms, which can be separated by isoelectric focusing[1]. This tubulin heterogeneity could result from different kinds of cells having different tubulin forms or from single cells having multiple tubulin forms, each serving different cellular functions.

We have analyzed the tubulin forms present in mature sympathetic neurons grown in dissociated cell culture. Non-neuronal cells are eliminated with cytosine arabinoside. Cultures of ~5000 cells were labeled with [^{35}S]methionine, and tubulin was isolated by vinblastine precipitation in the presence of unlabeled brain carrier. When analyzed by isoelectric focusing and autoradiography, tubulin from the cultures exhibited a similar pattern to brain tubulin. Solitary neurons growing in microwells of Terasaki tissue culture plates were labeled and analyzed in the same way; we are showing here for the first time the successful isolation and characterization of a protein from a single mammalian cell. Single neurons exhibited a tubulin isoelectric pattern identical to that of the mass cultures. Multiple tubulin forms thus can be found in a single cell.

Conditioned medium from heart cells induces the synthesis of acetylcholine in these otherwise adrenergic neurons[2] and alters the expression of several cell surface and extracellular proteins[3]. In dense cultures, conditioned medium also appears to cause the neuronal cell bodies to assume a more flattened morphology, as observed by phase-contrast microscopy. Close inspection of the tubulin forms present in cultures grown with and without conditioned medium reveals a small but reproducible quantitative difference which may correlate with the change in cell shape.

247.15 DEVELOPING NODES OF RANVIER IN FROG AND RAT PERIPHERAL AND CENTRAL AXONS. Jung-Hwa Tao-Cheng* and Jack Rosenbluth. (SPON: E.SIMON). Depts. of Physiology and Rehab. Medicine, New York University School of Medicine, New York, N.Y. 10016.

In an ultrastructural study of myelinogenesis in tadpole sciatic nerves it was shown that the length of the presumptive nodal membrane is generally much more extensive than that of the adult node and that the appearance of the nodal "undercoating" and E face particles are very variable during development. Paranodal regions develop asymmetrically, and typically the paranodal "loops" are widely separated from each other. Those closest to the node consistently exhibit the characteristic "transverse bands" and associated ER cisternae flattened against the junctional Schwann cell membrane while the loops further removed from the node usually do not.

Study of myelinogenesis in a mammalian peripheral nerve and in the mammalian and amphibian central nervous system shows that the sequence of events is comparable in these locations, but differs in some details. In the sciatic nerve of 2-3 day rats the developing nodes are also usually relatively long and the paranodal loops widely separated. Here too only the loops closest to the node exhibit distinct transverse bands in association with ER cisternae against the Schwann cell junctional membrane. However, unlike developing nodes in tadpole peripheral nerves, where well-differentiated paranodal junctions are frequently observed even when there are only two or three Schwann cell loops present, those in young rats usually do not exhibit distinct transverse bands until the sheath contains at least five layers. The staining of the transverse bands is also less intense in rats than in tadpoles. In the optic nerves of both young rats and tadpoles, developing nodes also tend to be very elongated compared with adult nodes. Paranodal loops are widely spaced, and again only those paranodal loops closest to the node have transverse bands. However, ER cisternae are not consistently observed in these loops, and when they are present they are not necessarily closely apposed to the junctional glial membrane.

Thus, in developing mammalian as in amphibian nerves, both centrally and peripherally, the paranodal transverse bands appear consistently in the glial or Schwann cell loops closest to the nodal region but not in those further removed; the node is initially elongated and gradually becomes restricted in length as the paranodal regions develop; the paranodal regions usually mature asymmetrically and the paranodal loops become more closely spaced as development pregresses. These observations indicate that the same mechanisms probably operate in myelin formation by oligodendrocytes in the central nervous system and by Schwann cells in the peripheral nervous system.

247.16 MEMBRANE SPECIALIZATIONS IN FROG EPENDYMAL ASTROCYTES. Gary E. Korte* and Jack Rosenbluth. Depts. of Physiology & Rehabilitation Med., New York University School of Medicine, New York, N.Y.10016.

Ependymal cells in the amphibian central nervous system have characteristics of both ependymal cells and astrocytes, and hence have been called "ependymal astrocytes." Those in the cerebellum of the frog Rana pipiens have an orderly arrangement which makes them advantageous for study in thin sections and freeze-fracture replicas.

The cell bodies line the fourth ventricle and extend microvilli and cilia into the cerebrospinal fluid. The outer surface of the membrane facing the ventricle binds positively charged ferric oxide, signifying the presence of abundant anionic molecules at this surface. The binding is markedly reduced after neuraminidase treatment, indicating it is largely due to sialic acid. We did not observe binding on the membrane of the lateral and pial surfaces of the cells.

Basal processes arise from the cell bodies, traverse the granule cell layer and molecular layer, and terminate as subpial endfeet. At all levels they contain conspicuous glycogen particles and 9-10nm filaments. Along their course the processes give rise to lamellar appendages which, in the molecular layer, selectively enwrap synapsing parallel fiber boutons and Purkinje cell dendritic spines in one to several cytoplasmic sheets. Other types of synapses are not so ensheathed. Lamellar appendages also contact neuronal somata and their processes and form incomplete though extensive sheaths around capillaries.

In freeze-fracture replicas the intramembranous particles of the ependymal astrocyte plasma membrane have a higher concentration and a greater mean size than those of neuronal membranes in the same replicas. Numerous gap junctions occur, some with particle-poor "windows." Some windows appear to be forming by the addition of rows of particles at the periphery of the gap junction. Tight junctions were not observed; nor did we find orthogonal"assemblies"of particles such as those described in mammalian astrocyte and ependymal cell plasma membranes.

The observations support the notion that these cells combine the morphological characteristics of ependymal cells and astrocytes. Presumably, they also combine the functions that have been attributed to both cell types, such as isolation of synapses by ensheathment,and secretion, absorption or reception at the ventricular surface, requiring a biochemically specialized plasma membrane at this site. The freeze-fracture observations also emphasize the marked morphological differences between ependymal astrocyte and neuronal plasma membranes, which probably reflect significant biochemical differences between them.

Supported by Fellowship #F32-NS05846-02 and grant #NS 07495 from the NIH.

247.17 ELECTRON MICROSCOPIC QUANTIFICATION OF TRANSPORTED RADIOACTIVITY AND SYNAPTIC MORPHOLOGY IN AUTORADIOGRAPHS: A PRACTICAL APPROACH FOR ROUTINE USE. D.L. Oliver, L.T. Andrus*, and D.K. Morest. Dept. of Anatomy, Univ. Conn. Hlth. Ctr., Farmington, CT

EM autoradiography of synaptic endings after axonal transport of ^{3}H amino acids can be used to relate the fine structure of synapses to their connections. However, the method is limited by resolution and subjective observations. Quantitative methods accurately establish sources of radioactivity and discount silver grains due to beta scatter. Quantitative methods can demonstrate synaptic types that differ in subtle ways. In these methods, we use two batteries of FORTRAN programs with an LSI-11 microprocessor and a Graf Pen Digitizer.

We injected ^{3}H-leucine and/or proline in the caudal cochlear nucleus of cats and examined the resulting label in the inferior colliculus. Autoradigraphs were exposed for 8-34 weeks and quantified after the method of Blackett & Parry ('77). This method compares the actual distribution of grains to a hypothetical random distribution of silver grains and sources generated from the resolution formulae for the material. The silver grains were counted in the following compartments: postsynaptic structure, axon,glia, endings with round vesicles, with flattened vesicles, or combinations of these. A best fitting routine was used to minimize the differences between the real and hypothetical grain distributions and calculate the relative amounts of activity in each potential source. In our material, most silver grains were over axons, endings with round vesicles, or axon/glia. Our analysis showed that the labeling of endings was 3-30x greater than expected if random. The frequency of axonal and glial labeling was less than expected if random, yet it was not completely explained by scatter. Hence, the axons and glia also contain radioactivity.

In the digitizing process we measured area, perimeter, long axis, average diameter, and roundness of synaptic vesicles in normal sections and autoradiographs. We found that endings clustered into three groups containing synaptic vesicles of different average diameter and roundness. Each group may contain subgroups distinguished by terminal size and vesicle concentration. Most labeled terminals fell into the group with smaller-sized, round synaptic vesicles. Thus, the quantitative analyses systematically indicate each of the particular classes of axon terminals that are labeled following injections in the caudal cochlear nucleus.

(Supported by USPHS grant 5 RO1 NS14347.)

247.18 THE USE OF A WHEAT GERM AGGLUTININ - HORSERADISH PEROXIDASE CONJUGATE FOR ANTERO- AND RETROGRADE TRACING IN THE CNS. C.W. Scouten and C.W. Malsbury. Department of Psychology, Memorial University of Newfoundland, St. John's, Newfoundland, Canada, A1B 3X9.

Wheat germ agglutinin (WGA) binds to neuronal membranes and can be absorbed by phagocytosis, a more rapid and efficient uptake mechanism than that which allows non-binding molecules, such as horseradish peroxidase (HRP) to enter cells. Like HRP, WGA undergoes axonal transport and has been used for the retrograde tracing of neural connections. Pressure injections of radio-labeled WGA (^{125}I) have been used to demonstrate afferent connections of the hippocampus (Schwab et al. Brain Res., 1978) and hypothalamus (Wiegand & Price, Soc. Neurosci. abst., 1979). In these cases autoradiography was used to visualize WGA-labeled cells. One of the disadvantages of this method is the time required for exposure of the autoradiograms. Gonatas et al. (J. Histochem. Cytochem., 1979) have now reported that WGA coupled to horseradish peroxidase (HRP) can be used as a retrograde tracer. This has the advantage of enabling one to use an easy, rapid and sensitive histochemical procedure (Mesulam, J. Histochem. Cytochem., 1978) to visualize the location of the WGA-HRP conjugate. In addition, Gonatas et al. found that WGA-HRP was 40 times more sensitive than free HRP for the retrograde labeling of neurons innervating the submandibular gland of the rat.

The present results demonstrate that WGA-HRP is also an extremely useful tool for tracing connections when applied intracerebrally. We have used a commercially available WGA-HRP conjugate (Sigma #L9008, WGA to HRP Type VI) and have found: 1) as with free HRP, WGA-HRP can be applied using the iontophoretic method via micropipettes; 2) there appears to be less diffusion away from the injection site as compared to that seen with free HRP; 3) the vascular staining (uptake by pericytes) characteristic of injections of free HRP is nearly eliminated; and 4) the method is sensitive, as both anterograde and retrograde transport can be demonstrated even with small injection sites. The ability to produce well-localized injections with less diffusion than free HRP and no vascular staining gives WGA-HRP significant advantages for tracing CNS connections. These properties, and the sensitivity of the method, are probably due to the rapid binding of WGA to neuronal membranes near the injection site, followed by phagocytosis and transport.

247.19 IDENTIFICATION AND ISOLATION IN-VITRO OF PRESUMPTIVE MOTONEURONS MARKED BY RETROGRADE TRANSPORT OF A NEW FLUORESCENT TRACER. Martha McPheeters and Lawrence M. Okun*, Department of Biology, University of Utah, Salt Lake City, Utah 84112.

As an approach to obtaining cell populations enriched for selected neuronal classes, we are exploring the automated sorting of neurons rendered fluorescent by retrograde transport.

We have prepared a tracer potentially suitable for this purpose from wheat germ agglutinin, a plant lectin that is efficiently accumulated in neuronal cell bodies when injected near their axon terminals (Schwab et al, Brian Res 152: 145-150, 1978), by conjugating it with Lucifer Yellow VS, a fluorochroming reagent that combines good quantum yield and resistance to fading under exciting illumination (Stewart, Cell 14: 741-759, 1978). This conjugate, WGLY, when injected into hindlimb muscles of chick embryos, yielded brightly fluorescent labeling, mostly in the form of small cytoplasmic granules, of neurons at expected positions in spinal cord (and at scattered positions in ipsilateral, lumbosacral DRGs) visible in formalin-fixed, frozen sections from embryos sacrificed 12-18 hours after the injections. The numbers and positions of spinal-cord neurons labeled by WGLY were comparable to those of cord neurons labeled by control injections of horseradish peroxidase (HRP), in 30-fold higher amounts, delivered to the same muscles.

Fluorescent cells were also found, at expected low frequencies, in dissociated-cell suspensions prepared from spinal cords marked by transport of WGLY from muscle, and the level of fluorescence in the dissociated cells was sufficient for detection by a commercially available, fluorescence-activated cell sorter (FACS III, Becton Dickinson) which could provide samples enriched, virtually to purity, for fluorescent cells.

From their appearance and location in situ as well as from their correspondence to populations marked by retrograde transport of HRP, the spinal-cord neurons labeled by WGLY injected into muscle may be regarded as motoneurons. It remains to be determined whether any cord cells unlabeled by WGLY in situ become fluorescent during dissociation or other preparative steps prior to the fluorescence-activated sorting. If they do not, then the sorted samples will constitute highly-enriched preparations of rigorously-identified spinal motoneurons. The same approach can, in principle, permit preparation of enriched samples of any neuronal class that can be selectively labeled by somatopetal transport of a fluorescent substance. (Supported by NIH Grant NS 10615, by a Graduate Fellowship from the Danforth Foundation to M.M. and by an Established Investigator Award from the American Heart Association to L.M.O. Lucifer Yellow VS was a gift from W. Stewart.)

247.20 IDENTIFICATION OF OSMIUM IMPREGNATED MYELINATED AXONS IN THE SCANNING ELECTRON MICROSCOPE UTILIZING THE BACKSCATTER ELECTRON MODE. Peter L. Friedman* and Mark H. Ellisman (Spon: S.D. Flanagan), Dept. of Neuroscience, U. Calif. at San Diego, La Jolla, CA 92093

No morphological criteria currently exists for identifying specific cellular or fibrillar components of the nervous system with the scanning electron microscope (SEM). This inability to differentiate neuritic from glial components or even axons from dendrites constitutes a primary deterrent to the reliable and routine use of the SEM in the further morphological characterization of the nervous system.

Three techniques have been combined that facilitate the identification of myelinated axons in the SEM: A) aqueous cryofracture; B) a modified osmium-thiocarbohydrazide-osmium (OTOTO) regime permitting unrestricted secondary electron (SE) mode examination of nervous tissue in the SEM at magnifications in excess of 80,000X, and C) backscatter electron (BSE) mode identification of myelinated axons.

Human spinal cord and spinal nerves, and rat cerebral and cerebellar cortex, retina and cochlea were fixed by immersion or perfusion in 3% glutaraldehyde and 1% paraformaldehyde in 0.135 M Na-cacodylate buffer, pH 7.35 containing 3.5% sucrose. Tissues were rinsed in buffer, post-fixed in 2% OsO_4 (buffered as above) for 1.5h., and again rinsed in buffer. Tissues were then frozen in slush point liquid nitrogen for 3-10 min. and cryo-fractured under nitrogen. Tissues were then placed immediately into 2% buffered OsO_4 for 30-60 min., rinsed, immersed in a fresh, saturated, filtered, aqueous solution of thiocarbohydrazide (TCH) for 15 min., rinsed, immersed in 1% aqueous OsO_4 for 30 min., rinsed, placed into TCH for 15 min., rinsed, immersed in 1% OsO_4 for 30 min., dehydrated with ethanol and critical point dried with CO_2. Tissues were examined in an ETEC Autoscan equipped with a solid state, independent BSE detector at 20kV.

The location and amount of osmium in spinal nerves and in bipolar neurons after OTOTO impregnation was determined by transmission electron microscopy, energy dispersive microanalysis of x-rays, and by the analog line scan of SEM specimens. These approaches yielded both qualitative and semi-quantitative evidence suggesting that the greatest concentration of osmium was confined to the myelin sheath. This enhanced impregnation of myelin by osmium appears to form the basis for the BSE identification of myelin sheaths.

247.21 SILVER IMPREGNATION OF PRE-MOUNTED NEURAL TISSUE. A. Firl*, E. J. Mufson and D. G. Stein, Clark University and U. Mass. Medical Center, Worcester, MA 01610 and Beth Israel Hospital, Boston, MA 02215.

The Fink-Heimer technique for the demonstration of axonal degeneration involves the soaking of free floating sections in several solutions prior to mounting on glass slides. This procedure has several disadvantages including shrinkage of tissue, textural tissue changes, as well as tearing and wrinkling of tissue. These factors make tissue mounting and data analysis difficult. We present a modification of the Fink-Heimer method in which tissue is mounted on glass slides prior to staining.

Rats were perfused (.9% physiological saline followed by 10% formol-saline) 1-14 days after central nervous system (CNS) lesions and their brains were removed and placed in 10% formalin for several days and then soaked in 30% sucrose-formalin until the brains sank. The brains were then embedded in a 12% gelatin-egg yolk matrix, hardened in 10% formalin, placed in 30% sucrose-formalin for 5 days, cut at 25 µm on a freezing microtome and stored in 10% formalin. Sections were mounted from distilled water onto slides pretreated with 1% pig-gelatin solution and air dried. All solutions were prepared with distilled water. Following two 3 minute rinses, slides were placed in .05% potassium permanganate for a predetermined period, rinsed (twice at 3 min), bleached (equal parts of 1% oxalic acid and 1% hydroquinone), rinsed (twice at 3 min), placed in 2.5% uranyl nitrate (10 min), rinsed (1 min) and placed in 2.5% silver nitrate (60 min). Sections were then rinsed (3 min) and immersed for 2 minutes in a freshly prepared ammonical silver solution consisting of: Part A- concentrated ammonium hydroxide and 2.5% sodium hydroxide in a ratio of 3:1; part B- 2.5% silver nitrate and 100% ethanol in a ratio of 2:1. Solutions A and B were combined until the brown precipitate disappeared. The pre-mounted slides were transferred into a reducing solution (900 ml distilled water, 75 cc 95% alcohol, 17 cc 10% formalin, 20 cc 1% citric acid), rinsed, soaked in .5% sodium sulfate (1 min), dehydrated in 95 and 100% alcohol, cleared in xylene and coverslipped.

The results obtained with the pre-mounted method were consistent with results obtained with standard techniques for the demonstration of degenerating axons in the CNS.

247.22 EARLY SPINAL CORD TRAUMA ASSESSED BY DIFFUSE AXONAL UPTAKE OF HRP. C.LaMotte, Sect. of Neurosurgery, Yale Univ., New Haven, CT,06510.

The most severe effects of spinal cord trauma result from interruption of fiber tracts. Damage from the primary traumatic lesion may to be further increased within a few hours by secondary lesions resulting from hemorrhages, changes in blood flow, edema, and necrosis. Determination of the contributions of both the primary and secondary effects to final neuronal destruction is of critical importance for early therapeutic intervention. However, traditional methods of staining for axonal injury, such as degeneration or Marchi methods, do not detect damage until 2 or more days after injury. This study was aimed at developing a method of direct assessment of damage to fiber tracts within the first 24 hours after impact, using diffusion uptake of horseradish peroxidase (HRP) as a marker for axonal injury.

To test uptake of HRP by normal and injured axons, lesions were studied in which the locations of cut axons and normal axons were known: in 15 cats, the dura was opened and the cord hemisected. Then a gelfoam 'garter' soaked with HRP was wrapped around the cord at the site of incision. After 1 to 24 hours, the animal was sacrificed by aortic perfusion. Sections were reacted with diaminobenzidine. Label was found in almost all the axons on the hemisected side; the axons on the intact side and in controls with no lesions were free of HRP.

The method was then applied to traumatized cords. Using a standardized weight-drop technique, a 20g weight was dropped from 10 or 25cm. onto exposed cat thoracic cord and the animal sacrificed after 3 hours. Results of 10 cats showed that in both 20g-10cm and 20g-25cm cats, most axons in the dorsal columns, lateral white and ventral white were stained. The 20g-25cm cords had more swollen axons and destruction of grey matter.

These results indicate HRP uptake occurs with partial or complete axon breakage or with increased membrane permeability sufficient for passage of the 40,000MW HRP molecules. The 20g-25cm impact produces severe paraplegia in cats and the widespread HRP uptake may mainly be by permanently broken axons. However, 20g-10 cm impacts initially produce paraplegia but cats usually recover function after a few days; in these, HRP uptake may reflect either membrane permeability changes or minimal breakage which is repairable but could account for temporary loss of function.

This study demonstrated that the diffuse uptake of HRP by damaged axons provides an immediate assessment of axonal distrubance following impact. We have used it to show that the large majority of spinal axons must suffer substantial and immediate damage even at mild impact (20g-10cm). This labelling method may be further applicable in assessing processes of natural and therapeutic recovery through measuring changes in membrane permeability associated with axonal repair. (Supported by NIH grant NS 10174).

247.23 LIGHT AND ELECTRON MICROSCOPIC STUDIES OF THE DORSAL VAGAL MOTOR NUCLEUS AFTER HRP INJECTIONS IN THE VAGUS NERVE AND BRAINSTEM IN THE CAT. J.H. McLean* and D.A. Hopkins. Dept. of Anatomy, Fac. of Medicine, Dalhousie University, Halifax, N.S., Canada B3H 4H7.

Two distinct neuronal types have been described in the dorsal motor nucleus of the vagus nerve (DMV) in the cat using light and electron microscopy (McLean and Hopkins, Can. J. Neurol. Sci., 1979). At all levels of the nucleus, medium-sized neurons (18 x 25 µm) containing a non-invaginated nucleus and abundant cytoplasm are at least three times more numerous than small neurons (9 x 15 µm) with an invaginated nucleus and scanty cytoplasm. In the present study, the efferent connectivity of these two neuronal types has been studied by examining the DMV using light and electron microscopy following horseradish peroxidase (HRP) injections in the cervical vagus nerve or brainstem.

After HRP injections into the cervical vagus, 40 µm frozen sections were processed according to the method of Mesulam (1978). A range of sizes and shapes of neurons in the DMV was retrogradely labeled but the large majority of labeled neurons were medium-sized, with average dimensions of 17 x 25 µm. Following vagus injections and incubation with diaminobenzidine (DAB) or Hanker-Yates reagents, blocks containing the DMV were processed for electron microscopy. The soma of almost all medium-sized neurons contained reaction product when observed in 1 µm sections with light microscopy. In thin sections stained with uranyl acetate but not lead citrate and viewed by electron microscopy, electron-dense reaction products in lysosomes were observed in the soma of the medium-sized neurons of the injected side. In contrast, lysosomes in the medium-sized neurons of the control side were unlabeled. No small neurons were labeled in either DMV. The results were similar using the DAB or Hanker-Yates reagent.

In order to determine if the small neurons project to higher levels of the neuraxis, injections of HRP (1-2 µl total) were made in one side of the mesencephalon or pons giving a hemi-injection of the brainstem at those levels. The medulla was then processed for light microscopy of retrogradely labeled neurons. In different cases, several small neurons were labeled in rostral to caudal levels of the DMV, although not all small neurons were labeled. No medium-sized neurons were labeled. Electron microscopic studies of the small neurons are now in progress.

The results indicate that in the DMV of the cat only medium-sized neurons project into the vagus nerve and at least some small neurons project to higher levels of the neuraxis.

247.24 ULTRASTRUCTURAL CHANGES IN FACIAL AND VAGAL MOTOR NEURONS FOLLOWING AXOTOMY IN THE ADULT HAMSTER. S.K. Jacob. Dept. of Anat., Rush Coll. Hlth. Sci., Chicago, IL 60612.

Concomitant with a study of histological and population changes during the axon reaction in the facial and vagal nuclei of the adult hamster, an ultrastructural examination was performed on these nuclear groups after severance of the facial and vagus nerves. Our previous study has shown the facial motor neurons exhibited a transient chromatolysis and no neuronal loss following axotomy resulting in a relatively normal morphology by 30 days postoperative (dpo). On the other hand, the neurons in the dorsal motor nucleus of the vagus show dramatic morphological and population changes resulting in 60% loss by 30 dpo. The purpose of this project was to compare the cytological profiles in these two groups of reacting neurons.

Two groups of six adult hamsters underwent axotomy and removal of a distal segment of the right facial and vagus nerves. The left nerves remained intact to serve as a control. Brains of both groups were perfusion-fixed at 5 and 30 dpo. The facial and vagal nuclei were dissected out and further processed for routine ultrastructural examination.

Facial motor neurons showed few changes following axotomy. At 5 dpo, neurons contained few aggregates of RER and there were many scattered ribosomes throughout the cytoplasm. By 30 dpo, these cells showed an increase in parallel cisterns of RER. No autophagic vacuoles or accumulations of lipid inclusions were seen in either postoperative group.

Vagal neurons showed more dramatic changes following axotomy. At 5 dpo, neurons displayed a dilute cytoplasm with a reduction in the amount of organized RER, also observed were a few nuclear membrane infoldings. By 30 dpo, many degenerative changes were seen in the neurons. Most cells showed no aggregated RER and a highly folded nuclear configuration. The cytoplasm was vacuolated and contained many lipid accumulations.

This investigation has studied two extremes in the response to axotomy and has shown cytological changes unique to the degenerating neurons as compared to those which survive axotomy. While the reason for this range in response is unknown, it seems we have a model in the hamster that will allow us to readily compare different types of axon reactions within the same animal thus avoiding the problems of species variation in future studies.

247.25 THE RAT CLAUSTRUM: A LIGHT- AND ELECTRON-MICROSCOPIC ANALYSIS. Lawrence R. Edelstein and Frank J. Denaro*. Dept. of Psychol., SUNY at Stony Brook, Stony Brook, NY 11794.

To date, there have been no contributions to the literature with respect to the rat claustrum from an electron-microscopic perspective. While the claustrum has been shown to be an area of high multisensory convergence (Spector et al., BR, 1974 - cat) and possessive of a high degree of reciprocity with respect to connections with vision-related cortical and subcortical regions (Kunzle, BR, 1976 - monkey; Buchholtz & Sanides, EBR, 1979 - cat; and Carey et al., JCN, 1979 - tree shrew) little has been done with respect to a comparative ultrastructural approach. Therefore, we offer the following preliminary data on our study of the claustrum of the albino rat.

Rats were perfused with 5% dextrose - 0.1M phosphate buffer (PB) with a pH of 7.2, followed by 2% EM grade glutaraldehyde - 1% paraformaldehyde - 0.1M PB. Postfixation was carried out in 2% OsO_4 - 0.1M PB at 4°C with tissue cores taken through a graded ethanol dehydration schedule. Cores were embedded in Araldite 502 resin. Semithin sections were stained with toluidine blue for light-microscopic observation. Ultrathin sections were stained with uranyl acetate and lead citrate and examined with a JEM 100B electron microscope.

Light-microscopic analysis reveals a fairly homogeneous organization in all planes with little variation in cell distribution. The predominant cell type is round/slightly elongated, medium in size (15-20um), with a large, relatively smooth nucleus containing slightly aggregated chromatin, and possessing a large prominent nucleolus. Dorsally, the claustrum is almost indistinguishable from cortex, while ventral claustrum is more readily demarcated. The area in and around the claustrum was found to be highly vascularized, with a large number of glia of several types generally staining more darkly than the claustral neurons.

Electron-microscopic examination reveals a predominance of axo-dendritic synapses of the asymmetric variety, possessing clear spherical vesicles. Axo-somatic were noted but with not nearly the frequency of the axo-dendritic synapses. A large number of multisynaptic areas were noted in most sections, in addition to "synaptic islands." Perikaryon was relatively narrow, with a fair number of round and elongated mitochondria and containing poorly organized ribosomes most often taking the form of rosettes.

247.26 A GOLGI STUDY OF THE PRIMATE MAMMILLARY NUCLEI. R.B. Veazey and D.G. Amaral. Dept. of Anatomy and Neurobiology, Wash. Univ. Sch. of Med., St. Louis, Mo. 63110

The mammillary and supramammillary regions of *Macaca fascicularis* have been examined in Golgi-Cox preparations. The majority of neurons in the medial mammillary nucleus (MMN) had smooth, ovoid or triangular perikarya, with diameters ranging from 10 to 50 µm. Generally, 1-4 large caliber dendrites radiated from the somata and these, in turn, give rise to a few, long, spiny branches which rarely passed beyond the capsule of fibers surrounding the nucleus, before terminating in delicate tufts. The axons of the MMN neurons were approximately 0.5 µm in diameter, and usually became myelinated a short distance from their origin. The somata in the medial portion of the MMN tended to be larger than those situated more laterally, and the cells in the ventrolateral part of the nucleus tended to have more highly branched dendrites and thinner axons.

Neurons in the lateral mammillary nucleus (LMN) had ovoid, or multipolar, cell bodies with diameters ranging from 24-36 µm and were generally larger than those of the MMN. Two to four main dendrites radiated from the somata with a dominant dorsomedial to ventrolateral orientation. These dendrites branched infrequently, and quite often left the confines of the nucleus. Widely-spaced, multiform, spines occurred along the dendritic shafts.

The midline region (nucleus medianus) between the medial mammillary nuclei contained mainly ovoid neuronal cell bodies from which 2-4 dendrites radiated dorsoventrally. These dendrites were branched more than those of the MMN or LMN and terminated by means of a thorny tufted appendage.

The supramammillary region presented a more complicated appearance being comprised of neurons with a variety of shapes and sizes. Interestingly, some large supramammillary neurons, near the midline, extended dendrites far into the contralateral side.

247.27 FINE STRUCTURAL ANALYSIS OF THE INTRAVENTRICULAR NEURONAL COMPLEX OF THE GOLDEN HAMSTER BRAIN AND ITS RELATIONSHIP TO THE SUBJACENT MEDIAN EMINENCE. J.A. Mitchell and J.P. Card. Department of Anatomy, Wayne State University School of Medicine, Detroit, Michigan 48201.

The golden hamster is unique among mammalian species studied to date in that it possesses a highly organized intraventricular ganglion-like aggregation of neuronal cells and processes consistently located immediately rostral to the infundibular recess of the third ventricle. Previous studies from our laboratory (Card and Mitchell, 78, 79) have utilized scanning (SEM) and transmission (TEM) electron microscopy in descriptions of the fine structure of this cluster and its associated process network. The present report extends those observations with respect to the types of terminals found in the cluster and its relationship to the subjacent median eminence (ME). Adult golden hamsters of both sexes were perfused with buffered aldehyde solutions, the brain removed and the ME and surrounding tissue prepared for either SEM or TEM analysis. TEM analysis of the cluster confirmed previous observations of axon terminals containing spherical electron lucent vesicles (40 nm mean diameter) and dense-cored vesicles (60 nm mean diameter) in synaptic contact with neuronal perikarya and dendrites. However, of particular interest with respect to some of the specimens examined was the large number of terminals reminiscent of Herring bodies. Like Herring bodies in the posterior pituitary the majority of these endings contained large neurosecretory granules, small spherical electron lucent vesicles and mitochondria. These endings were generally ensheathed in fibrous astrocytic processes within the core of the cluster but were sometimes observed at the peripheral aspects of the cluster, free within the cerebrospinal fluid. Another interesting finding of the present study was the extensive interrelation that the cluster maintained with the ME via bundles of axons that connected the cluster with neuropil of the ME via discontinuities in the ependymal lining. At the SEM level faciculated bundles of axons coursing rostrally and caudally from the cluster became intimately enmeshed with processes of the exposed neuropil of the ME. Analysis of analogous regions with TEM confirmed this observation and also revealed numerous axon terminals forming synaptic contacts with dendrites at such sites. In conclusion, the present study has demonstrated two new features with respect to the intraventricular cluster of the golden hamster. First, some specimens contain large numbers of neurosecretory-like endings, some of which terminate freely within the ventricular lumen. Second, many specimens exhibit extensive interconnections between the cluster and the subjacent ME. The significance of the findings are presently under investigation. Supported by NIH RR-05387.

247.28 MORPHOLOGY OF HIPPOCAMPAL FORMATION NEURONS RESPONSIVE TO ELECTRICAL STIMULATION OF THE FIMBRIA-FORNIX. David M. Finch and Thomas L. Babb. Brain Research Institute and Reed Neurological Research Center, UCLA, Los Angeles, CA 90024.

Male Long-Evans strain rats were prepared for acute neurophysiological experiments under Equi-Thesin anesthesia (3 ml/kg, ip, supplemented as necessary). Twisted bipolar stimulating electrodes were implanted in the fimbria-fornix, and horseradish peroxidase-filled recording micropipets (4% HRP in 0.05 molar Tris and 0.2 molar KCl, buffered to pH 7.4 or 8.6 with HCl) were lowered to the hippocampal formation. The fornix was stimulated electrically with 0.2 msec pulses of 20-150 µA intensity, presented at 0.5/sec.

We have reported physiological data (Soc. Neurosci. Abstr., 5, 1979, 273; and Brain Res., 1980, in press) showing that the majority of subicular neurons respond to fornix stimulation with recurrent inhibition. HRP was injected into these responsive cells, and was visualized with the TMB technique of Mesulam (J. Histochem. Cytochem., 26, 1979, 106-117). The cells were identified in histological sections, and could be classified as pyramidal neurons. Therefore, both physiological and morphological evidence indicate that pyramidal cells of the subiculum have a recurrent inhibitory organization similar to that of pyramidal cells of the hippocampus proper. Responsive entorhinal neurons were also studied and reported on as well. The TMB technique used here - although sensitive - did not appear suitable for the study of fine structure such as dendritic spines, apparently because of the coarse size of reaction product granules.

Supported by BRSG Grant SO7 RR05756 from NIH.

247.29 MORPHOLOGICAL CHANGES IN HIPPOCAMPAL CA1 PYRAMIDAL CELL DENDRITES AFTER CHRONIC ETHANOL CONSUMPTION IN THE RAT - A GOLGI STUDY. P.A. McMullen*, J.A. Saint-Cyr, T.L. Petit, P.L. Carlen, D. Durand. Playfair Neuroscience Unit, Toronto Western Hospital, Depts. of Anatomy, Medicine, Physiology, Biomedical Engineering, Psychology, University of Toronto, Addiction Research Foundation, Toronto, Ontario.

CNS damage associated with chronic alcoholism is particularly evident in limbic system structures. Depression of long term potentiation has been demonstrated in vitro in the Schaffer collateral-CA1 synapses (see Durand et al., Neuro. Sci. Abstr., Vol. 6, 1980) in slices taken from rats chronically fed ethanol compared to pair fed controls. Blocks of tissue from the contralateral hippocampi of 3 pairs of these animals plus 2 additional pairs were stained with the Golgi-Cox technique.

Male Sprague-Dawley rats had ad libitum access for 8-9 months, to measured amounts of liquid diet containing 35% of caloric content as ethanol (equivalent to an average of 10mg/kg/day.) The pair fed control group received isocaloric amounts of the same diet with maltose-dextrins replacing the ethanol.

Well stained CA1 pyramidal cells from both groups were drawn at 1500X with a camera lucida. Measurements of total, apical, and basilar dendritic lengths, basilar dendritic area as well as total, apical and basilar Sholl analyses were evaluated with the Mann-Whitney U statistic.

A Sholl analysis of the total neuronal tree revealed that the amount of dendritic branching in the ethanol group cells, 20-60 µm from the cell body, was significantly less than that of the controls at the $p \leq .05$ level. At distances of 60-380 µm, dendritic branching in the ethanol group cells was significantly less than that of the controls at the $p \leq .001$ level.

These studies quantitatively demonstrate that CA1 hippocampal pyramidal cell dendrites become attenuated in animals chronically fed ethanol.

247.30 A BIMODAL POPULATION OF DENTATE GYRUS GRANULE CELLS DEMONSTRATING AGE-RELATED CHANGES. Steven F. Hoff*, Stephen W. Scheff and Carl W. Cotman (SPON: J. Angevine). Dept. Psychobiology, Univ. California, Irvine, CA and Dept. Anatomy, Med. Center, Univ. Kentucky, Lexington, KY 40536.

The hippocampal formation contains two primary cell types, pyramidal cells and granule cells. The densely packed granule cell layer of the dentate gyrus is commonly thought to consist of only one type of granule cell. We report here evidence for a bimodal population of granule cells. One population of cells stains more intensely with toluidine blue and appears different when examined with the electron microscope. These cells are more prevalent in younger animals.

Young (3 month) and aged (27-30 month) Sprague-Dawley rats were killed and the hippocampal formation processed for electron microscopy. Coronal sections through the dentate gyrus were stained to reveal cell bodies in semithin sections with toluidine blue. Camera lucida drawings of the cell layer from serial sections revealed a greater percentage of darkly staining cells in younger animals as compared to that observed in material from the aged rats. While the overall number of granule cells did not change the percentage of dark and lightly staining cells did.

Electron microscopic examination of the dentate gyrus also revealed two very distinct populations of granule cell bodies. The electron lucent variety conform to the classically described granule cell (J. Comp. Neurol., 128:359, 1966). The second and slightly smaller granule cell is quite different. The nucleus and cytoplasm of this cell type are very electron dense. The chromatin is evenly but more compactly dispersed than the electron lucent granule cell. The more commonly seen nucleoli in these cells is often centrally located as opposed to the eccentric location in the electron lucent variety. The electron dense cytoplasm of the dark cells displays an increase in the number of free ribosomes. While the dendrites of the electron lucent granule cells arborize throughout the dentate molecular layer, initial observations indicate that the dendrites of the dark cells are primarily restricted to the inner one-third of the molecular layer in the naive animal. Both the electron dense and lucent cell types receive axosomatic and axodendritic (including complex type) synapses.

The apparent decrease in percentage of darkly staining granule cells observed in the older animals may reflect a developmental change associated with the aging process. It might also indicate a change in the metabolic function of these cells. These data demonstrate a probable age-related cellular change in dentate granule cells. (Supported by research grant AG 00538)

247.31 THE MORPHOLOGY OF NONPYRAMIDAL NEURONS IN PHYSIOLOGICALLY IDENTIFIED RABBIT AUDITORY CORTEX. N. T. McMullen and E. M. Glaser, Dept. of Physiology, University of Maryland School of Medicine, Baltimore, Maryland, 21201.

Relatively little is known about the types and distribution of neurons in the auditory cortex and how they might correspond to those described for neurons of the visual and somatosensory cortices. Neuronal morphology of the latter areas has been rather extensively investigated in a variety of species. We have studied the morphology of nonpyramidal neurons in the physiologically identified primary auditory cortex of Dutch Belted and New Zealand rabbits. The primary area was identified by electrophysiological mapping experiments (see Glaser & McMullen, this volume). The brains were processed according to the Golgi Cox Nissl method and sectioned at 300 µm. Nonpyramidal neurons along the electrode tracks were surveyed and drawn using camera lucida techniques. Nonpyramidal neurons are found in all layers of the auditory cortex. They are located primarily in Lamina I-IV and are infrequently seen in the deeper cortical layers. At least three types of nonpyramidal neurons are seen in Lamina I: a) small, sparsely spined stellates, b) spine-free horizontal cells, and c) large, sparsely spined multipolar neurons. The stellates and horizontal neurons have tangentially running axons confined to Lamina I whereas the multipolar cells have descending axons that may reach Lamina IV. In Lamina II and upper Lamina III, nonpyramidal neurons are particularly heterogeneous with respect to dendritic and axonal projections. Both spiny and sparsely spined types are present as are types with ascending and descending axons. The density of nonpyramidal neurons is greatest in Lamina IV and lower Lamina III. The most common neuronal type in these layers is the large, multipolar, spine-free stellate with radiate and bitufted dendrites. The stout dendrites are frequently beaded and exhibit little taper. Spine-free, Lamina IV stellates with well stained axons were seen only rarely. Their axons are thick and ramify within Lamina IV and lower Lamina III. Less frequently seen in these layers were spiny stellates which have vertically aligned, spine-covered dendrites, and ascending axons with horizontal collaterals arborizing in Lamina II and III. Large multipolar sparsely spined nonpyramidal neurons were only occasionally seen in Lamina V and VI.
Supported by NSF Grant BNS 78-05502.

247.32 THE SCANNING ELECTRON MICROSCOPE: VIEWS OF CEREBELLUM AND HIPPOCAMPUS. L.A. Paul*, I. Fried*, P.T. Duong*, and A.B. Scheibel. Depts. of Anatomy, Psychiatry, and Psychology, University of California, Los Angeles, CA 90024.

As demonstrated in our previous report (Scheibel et al., Soc. for Neursci. Abstr., 1979, #1464), scanning electron microscopy provides a bridge between Golgi-visualized microstructure and the ultrastructural detail of the transmission electron microscope (TEM). Using careful dissection techniques, "creative tearing," standard paraformaldehyde fixation in animal material, and standard critical point drying and sputter-coating, we have examined selected regions of hippocampus and cerebellum in rodent and in human. Comparative views of these structures following Nissl and Golgi staining both provide a familiar context and dramatize the tridimensionality of the tissue matrix. The accompanying photographs indicate the range of neuronal relationships and synaptic geometry found in these regions. Of special interest are the dense clusters of cerebellar granule cells and their fine axons contrasting with the large-caliber afferent mossy fibers and terminal tufts. Basket fibers often cover the Purkinje cell bodies and, where they have been stripped off by tissue preparation, residual finger-like indentations are visible on the somal surface. Climbing fibers, glial cells, and glomeruli can also be identified. Low magnification photographs of the hippocampal-dentate complex reveal the pyramidal cell layer, while closer views show densely packed pyramidal cells with their complement of afferent terminals, mossy tufts, and glial surround. Arrays of dentate granule cells embedded in a mesh of fine fibers are also visible. The synaptic scale covering somata in both regions is particularly prominent.

Scanning electron microscopy in the central nervous system offers, in addition to an unprecedented esthetic experience, a view of topographical reality heretofore approached only by serial reconstruction of TEM photomicrographs. It is apparently robust enough to provide data even in the case of suboptimally fixed human tissue.

(With grateful acknowledgment to the Brain Research Institute and Dr. J. Berliner, Dept. of Pathology, UCLA School of Medicine.)

247.33 $CANNING ELECTRON MICROSCOPY (SEM) OF THE RESPONSE TO CEREBRAL LACERATION OR CONTUSION. H. M. Murray, D. M. Feeney and W. G. DAIL Departments of Anatomy and Psychology, University of New Mexico, Albuquerque, NM 87131

Adult rats were used to study tissue response to cerebral laceration or contusion. Animals were perfused with 1% paraformaldehyde-2.5% glutaraldehyde in 0.2M phosphate buffer (pH 7.3) at 1, 4, 9, 15 and 30 days after injury. Brain specimens were prepared by routine SEM procedures. At one day after laceration (L + 1), the cavity formed by the lesion is filled with large numbers of erythrocytes and fine fibrils. When the lesion impinges on subcortical white matter, axons exhibit swelling. The lesioned area at L + 4 contains erythrocytes, macrophages and fibroblast-like cells; neutrophils or lymphocytes are not evident. Macrophages display many large surface blebs. Fibroblast-like elements are loosely arranged; a few of these cells have flattened morphology although the majority have a more rounded profile. By L + 9, fibroblast-like elements form a layer that is several cells in thickness. Deeper cells in the lesion wall are flattened and primarily smooth, although scattered, small microvilli are observed on their surface. More superficially-located cells are more rounded and display cytoplasmic projections extending across the surface of the more flattened cells. The projections give rise to randomly-oriented fine cytoplasmic filaments and elongated microvilli. Macrophages and crenated red blood cells are still evident within the lumen of the cavity. Fewer macrophages and erythrocytes are present within the cavity at L + 15 and L + 30 than at earlier time intervals. The formation of the wall is more advanced with the majority of fibroblast-like elements being flattened. Intercellular spaces between these cells are still evident at L + 15 but decrease in size and number by L + 30. No well-formed fenestrae are observed in the lining of the cavity. Extracellular material closely associated with fibroblast-like cells appears at L + 15 and is increased in amount at L + 30. The response to cerebral contusion differs little from that described above except that there is a delay of 7-15 days in the temporal sequence of events. The reason for this is not known at present but may be related to the amount of tissue damage produced by the contusion. The results of the study show that hematogenous elements are retained within a lesion cavity long after the insult and that fibroblast-like cells participate in the formation of neural-extraneural interface. Thus SEM provides a useful tool to study brain injury by allowing visualization of large areas (not possible with TEM) and at greater resolution than light microscopy. This provides a "3-dimensional" view of the complex morphological interactions that occur subsequent to the loss of structural integrity in the central nervous system.

Supported by NIH #NS 13684-02

247.34 CLUSTERING OF SUPRAEPENDYMAL CELLS IN THE RAT THIRD VENTRICLE AFTER MULTIPLE INJECTIONS OF P-CHLOROAMPHETAMINE. L.C. Saland and A.T. Munger*. Dept. of Anatomy, Univ. of New Mexico School of Medicine, Albuquerque, NM 87131

P-chloroamphetamine (PCA) is an agent which causes long-lasting depletion of brain serotonin in rats, and appears to cause degenerative changes in "selected" central nervous system serotonergic fibers and cell bodies. The depression in brain serotonin levels after PCA appears at 3-5 days and lasts for weeks or months (Sanders-Bush and Steranka, '78). Three sequential injections of 10 mg/kg PCA reduce serotonin levels by 30% and cause degeneration of some neurites in the median eminence of the hypothalamus (Saland, Dail and Reyes, 1980, J. Neurobiol., in press). Several investigators have suggested that supraependymal neuronal elements within brain ventricles are serotonergic. This study examines effects of PCA on supraependymal cells and fibers in the rat third ventricle. Adult male Sprague-Dawley (150-200 gm) rats received three sequential injections (10 mg/kg each, separated by 24 h) of PCA, were anesthetized with pentobarbital and perfused intracardially with (0.15 M) cacodylate-buffered 1% paraformaldehyde/2.5% glutaraldehyde (pH 7.2, room temp.) at 8, 12 and 14 days after the initial PCA injection. SEM examination of medial basal hypothalamus (MBH) at 8 days post-injection revealed large clusters of cell bodies atop the ependyma in every experimental animal, with numerous fibers intermingling among the larger cells. Large numbers of fibers were also present on the ependymal surface, many with "varicosities". MBH regions from saline-injected controls contained variable numbers of supraependymal cells and fibers, usually isolated or in occasional small groups. Observations by TEM of sections of re-embedded SEM specimens illustrated parts of some cell clusters and processes which appeared to be neurons, while other cells were mononuclear with abundant free ribosomes. Macrophage-like elements were not usually seen after PCA. Cells and fibers did not appear to be degenerative at any time period. At 12 or 14 days, some brain regions appeared to revert to the appearance of areas in control rats, while others still contained some large cell clusters. Other studies (Card and Mitchell, 1978, J. Comp. Neurol., 180: 43; Coates, 1978, Anat. Rec., 190: 366) have shown clusters of supraependymal elements in normal vertebrates, and have suggested sensory and/or secretory roles for the cells within cerebro-spinal fluid. Consistent changes in the supraependymal region after PCA may indicate the ability of specific cells to respond to drastic alterations in serotonin levels.

(Supported by NIDA grant DA-02269-01).

247.35 SCANNING ELECTRON MICROSCOPY OF MACROPHAGES IN THE BRAIN AND SPINAL CORD FOLLOWING EXPERIMENTAL INJURY. C. H. Phelps, J. C. Pearson*, J. C. Christian*, R. P. Nieser*. Department of Anatomy, Wright State University, Dayton, Ohio 45435.

Macrophages appear within central nervous system wounds within two or three days following experimental injury. The origin of these cells has been debated but current evidence favors their origin from blood monocytes (Fujita et. al. Prog. Neuropath. 3, 1976). In the present study macrophages were examined with scanning electron microscopy (SEM) following cortical or spinal wounding. Adult male Sprague-Dawley rats received either a small stab wound in the parietal cerebral cortex or a hemisection in the lower cervical spinal cord and the migration, transformation, and subsequent phagocytic activity of macrophages was characterized. After survival times of 2, 3, 5 or 7 days the animals were perfused with a mixture of glutaraldehyde and formaldehyde and tissue blocks containing the lesions were processed for SEM. Some tissues were embedded in Epon 812 and sectioned for light microscopy and transmission electron microscopy to confirm the identity of various cell types. On the second day following injury, macrophages were observed migrating into and around the blood clot within the wound. The macrophages are large cells with extremely irregular surface features including lamellopodia, filopodia and blebs. They were sometimes seen in the process of engulfing erythrocytes which had been trapped in the fibrin clot within the cavity of the wound. In the central canal of the spinal cord adjacent to the lesion, macrophages were seen associated with Reissner's Fiber. It appeared that the macrophages used the fiber as a substrate for migration either to or from the lesion and lamellopodia were often seen spreading out over the surface of Reissner's fiber. Sometimes erythrocytes were observed attached to the surface of these macrophages.

247.37 TOXICITY OF OXYGEN IN IRON-RICH AREAS OF RAT BRAIN. Robert C. Switzer, III. Laboratory of Brain Evolution and Behavior, National Institute of Mental Health, Bethesda, MD 20205.

As a part of a series of experiments demonstrating a component of globus pallidus in olfactory tubercle, oxygen at high pressure (OHP) was used to induce degeneration in pallidum. This was prompted by earlier reports of the effects of OHP by Ballentine who exposed female rats for 50-60 min daily to OHP at 57 psi until they were paralyzed. Histology revealed severe necrosis of several brain areas, including globus pallidus.

In the current study, the early effects of OHP on neuronal perikarya were sought using the cupric-silver method of deOlmos. Female rats were exposed to OHP at 57 psi for 50 min daily for 1-5 days and sacrificed 2 days after their last exposure. After only one exposure, degeneration was conspicuous in all of the auditory nuclei, facial motor nucleus, and a well defined patch in the extreme entorhinal cortex. With longer exposures, the degeneration increased in these areas and also occurred in other areas which include: ventrolateral thalamus, interpeduncular nucleus, medial dorsal thalamus, cerebellar nuclei, pallidum, and n. reticulata of substantia nigra. This list closely matches a list of iron-rich areas of the brain as revealed by the Perl reaction for ferric iron; however, the degree of degeneration does not appear to be directly related to the relative amount of iron.

There is convincing evidence that the damage of OHP is due to the production of lipid membrane-damaging free radicals. Since the free radicals superoxide, peroxide, and hydroxyl are readily generated by an iron-oxygen interaction, it is not surprising that the iron-rich areas would be susceptible to damage under these conditions. However, it is surprising that the areas with the highest amount of iron, globus pallidus and n. reticulata of substantia nigra, are not the first to be damaged. An explanation is provided by the metabolic activity maps using 2-deoxyglucose. Inferior colliculus and other auditory nuclei with a moderate amount of iron, have the highest metabolic activity while pallidum and nigra exhibit a lower metabolic rate. Other areas of high metabolism but without demonstrable iron did not show damage.

It is concluded that susceptibility of brain structures to damage by OHP is a function of the iron levels of a given region and its metabolic rate.

247.38 HISTOCHEMISTRY OF RAT SPINAL CORD VASCULATURE. [1]M.S. Cannon,* [1]J.B. Gelderd, [1]D.E. Bowers,* [2]W.P. Fife* and [2]D.W. Welch.* Dept. of Anatomy, College of Med.[1]; Dept. of Biology, College of Science,[2] Texas A&M Univ., College Station, TX 77843.

Sections of spinal cord from the mid-thoracic region of normal, adult Long-Evans female rats were surgically removed under sodium pentobarbital (200mg/kg body wt.) anesthesia for histochemical examination of arteries and arterioles. The histochemical reactions utilized represented a number of metabolic pathways, including; glycolysis, the hexose-monophosphate-shunt, Kreb's tricarboxylic cycle, β-oxidation of fats and the respiratory chain. Enzymes were generally evaluated from fast frozen material, while substrates such as glycogen and neutral fat were examined from fixed and/or frozen tissue.

Some findings were as follows; Kreb's cycle: succinate, isocitrate and malate dehydrogenases showed more activity in larger than in smaller vessels. Glycolysis: utilizing the periodic acid-Schiff reaction, glycogen appeared to be present in nearly equal amounts in large and small vessels; lactate dehydrogenase showed a similar distribution. Hexose-monophosphate-shunt: DPN diaphorase demonstrated slight activity in both large and small vessels, while glucose-6-phosphate dehydrogenase showed moderate to strong activity in both types of vessels. The methyl green/pyronin and Azure B staining techniques showed DNA and RNA to be present in relatively small amounts in both large and small vessels. Respiratory chain: cytochrome oxidase demonstrated relatively little reactivity in both large and small vessels, while ubiquinone showed considerably more activity in large than small vessels. Lipid metabolism: lipase activity was minimal in both large and small vessels as was the presence of neutral fat; free fatty acids were present in considerably greater amounts in larger than in smaller vessels. β-hydroxybutyrate dehydrogenase showed more activity in larger than in smaller vessels. Energy consuming reactions: myosin- and Wachstein-Meisel ATPases demonstrated strong activity in both large and small vessels, while alkaline phosphatase showed virtually no activity.

The present preliminary histochemical data would tend to indicate that a strict metabolic heterogeneity (preference for aerobic or anaerobic metabolism) may not exist between large and small vessels in the rat spinal cord, although large vessels indicated some preference for aerobic metabolism. This would be in contrast to previous studies on coronary arteries and arterioles in the rat and dog which show that in general, arterioles have a higher capacity for aerobic metabolism than do arteries, which appear more adapted for anaerobic pathways. 247.39 ECTOPIC DENDRITIC GROWTH AND MEGANEURITE FORMATION IN PORENCEPHALY WITH POLYMICROGYRIA: A GOLGI STUDY. R.F. Mervis and A.J. Yates. Division of Neuropathology, Ohio State University College of Medicine, Columbus, Ohio 43210

A six year old boy with a history of mental retardation and seizure disorder since 1 year of age died as a result of aspiration pneumonia. The brain was small (650 gm) and had bilaterally symmetrical clefts in the region of the Sylvian fissures allowing free communication between the subarachnoid space and the lateral ventricles (schizencephalic porencephaly). The cerebral cortex at the margins of the clefts grossly had the appearance of polymicrogyria. Histological preparations of this tissue and that from grossly normal areas were stained with H&E and Luxol blue-PAS stains and impregnated with the Rapid Golgi method. There was fusion of the molecular layer and along the lines of fusion were numerous astrocytes. Cortical layering and neuronal organization in these areas were abnormal, but in both the areas of polymicrogyri as well as the grossly normal cortex many stellate and pyramidal cells had somatic distortion and meganeurite-like structures with aberrant ectopic dendritic growth. In humans, meganeurites have been found previously only in ganglioside storage disorders. Most dendritic processes of abnormal as well as the normal-appearing neurons were otherwise heavily spined.

The findings in this case of schizencephalic porencephaly demonstrate that in the areas of polymicrogyria there are both architectonic and cytological abnormalities. While the specific pathogenetic mechanism leading to these structural abnormalities are unknown, it is tempting to speculate that both could be the consequence of a single, unknown defect resulting in abnormalities of neuronal shape and migration.

248.1 CORRELATION OF AGING CHANGES IN THE OLFACTORY EPITHELIUM AND OLFACTORY BULB OF THE RAT. J. W. Hinds and N. A. McNelly*. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston MA 02118.

In the present study two regions linked synaptically (olfactory epithelium and olfactory bulb) have been compared in an age-graded series of rats. Previous studies from this laboratory on the aging olfactory bulb in Sprague-Dawley Wisconsin (SD) rats have shown a striking increase in volume of the olfactory bulb, number of synapses, and size of mitral cell bodies and their dendritic trees from 3 to 24-27 months and then a decrease at 30 months. These findings have now been confirmed in Charles River rats (Crl:CD(SD)BR) and extended to include correlations with aging changes in the olfactory epithelium. In the olfactory bulbs of Charles River rats the volume of the layers, the number of olfactory axo-dendritic synapses in the glomeruli, the total volume of glomerular dendrites, and the size of mitral cell bodies all approximately double between 3 and 24-27 months, and then all have decreased by 36 months. Unlike SD rats, however, no loss in the number of mitral cells occurs in Charles River rats, and the increase in volume of the olfactory bulbs from 3 to 24 months is approximately double that of SD rats. In the olfactory epithelium the total number of septal olfactory receptors more than doubles between 3 and 18-24 months and then declines markedly, as does the volume of olfactory axons in olfactory bulb glomeruli. Comparing the regression lines for change in number of septal receptors with that of the size of mitral cell bodies discloses that the peak for number of receptors is reached several months earlier than for mitral cell size. This suggests that the atrophic changes in the olfactory bulb may in part be secondary to changes in the receptors in the olfactory epithelium. Synapses in the glomeruli appear to decline less markedly with age than the number of receptors, and a significant increase in number of synapses per receptor occurs in the oldest group studied (33 months), suggesting a compensatory increase in the relative number of synapses per receptor in the surviving receptors.

248.2 DENDRITIC INCREASES IN THE AGED RAT SOMATOSENSORY CORTEX. J.R. Connor, S.E. Beban*, B. Hansen*, P. Hopper*, and M.C. Diamond. Dept. Physiology-Anatomy, Univ. of California, Berkeley 94720.

For the past two years, our laboratory has investigated basal dendrites from superficial pyramidal neurons in the occipital cortex of old rats. Specifically, we have observed increases in total dendritic branching, total spines per unit area and increased dendritic density from 444 to 630 days of age in the occipital cortex of socially housed animals. The present study supports our previous findings and extends them to the somatosensory cortex of the same animals.

Animals who had been housed 3 to a cage (30X20X28cm) were anesthesized with nembutal at 444 days of age (n=12). The brains were then removed and placed in a Golgi-Cox solution. Littermates of these animals remained in the social conditions until they were sacrificed at 630 days of age (n=7). Two or three coronal sections through the somatosensory cortex were taken and 7 neurons per section were drawn with the aid of a camera lucida. Data on dendritic branching and density were gathered from basal dendrites of superficial pyramidal cells.

The first order branching for both the 444 and 630 day old animals was identical. All other orders were greater in the older group than the younger group, but only the third ($p < .05$) and sixth orders ($p=.02$) were statistically different.

Dendritic density was analyzed according to the Sholl method and included an orientation factor introduced by Valverde (1968). Compared with the 444 day old rats, the dendrites from the 630 day old animals had increased density 0-50μm from the soma ($p < .05$), 100-150μm from the soma ($p < .01$) and 150-200μm from the soma ($p < .001$). The 630 day old animals had a greater density of branches in the upper angle in the 0-50μm range than the 444 day old animals ($p < .01$).

This study supports our previous findings in the occipital cortex and extends them to the somatosensory cortex. These data further suggest that brains from socially reared animals do not display the negative aging changes as reported by some other investigators. We thus raise the question of whether or not reported aging changes are due to age or are environmentally induced.

248.3 AXONAL MYELIN RELATIONSHIP FROM DEVELOPMENT INTO SENESCENCE IN THE LONG EVANS RAT CAUDATE NUCLEUS. Martin R. Krigman, Cynthia W. Brashear*, Jeffrey J. Gaynor*, and Robert C. Elston*. Depts. Pathology and Biostatistics, Univ. North Carolina at Chapel Hill, Chapel Hill, NC 27514

The axon diameter of myelinated axons and the number of their myelin lamellae were determined from electron photomicrographs in a preselected region from the head of the caudate nucleus. The studies are based upon three or more bundles of axons per caudate. These were made in 30, 60, 120, 365, and 730 day-old male rats, from two or more litters per age group.

Statistical analysis of the data reveals that both axon diameter and number of lamellae change significantly with age, and that within each age group the variability from rat to rat, as well as that from bundle to bundle, is very small compared to the variability within bundles. Axon-to-axon differences within bundles accounted for between 85% and 95% of the total variability within each age group. Average axon diameter decreases significantly with aging ($p < .05$), whereas the average number of myelin lamellae, either per axon or per unit of axon diameter, increases significantly with age ($p < .05$). This increase is of a cubic form: there is a sharp increase between 30 and 60 days, little change between 60 and 365 days, and a moderate increase between 365 and 730 days.

Myelination continues in the caudate nucleus of the Long Evans rat despite a significant drop in mean axon size. The myelinated axons examined represent a diverse population of corticopetal fibers and local connections twixt the diencephalic and subcortical ganglia. Examination of their distribution in the different age groups suggests that the changes in the number of myelin lamellae represent select population changes: in a majority of the axons the number of lamellae does not increase, while in a small group of axons the number of lamellae increases with age.

248.4 SPECIFICITY OF AGE-RELATED CHANGES IN STRIATAL DA RECEPTORS: PLASTICITY IN THE FACE OF A DEFICIT. J. F. Cubells,* C. R. Filburn,* G. Roth,* B. T. Engel* and J. A. Joseph. (SPON: J. B. Wirth). Gerontology Res. Ctr. NIA, Baltimore, MD 21224.

Age-related differences in the development of striatal dopamine (DA) degeneration hypersensitivity were examined in forty (10/group) male and female mature (6-8 mo) and senescent (24 mo) Wistar rats. 3[H] spiroperidol specific binding and DA stimulation of adenyl cyclase activity were measured in striatal preparations from these rats one month after unilateral 6-hydroxydopamine (6-OHDA) lesions of the left substantia nigra. Striata from the lesioned (hypersensitive, left) hemisphere were compared to striata from the non lesioned (right) hemisphere in each group by computing a left/right ratio for each animal in each assay condition. Ratios of 3[H] spiroperidol specific binding in the left striata relative to the unlesioned striata were determined at the 3[H] spiroperidol concentration which gave the highest amount of specific binding in each experiment (5 to 10 nM). Ratios of DA stimulation of adenyl cyclase in lesioned and unlesioned hemispheres (left/ right) were determined from these same preparations. Results showed no age related decrements in L/R ratios of either 3[H] spiroperidol specific binding or 100 uM DA stimulation of adenyl cyclase (3[H] spiroperidol, young $\bar{X}$= 1.5±sem .18, old=1.5±.13; 100uM DA-AC, young 1.3±.06 old 1.2±.11).

Prior behavioral confirmation of these alterations in DA receptor density had been obtained in these animals by administering lergotril, a DA receptor agonist, which has its greatest action on the hypersensitive left striatum and produces contralateral rotation (in this case turning toward the right). Analysis of the right turns/left turns/30 min for each animal showed no age differences in rotational behavior (young 192.9 ± 16.0 old $\bar{X}$ 173.2 ± 35.0). Previous experiments indicate that specific binding to neuroleptics (i.e., 3H haloperidol), in the inact striatum declined with age. These findings, and those above, suggest that even though striatal DA receptor density is lower in the old animal, the ability to proliferate DA receptors following lesions of the substantia nigra remains intact. Further indirect evidence for this putative lowering of receptor density was provided by a second study in which rotational behavior was examined following intrastriatal injections of DA (50ug) through chronically implanted cannula in the right striata of young and old rats (10/group), previously lesioned in the left substantia nigra (6-OHDA). Results showed deficits in rotational behavior of the old animals (young $\bar{X}$=25.4 ± 4.9 old $\bar{X}$ 10.8 ± 1.64).

248.5 DIFFERENTIAL IMPAIRMENT OF DOPAMINERGIC RECEPTORS IN THE AGING BRAIN . M. Trabucchi, M. Memo, H. Kobayashi and P.F. Spano. Dept.s of Pharmacology, Universities of Milan and Brescia, Italy.

Several behavioural, neurochemical and pharmacological observations indicate that the activity of various neuronal populations is impaired during aging. In particular the dopaminergic system seems to be significantly affected. Changes in dopamine (DA) system, DA-sensitive adenylyl cyclase activity and DA receptor binding sites have been described in brain dopaminergic areas of aged rats. We and others have recently proposed the existence of distinct classes of DA receptors in the central nervous system, clas sified as D1 and D2 on the bases of their association to or independence from the enzyme adenylyl cyclase. In the present study we report radioreceptor binding experiments performed utilizing two different ligands for dopaminergic receptors, namely ^{3}H-spiroperidol, which seems to label both D1 and D2 receptors, and ^{3}H-(-)sulpiride, which seems to specifically label D2 receptors.

Mature (3-4 months) and aged (20-24 months) Sprague-Dowley male rats were used in our experiments. ^{3}H-spiroperidol and ^{3}H-(-)sulpiride bindings were performed as previously described. Kinetic studies of ^{3}H-spiroperidol specific binding in striatum of aged rats showed a decrease in the number of binding sites, with no si gnificant changes in the affinity constant (Bmax values are 188±9 and 121±8 fmol/mg prot. for mature and aged respectively). On the contrary, Scatchard analysis of ^{3}H-(-)sulpiride specific binding performed in striatal membranes obtained from mature and aged rats did not reveal differences in the number of binding sites or in the affinity constant. These results may be of significance in the light of the possible different functional roles of the D1 and D2 central dopaminergic receptors.

248.6 BEHAVIORAL AND BIOCHEMICAL EFFECTS IN OFFSPRING OF NURSING RATS EXPOSED TO DOPAMINE RECEPTOR ANTAGONISTS. J.A. Engel and P. Lundborg*. Department of Pharmacology, University of Göteborg, Box 33031, S-400 33 Göteborg, Sweden.

Previous studies in our laboratories have indicated that in rats and rabbits the dopamine containing neurons gradually develop their functions during the first week postnatally, suggesting that the first week of postnatal life may be considered as a vulnerable period for the functional maturation of central dopaminergic mechanisms. Accordingly the functional consequences of giving drugs that specifically affect central dopaminergicmechanisms during this vulnerable period was investigated.

Neonatal rats were given the dopamine receptor antagonists penfluridol or pimozide during the first postnatal week via their nursing mothers. This treatment resulted in deficits in the acquisition of an active avoidance response at the age of 4 weeks. Moreover the offspring of the rat mothers treated with penfluridol displayed an increased open field ambulation prepuberally followed by an abnormally decreased activity postpuberally. No deficits were found in the development of locomotion, air righting, startle response and eye opening.

Associated with the behavioral changes we have found a decreased synthesis(measured as the accumulation of dopa after inhibition of aromatic amino acid decarboxylase) and utilization (measured as the disappearance of catecholamines after inhibition of tyrosine hydroxylase) of dopamine in the mesolimbic, but not in the nigrostriatal, dopamine neurons at 4 weeks of age. Furthermore an increase in the specific bindning of ^{3}H-spiroperidol to membranes of the limbic forebrain, but not to those of the striatum, was found in the 4 weeks old offspring of penfluridol treated mothers. The finding that apomorphine caused a more marked decrease in the accumulatiom of dopa after inhibition of aromatic amino acid decarboxylase and pretreatment with gamma-butyrolactone in the 4 weeks old penfluridol treated rats suggest that also presynaptic receptors may be affected by the early postnatal penfluridol treatment.

In support of the assumption that the behavioral syndrome is related to a dysfunction of central, possibly mesolimbic, dopamine systems we have found that the learning deficits could be counteracted by amphetamine, which acts by increasing the functional activity of the catecholamine neurons.

248.7 COMPARISON OF β-NERVE GROWTH FACTOR PRODUCED BY CULTURED FIBROBLASTS FROM CONTROLS AND PATIENTS WITH FAMILIAL DYSAUTONOMIA. M.H. Grossman[1], J.P. Schwartz[2], and X.O. Breakefield[1]. [1]Dept. of Human Genetics, Yale Univ. Sch. of Med., New Haven, CT 06510; [2]Lab. Preclinical Pharmacology, NIMH, Washington, D.C. 20032.

Nerve Growth Factor (NGF) is essential for the survival and differentiation of sympathetic and sensory neurons. Previous studies (Schwartz and Breakefield, P.N.A.S., 77:1154, 1980) have shown that cultured human skin fibroblasts produce relatively small amounts (10-20 ng/mg cell protein) of a protein which competes with mouse β-NGF (purified from submaxillary glands) for antibodies prepared against it. Further, extracts from these fibroblasts can elicit neurite outgrowth from 14-day chick embryo dorsal root ganglia in a dose-dependent manner and this response is blocked by antiserum to purified mouse β-NGF.

Familial dysautonomia is an inherited neurologic disease characterized by deficits in autonomic and sensory functions, and by reduced neuronal numbers in sympathetic and dorsal root ganglia (Pearson et al., J. Neurol. Sci., 35:77, 1978). A comparison of β-NGF in fibroblasts from patients with familial dysautonomia and controls indicated that immunoreactive β-NGF from patients had about one-tenth the biologic activity as that from controls. Current studies have focused on attempts to compare the structure of β-NGF produced by these two cell populations. After growing cells in ^{35}S-cysteine and a ^{14}C-amino acid mixture, immunoprecipitating labelled proteins with antiserum to mouse β-NGF and analyzing proteins by SDS-polyacrylamide gel electrophoresis, both control and dysautonomic cells were found to synthesize an immunoprecipitable protein which comigrates with authentic purified mouse β-NGF (MW = 13,250 daltons). There was no apparent molecular weight difference between the β-NGF from control and dysautonomic cells. We are currently employing isoelectric focusing, non-equilibrium pH gradient electrophoresis and two-dimensional peptide mapping to elucidate possible alterations in amino acid sequence of β-NGF from dysautonomic cells. (This work was supported by the Dysautonomia Foundation and by USPHS Grant GM20124.)

248.8 LEARNING/RETENTION DEFICITS IN THE RAT FOLLOWING MILD PRENATAL CARBON MONOXIDE EXPOSURE. C.F. Mactutus, Z. Annau & L.D. Fechter The Johns Hopkins University, School of Hygiene and Public Health Baltimore, MD 21205

Behavioral tasks which evaluate learning and memory abilities may be particularly sensitive indicies of neurotoxicity as these behaviors require the functional integrity of the central nervous system. It was recently reported that the offspring of rats exposed prenatally to a low concentration of carbon monoxide, which results in carboxyhemoglobin levels approximating those maintained by human cigarette smokers, may show reduced birth weight and decreased weight gain (Science, 1977, 197, 680), as well as retarded development of reflexive (negative geotaxis and auditory startle) and simple (homing) behaviors (Neurobeh. Tox., in press). We now report more serious functional consequences of low level prenatal CO with a behavioral index of learning and memory.

Pregnant female Long-Evans rats, bred in our laboratory, were housed throughout gestation in exposure chambers which received either compressed filtered air or air diluted with CO (150 ppm). Within 12 hr of birth the neonates were counted, weighed, and examined for gross teratogenesis. Litters were culled to 8 pups.

The ontogeny of learning and retention for two-way avoidance was assessed. Six pups from each litter were randomly selected; one male and one female were trained at 16, 23 and 30 days of age. All subjects received 100 acquisition trials followed by a 24-hr retention interval and 100 reacquisition trials.

Body weight data revealed that neither at birth nor throughout the developmental period sampled were the CO subjects significantly lighter than their AIR counterparts. No gross abnormalities were observed in either group.

Avoidance acquisition was minimal at 16 and 23 days of age. At 30 days of age a significant sex by exposure treatment interaction indicated the CO males, but not the CO females, made significantly fewer avoidance responses relative to their respective controls. Shock escape latencies on the initial five trials suggested the prenatal CO treatment had not altered pain sensitivity nor motivational factors. Significant savings were noted for the AIR but not CO males, and for both the CO and AIR females. Whether the lack of savings for the CO males reflects a retention impairment above and beyond the original acquisition deficit is under study.

The highlights of the present data are: 1) a significant deficit in learning/retention ability consequent to mild prenatal CO exposure which would have gone undetected by conventional measures of teratogenesis, enhanced mortality, or decreased birth weight, and 2) the greater resistance of female over male pups to the neurobiological consequences of prenatal CO exposure.

248.9 Distribution of Acetylcholinesterase - positive fibers in the normal and reeler mutant mouse cochlear nucleus. Michael R. Martin, LNO, NINCDS, NIH, Bethesda, MD 20205

The reeler gene is an autosomal recessive mutation affecting cell migration, cell orientation and granule cell number in cerebral and cerebellar structures (c.f. Caviness and Rakic, Ann. Rev. Neurosci. 1: 297, 1978, for review). It is believed that these abnormalities are due to aberrant cell-to-cell recognition patterns rather than disorders of cell proliferation or synapse generating mechanisms. The dorsal cochlear nucleus (DCN) in the reeler shows a similar description of laminar organization and loss of granule cells. One of the few known inputs to the granule cells of the cochlear nucleus is the acetylcholinesterase (AChE)-containing fibers from the superior olivary complex (Rasmussen, In Sensorineural Hearing Processes and Disorders, A.B. Graham, ed., 1967). The current study was designed to ascertain the effects of the reeler gene on the AChE-positive fibers innervating the cochlear nucleus.

The direct-coloring method of Karnovsky and Roots (J. Histochem. 12: 219, 1964) was used to demonstrate cholinesterase activity. For controls, ethopropazine was used to inhibit pseudocholinesterases or BW 284C-51 to inhibit AChE. Reeler mutant mice and littermate controls were obtained from the B6C3 colony at Jackson Labs.

In the normal mouse AChE-positive fibers enter the medial anterior and posterior ventral cochlear nuclei (AVCN, PVCN) via the acoustic stria. The granule cell bridge between the DCN and PVCN receives a number of fibers. A few of these fibers enter the deep DCN and caudal PVCN. None continue into the molecular layer of the DCN. AChE-positive fibers reach the granule cell layer covering the lateral aspect of the PVCN by first traversing the PVCN. The PVCN and interstitial region of the caudal AVCN receive a large number of AChE-positive fibers. Very few fibers enter the other regions of the AVCN. In reeler AChE-positive fibers in the granule cell bridge between the DCN and PVCN are greatly reduced. No fibers innervate the DCN or the lateral granule cell layer. The number of fibers in the PVCN and interstitial region are also greatly reduced.

It is concluded that the AChE-positive afferent innervation of the cochlear nucleus is abnormal in reeler. Several possible factors may be involved including a lesion affecting the cells of origin for these fibers or an abnormality in cell-to-cell recognition patterns between AChE-positive fibers and the postsynaptic cells of the cochlear nucleus.

248.10 ELECTROPHYSIOLOGICAL CORRELATES OF ALUMINUM NEUROTOXICITY IN THE ABSENCE OF NEUROFIBRILLARY DEGENERATION. B.J. Farnell*, U. De Boni* and D.R. Crapper McLachlan. Dept. of Physiology, Univ. of Toronto, Toronto Canada M5S 1A8.

Elevated aluminum concentration occurs in several human brain diseases but the physiological significance of this observation is unknown. The in vitro hippocampal slice preparation was employed to investigate the electrophysiological consequences of an aluminum induced encephalopathy. Four week old rabbits received .05 ml of either 5 µmoles aluminum lactate (n=23) or 15 µmoles sodium lactate (n=12) into each dorsal lateral ventricle. Slices were prepared from the right dorsal hippocampus at 5,10,15 and 20 days post injection. Input-output curves relating stimulus strength to input fiber prepotential, population EPSP and population spike were analysed.

Thirty six slices from 5-day (n=5) and 10-day (n=5) post aluminum treated animals and twelve slices from six sodium lactate injected animals exhibited orthodromic and antidromic excitability characteristics indistinguishable from control slices. All 17 slices from 15-day aluminum treated animals (n=5) demonstrated a significant reduction in the magnitude of the CA1 pyramidal cell layer population spike evoked from both apical and basilar orthodromic inputs. Thirty one slices from either 20-day post aluminum treated animals demonstrated a further significant decline in the evoked population spike response. These changes occur without alterations in the input-output curves relating stimulus strength, input fiber prepotential, dendritic population EPSP and antidromic excitability.

All of the slices were tested for their ability to sustain Long Term Potentiation of the population spike. The conditioning stimulus was a 1 sec. 100 Hz train at a voltage selected from 1/2 to 2/3 along the input-output curve, and applied to the stratum radiatum input to CA1. The criteria for potentiation was a population spike showing an increase of at least 25% above the baseline response for thirty minutes after the tetanization. The percentage of slices meeting this criteria were; 68% untreated and sodium lactate treated controls, 50% for 5-day, 35% for 10-day, 30% for 15-day, and 20% for 20-day post aluminum treated animals.

These studies indicate that aluminum causes a delayed reduction in the ability of the CA1 pyramidal cell population to demonstrate long term potentiation as well as an even later developing decrement in its ability to generate the population spike in response to afferent input. The Bielchowsky stain revealed that these electrophysiological changes occur in the absence of neurofibrillary degeneration of the CA1 pyramidal cells. The development and time course of these electrophysiological changes is consistent with delayed effects of aluminum upon brain metabolism. Supported by the Canadian Geriatrics Research Society.

249.1 GENETIC VARIATION IN NUMBER OF DOPAMINE NEURONS IN HYPOTHALAMUS AND PREOPTIC REGION OF TWO INBRED MOUSE STRAINS: H. Baker, T. H. Joh, D. J. Reis, Laboratory of Neurobiology, Dept. of Neurology, Cornell Univ. Med. College, New York, NY 10021.

Strain dependent variations in the activity of tyrosine hydroxylase (TH) in the midbrain tegmentum of mice of the BALB/cJ and CBA/J strains is entirely consequent to variations in the number of dopaminergic (DA) neurons (Baker et al., PNAS, 1980). We sought to determine whether there are comparable strain-dependent variations in the numbers of neurons in the hypothalamic DA systems including those of the tuberohypophysial (A12) group, the incerto hypothalmic (A13) group and a rostrally extending periventricular (A14) group which in the mouse is quite large in the preoptic area. TH activity was determined in microdissected blocks of brain, one containing the A12 and A13 groups and the other the preoptic portion of the A14 group. In both regions TH (nmols/mg prot./hr activity was greater in BALB/cJ than CBA/J mice:

Area	BALB/cJ	CBA/J	CBA/BALB	P
A12-13	2.67 ± .07	1.58 ± .02	.59	<.01
A14	1.23 ± .03	0.92 ± .10	.75	<.05

The greater TH activity in the BALB/cJ than CBA/J mice reflects differences in TH activity in DA and not noradrenergic neuronal systems since dopamine-β-hydroxylase activity in the A12-13 region was greater in CBA/J than BALB/cJ mice. DA neurons were immunocytochemically stained with specific antibodies to TH and counted through the entire hypothalamic-preoptic region. The total number of stained neurons in the A12-13 region was significantly greater (P<.05) in BALB/cJ than CBA/J mice (7012 ± 537 and 4984 ± 359 respectively). Similarly, at the level of the medial preoptic nucleus there were more A14 neurons in the BALB/cJ than CBA/J mice (3876 ± 522 and 1623 ± 310 respectively). We conclude that: (a) there is a strain difference (BALB/cJ > CBA/J) in hypothalamic TH activity between two inbred mouse strains; (b) the differences in TH activity can be attributed to greater numbers of neurons in all DA cell groups in this region, including A12-A14. These data suggest that genetic control of the number of DA neurons in these mouse strains is not restricted to midbrain DA systems but may be generalized.

249.2 LURCHER ↔ WILD-TYPE CHIMERIC MICE: CEREBELLAR PURKINJE CELLS ARE PRIMARY SITE OF GENE ACTION. Richard Wetts and Karl Herrup. Dept. of Human Genetics, Yale Med. Sch., New Haven, CT 06510.

Lurcher is an autosomal dominant mutation in the mouse which causes ataxia in the heterozygote (+/Lc). Morphological and developmental studies (Caddy and Biscoe, 1979; Swisher and Wilson, 1977) have shown a dramatic series of cellular degenerations in the +/Lc brain. The cerebellar cortex is most severely affected. Virtually all of the Purkinje cells and a large majority of the granule cells degenerate during the first postnatal month. In the brain stem, the number of cells in the inferior olive (source of cerebellar climbing fibers) is also greatly reduced. As with most other neurological mutants studied, one can ask what is the primary site of gene action and which of the described defects are secondary epigenetic phenomena.

To answer this question we have made lurcher aggregation chimeras. Pairs of lurcher (+/Lc;a/a;Gus^{b}/Gus^{b}) and wild-type +/+;A/A;Gus^{h}/Gus^{h}) 8-cell embryos were aggregated, cultured overnight and transferred to a host female to finish development. All of the verified lurcher chimeras examined thus far have been behaviorly normal, including one animal (χ11) who was 90-95% lurcher in composition. Upon opening the skull, the chimeric cerebella were found to be intermediate in size between lurcher and wild-type. Cytological examination revealed a well ordered trilaminar arrangement in the cellular cortex. Both molecular and granule cell layers appeared roughly normal in width and cell density. The Purkinje cell layer, by contrast was sparsely populated. In sections from χ11, entire folia were commonly found with fewer than 5 Purkinje cells present. The inferior olivary nuclei appeared normal in size and cell density. β-glucuronidase histochemistry revealed that all Purkinje cells present in the chimeras were Gus^{h}/Gus^{h} hence +/+ in genotype. The cells of the inferior olive were a mixture of the two genotypes whose proportions reflected the overall ratio of genotypes in the chimera. Significant in this context was the finding that in χ11 most of the olivary neurons were +/Lc. β-glucuronidase is unfortunately not an appropriate marker for granule cells.

The findings strongly implicate the Purkinje cell as a primary site of gene action thus confirming the hypothesis of Caddy and Biscoe. Despite the mosaic of genotypes in which they develop, not a single lurcher Purkinje cell survived to 3 months of age. By contrast, the +/Lc olivary neurons are "rescued" by the presence of wild-type cells in the chimera suggesting their demise is a secondary event in the +/Lc mutant.

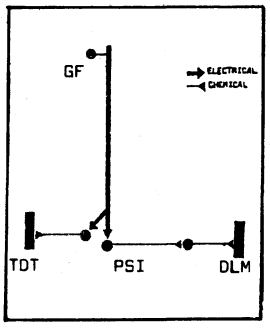
249.3 MUTATIONS AFFECTING THE GIANT FIBER SYSTEM OF DROSOPHILA. John B. Thomas* (SPON: R.J. Wyman) Dept. of Biol., Yale Univ., Box 6666, New Haven, CT 06511.

Identified neurons of the giant fiber system in D. melanogaster, as diagrammed in the figure, have been studied in our lab using physiological and anatomical techniques. Each of the bilaterally paired giant fibers (GF) monosynaptically drives the ipsilateral TTM (jump muscle) and disynaptically, via the PSI interneuron, the contralateral DLM (flight muscle) (King and Wyman, J. Neurocytol., in press). The giant fibers can be reliably driven by a light-off stimulus in white-eyed flies of the brown; scarlet genotype.



Mutations on the X-chromosome affecting the structure and/or function of the giant fiber system were isolated using a behavioral screen to select flies failing to jump to the light-off stimulus. 40,000 flies carrying EMS-mutagenized chromosomes were screened. Non-jumpers were tested for physiological defects. Two mutants, nj75 and nj156, were found which have abnormal giant fiber output. In a third, nj42, there is apparently selective degeneration of the TTM.

In nj75 flies the TTM is driven normally by the giant fiber, but the DLM is not. The DLM can be driven only at abnormally low frequencies, and its latency is long and variable (2.5-3.0 msec vs. the normal 1.5 msec*). Since the neuromuscular junctions are normal, the defect is likely to lie in the PSI, or its synaptic input or output.

Neither muscle is driven normally by the giant fiber in nj156 flies, although the nmjs are normal. There is no response in the DLM; the TTM can be driven only at low frequencies and with a longer than normal latency (1.7 vs. 1.0 msec*).

In both mutants the morphology of the giant fiber appears normal using intracellular injection of Lucifer Yellow.

Supported by USPHS #NS-07314 to R.J. Wyman.

249.4 ALTERED CONDUCTION OF IMPULSES AND REDUCED TRANSMITTER RELEASE INDUCED BY SINGLE GENE MUTATION IN MICE. A. Mallart, J.J. McArdle, D. Angaut-Petit and R. Bournaud. Lab. Neurobiol. Cellulaire, CNRS, 91190 Gif/Yvette, France.

Neuromuscular impairement in the single gene mutation of mice called motor end-plate disease (med) starts at 11 days of age and becomes increasingly severe until death occurs by the end of the 3rd week. We performed an in vitro electrophysiological study of impulse conduction by the motor nerves and of transmitter release at the motor endings both in med and in Swiss mice of the same age which served as a control. Altered conduction of nerve impulses was the more constant finding in med mice : all the examined motor axons innervating the deep thoracic muscle were affected in a more or less severe way irrespective of the age of the animal. The intercostal motor nerves were stimulated with suction electrodes and the nerve action potentials or end-plate potentials (e.p.p.s) recorded with microelectrodes. The conduction velocity was 2.68 ± 0.7 $m.s^{-1}$ (S.D., N = 35) for the whole med population as compared to 8.28 ± 3.3 (N = 59) for the controls. The absolute refractory period of conduction, measured by stimulating the nerve with paired shocks of variable interval was on the average 11.33 ± 3.6 msec, (N = 29) in med and 2.61 ± 0.6 msec (N = 28) in controls. By raising the bath temperature above 21°C, all or none conduction block of impulses occurred in med nerves at temperatures ranging between 23 and 36°C, while nerves from controls were blocked at 46-49°C. Spontaneous transmitter release in both young and old med mice was comparable to that observed in control at corresponding ages. On the contrary, evoked transmitter release in med aged 19-23 days was greatly reduced as compared to younger med and to controls. As a consequence 3-4 times less magnesium was required in the former to block neuromuscular transmission. We conclude that altered conduction of impulses is the major neurobiological defect in the med mice, yet we cannot ascertain whether defective transmitter release is a consequence of alterations of the motor axon or both correspond to independent expressions of the med gene. Supported by the D.G.R.S.T. grant n° 79 7 1066.

249.5 FIRST EYE-OPENING: BLACK VS. ALBINO C57BL/6J-c^{2J} LITTERMATE MICE. I. S. Westenberg. Ill. Inst. Devel. Disabil., Chicago, IL 60608.

Wang (1927) noted that pigmented rat pups' eyes open 1-2 days later than albino rat pups' eyes. This suggests that visual system anomalies recently associated with albinism in adult rodents may be related to abnormalities in the timing of the developmental sequence of the albinic visual system. Unfortunately, early comparisons were between pigmented rodents of one strain and albinos of some other strain. Thus, the variables of albinism and strain were confounded. This problem is solved here by comparison of black vs. albino littermates of the same inbred mouse strain, C57BL/6J-c^{2J}. The hypothesis is: For litters of blacks and albinos the first-detected eye-openings are more likely to be in albinos than in blacks.

Albino mice had 2 mutant c^{2J} genes at the albino, or c, locus (c/c); their black littermates had 1 mutant c^{2J} gene and 1 normal gene at the c locus (c/+). Each litter was checked daily; there were 3 possible outcomes: The first eye-opening could be in c/c (a), in c/c and c/+ (tie), or in c/+ (b).

Results in 32 litters were 9 a, 16 tie, and 7 b; these did not differ significantly from those expected by chance (χ^2 test). To detect sex effects the data for males and females were analyzed separately; neither males' nor females' frequencies of a and b differed significantly from chance. To detect maternal effects the data for litters by c/c mothers and litters by c/+ mothers were analyzed separately; again, a, tie, and b frequencies were close to chance. To detect c/c - c/+ differences in litters with early first eye-opening the data for litters with first openings on or before day 12 were analyzed separately; a and b frequencies were not significantly different from chance. In summary, no c/c - c/+ differences were found. Thus, at least for this strain of this species of rodent, precocious eye-opening does not appear to be specifically associated with albinism.

The difference between these results and Wang's may be related to: Experimental design (within-strain vs. between-strains comparison); species (mouse vs. rat); genotype of pigmented rodents (c/+ vs. +/+). The within-strain design was chosen as more efficient for isolating the effects of single mutant genes. Mice were used for genetic controls not yet available in rats. It is unlikely that c/+ black mice's results would have differed from +/+ black mice's, but this remains to be tested. It is possible that c/c - c/+ comparisons in other mouse strains will produce different results. Of course, the present results do not rule out the possibility of abnormalities in the timing of the developmental sequence of the visual system in albinos; the entire sequence must be examined with proper genetic controls.

249.7 Neurobiological defects of muscle and nerve in murine muscular dysgenesis (mdg/mdg).

F. Rieger, R. Bournaud, M. Pinçon-Raymond, P. Dreyfus and B. Blondet.
Groupe Biologie et Pathologie Neuromusculaires INSERM U 153 75005 PARIS FRANCE and Lab. Physiologie Générale Université Paris XII Creteil FRANCE.

Muscular dysgenesis (mdg) in the mouse is a single recessive autosomal lethal mutation. Affected embryos never show any sign of contractile activity during the whole gestation period and are dead at birth. Mdg/mdg muscles present immature cytological aspects, although less accentuated in diaphragm. Cytochemically demonstrable acetylcholinesterase is localized all over mdg/mdg muscles, in discrete foci of high acetylcholinesterase activity. Isolated single myofibers possess several areas of acetylcholinesterase accumulations and acetylcholine receptors clusters, suggesting multiple innervation. Silver nitrate staining of the motor innervation of skeletal muscles in mdg/mdg embryos at the time of birth evidences a spectacular overgrowth of mdg/mdg nerves and a generalized collateral and ultraterminal sprouting of axons. Neuromuscular transmission exists in mdg/mdg embryo's diaphragm, but the spontaneous myofiber membrane activities are higher in mdg/mdg then in +/mdg? muscle. The spontaneous activities are generated by the release of acetylcholine : they can be blocked by d-Tubocurarine in both +/mdg? and mdg/mdg phrenic nerve - diaphragm preparations. Direct evidence for multiaxonal innervation is found in both +/mdg? and mdg/mdg muscle, since the end-plate potentials varie in a step-wise manner with increasing stimulation. Moreover, an mdg/mdg myofiber can be innervated in several locations, as it was often found that different intensities of stimulation evoke end-plate potentials with different latencies and time course. Thus, mdg/mdg myofibers and axons are in functional contact, in several regions of each myofiber and in morphologically variably mature appositions, and multiple innervation develops more in mdg/mdg embryos than in normal ones.

249.6 WEAVER MUTANT GRANULE CELL DEFECT EXPRESSED IN CHIMERIC MICE. D. Goldowitz and R.J. Mullen*. Dept. of Anatomy, Univ. of Utah College of Medicine, Salt Lake City, Utah 84132.

The cerebella of both heterozygous and homozygous weaver (wv) mutant mice have abnormalities in granule cells, Bergmann glia (Golgi epithelial cells), and Purkinje cells. To determine in which cell type(s) the mutant gene is acting we produced experimental chimeras containing mixtures of genetically mutant and genetically normal cells. For Purkinje cells, allelic differences in β-glucuronidase activity (Gus) was used as an independent cell marker to determine the genotype of a cell irrespective of its phenotype. In wv/+ $Gus^b/Gus^b \leftrightarrow$ +/+ Gus^h/Gus^h chimeras we found ectopic Purkinje cells included some that were Gus^b (high glucuronidase) and hence wv/+ but also some that were Gus^h (low glucuronidase) and hence +/+ in genotype. The latter we interpret to mean that the Purkinje cell ectopia is not caused by the wv locus acting within the Purkinje cell.

In normal mice a fraction of one percent of the granule cells are found ectopically within the molecular layer whereas in wv/+ mice many granule cells are stranded there during their migration from the external granule cell layer to the internal granule cell layer (IGL). For granule cells, the ichthyosis (ic) locus was used as an independent cell marker. In ic/ic cells there is a greater tendency for the heterochromatin to be clumped in the center of the nucleus rather than being distributed along the nuclear membrane. In wv/+ +/+ ↔ +/+ ic/ic chimeras the internal granular layers were a mixture of +/+ and wv/+ cells. The ectopic granule cells, however, were almost exclusively wv/+ in genotype regardless of the proportion of wv/+ cells in the IGL. These results with wv/+ chimeras suggest that the wv locus does act intrinsically within the granule cell.

At present, we do not know whether the Bergmann glia are directly affected by the wv locus or what interaction might be occurring between the neuron and glia. Additional studies and studies of homozygous weaver chimeras might shed light on these questions. (Supported by NIH Grant NS 16156 and the March of Dimes Birth Defects Foundation.).

250.1 EARLY ONTOGENETIC RESPONSES TO THE SEROTONERGIC AGONIST, QUIPAZINE. Linda A. Ristine* and Linda Patia Spear, Department of Psychology, S.U.N.Y., Binghamton, N.Y. 13901.

Three day old Sprague-Dawley rat pups were given saline, 1, 2.5, 5, or 10 mg/kg quipazine and placed in an incubator at room temperature (22±1°C.) or nest temperature (35±1.5°C.). Beginning 5 min. post-injection, behavioral-time sampling data were collected every 20 sec. for a test duration of 20 min. Quipazine induced a marked dose-dependent increase in activity which included increases in forward locomotion, wall climbing, rolling onto back, forelimb paddling, and hindlimb treading movements. Quipazine also induced a characteristic posture and tremor of the fore- and hindlimbs frequently evident when the animal was stationary -- the paws were held up in the air with the elbows on the floor of the apparatus. Straub tail was induced by the highest doses of quipazine only in neonates tested at room temperature. Quipazine induced an increase in mouthing which was much more prevalent at nest temperature than at room temperature. Not only was this mouthing temperature dependent, it also was positively correlated with length of deprivation of the pup away from the mother.

These results suggest that administration of a serotonergic agonist can have marked behavioral effects in the neonatal rat pup. Some aspects of these behavioral responses are similar to those seen after serotonergic agonist administration to adult animals (e.g., forelimb paddling, Straub tail, unusual limb posture) (Jacobs, Life Sci., 1976, 19, 777), while other behavioral responses are unique to developing animals (e.g., increases in motor movements and mouthing). That quipazine induces temperature- and deprivation-dependent mouthing early in life is interesting as quipazine inhibits rather than accentuates suckling behavior in deprived weanling rats (Nock, et al., Pharmacol., Biochem. Behav., 1978, 8, 277). Further implications of these results will be discussed.

250.2 ENKEPHALIN-LIKE IMMUNOREACTIVITY IN DEVELOPING AVIAN BASAL GANGLIA AND NUCLEUS SPIRIFORMIS LATERALIS. B.M. Davis*, N. Brecha and H.J. Karten. Department of Neurobiology and Behavior, State University of New York at Stony Brook, Stony Brook, N.Y. 11794.

Immunocytochemistry was used to follow the expression of enkephalin-like immunoreactivity (ELI) in two areas of the embryonic chick brain, the basal ganglia, and a pretectal nucleus, nucleus spiriformis lateralis (SpL).

Staged embryos (Lillie 1936) were dissected free of egg membranes and perfused with periodate-lysine-paraformaldehyde fixative. Whole embryos or brains were post-fixed for 2 hours and stored overnight in 30% sucrose phosphate buffer at 4°C. The embryos or brains were sectioned at 10μm on a cryostat. Sections were picked up on to warm gelatin coated slides and subsequently processed for ELI as described elsewhere (Brecha, et al 1979).

SpL is a nucleus located at the meso-diencephalic junction, whose cells receive a massive input from a basal ganglionic nucleus, paleostriatum primitivum (the avian equivalent of mammalian globus pallidus). SpL gives rise to a large projection upon the ipsilateral optic tectum. In the adult, all cells in SpL have ELI. SpL neurons arise between the 5th and 6th day of embryogenesis (Kuhlenbeck, 1936). Enkephalin positive cells are first seen in the pretectal area and probably presumtive SpL on the 6th day of embryogenesis. These cells are small neuroblast-like cells. In the adult, the cells are multipolar with diameters measuring approximately 25μm.

The avian basal ganglia is composed of four nuclei, distinguishable on the basis of their cytoarchitecture, connectivity and histochemistry. These nuclei are: paleostriatum augmentatum (PA), paleostriatum primitivum (PP), lobus parolfactorius (LPO), and intrapeduncularis telencephali (INP). Preliminary autoradiographic data indicate that PA cells begin to develope during the 4th day of embryogenesis. ELI was first observed in small, round neuroblast-like cells of five day old embryos (Stage 26). Enkephalin positive cells were first found near the external border of the telencephalic vesicles, at the level of the ventricular ridges, the proliferative zones which give rise to the basal ganglia. At later stages, enkephalin positive cells are located more internally. The pattern of expression of ELI results in an "external-internal" spatial temporal gradient. Enkephalin positive cells form a dense accumulation of somata and processes. The density of immunoreactive somata and processes increases up to stage 36, at which time the enkephalin positive cells begin to disperse. In the adult chicken, the enkephalin positive somata are widely separated and confined exclusively to PA and LPO. Fibers with ELI originate in PA and LPO and terminate in PP and possibly in INP. In the adult the enkephalin positive cells are 13-15μm in diameter.

250.3 ACETYLCHOLINESTERASE ACTIVITY IN NEURAL CREST CELLS OF THE AVIAN EMBRYO. P. Cochard* P. Coltey* and N.M. Le Douarin* (SPON: I.B. Black). Institut D'Embryologie Du CNRS 94130 Nogent Sur Marne - France.

Recent work by our group has demonstrated that mesencephalic neural crest cells in the process of migration possess the ability to synthesize significant amounts of acetylcholine (ACH) and, in fact, exhibit detectable activity of the ACH synthesizing enzyme choline acetyltransferase, a fundamental marker of the cholinergic system. The significance of this observation still remains to be established. The present study was undertaken to determine whether another trait of the cholinergic metabolism, the ACH catabolic enzyme acetylcholinesterase (ACHE) was also present in neural crest cells at the onset of migration. Transverse sections of quail and chick embryos at various stages of development were processed for histochemical and cytochemical demonstration of ACHE activity. Results obtained at the optical level showed that ACHE activity was present in cephalic as well as truncal neural crest cells before and during their migration. Enzyme activity was first histochemically detectable at the time of closure of the neural tube, in cells of the neural fold. Activity increased thereafter and maximum staining occurred at the time of individualization of the neural crest. The histochemical reaction then diminished in the migrating crest cells. Identical results were obtained with both quail and chick embryos although the intensity of the reaction was somewhat stronger in crest cells of the latter. Intracellular distribution of the cytochemical reaction product was also studied. Strong ACHE staining was found mainly in perinuclear cisternae and smooth endoplasmic reticulum of crest cells, before and during their migration. Reaction product was sometimes observed in the Golgi apparatus but was never found associated with cell membranes or cell processes. A small proportion of the migrating crest cell population appeared totally devoid of ACHE activity.

These findings indicate that neural crest cells from each level of the neural axis possess the enzyme responsible for ACH degradation well before they start migrating. Moreover it appears that they retain this characteristic while migrating. Thus, it seems that neural crest cells develop some traits of cholinergic metabolism at an early stage of development. This phenomenon could represent the expression of an early differentiation of presumptive cholinergic neuroblasts or be an intrinsic property of all developing neuroblasts. Alternatively the metabolism of ACH might be related to the migration process.

This work was supported by the NIH and the CNRS, France.

250.4 EFFECTS OF TUNICAMYCIN ON NEURITE OUTGROWTH, GLYCOCONJUGATE SYNTHESIS AND LECTIN BINDING IN GOLDFISH RETINA EXPLANTS. Anne M. Heacock. Neuroscience Laboratory, University of Michigan, Ann Arbor, MI 48109.

Tunicamycin (TNI), a blocker of glycoprotein synthesis via the dolichol pathway, inhibits outgrowth of neurites from explanted goldfish retina (Heacock, Neurosci. Abst. 5, 756 (1979). Dolichol sugars participate in the sequential addition of carbohydrate units to long chain isoprenoid alcohols which act as glycosyl carriers for ultimate transfer of core oligosaccharide to protein-bound asparagine residues. TNI (gift of G. Tamura) interferes with an early step in this pathway, the synthesis of N-acetyl glucosaminyl pyrophosphoryl dolichol, thus preventing formation of dolichol oligosaccharides. This report further characterizes the effects of TNI on goldfish retina explants and on intact retina in vitro.

Tunicamycin at 1, 5 or 10 μg/ ml inhibited neurite outgrowth by 32, 61 and 80%, respectively. The neurites which did grow out had an appearance similar to controls. In order to determine if the neurite membrane assembled in the presence of TNI was deficient in glycoproteins, the lectin binding ability of these neurites was compared to that of untreated cultures. Fluorescence photomicrography, following labeling with rhodamine Concanavalin A, indicated a decreased binding in the TNI-treated cultures.

The mode of action of TNI was examined by labeling studies with various precursors. Maximal inhibition of ^{3}H-glucosamine and ^{3}H-mannose incorporation into glycoprotein (46-54%) occurred with 5 μg/ml TNI. Protein synthesis was inhibited only 13% under these conditions. Because of the limited amount of tissue in the explants, further studies were carried out with intact retinas incubated in vitro. A 4-6 h preincubation with TNI was necessary for maximal inhibition of glycoprotein labeling (40-50%). The residual labeling may at least partially represent more distal attachment of carbohydrate to pre-existing, incomplete glycoproteins. SDS gel electrophoretograms of ^{3}H-glucosamine-labeled homogenates from control and TNI-treated retinas were very similar except for a low molecular weight gel region where labeling was almost abolished by TNI. Material in this region, which was also labeled with ^{3}H-mannose and ^{3}H-glucose, was extractable in $CHCl_3$:MeOH:H_2O (10:10:3) and appears to represent dolichol oligosaccharide. The magnitude and concentration dependence of the TNI effect on the synthesis of this presumptive dolichol oligosaccharide closely resembled that for neurite outgrowth. SDS PAGE revealed at least one ^{3}H-leucine-labeled protein band which was present in TNI-treated but absent in control retinas. (Supported by NS 13743.)

250.5 ANALYSIS OF ABUNDANT mRNAS IN THE DEVELOPING RAT CEREBELLUM. M. Morrison* and W.S.T. Griffin. (SPON: A. Ehle). Dept. of Neurology and Cell Biology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, Tx 75235.

Although many brain functions are dependent on the regulated synthesis of specific proteins, little is known about the synthesis and utilization of their messenger RNAs (mRNAs) during development. We have used two-dimensional gel electrophoresis to compare both the pattern of abundant steady state proteins and the steady state levels of their cerebellar mRNAs. At various stages of postnatal development there were reproducible increases in the steady state levels of several proteins with pIs between 4.5 and 7.0. Of particular interest was a decrease in the levels of the more basic tubulin subunits with age. In order to determine whether these changes were a consequence of alterations in cerebellar mRNA levels, total cytoplasmic RNAs were isolated and compared by two dimensional gel analysis of their in vitro synthesized translation products. During early postnatal development (day 2-6), the mRNA profiles are relatively similar. By day 14, at a time when cell division is slowing and synaptogenesis and myelination are occurring, the mRNA pattern characteristic of adult cerebellum is emerging. By 30 days, this pattern is dominant and remains almost unchanged thereafter. Quantitation of synthesized proteins show that there is a 65% decrease in the synthesis of the tubulin subunits. This decrease is especially marked for the mRNAs coding for the more basic tubulin subunits, T_{β}. Their ratio relative to the mRNAs for the acidic subunits, $T_{\alpha 1}$ and $T_{\alpha 2}$ falls from 1.17 at day 2 to 0.57 at day 90. There is also a 61% decrease in the relative amount of actin mRNA as well as in the mRNAs coding for several as yet unidentified proteins (e,q,s,v,5). Although there is a dramatic decrease in the levels of protein s mRNA between days 2 and 6 and in the levels of protein 5 mRNA between days 6 and 14, most changes occur somewhere between days 14 and 30. The steady state levels of other mRNAs increase with age (p,k,1). Each of these shows different developmental patterns with 1 mRNA increasing steadily throughout development, p mRNA being dramatically induced between 14 and 30 days and k mRNA only being substantially increased after 30 days. This study supports the idea that periods of rapid brain development are accompanied by precisely regulated steady state levels of specific mRNAs.

Support for this work was provided by NIH AI 14663 and a grant from the Leland Fikes Foundation.

250.6 THE DEVELOPMENT OF GLUTAMIC ACID DECARBOXYLASE (GAD) AND CHOLINE ACETYLTRANSFERASE (ChAT) IN THE VISUAL CORTEX AND DORSAL LATERAL GENICULATE NUCLEUS OF THE RAT. J.K. McDonald, S.G. Speciale* and J.G. Parnavelas. Depts. of Cell Biology and Psychiatry, Univ. Tx. Health Sci. Ctr., Dallas, TX 75235.

Although the mammalian visual system is anatomically and electrophysiologically one of the most extensively investigated systems in the brain, there are surprisingly few accounts of its neurochemistry. It is in this regard, that we sought to investigate the activity of glutamic acid decarboxylase (GAD) and choline acetyltransferase (ChAT), the enzymes responsible for the synthesis of γ-aminobutyric acid and acetylcholine respectively, in the visual cortex and the lateral geniculate nucleus of the adult and developing rat.

Sprague-Dawley albino rats of both sexes 0,4,6,8,14,18,21,24 days and 5 months old were used in this study. The animals were decapitated, their brains were rapidly removed and frozen on dry ice and 300 μm coronal sections were cut with a cryostat. Punches of 500 μm in diameter were taken from the visual cortex and lateral geniculate nucleus of adult and developing rats, using 50 μm stained sections as guides, and analyzed for GAD and ChAT (Fonnum et al., Brain Res. 20:259-275 1970; Fonnum et al., Biochem. J. 115:465 472, 1969). Protein determinations were performed with a modified technique of Lowry et al. (J. Biol. Chem. 193:265-275, 1951).

GAD activity in the visual cortex was very low during the first few days of postnatal life and showed a gradual increase between days 4 and 8. Significant increases were observed between days 8 and 14 (4-fold) and days 14 to 18 (2-fold) and after this time only slight increases were observed until day 24. Adult rats showed slightly lower GAD activity in the visual cortex compared to the 24 day animals. GAD activity in the dorsal lateral geniculate nucleus exhibited a similar developmental pattern as in the visual cortex with significant increases occurring between days 8 and 18.

At birth, rats had very low ChAT activity in the visual cortex. This activity showed a moderate increase until day 14 and a dramatic increase between days 14 and 21 of postnatal life. ChAT activity in the dorsal lateral geniculate nucleus displayed a similar developmental pattern as in the visual cortex with the most significant increases occurring between days 14 and 18 and between days 21 and 24. These results will be discussed in the light of existing morphological studies of the visual cortex and the lateral geniculate nucleus of adult and developing rats.

250.7 MORPHOLOGICAL DEVELOPMENT AND FUNCTIONAL RESPONSIVENESS OF SUBCORTICAL NE AND DA SYSTEMS IN FETAL RAT BRAIN. M. Schlumpf and W. Lichtensteiger, Inst. Pharmacol. Univ. Zürich, CH-8006 Zürich, Switzerland.

In the rat fetus, the responsiveness of central catecholamine (CA) systems to cholinergic action closely follows the morphological development of these neuron systems. Ascending and descending CA projections develop during the last gestational third. When studied with a modified histofluorescence technique, subcortical target regions (hypothalamus, preoptic and septal areas) are found to be reached by CA fibers around ED 15 (ED 1 = 24 hr after the 2 hr mating period). By then intensely fluorescent fibers of the descending CA systems are also seen in the marginal layer of the spinal cord.

The functional capacity of fetal norepinephrine (NE) and dopamine (DA) systems was analyzed by measuring turnover rates in different brain regions. Nicotine which had been found to affect DA levels in fetal brain (Schlumpf et al., Neurosci. Abst. Vol. 5, 177, 1979), was used to influence the functional state of CA systems. In the adult rat, this drug increases firing in zona compacta of substantia nigra (Lichtensteiger et al., Brain Research 117, 85, 1976) and in locus coeruleus (Svensson and Engberg, Acta physiol. scand., in press). Experiments were conducted mainly at ED 19 3/4.

The mother rat was anesthetized with chloral hydrate Fetal brains were dissected before and 25-75 min after α-methylparatyrosine (α-MT, 250 mg/kg s.c.). NE and DA were determined by a COMT assay in 4 regions of the fetal brain: lower brainstem, midbrain, anterior thalamus + hypothalamus and rostral forebrain with caudate-putamen. According to our preliminary observations, turnover rates of NE and DA of fetuses from untreated mothers differed only moderately, at ED 19 3/4, from adult values. Nicotine increased NE turnover in male and female rat fetuses while its effect on DA turnover varied with the brain region studied.

Our data indicate that certain types of input to central CA systems can be activated in the prenatal period when these systems are still developing.

250.8 REGIONAL CHANGES IN NOREPINEPHRINE CONTENT IN THE MOUSE BRAIN FOLLOWING NEONATAL 6-HYDROXYDOPAMINE TREATMENT. K. L. Lovell. Pathology Dept., Michigan State Univ., E. Lansing, MI 48824.

Previous studies demonstrated that 6-hydroxydopamine (6-OHDA) injected systemically into newborn rats permanently destroys norepinephrine (NE) fibers in the cortex. In the brainstem and cerebellum, NE content and ^{3}H-NE uptake are initially reduced after 6-OHDA treatment but show recovery, with the final levels achieved dependent on dose and age of the rats during injection. The present study was designed to characterize the short-term effects of 6-OHDA and to analyze the dynamics of recovery of NE concentrations in the mouse brain. Mice were injected subcutaneously with 6-OHDA (34, 50, 68 or 100 mg/kg) on various schedules beginning on day 1 after birth. NE content, assayed by a radioenzymatic method, was measured in the cerebellum, cortex and brainstem 24 hr after the last injection or at 18 days of age. For animals given 3 or 5 injections between days 1 and 5, increasing the dose or number of injections above 3 injections of 50 mg/kg did not increase NE depletion measured on day 6 in the cerebellum, but did increase NE depletion in the cortex. Thus these regions show different dose-response characteristics. To investigate variables regulating recovery of the NE system in mice, neonates were given 6-OHDA injections of 50 mg/kg on day 1, days 1 and 3, or days 1, 3, and 5. In the cerebellum NE content was reduced to 20-30% of control values 1 day after the last injection for all groups. There was a significant difference among the groups in the extent of recovery at 18 days of age, with NE content 180%, 132% and 85% of control values after 1, 2 and 3 injections, respectively. In the brainstem, however, the extent of recovery was similar for all schedules of injection, with recovery to 175-200% of control values at 18 days of age. In contrast to studies in rats showing similar short-term cortical depletion, some recovery was seen in the mouse cortex, with initial depletion up to 10% of control values and recovery to 50-60% of control values on day 18. Thus peripheral 6-OHDA treatment in mice produces regional variations in NE depletion and recovery of NE content, dependent on dose and time of treatment, but dose-response relationships and subsequent development of the NE system are different in some respects from those in rats. Association of differences between species with the stage of development or other factors can help delineate variables regulating growth and regeneration of NE fibers. 250.9 FUNCTIONAL ONTOGENY OF DOPAMINE PRESYNAPTIC RECEPTOR REGULATION
Ismail A. Shalaby, Peter S. Dendel* and Linda Patia Spear
Dept. of Psychology, S.U.N.Y., Binghamton, N.Y. 13901.

Dopamine (DA) presynaptic and autoreceptors exert inhibitory feedback control on DA biosynthesis and neural activity. Interruption of impulse flow along afferent DA pathways with lesions or by pharmacological blockade with drugs such as gamma-butyrolactone (GBL) results in an increase in tyrosine hydroxylase activity and DA content in the terminal regions of these pathways, an effect which is attenuated by pretreatment with DA agonists such as apomorphine. This effect is thought to be mediated through presynaptic receptors that function to regulate DA biosynthesis. It has also been suggested that the behavioral sedation induced by low doses of apomorphine is due to preferential stimulation of these inhibitory presynaptic receptors.

In a previous report (Shalaby and Spear, Soc. Neurosc. Abst., 1979) we observed that while high doses of apomorphine were able to increase the behavioral activity of rat pups as early as 7 days postnatally, presumably due to stimulation of DA post-synaptic receptors, low dose apomorphine-induced sedation was apparent no earlier than 4 weeks of age. It was suggested that this effect might be due to late ontogeny of DA autoreceptors. In the present report, the ontogeny of DA presynaptic receptor regulation was examined neuropharmacologically in 7, 14, 21, 28 and 35 day old rats. Animals were injected with either GBL (750mg/kg) alone, apomorphine (1mg/kg) alone, a combination of apomorphine and GBL, or saline alone. 40 minutes later, animals were sacrificed and the striata and olfactory tubercles were extracted and assayed for DA content. As early as 7 days of age GBL significantly increased DA levels in striata, an effect attenuated by apomorphine pretreatment. However, no increase in DA was observed after GBL in the olfactory tubercles until animals were 21 days of age, when apomorphine was also able to attenuate the increase in DA. These results suggest that the DA presynaptic receptors in mesolimbic brain regions mature several weeks later than the early maturing striatal brain regions. Results will be discussed with respect to possible connections with previous behavioral findings on ontogeny of DA presynaptic receptors.

250.10 GANGLIOSIDE DISTRIBUTION IN THE NEONATAL RAT HIPPOCAMPUS.
L.N. Irwin and C. C. Irwin. Dept. Biol., Simmons College, Boston, MA 02115 and Shriver Ctr. Ment.Retard. Waltham, MA 02154.

The cellular localization of specific gangliosides during neural differentiation remains unclear. Therefore, we have studied the subcellular and subregional distribution of the major gangliosides present at early stages of morphogenesis in the hippocampus. Gangliosides were isolated by a miniaturized procedure (Irwin&Irwin. 1979. Analyt. Biochem. 94:335) from intact hippocampal formations, specific subfields (CA1, CA2-3, and area dentata) of the hippocampus, or subcellular fractions of each of these, and analyzed by thin-layer chromatography. Previous results (Irwin&Irwin. 1979.Dev. Neurosci. 2:129)showing an essentially mature ganglioside pattern at birth except for low levels of GM1 and GD1a were confirmed. Our present results showed this to be true even for the area dentata, prior to extensive synaptogenesis. However, the relative amount of a slowly migrating band tentatively identified as a tetrasialoganglioside, was conspicuously lower in this less differentiated subfield of the hippocampus. Also, some membrane subfractions yielded less GD3 - a ganglioside characteristic of early neurogenesis - than did unfractionated tissue. These results suggest that in the rat hippocampus, the ganglioside most closely correlated with synaptogenesis is a tetrasialoganglioside, and that GD3 may have a subcellular localization separate from other gangliosides or be more labile to preparative and isolation procedures. (Supported by NIH grant 1R01NS15924 and a grant from the Simmons College Fund for Research.)

250.11 DIFFERENCES IN PHOSPHORYLATION BETWEEN THE TWO LARGE SUBUNITS OF BRINE SHRIMP NA^+,K^+-ADENOSINE TRIPHOSPHATASE.
Lynn Churchill and Lowell E. Hokin*. Department of Pharmacology, University of Wisconsin Medical School, Madison, WI 53706.

In brine shrimp Na,K-ATPase, there are two large subunits which function as catalytic sites. Previous observations indicated that both large subunits were specifically phosphorylated from ATP in the presence of Na^+ and Mg^{++} and dephosphorylated in the presence of K^+ [Peterson et al. (1978) JBC 253: 4762]. More recently, Peterson et al. (in preparation) have demonstrated that both subunits have similar peptide maps. In spite of their striking similarities in peptide maps, these two subunits migrate at different positions in Na^+ dodecyl sulfate gels and have different ouabain binding characteristics [Churchill et al. (1980) J. Supramol. Struc., Suppl. 4: 100a]. The presence of two large subunits and similar differences in ouabain binding characteristics have also been observed in mammalian brain Na,K-ATPase [Sweadner (1979) JBC 254: 6060]. In the process of studying the differences in ouabain binding, differences in phosphorylation were also observed between the two subunits. The phosphorylation of the lower large subunit isolated on a pH 7.4 gel was very small at low ATP concentrations (0.8 and 0.08 μM); however, when 10^{-3} M ouabain was present, the inhibition of K^+ dephosphorylation made the phosphorylation of this subunit at 0.08 μM ATP more demonstrable. The phosphorylation at higher ATP concentrations (8 and 80 μM) was easily observed for both large subunits. Since the phosphorylated intermediates are more stable at a lower pH, we analyzed phosphorylation of the two subunits after isolation in a pH 2.4 gel [Avruch and Fairbanks (1972) PNAS USA 69: 1216]. In this gel system, the proportion of the two subunits shifted so that the lower large subunit was more prominent. (In the pH 7.4 gel, the upper large subunit is more prominent for the same preparation of enzyme from 12 h nauplii.) Also, the phosphorylation of the upper large subunit was not observed at 0.08 μM ATP unless ouabain at 10^{-3} M inhibited the K^+ dephosphorylation, but was easily observed at 80 μM ATP. These results suggest that the upper and lower large subunits have charge differences that cause them to migrate to different positions at different pHs. Since the concentration of the lower large subunit at pH 7.4 decreased during development, while the concentration of the upper large subunit at pH 7.4 increased, the synthesis of the two subunits was analyzed to determine if there was a precursor-product relationship (Peterson et al., in preparation). The pulse-chase labeling showed that the lower subunit was not a precursor. Since the lower subunit at pH 7.4 has a more labile phosphorylated intermediate and is less sensitive to ouabain, it may be the catalytic site of an isozyme during early development of brine shrimp nauplii.

250.12 TURNOVER OF TUBULIN IN DEVELOPING RAT BRAIN.
June L. Dahl and Victor J. Weibel*, Department of Pharmacology, University of Wisconsin Medical School, Madison, WI 53706.

The difference between protein synthesis and degradation rates must, to a great extent, control the growth of the brain during its critical stages of development. While it is generally agreed that rates of protein synthesis are higher in the developing brain than they are in the adult animal, there have been conflicting reports regarding the contributions of changes in rates of protein degradation. Previous results from our laboratory (Biochem. J., 180:423, 1979) suggested that a reduced rate of protein degradation is an important factor contributing to the overall increase in protein content in neonatal rat brain. To further examine the role of protein degradation in determining the protein content of developing brain, we have measured the degradation rate of tubulin, the microtubule subunit protein. Tubulin is particularly interesting because its concentration decreases with increasing developmental age.

Five-day-old rats were injected intraperitoneally with 1 mCi of (^{14}C)$NaHCO_3$ per 100 g body weight. Groups of five animals were killed at intervals up to 13 days later. Brains were rapidly removed and individually homogenized. A portion of each homogenate was centrifuged at 100,000 x g to prepare a soluble protein fraction. Tubulin was isolated from the remainder by $(NH_4)_2SO_4$ fractionation and DEAE-cellulose chromatography. Purity of tubulin preparations was monitored by SDS polyacrylamide gel electrophoresis; tubulin content was measured by a colchicine binding assay.

Our results show that tubulin is degraded more rapidly in neonatal than in adult brain. Furthermore, whereas soluble proteins have shorter half-lives than tubulin in adult brain ($t_{½}$ ~ 3 days compared with $t_{½}$ ~ 9.8 days), in the neonatal animal, there is little difference between their degradation rates. These results provide further evidence for the importance of the degradative process in regulating the protein content of developing brain.

250.13 SYNAPTIC MEMBRANE ANTIGENS IN RAT BRAIN CORTEX DURING POSTNATAL DEVELOPMENT. S.P. Mahadik, A.Korenovsky*, V.Ciccarone*, H.Laev* and M.M. Rapport, Div. of Neuroscience, N.Y. State Psychiatric Inst. and Dept. of Biochemistry, Columbia Univ. N.Y.,N.Y.,10032.

Using an antiserum to a highly purified synaptic plasma membrane (SPM) fraction from rat brain cortex, we have recently detected six polypeptide antigens (56K,58K,62K,63K,64K,66K). The concentrations of the first 5 are higher in SPM than in other subcellular fractions of adult rat cerebrum (1,2). We have now determined the quantities of these 6 antigens in frontal cortex at 6 stages of postnatal development: 0-1,5,14,28,60 & 180 days. Antigenic content was determined in a total membrane fraction (145,000xg pellet) to avoid selective losses, particularly in immature tissue. Polypeptides in the pellet were separated on SDS-polyacrylamide slab gels and stained with Coomassie Blue. Stained bands, representing polypeptides of determined size,were then examined for antigenic content by measuring rocket areas obtained by rocket immunoelectrophoresis. Results are tabulated:

	Rocket area (cm^2) for 250 µg protein from the total membrane fraction					
Postnatal Age (Days)	56K	58K	62K	63K	64K	66K
0-1	0.23	0.71	0.16	<0.05	<0.05	<0.05
5	0.20	0.68	0.14	<0.05	<0.05	<0.05
14	0.55	0.75	0.35	0.09	<0.05	<0.05
28	0.66	2.28	0.71	0.19	0.16	<0.05
60	0.27	1.09	0.91	0.19	0.10	0.08
180	0.24	1.43	1.65	0.57	0.11	0.06

Only three antigens (56K,58K,62K) were present at birth; the other antigens (63K,64K,66K) were only detected at 14,28 and 60 days of age, respectively. Three antigens (56K,58K,62K) increased rapidly during the period of maximal synaptogenesis (12 to 28 days). Two of these (56K,58K) then decreased considerably in the 28 to 60 day period. Two antigens (62K,63K) increased continuously from birth to 180 days, the 62K antigen with differential incremental rates at different developmental periods and the 63K antigen at a relatively constant rate. The contrasting changes in the content in rat brain frontal cortex of these 6 SPM antigens during postnatal development suggest that antigens whose rapid increase coincides with the rapid phase of synaptogenesis could be related to synapse formation. The others may reflect either proteins concerned with synaptic stabilization or proteins in synaptic connections of diverse types.

250.14 DEVELOPMENT OF SEROTONIN RECEPTORS IN THE CHICK SPINAL CORD. W. Prozialeck*, A. Pylypiw*, W. Chmelewski* and L. Ross. Department of Anatomy, The Med. Coll. of Penn., Phila., PA 19129.

The avian spinal cord receives a substantial serotonergic input from supraspinal levels. Serotonin-containing fibers originating in the brainstem descend via the anterior and lateral funiculi and terminate in the ventral horn, the dorsal horn, and in the nucleus of Terni, where cell bodies of the pre-ganglionic sympathetic neurons are located. Although it is known that these descending serotonergic fibers establish their first synaptic contacts with neurons in the spinal cord at about 10 days in ovo, the functional development of this system is much less clear. We have therefore characterized and examined the ontogeny of serotonin receptors in this region. The binding of tritiated serotonin to washed membrane preparations of chick thoraco-lumbar (T-L) spinal cord was measured by the method of Bennett and Snyder (Mol. Pharm. 12: 373-389, 1976). Specific binding was defined as the amount of radiolabeled serotonin that could be displaced by an excess (5 µM) of non-labeled serotonin. Receptor density (Bmax) and the apparent dissociation constant (Kd) were calculated from Scatchard plots. Results on T-L spinal cords from 3-4 week old chicks showed that serotonin bound specifically to two distinct types of sites, a high affinity site, Kd=5nM, Bmax= 4.8fmoles/mg tissue, and a lower affinity site Kd=25nM, Bmax= 6.8fmoles/mg tissue. The high affinity binding site displayed pharmacological properties which are characteristic of serotonin receptors. For example, bromo-LSD and non-labeled serotonin were 100 times more potent than propranolol, phentolamine, or dopamine at inhibiting the specific, high affinity binding of serotonin. Studies aimed at characterizing the lower affinity binding site are in progress.

During development, high affinity binding sites were present as early as eight days in ovo (Bmax$\sim$2.0fmoles/mg tissue), the youngest age examined. From day 8 to day 12 the density of receptors increased to $\sim$4.6fmoles/mg tissue and remained constant until day 21 when a marked increase was seen (Bmax$\sim$6.5fmoles/mg tissue). Receptor density remained at this peak level for the first week after hatching and then gradually fell off to $\sim$4.8 fmoles/mg tissue by day 30. The Kd for the high affinity binding of serotonin remained $\sim$4-7nM throughout development.

Since serotonin receptors are present at least two days before descending serotonergic neurons form synaptic contacts with target cells in the spinal cord, it appears that the initial development of serotonin receptors does not require a neuronal input. The role of these serotonin receptors in the development and maintenance of synapses is under investigation.

Supported by NIH Grants NS13768 and NS07061.

251.1 ORGANIZATION OF THE RETINOGENICULATE PROJECTION IN POND TURTLES, PSEUDEMYS AND CHRYSEMYS. P. S. Ulinski. Dept. of Anatomy, The Univ. of Chicago, Chicago, IL, 60637.

The dorsal lateral geniculate nucleus (DLGN) in turtles is an elongate structure which is situated dorsomedial to the optic tract and is bordered rostrally by nucleus ovalis. It is known to receive a direct retinal projection and to project to the dorsal cortex. However, the organization of the retinogeniculate projection is unknown. Accordingly, I examined the retinogeniculate projection by making a series of restricted retinal lesions and studying the resulting degeneration which was visible in Fink-Heimer preparations of DLGN after 14 to 28 days of survival. The experiments demonstrated that the retina projects topographically to DLGN and nucleus ovalis. Thus, lesions of the temporal edge of the retina produced degeneration in the caudal segment (Rainey, 1979, Neurosci. Abstr., 5:804) of DLGN. Lesions situated at successively more nasal points on the retina produced degeneration at successively more rostral levels of DLGN. Lesions of the nasal edge of the retina produced degeneration in nucleus ovalis. Thus, the horizontal meridian of the retina is represented along the rostrocaudal axis of the DLGN-ovalis complex. Since these turtles have a well developed visual streak, consisting of a line of densely packed ganglion cells oriented along the horizontal meridian of the retina (Peterson and Ulinski, 1979, J. Comp. Neurol., 186:17), this result suggests that the retinogeniculate projection is dominated by a magnified representation of the visual streak. (Supported by PHS Grant NS-12518).

251.2 ORGANIZATION OF THE TECTAL PROJECTION TO NUCLEUS ROTUNDUS IN POND TURTLES. W.T. Rainey. Department of Anatomy, University of Chicago, Chicago, IL 60637.

In most reptiles and birds, the optic tectum projects to the thalamic nucleus, nucleus rotundus, which projects in turn to the telencephalon. Two types of evidence suggest that the tectorotundal projection is non-retinotopic in the pond turtles Pseudemys scripta elegans and Chrysemys picta bellii. First, large, non-total injections of HRP into the optic tectum result in anterogradely-filled, tectorotundal axons that are scattered throughout all of rotundus. Primary axonal shafts in the tectothalamic tract give off primary collaterals that enter the caudolateral sector of rotundus. These collaterals produce sparsely-branched, conical arborizations that are often oriented caudolateral to rostromedial in much of the nucleus. Preterminal branches in these arbors bear thin collaterals that have varicosities along their lengths. Although the total spread and complete shape of a primary collateral's arborization is unknown, many arbors probably extend the full length of rotundus and spread fairly widely across the width of the nucleus. Since rotundal neurons have dendritic fields that span one-third to one-half of the dimensions of the nucleus (Rainey, J. Morph. 160:121), the domain of an arbor would intersect the dendritic fields of many rotundal neurons. Second, EM-degeneration analyses provide evidence that tectal synapses are distributed along much of the length of rotundal dendrites. Degenerating boutons have asymmetrical active zones and vesicle sizes that are somewhat larger or smaller than the size of round vesicles in normal boutons with asymmetric active zones. Degenerating boutons are observed on thin dendritic profiles, less than 0.5μ in diameter, medium-sized profiles and large profiles, greater than 1.5μ in diameter. Therefore, they are probably distributed along all segments of rotundal dendritic arbors, but tectal boutons are more common on the distal two-thirds of these arbors. In conclusion, the tectorotundal projection is non-retinotopic and highly convergent upon single neurons. Furthermore, each arborization of a primary collateral will provide a divergent projection to a large number of rotundal neurons. (Supported by PHS Grants GM-00094 and NS-12518).

251.3 RECIPROCAL TECTO-GENICULATE CONNECTIONS IN A SNAKE (Thamnophis sirtalis). D.M. Dacey* (SPON.: R. Tarr). Dept. of Anatomy, The University of Chicago, Chicago, IL 60637.

In addition to retinal input, the lateral geniculate complex of snakes receives a massive tectal projection (Ulinski, J. Comp. Neurol., 173: 1977). This raises the possibility that there is a major interaction between two retinofugal pathways in the lateral geniculate. However, there is no information about the organization of either the retinal or tectal input to the lateral geniculate, so that the precise relationship between the tectal and retinal afferents is unknown. In the present study, restricted injections of HRP were placed in the tectum to examine the organization of the connections between the tectum and the lateral geniculate. There are two major findings. First, there is a discrete projection from both the dorsal and ventral segments of the geniculate to the tectum. Second, connections between the tectum and geniculate are reciprocal and topographically organized.

A single, punctate injection of HRP into the tectum, anterogradely filled tecto-thalamic axons and retrogradely filled geniculate cells. Labelled cells formed a small cluster in both the dorsal and ventral segments of the lateral geniculate. Each cluster was precisely overlapped by a patch of fine terminal arbors. Multiple, non-overlapping tectal injections produce multiple, non-overlapping clusters of labelled cells.

Cobalt enhanced, DAB reacted material provided information about the morphology of the labelled elements. Thus, geniculate cells projecting to the tectum ranged from large, multipolar to small, fusiform types. Tectothalamic axons enter the geniculate by either descending in the axial optic tract or by travelling rostroventrally along the medial face of the marginal optic tract. Axial fibers give off a dense, beaded collateral network, which extends horizontally into both the dorsal and ventral clusters of labelled cells. Marginal fibers turn medially into the geniculate, to form a highly branched terminal arbor, which is flattened in the horizontal plane.

This report provides the first description of a projection from the dorsal segment of the lateral geniculate to the optic tectum. In addition, the tecto-geniculate connections are reciprocal and topographically organized. Thus, in Thamnophis, there is a strong interaction between two retinofugal visual structures in which retinotopy may be preserved. (Supported by PHS Grants GM-00094 and NS-12518).

251.4 VISUAL AND INFRARED INTERACTIONS IN THE OPTIC TECTUM OF RATTLESNAKE: CROSS-MODALITY SUMMATION, ENHANCEMENT AND DEPRESSION. Eric A. Newman* and Peter H. Hartline (SPON: Janice I. Gepner). Eye Research Institute of Retina Foundation, Boston, MA 02114.

We have investigated interactions between the visual and infrared (IR) systems in the tectum of the pit viper (Crotalus viridis) using single unit recordings. Separate, precisely repeated IR stimuli (directed at the heat-sensitive pit organ) and visual stimuli were interleaved with simultaneously presented visual-IR stimuli. By comparing responses (spike counts and histograms) to these three stimulus conditions we evaluated modality summation characteristics. Of the 135 units thus far characterized, 80 were influenced to some degree by both visual and IR modalities. 20 responded well to either stimulus presented alone. These units summed to give a greater response to simultaneously presented stimuli, some summing more, and others less, than linearly. Another 33 cells were driven reliably by only one of the two stimulus modalities (the primary stimulus), but gave enhanced responses when a stimulus in the other modality (the secondary stimulus) was presented simultaneously. In 12 of these units the primary stimulus was visual; in 21, the primary stimulus was IR. In these cells, the secondary stimulus enhanced the response (number of spikes) to the primary stimulus by as much as 300%. Another 3 units responded poorly or not at all to either stimulus alone, but responded reliably when both stimuli were presented simultaneously. Finally, in 24 bimodal cells, the response to a stimulus in one modality was depressed by a stimulus in the other modality. In some cases, this depression abolished the responses completely. In 12 of these units, the primary (excitatory) stimulus was visual; in 12, the primary stimulus was IR.

The cross-modality interactions described here indicate that the rattlesnake tectum is an important center for the integration of visual and IR information. Among the possible functions that might be attributed to these interactions are: 1) cross-modality 'feature-detection' of biologically significant stimuli and 2) enhancement of detection and localization of weak, dual-modality stimuli. Our use of combined stimulation and quantitative comparison of responses revealed multimodal interactions in many units that otherwise would have been classified as unimodal. These techniques, which have not been applied to the tecta and superior colliculi of other animals, might reveal the presence of similar types of multimodal interactions in many species. This research was supported by the Charles A. King Trust, Boston, MA, NIH grant EY 07028 and by NSF grants BNS-7824162 and BNS-7817084.

251.5 VISUAL SYSTEM OF ZEBRAFISH OPTIC TECTUM. P. Sajovic and C. Levinthal, Dept. Biological Sciences, Columbia University, New York City, New York 10027.

We have carried out studies of the visual system in the optic tectum of the zebrafish with the objective of correlating the physiology, morphology, and synaptic interactions of particular cell types. The laminar organization of the tectum is similar in essential respects to other teleosts. Rapid Golgi stains show morphological cell types similar to other fish as well; periventricular layer (SPV) cells have a "pyriform" morphology.

Our physiological studies utilize a computer system for stimulus control and data recording. Single units are recorded using extracellular electrodes plated with silver for marking. Both retinal fibers and tectal cells can be recorded in the tectum; the two are distinguished by an optic-nerve-shock latency test. Retinal units of the most common type give phasic on and off responses to small spots over receptive fields (RF's) about 15 degrees in diameter. There is no evidence of concentric organization.

Tectal cells responsive to visual stimulation fall into four classes, with many cells exhibiting intermediate characteristics. The recording sites for all four response types are usually in the SPV, indicating that cells of the pyriform morphology can exhibit different behaviors. Type I cells show low spontaneous activity and give phasic on and off responses to small spots. The RF's are large (50 degrees) and are often composed of disconnected areas; there is no concentric organization. The excitatory response is briefest where it is strongest, suggesting that it is cut short by an inhibitory process. Response to a large stimulus covering the RF is greatly reduced in comparison to a standard spot. These and other lines of evidence suggest that tectal cells of type I receive inhibition from near neighbor cells of the same type.

Type T cells show tonic firing in the dark. Pure inhibitory RF's can be observed as well as excitatory areas. The phasic excitatory responses are more prolonged than those of type I cells and the reduction of response produced by a large whole-RF stimulus is much less pronounced.

Type S cells are similar to type I except that responses to light on are sustained rather than phasic. Finally there are tectal cells of type B which exhibit spontaneous bursting in the dark; light stimulation may increase or decrease the burst rate.

The results of these studies indicate: 1) that cells of a single layer and common morphological type can exhibit a number of different physiological properties; and 2) some tectal cells appear to derive important properties from inhibitory connections with their near neighbors of similar response type.

251.6 SUBCORTICAL AFFERENTS TO THE SUPERIOR COLLICULUS IN THE HAMSTER. R. L. Van Buskirk. Dept. of Psychology, University of Wyoming, Laramie, WY 82071.

The deep layers of the superior colliculus (S.C.) have been implicated in orienting and attentional functions such as visual fixation, auditory location and lordosis, and respond to somatosensory, auditory and visual stimuli in a variety of mammalian species (Stein, 1975; Chalupa & Rhoades, 1977). Anatomical demonstrations of deep S.C. subcortical afferents have largely been restricted to the cat (Grofova, et al., 1978; Edwards, et al., 1979). This study demonstrates deep S.C. afferents in the hamster using horseradish peroxidase (HRP, Sigma VI, .02 - .05 μl). After 72 hours the animals were sacrificed and the brains reacted with the TMB chromogen (Mesulam, 1978). In the hamster, most somatosensory afferents to the deep S.C. were contralateral to the injection site, including the lateral cervical nucleus and cervical dorsal horn, spinal trigeminal caudalis and oralis, n. gracilis and cuneatus, trigeminal n. principalis and n. intertrigeminalis. Potentially somatosensory afferents were found bilaterally in the external n. inferior colliculus and n. intercollicularis. Auditory afferents were either ipsilateral (medial and lateral superior olives) or bilateral (ventral nucleus of the lateral lemniscus and the nucleus of the inferior collicular brachium). Visually-related afferents included the ipsilateral n. pretectalis profundum and ventral lateral geniculate nucleus, the contralateral deep S.C., and bilaterally the parabigeminal, peri-parabigeminal and pretectal thalamic nuclei. Visual-motor afferents were strictly contralateral in origin (abducens and peri-abducens), whereas cerebellar and related motor afferents were either contralateral (n. dentatus and lateral reticular nucleus) or bilateral (n. reticularis tegmenti pontis and the dorsal-laterally adjacent area). Reticular and nonspecific afferents to the deep S.C. included the dorsal raphe' nucleus, the ipsilateral central gray lateralis, substantia nigra, zona incerta and n. posteriori commissuralis, contralaterally the cervical reticular formation lateral to the dorsal horn and n. prepositus hypoglossi, and bilaterally n. gigantocellularis, n. reticularis pontis caudalis and oralis, n. cuneiformis and subcuneiformis and the ventral central gray. Larger injections which spread into the central gray and n. cuneiformis led to labelling ipsilaterally in the dorsal-medial and lateral hypothalamus and n. lateralis thalami, contralaterally in n. supragenicularis pontis, and bilaterally in locus ceruleus and n. trapezoid. This multiplicity of inputs undoubtedly provides the basis for the sensory, reticular and motor interactions underlying the attentional and orientation functions of the deep superior colliculus.

251.7 THE MORPHOLOGY OF SINGLE AXONS INNERVATING THE HAMSTER'S SUPERIOR COLLICULUS. George M. Sachs* and Gerald E. Schneider (SPON: R. Held). Dept. of Psych., M.I.T., Cambridge, MA 02139

The superior colliculus of the hamster receives partially overlapping, retinotopic projections from the contralateral retina and the ipsilateral visual cortex. Retinofugal axons terminate heavily throughout the stratum griseum superficiale (SGS) whereas the cortex projects mainly to the deepest 1/3 of this layer. In order to visualize single axons of these projections, we made small injections of horseradish peroxidase (HRP) into the brachium of the superior colliculus in adult hamsters. Filled axons and their terminal arbors were followed through serial parasagittal sections and traced with the aid of a drawing tube.

A majority of the filled axons took a straight course within the stratum opticum (SO), turned dorsally into the SGS, sometimes as a pair of branches, and through a series of bifurcations formed a dense terminal arbor in the upper portion of this layer. Their terminal fields were confined to the superficial 2/3 of the SGS and consistently extended 100-150 μm along the antero-posterior (AP) axis of the tectal surface. Less numerous but commonly filled were thicker axons which terminated in deeper portions of the SGS. These axons often divided into several branches within the SO. Some collaterals ascended directly to the terminal field while others continued further caudally only to loop back before terminating. Thereby, despite widespread branching, single axons of this sort also showed terminal fields confined to 100-150 μm in the AP direction. Occasionally, fibers with diffuse terminal fields or irregular trajectories were observed. Some of these gave rise to a few widely separated branches which distributed terminals over a distance of 600 μm along the AP axis.

To investigate the source of these axons, adult hamsters underwent eye removal or transection of posterior cortical efferents 1-3 wk prior to injection. The thinner, superficially projecting axons survived the cortical lesion but were absent after removal of the contralateral eye. Neither cortical lesion nor eye removal alone eliminated all of the thick, deeply projecting fibers.

Previous studies of degenerating retinal projections have noted that terminal degeneration appears initially in the deep 1/3 of the hamster's SGS with more superficial terminals degenerating later. The thinner superficial fibers seen in the present study probably account for the later phase of degeneration. Although alternative sources must still be tested, those thicker, deeply projecting fibers which survive cortical lesions may belong to the deep portion of the retinal projections.

251.8 A GOLGI IMPREGNATION STUDY OF CELL MORPHOLOGY IN THE HUMAN SUPERIOR COLLICULUS, T.W. Robertson* and T.L. Hickey. School of Optometry/The Medical Center, University of Alabama in Birmingham, Birmingham, Alabama 35294.

The morphology of cells in the superficial (0-1000 micrometers), intermediate (1000-2000 micrometers) and deep (2000-5000 micrometers) regions of the human superior colliculus has been studied in Golgi impregnated material.

The superficial region is composed of the stratum griseum superficiale (SGS; 0-500 micrometers) and the upper half of the stratum opticum (SO; 500-1000 micrometers). Cells located in the SGS tend to have either vertically or radially oriented dendrites. Neurons with vertically oriented dendrites are characterized by eccentrically placed cell bodies (within the dendritic field) from which several dendrites extend either toward the surface of the colliculus (wide- and narrow-field vertical cells) or down toward the intermediate region (marginal cells). Other cells in this region exhibit medium caliber dendrites that extend radially from a more centrally placed cell body (stellate cells). The upper half of the SO is characterized by neurons with horizontally oriented dendrites and centrally placed perikarya. For most of these cells, the total horizontal extent of the dendritic tree is between 250 and 500 micrometers, although a few cells exhibit dendritic spreads of up to 1 millimeter.

The intermediate region of the human superior colliculus is composed of the lower half of the SO and contains cells with vertically oriented dendrites and cells with radially oriented dendrites. Vertically oriented dendrites can be seen extending either above or below the perikaryon for some cells and both above and below the perikaryon for other cells. The total dendritic spread of these latter cells can reach over 1 millimeter. The radially organized stellate cells seen in this region exhibit either smooth or spine laden dendrites and tend to be larger than the stellate cells seen in the superficial region.

The analysis of cell morphology in the deep region of the human superior colliculus is less complete since the Golgi impregnation technique used tends to stain few cells below 2000 micrometers from the colliculus surface. So far two cell types have been studied in this region: large cells with vertically oriented dendrites and large cells with horizontally oriented dendrites. Although these cell types resemble those seen in the superficial and intermediate regions, the cells in the deep region tend to have even larger perikarya and dendritic spreads.

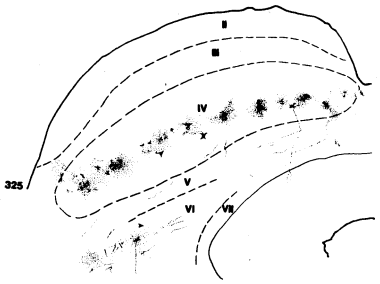
251.9 THE TRIGEMINOCOLLICULAR PATHWAY IN THE CAT: PATCH-LIKE TERMINATIONS. Michael F. Huerta. Dept. of Anatomy, Univ. of Wisconsin, Madison, WI 53706

HRP studies have shown that cells within the cat's trigeminal complex project to the superior colliculus (SC). In order to determine the distribution of trigeminocollicular axons, either of two anterograde tracers were used; i.e., ^{3}H-proline or HRP liganded to wheat germ agglutinin (HRP-WGA).

Following an injection of ^{3}H-proline into the magnocellular alaminar subdivision of the spinal trigeminal nucleus, discrete patches of label are present contralaterally within the middle of the dorsal-ventral dimension of the stratum griseum intermediale (SGI). Patches of transported protein are also found in the stratum griseum profundum (SGP), but they are fewer in number and less discrete than those in the SGI. In the SGI, patches of label: (1) typically measure 330μ by 250μ, with their long axis parallel to the collicular surface, (2) are separated by 150μ label-free zones, (3) span the entire medial-lateral expanse of the SGI and (4) are present throughout most of the SC, but not present in the caudal pole.

Injections of HRP-WGA which involve the entire trigeminal complex, as well as adjacent structures, result in a distribution and pattern of anterograde label which is identical to that just described. In addition, isolated groups of retrogradely labeled SC cells lie in close proximity to many of the patches of anterogradely transported HRP-WGA (see fig.). The intimate association of retrogradely labeled cells with the anterogradely transported HRP-WGA is especially apparent in the SGI. Approximately half of the backfilled cells in the SC are between 25μ and 40μ in diameter (i.e., medium sized), the remainder have diameters which range from 16μ to 49μ. (Supported by EYO 1277).



251.10 DISCRETE PATCHES OF RETINOTECTAL ARBORS IN NORMAL FROGS (XENOPUS AND RANA). Susan B. Udin. Div. of Neurobiology, Dept. of Physiology; SUNYAB; Buffalo, NY 14214.

The retinotectal projection of amphibians has previously been thought to cover the tectum uniformly. However, filling of cut optic axons with horseradish peroxidase now reveals a very striking pattern of "puffs" of terminals in the stratum zonale, the most superficial of the retinal-recipient laminae of the tectum of Rana pipiens. Cut optic nerves were exposed for 2-6 days to gelfoam or filter paper soaked with horseradish peroxidase. Brains were cut at 25 μ in the transverse or horizontal plane or tecta were removed, flat-mounted, and sectioned tangentially at 25 μ. Filled axons were stained with benzidine dihydrochloride.[1]

The patchy distribution is most visible in the rostral region of the tectum, where the stratum zonale is thickest. The arbors occupy approximately the middle 60% of the lamina, as seen in cross section. When cut tangential to the surface, the puffs are seen to be 25-50 μ in diameter and are round or oval in shape.

In Xenopus laevis, the same methods reveal patchiness, but the segregation is far less distinct than in Rana. Rather than forming discrete puffs of terminals, Xenopus retinotectal arbors are distributed in patches of greater and lesser density in the superficial tectum. The patches of greater density are roughly the same size as the puffs in Rana.

In neither species do the patches form obvious rostrocaudal rows. In this respect they differ from the bands formed by the ipsilateral retinotectal projection of cats[2] and monkeys[3], as well as from the bands observed in three-eyed Rana pipiens[4]. Moreover, the puffs in normal Rana are smaller in size than the bands in three-eyed Rana.

The stratum zonale, the lamina where this patchiness is found in normal frogs, receives not only direct input from the contralateral eye, but also receives an indirect input from the ipsilateral eye, relayed via the nucleus isthmi.[5] The patchy pattern of termination thus may underlie an ocular dominance arrangement of visual inputs to the tectum.

251.11 THE DUPLEX TECTO-ISTHMO PROJECTION OF THE FROG: AN ANATOMICAL STUDY. R. Leventhal*, S. Glasser, and S.C. Sharma. (Spon: M. Romeskie). Dept. Ophthal., N.Y. Med. Col., Valhalla, N.Y. 10595.

The rostral tectum of the frog receives input from both contralateral and ipsilateral retina.

Fibers from the contralateral retina project directly through the optic chiasm to the tectum. Ipsilateral retinotectal input is relayed first through contralateral tectum and then nucleus isthmi (Keating and Gaze, 1970; Glasser & Ingle, 1978). Fibers from nucleus isthmi, however, terminate in caudal (monocular) as well as rostral (binocular) tectum (Gruberg & Udin, 1978; Grobstein et al. 1978). Destruction of nucleus isthmi not only abolishes ipsilateral units contralaterally, but also produces a significant increase in spontaneous activity throughout both tecta (Glasser & Ingle, 1978). The binocular component of the (isthmotectal) projection arises from ventral and medial rim cells of the nucleus. Fibers from medullary neurons of nucleus isthmi terminate throughout the entire contralateral tectum, (Grobstein et al.1978) and therefore may be responsible for modulating overall tectal activity.

To determine the location of tectal cells projecting to each region of nucleus isthmi, horseradish peroxidase was locally iontophoresed into either rim cell or medullary regions. After survival of 2-14 days and sectioning, the brains were reacted with benzidine dihydrochloride. Neurons projecting to the rim cell region of nucleus isthmi were found at the layer 6-7 border, whereas cells giving rise to the medullary component of the tecto-isthmo projection were found deeper in layer 6.

The implications of these findings will be discussed

251.12 FOURIER ANALYSIS ON FEATURE EXTRACTION. E. Tzanakou, and A.N. Gentile*. Physics Department, Syracuse University, Syracuse, New York 13210.

In research done in the past, the Receptive Field (RF) of a visual neuron is viewed as a spatial filter capable of processing three independent parameters - spatial frequency, phase and orientation. It has also been shown that a local two-dimensional Fourier-like transform domain provides a good first approximation to the pattern space in which cortical units could be processing stimuli.

We analyze visual RF's in the frog tectum by using a two-dimensional Fast Fourier Transform (FFT). The RF's are mapped by a scanning technique previously described. The intensity patterns that describe the RF's of the individual neurons are then analyzed by a FFT, and the neurons are classified according to their low or high frequency components.

A clustering algorithm segregates multiple, repetitive pattern elements into homogeneous brightness levels as a function of pattern element form, configuration and intensity. Performing Fourier analysis to the RF as a whole and as a separate region as defined by our clustering algorithm, one is able to find the influence at different spatial frequencies from regions surrounding the center of the RF where proximity and similarity are viewed as quantitative parameters in terms of Fourier analysis that relates space grouping to pattern element configurations.

The feature extraction done by our response feedback method (ALOPEX) adds another parameter into our analysis - time. As the pattern approaches the optimal stimulus and therefore the maximum sensitivity of the neuron, the Fourier components segregate.

251.13 METABOLIC MAPPING OF STIMULUS-INDUCED NEURAL ACTIVITY IN THE BASS OPTIC TECTUM: COMPARISON OF ^{14}C-2-DEOXY-D-GLUCOSE WITH ^{14}C GLUCOSE. Kim Traub*, D.P.M. Northmore*, and Leslie C. Skeen (SPON: S. Barnes). Department of Psychology and Institute for Neuroscience, University of Delaware, Newark, DE. 19711.

Recent studies indicate that ^{14}C glucose may provide a number of advantages over ^{14}C-2-deoxy-D-glucose for mapping stimulus-induced patterns of neural activity in the brain (Hawkins & Miller '78). Therefore, we compared glucose and deoxyglucose for functional mapping in the optic tectum of the large mouth bass and explored various modifications of the standard X-ray film autoradiographic method in efforts to improve resolution.

Fish that had been enucleated in one eye 7 days earlier were injected with glucose (S.A. 301mCi/mM, NEN) or deoxyglucose (S.A. 318mCi/mM, NEN) in the dorsal musculature (0.1 µCi/g in 10 µl fish Ringers) and placed in a transparent water-filled cylinder that was surrounded by rotating vertical stripes whose direction alternated every 2 minutes. After 50 min. of visual stimulation one of two procedures was followed: 1) The brain was removed and immediately frozen, or 2) The brain was fixed in 2.5% glutaraldehyde-1% paraformaldehyde by transcardial perfusion and then removed and frozen. Sections were then cut on a cryostat (30µm), dried, and exposed to X-ray film for autoradiography.

Regional optical density measurements from the autoradiographs of all cases showed consistently greater uptake of label in the tectum contralateral to the stimulated eye. Comparisons of these differences between the stimulated and unstimulated optic tecta showed that stimulus-induced labeling was much greater for glucose than for deoxyglucose, and that these differences were further enhanced by perfusion. Autoradiographic resolution was assessed in these same cased by measuring the density gradients across the layers of the stimulated optic tecta. All cases displayed a broad band of increased optical density in the central layers (SFGS & SGC), a drop in density over a deeper fiber layer (SAC), and then a narrow band of increased density over the innermost cell layer (SPV). Comparisons of these tectal density gradients showed that the autoradiographic resolution was greater for glucose than for deoxyglucose and, again, was further enhanced by perfusion. Finally, intertectal density differences and measures of resolution were both improved in the glucose cases by washing the sections with an ethanol/ether solution.

251.14 THE MORPHOLOGY AND ULTRASTRUCTURE OF TECTAL NEURONS WITH KNOWN EFFERENT PROJECTIONS. Paul J. May and William C. Hall. Dept. of Anatomy, Duke University, Durham, N. C. 27710

Neurons in stratum griseum intermediale of the superior colliculus are of special interest since they project to contralateral paramedian reticular regions known to play an important role in the control of eye movements (Holcombe & Hall, '79). We devised a technique which homogeneously fills the soma and dendrites of neurons with HRP reaction product. This procedure allows us to correlate our light and electron microscopic examinations of these neurons in the grey squirrel (Sciurus carolinensis). To label the neurons a mixture of HRP in 10% saponin is injected into their axons where they cross the midline in the predorsal bundle. After a survival period of 2 to 4 days, the animals are perfused and their brains are sectioned with a vibratome. The tissue is then reacted using an adaptation of the ortho-tolidine technique (Somogyi et al., '79).

The neurons we have labelled exhibit medium-sized (10 x 20µm) somas with several large primary dendrites which typically branch into 2 or 3 smaller secondary dendrites. Fine, beaded tertiary dendrites are also present. The sparsely-branching dendritic field extends up to 200µm from the cell body and is almost always confined to stratum griseum intermediale. Similar neurons can also be observed among Golgi impregnated cells of this layer.

For the electron microscopic experiments, 80µm sections which have been reacted with O-tolidine are osmicated and flat-embedded in araldite. Single labelled cells are cut from the araldite wafer and thin-sectioned. In electron micrographs, the label appears as a darkening of the cytoplasm in the somas and dendrites of filled neurons. The filling with HRP does not seriously disrupt the ultrastructure of either the labelled cells or their synaptic contacts. Synaptic terminals, containing either round or pleomorphic vesicles, make contacts on both the somas and the dendrites of the labelled cells. Often these profiles entirely surround the darkened dendritic shafts for short distances. Thus, with the use of this relatively simple technique, the ultrastructure and afferent connections of single neurons with known efferent projections can be studied.

Supported by N.I.H. Grant NS-09623

251.15 VISUAL WULST NEURONS PROJECTING TO THE OPTIC TECTUM AND THALAMUS IN PIGEONS: RECEPTIVE FIELD PROPERTIES L.R.G. Britto, R. Golfetti* and M.T.R. Perez* Dept. Physiology and Biophysics, UNICAMP, 13100 Campinas, S.P., Brazil.

The hyperstriatal area known as visual Wulst (W) gives rise to fiber systems directed to the optic tectum (TeO), thalamic dorsolateral complex (DLC), pretectum (PT) and other structures. Those W efferents modulate activity at the level of TeO, DLC and PT, primary visual relays in birds, making possible a close comparison of such a projection with mammalian corticofugal systems. The present experiments aimed to identify the W neurons projecting to TeO and DLC, and to characterize their visual response patterns. In anesthetized (Urethane) or paralyzed, artificially ventilated and only locally anesthetized pigeons, stimulating electrodes were placed at TeO and DLC, and in some experiments, at both optic tracts as well. Conventional procedures were used to record extracellular unitary activity of 145 W efferent neurons, identified by antidromic invasion from TeO (latencies ranging 3.2-7.1 msec) or from DLC (2.6-5.2 msec). The main results can be summarized as follows:1. The great majority of W efferent cells could be activated from both ipsi- and contralateral optic tracts, with latencies ranging, respectively, 24-53 msec and 32-81 msec.2. All of them showed anteriorly located fields, approximately rectangular, covering areas from 15 to 380 deg^2, what corresponds to 4-20 deg in their longer axes.3. Those receptive fields appeared highly organized, with several "ON" and "OFF" regions and, accordingly, their responses depended on the form, dimension and orientation of visual stimuli projected on a screen.4. The most effective photic stimuli were moving spots or bars, and all neurons had directional preferences. Further, many were sensitive to specific scan velocities.5. Ipsi- and contralateral receptive fields were similar, but we could observe some degree of dominance, when considering magnitude of responses in terms of total number of spikes elicited. These results agree with anatomical studies which indicate that W projections could subserve some functions in binocular processing and suggest that W neurons convey complex information back to DLC and TeO.

251.16 ALTERATION OF CORTICAL ACTIVITY AFTER ABLATION OF SUPERIOR COLLICULUS IN RABBIT, Lex C. Towns, Ph.D., Department of Anatomy, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501

It is well established that the superior colliculus sends axons to terminate in those thalamic nuclei, principally the dorsal lateral geniculate nucleus and lateral posterior nucleus, which project to visual cortex. In the present experiment, a 2-Deoxy-D-glucose (2DG) technique adapted from that described by Sokoloff and his associates (Sokoloff, et al., J. Neurochem, 28, 897-916; 1977) was used to assess alternations in visual cortical activity which accompany removal of collicular input to the visual thalamus.

In each of five 1.5-2.0 kg rabbits, the superior colliculus was ablated unilaterally under Nembutal anesthesia. One week later 2-Deoxy-D-1-[^{3}H]-glucose was injected i.v. (500,µCi/kg) and each animal was immediately placed in a visual stimulating cylinder and stimulated for 45 minutes. Upon completion of visual stimulation, the rabbit was killed, briefly perfused with saline followed by fixative and the brain was rapidly removed, blocked and frozen by slow immersion in a dry ice/acetone bath. Coronal sections of the whole rabbit brain were cut on a cryostat and rapidly dried onto coverslips. Arrays of coverslip-mounted sections were placed in contact with a film sensitive to the low energy beta particle (Ultrofilm, LKB) and exposed for 4 weeks. A qualitative comparison of these autoradiograms revealed a reduction in functional activity of the visual cortex on the ablated side when compared to the intact side. The decrease in activity was particularly apparent in layer IV of striate cortex but there was a generalized decrease throughout both striate and occipital cortex. In addition to the alteration of cortical neuronal activity, there was a consistent decrease in the neuronal activity in the dorsal lateral geniculate nucleus on the ablated side. These results suggest that visual cortex function, at least as that function is related to glucose metabolism, is partially determined by input relayed from the superior colliculus. Supported by NIH EY02285.

252.1 IMMUNOCHEMICAL STUDIES ON ELECTROPHORUS ELECTRICUS ACETYLCHOLINE RECEPTOR USING MONOCLONAL ANTIBODIES. S.J. Tzartos*, D.E. Rand*, and J.M. Lindstrom. Receptor Biology Lab., The Salk Institute for Biological Studies, P.O. Box 85800, San Diego, California, 92138.

Forty cell lines producing monoclonal antibodies (mAbs) against Electrophorus electricus acetylcholine receptor (eel AChR) have been established and characterized. In a previous report (1) mAbs to Torpedo AChR disclosed the existence of a main immunogenic region on Torpedo AChR located on the α subunit, distinct from the toxin binding site and exposed on the extracellular surface of the membrane. We also described immunochemical similarities between α and β as well as between γ and δ Torpedo AChR subunits as revealed by two mAbs. We now have extended our library of anti-AChR mAbs with 33 mAbs derived from rats immunized with Triton X-100 solubilized eel AChR and 7 mAbs from rats immunized with SDS-denatured eel AChR subunits.

These 40 mAbs have shown some characteristic similarities with the 17 anti-Torpedo AChR mAbs (1). Thirty bound detectably to SDS-denatured eel AChR subunits, the majority of which (24) were directed against the α' subunit. Three others were anti-β' and one anti-δ'. Two mAbs crossreacting with two subunits each were also found (one with α' - β' and another with γ' - δ').

Most of the anti-α' mAbs crossreacted with native Torpedo AChR, but usually with lower affinity. Half of the anti-α' also crossreacted with fetal calf muscle AChR, generally with very low affinity. The mAb #35, however, had a titer for fetal calf AChR comparable to that for eel AChR (3 μM against 15 μM). The group of six mAbs directed to other than α' subunits were absolutely species-specific.

Using a technique described previously (1), pairs of antibodies were tested for their capacity to bind simultaneously on Sepharose-bound AChR or compete with each other for the same region on the receptor. We found that a main immunogenic region also exists on eel AChR, when injected in rats, that is located on the α' subunit and is rather homologous to the Torpedo AChR main immunogenic region. Indeed, all 10 anti-α' mAbs which so far have been studied were found to compete with each other for the same region on eel AChR. These mAbs also compete with anti-Torpedo mAb #6 which binds to the main immunogenic region of Torpedo AChR (1) and crossreacts with eel AChR. However, in contrast to the mAbs directed against the Torpedo AChR main immunogenic region, the above 10 mAbs crossreact well with SDS-denatured α' subunit. (Supported by grants to J.M.L. from NIH and MDA, and a MDA fellowship to S.J.T.)

(1) Tzartos, S.J. and Lindstrom, J.M., PNAS, 77, 755-759, 1980.

252.2 BINDING OF ANTI-ACETYLCHOLINE RECEPTOR ANTIBODIES TO DETERGENT-SOLUBILIZED AND MEMBRANE-BOUND RECEPTORS. S. C. Froehner* (SPON: N. G. Bacopoulos). Dept. of Biochemistry, Dartmouth Medical School, Hanover, NH 03755.

The accessibility of antigenic sites on detergent-solubilized and membrane-bound Torpedo acetylcholine receptors (AChR) has been investigated with two classes of antisera. Antisera to native AChR (anti-nAChR) or to SDS-denatured AChR (anti-dAChR) were raised in rabbits. Both animals injected with native AChR developed muscle weakness while the two injected with denatured AChR did not. Antibody activity determinations with ^{125}I-AChR showed that all four antisera preferred native to denatured antigen. Titers of anti-nAChR were 2-4 fold higher than those of anti-dAChR when native ^{125}I-AChR was used. Reaction of antisera with the subunits of AChR separated by SDS gel electrophoresis indicated that all four antisera recognized determinants on each of the subunits.

The ability of these antisera to react with membrane-bound AChR was determined by incubating a constant amount of antiserum with various concentrations of AChR-rich membrane vesicles. After removal of the membrane-bound antibodies by centrifugation, the supernatant was assayed for anti-AChR activity. In the presence of an excess of AChR-rich membranes, approximately 70-80% of anti-nAChR was bound while only 10-20% of anti-dAChR reacted. Control experiments indicated that rabbit anti-α-bungarotoxin (anti-αBuTx) antibodies did not bind to the membranes. Thus, the anti-nAChR sera are directed predominantly against sites exposed in the membrane, while anti-dAChR sera primarily recognize antigenic sites that are not accessible in the membrane. Alkaline extraction of the AChR-rich membranes, which removes a polypeptide of 43,000 mol. wt., causes a 4-6 fold increase in their ability to bind anti-dAChR. Treatment of the membranes with saponin to allow access of antibodies to the interior of the vesicles also enhances anti-dAChR binding. Neither alkaline-extraction nor saponin treatment promotes non-specific binding of anti-αBuTx antibodies. Thus, these treatments expose antigenic sites on membrane-bound AChR which are normally inaccessible to antibodies. Supported by NIH grant NS 14871 and the Muscular Dystrophy Association.

252.3 Cationic sodium substitutes block endplate channels at the amphibian motor endplate. J.F. FIEKERS* (SPON: G.D. WEBB) Dept. Anatomy and Neurobiology, Univ. of Vermont College of Medicine, Burlington, Vermont 05405.

Previous studies demonstrated that complete substitution of TRIS or Glucosamine (GLU) ions for sodium in normal frog Ringers' solution (NFR) produces a voltage-dependent reduction in the amplitude of endplate currents generated by iontophoretically applied (EPCs) or spontaneously released (MEPCs) acetylcholine (ACh). (Fiekers, J.F. and Henderson, E.G. Biophys. J. 21:177A, 1978. This was manifested by a nonlinear peak current-voltage plot (I-V) in which peak current at negative membrane potentials was markedly reduced, but peak current at +40mV was approximately equal to control. The present experiments were undertaken to investigate the mechanism of blockade produced by these cationic substitutes. MEPCs and EPC fluctuations produced by iontophoretically applied ACh were obtained in single voltage clamped fibres from a monolayer preparation of the cutaneous pectoris muscle (Rana pipiens). Mean channel lifetime (τ), single channel conductance ($\bar{\gamma}$), MEPC amplitude and time constant of decay (τMEPC) were determined and the variation of these parameters as a function of voltage and concentration of each substitute was analyzed. In NFR, totally substituted, and partially substituted solutions MEPCs decayed as a single exponential function of time and the spectra were adequately fit by a single Lorentzian. The reversal potential was obtained by the actual reversal of mean EPC. With total substitution of TRIS or GLU for sodium in NFR, MEPC amplitude at hyperpolarized potentials was markedly reduced and measurement of $\bar{\gamma}$ was difficult. In four endplates $\bar{\gamma}$ was 2.3±1.4pS @ -80mV (19°C). Conversely $\bar{\gamma}$ estimated at +30mV was unaltered from values obtained in NFR (23.2±4.8pS). At a constant membrane potential (-80mV) $\bar{\gamma}$ decreased and τ_{noise} increased with increasing concentrations of TRIS and GLU. Partial substitution (50%) yielded values of $\bar{\gamma}$ of 6.3±1.3pS (TRIS) and 4.8±0.4pS (GLU) at -80mV (90°C); however, at +22mV $\bar{\gamma}$ was 24.5±2.1pS (TRIS) and 23.4±2.7pS (GLU). MEPC amplitude decreased and τ_{MEPC} increased with increasing concentrations of each substitute. τ_{MEPC} approximated τ_{noise} when measured in the same endplate. In the substituted solutions, $\bar{\gamma}$ increased and τ decreased as the membrane became more positive. These observations suggest that these cationic substitutes interact with endplate channels to reduce cation permeation. The dependence of this block on the value of membrane voltage suggests that these ions bind to a site within the endplate channel. These data provide an explanation for the nonlinear I-V plots obtained in the presence of these substitutes. Supported by PHS HL-22269-02.

252.4 FREEZE FRACTURE EVIDENCE SUGGESTS THAT AGGREGATED ACETYLCHOLINE RECEPTORS ON CULTURED EMBRYONIC MUSCLE LIE IN MEMBRANE REGIONS LOW IN CHOLESTEROL. P. C. Bridgman*. (SPON: Y. Nakajima) Dept. Biol. Sci., Purdue Univ., West Lafayette, IN 47907

Several sterol-specific cytochemical agents have been recently introduced for the freeze-fracture localization of cholesterol in cell membranes (1,2,3). These agents include the polyene antibotic filipin, the glycosylated sterol digitonin and the surface active agent saponin.

I have used all three of these sterol-specific agents on cultured noninnervated and innervated Xenopus embryonic muscle cells and the distribution of their sterol complexes was very similar. The appearance of these complexes, however, was markedly different. Filipin-sterol complexes were recognizable as 25-30 nm protuberances on the P-face of the replica and seemed to provide the best resolution and specificity for detecting cholesterol.

Freeze-fracture of 1 day and 7 to 8 day old muscle cell cultures revealed that sterol complexes were present on most of the membrane, but were absent from shallow depressions on the plasma membrane which probably represent coated pits (3). Complexes were also absent from long streaks of membrane usually found on thin extended processes of muscle cells. Occasionally areas of the plasma membrane which presumably underlie the nucleus also contained a low density of complexes. Cross-fractures revealed the absence of complexes from nuclear membranes which are known to be low in cholesterol content. The most striking observation, however, was the virtual absence of complexes from tight aggregates of large intramembrane particles characteristic of acetylcholine receptors (AChR's). This was true in both large clusters of aggregates which may represent AChR "hot spots" and in the area surrounding smaller isolated aggregates which are occasionally found on the membrane.

Treatment of 2 day old nerve-muscle cocultures again revealed the absence of complexes from areas of tightly aggregated large particles in the postsynaptic membrane.

Based on this evidence it appears that aggregated AChR's in embryonic muscle lie in membrane regions of low sterol content. A difference in the lipid content of the membrane containing high densities of AChR's may aid in restricting their dispersion. This may be one factor responsible for the stability of such AChR aggregates.

252.5 THE HILL COEFFICIENT OF THE ACETYLCHOLINE RECEPTOR DOSE-RESPONSE RELATION IS INDEPENDENT OF MEMBRANE VOLTAGE AND TEMPERATURE.
H.M. Hoffman* and V.E. Dionne* (SPON: S. Varon). Div. of Pharm., University of California at San Diego, La Jolla, CA 92093.

A rapid equilibrium dose-response method has been developed which allows effects of environmental factors on this relationship to be examined. Experiments were performed on the acetylcholine receptors of garter snake (sp. Thamnophis) twitch fiber neuromuscular junctions. These compact endplates were observed with Nomarski optics and voltage clamped with two microelectrodes, allowing agonist-induced changes in membrane conductance to be monitored. Agonists were applied iontophoretically from a point source located a measured distance form the endplate; this distance was chosen so that variation of source-receptor separation for different receptors on the endplate surface was $\leq$ 5%. Agonists were released from the source with a 5-8 second ramp of iontophoretic current such that the release rate of agonist ions increased linearly with time. The agonist concentration at the receptor surface was computed from the diffusion equation assuming the iontophoretic pipette transfer number was constant for currents above a critical value at which just-detectable release occurred. By plotting measured endplate current against predicted surface concentrations, an uncalibrated dose-response curve was obtained; on a log-log plot these curves were linear with nominal slope values near two for acetylcholine and carbamylcholine. Accurate evaluation of the slope -- termed the Hill coefficient, n_H -- depends on several factors, not all of which were measured in these experiments. We examined, however, the effects of temperature and voltage on n_H by recording as many as 24 separate, rapid dose-response curves from individual cells as these extrinsic variables were changed. In these experiments temperature was varied between 6-20°C and membrane voltage from -40 to -120 mV without effect; neither variable produced a significant systematic change in n_H. The average temperature dependence of n_H (normalized to unity) was -.0091 ± .0030 per °C, and the dependence on voltage was -.0010 ± .0018 per mV (mean ± S.D.).

252.6 PURIFICATION AND CHARACTERIZATION OF A NICOTINIC ACETYLCHOLINE RECEPTOR FROM *DROSOPHILA MELANOGASTER*.
T. Schmidt-Glenewinkel*, T.R. Venkatesh* and L.M. Hall, Dept. of Genetics, Albert Einstein College of Medicine, Bronx, NY 10461.

The central nervous system of *Drosophila melanogaster* contains an α-bungarotoxin binding component with the properties expected of a nicotinic acetylcholine receptor(Schmidt-Nielsen, B.K., J.I. Gepner, N.N.H. Teng and L.M. Hall, J. Neurochem., 29:1013, 1977). The isolation of this receptor from *Drosophila* has been approached with the underlying concept that the receptor in this species would be amenable to sophisticated genetic manipulation and analysis. The receptor was solubilized from a membrane preparation from heads of *Drosophila* in the presence of 0.5 M sodium chloride and 1% Triton-X-100. The solubilized form was initially purified by passage over an affinity column, composed of lectins from *Lentil culinaris* covalently linked to Biogel A-15m. It was eluted from this column with 2% methyl α-D-mannopyranoside in the presence of 1% azolectin. Further purification was achieved by two passages over a second type of affinity column prepared from α-cobratoxin from *Naja naja siamensis* linked to Sepharose 4B. Binding of α-bungarotoxin was determined with a modified DEAE-filter assay which allows the quantitation of the binding component in both its membrane-bound and solubilized form. Purification was monitored by one- and two-dimensional sodium dodecyl sulfate polyacrylamide gel electrophoresis and isoelectric focusing, using a sensitive silver staining procedure for the detection of proteins. The receptor binding properties of α-bungarotoxin derivatized with 4-methylazidobenzoimidate have been studied and the electrophoretic behavior of the receptor after cross-linking to α-bungarotoxin has been investigated. The acetylcholine receptor from *Drosophila* is a glycoprotein with a molecular weight in the range of 250,000-500,000. Data will be presented for its subunit composition, the possible acetylcholine binding site, and its pharmacological properties in the crude and purified extracts.
(Supported by grant 1126A from The Council for Tobacco Research-U.S.A., Inc. and NSF grant BNS-7929435. L.M.H. is a McKnight Scholar in Neuroscience).

252.7 BLOCKADE AND BINDING OF QUINUCLIDINYL BENZILATE AND α-BUNGAROTOXIN TO HELIX ACETYLCHOLINE RECEPTORS.
J. C. Hancock, D. B. Hoover and N. S. Talley, Department of Pharmacology, East Tennessee State University, College of Medicine, Johnson City, Tennessee 37601.

Quinuclidinyl benzilate (QNB) binds with great specificity to muscarinic receptors and α-bungarotoxin (αBT) binds with great specificity to nicotinic receptors in vertebrate systems. We have studied the effects of QNB and αBT on the electrophysiological response to acetylcholine (ACH) on identifiable cells in the nervous system of the snail Helix aspersia and the binding of ^{3}H-labeled QNB and ^{125}I-labeled αBT to subesophygeal ganglion preparation. Standard binding and electrophysiological techniques were used. Specific binding of QNB (1nmole) was obtained at a level of 17 fmole/μg protein. QNB binding to whole brain preparations was blocked by atropine (1μmole) but not by d-tubocurine (d-TC:50μmole) or hexamethonium (C_6:50μmole).α-BT (2.8nmole) bound specifically at the level of 0.39fmole/ug protein to brain homoginates. αBT binding was blocked by nicotine (100μmole). Its blockade by atropine, d-TC and C_6 have not been determined. Electrophysiological studies show several different types of responses to ACh. We have studied the effect of QNB and αBT on two of these responses. On inhibitory responses where the hyperpolarization is mediated by an increase in conductance to chloride, QNB (100μmole) blocked the hyperpolarization caused by ACh (5μmole). This response was also blocked by atropine (5-100μmole), d-TC(10-100μmole) or C_6 (10-100μmole). On excitatory responses, where the depolarization is mediated by an increase in sodium concentration, the minimum concentration of QNB that would block the depolarization caused by 5μmole ACh was 1mmole QNB. Soaking for 1 hr. in 10μmole αBT did not alter the hyperpolarization caused by 5μmole ACh. Atropine (5-100μmole) and d-TC(10-100μmole) blocked the ACh-induced depolarization of these cells. The results indicate that, while QNB and α-BT bind specifically to cholinergic receptors of snail brain, these agents are not highly specific for the cholinergic receptor types tested as demonstrated by the high concentrations necessary to block.

Cholinergic receptors of gastropods cannot be classified as distinctly nicotinic or muscarinic as evidenced by their blockade by either atropine or d-TC. This lack of differentiation may account for the failure of QNB and α-BT to prevent pharmacological responses to ACh. (Supported by Biomedical Research Development Grant 1-S08-RR 09171-01).

252.8 Effects of Physostigmine and Mecamylamine on the Response to Acetylcholine in Aplysia.
M.G. Filbert,* J.T. Moffitt,* P.G. Sokolove, D.O. Carpenter and M.J. McCreery.* (Spon: B. Hackley) USA Biomedical Laboratory, APG, MD 21010; Dept Biol, UMBC, Catonsville, MD 21228 and Bethesda, MD 20014.

It is widely accepted that the effects of physostigmine (physo) can be attributed to the accumulation and prolonged action of acetylcholine (Ach) due to inhibition of Acetylcholinesterase (AChE). However, evidence also suggests a direct action of physo on postsynaptic membranes (1,2). It has been shown that physo blocks binding of ^{125}I-α-Bungarotoxin (α-Btx) to ganglionic homogenates of aplysia and also blocks inhibition by α-Btx of the electrophysiological response to Ach (3). Recently, mecamylamine (meca), a nicotinic blocker was observed to inhibit α-Btx binding to Aplysia homogenates as well. The I_{50}'s for the inhibition of α-Btx binding by physo and meca were comparable to that of d-tubocurarine. (4)

We have examined the effects of these cholinergic agents on the electrophysiological responses of Aplysia neurones to iontophoretic application of Ach and carbechol (Carb). Iontophoresis of physo onto the cell just before Ach or Carb almost always resulted in a reduced response whereas its perfusion sometimes caused an increase in the amplitude and duration of the response to Ach as expected with inhibition of AchE. The sensitivity of the Ach and Carb response to inhibition by physo was dependent upon the conductance change elicited: $g_{Na^+} > g_{Cl^-} >> g_{K^+}$. Iontophoresis of meca resulted in diminution of the response irrespective of whether the voltage change was due to an increase in conductance to Na^+, Cl^- or K^+.

These results suggest that the classic anti-AChE physo can also interact directly with the ACh receptor. At low concentrations of physo, enzyme inhibition predominates leading to potentiation of the ACh response. Higher concentrations of physo results in its binding to the ACh receptor which reduces the ACh response amplitude and offsets the effects due to enzyme inhibition. Only a reduction in the response to the nonhydrolysing substate Carb was observed with physo. These data are consistent with the binding curves for physo with AChE (I_{50}=.25μm) and for its inhibition of α-Btx binding (I_{50}=5.0μm)(3). The ACh response is reduced by meca which has no enzyme inhibiting activity.

252.9 USE OF (^{3}H)BROMOACETYLCHOLINE TO LABEL NICOTINIC ACETYLCHOLINE RECEPTORS FROM THE CENTRAL NERVOUS SYSTEM. T.H. Large*, R.G. Siman*, and W.L. Klein. (Biological Sciences, Northwestern University, Evanston, IL 60201)

We report here the first use of (^{3}H)bromoacetylcholine (BAC) to quantify nicotinic acetylcholine (ACh) receptors in the central nervous system. High specific activity (^{3}H)BAC was synthesized from (^{3}H)choline and bromoacetylbromide and purified by TLC (butanol:water:ethanol:acetic acid::4:3:2:1). Previous work has shown that (^{3}H)BAC reacts covalently with reduced nicotinic ACh receptors from electrophlax (Damle, V.N., et al., Biochem. Biophys. Res. Comm. 84: 845, 1978). Similarly, using dithiothreitol-reduced membranes prepared from retinas of 1 day old chicks, we have found that 3 x 10^{-9} M (^{3}H)BAC specifically reacts with 1100 fmols of nicotinic sites per mg membrane protein. Labeling is complete within 90 minutes at 23°. Binding in the presence of 10^{-3} M nicotine is taken to be nonspecific. The IC_{50} of ACh for blockade of labeling by 3 x 10^{-9} M (^{3}H)BAC is 10^{-6} M. A ten-fold higher concentration of (^{3}H)BAC labels the same number of sites as the lower concentration but in a period of less than 30 minutes. The concentration of specifically labeled sites in membranes from 16 day old embryonic chick retinas is only 15% that measured in membranes from 1 day old animals, correlating with a similar difference in specific (^{125}I)alpha bungarotoxin binding sites between the two ages. Additionally, we have found that unlabeled BAC at concentration of 10^{-8} to 10^{-7} M irreversibly blocks 50% of specific (^{125}I)alpha bungarotoxin binding to chick retina, optic tectum, and skeletal muscle preparations. If membranes are not reduced with dithiothreitol, BAC reversibly blocks binding of 10^{-8} M (^{125}I)alpha bungarotoxin with an IC_{50} of 10^{-5} M. Not all of specific toxin binding can be irreversibly blocked by BAC, even at concentrations adequate to reversibly block binding 100%. The ability of BAC to block toxin binding and to covalently react with reduced sulfurs in both skeletal muscle and central nervous system preparations suggests considerable homology between muscle cell and nerve cell nicotinic ACh receptors. (Supported by NIH grant 5 RO1 NS15299-02 to WLK.)

252.10 ANALYSIS OF CHANNELS ACTIVATED BY ACETYLCHOLINE AND GLUTAMATE IN CRUSTACEAN MUSCLES. C. Lingle and A. Auerbach. Biology Dept., Brandeis U., Waltham,MA 02254; Lab. Neurobiol., San Juan, PR 00936

Striated muscles in the decapod crustacean foregut are innervated by either cholinergic or glutamatergic excitatory motor neurons. Some muscles that receive glutamatergic innervation also display ACh receptors extrajunctionally. Thus, it is possible to characterize both cholinergic and glutamatergic synaptic conductances on similar muscles and, further, to compare channels activated by either ACh or Glu on the same muscle fibers. Towards this end, ACh-induced currents were analyzed by two methods on cholinergic gm1 muscles of Cancer and Panulirus. First, current noise generated by ACh application to voltage-clamped regions of fibers was examined with fluctuation analysis. Second, decays of synaptically evoked currents were examined by averaging of focal extracellular synaptic potentials at cholinergic junctional sites. ACh application to cells evoked stable mean current increases and an increase in current noise variance. Power spectra of current fluctuations were fit to single Lorentzians from which values for both duration(τ) and amplitude(γ) of elementary events were obtained. At 12°C, τ(noise) was about 11.5 ms at -60 mV and about 16.5 ms at -100 mV. At -60 mV, τ(noise) was prolonged to 25 ms at 5°C and shortened to about 4 ms at 21°C. Single channel conductances were calculated assuming a reversal potential of 0 mV. In single fibers γ was voltage dependent varying between about 4.5 pS at -120 mV to about 8 pS at -40 mV. Average γ at 5°C was 2.7 pS (n=3); at 12.5 °C, 6.2 pS (n=14); and,at 21°C, 13.5 pS (n=13). The Q_{10} of both τ and γ is about 3. Decays of extracellular focal currents from single junctional sites were single exponentials over most of their time course. The voltage dependence of τ(decay) varied slightly among fibers, but at 13°C was about 10 ms at -60 mV and 15 ms at -100 mV. At -60 mV, τ(decay) was about 25 ms at 6°C and 5.5 ms at 21°C. The correspondence of the voltage and temperature dependence of τ obtained by both methods supports their validity and indicates that τ(decay) of synaptic currents at a crustacean cholinergic synapse is probably determined by channel closing rate. ACh responses of these muscles are pharmacologically similar to ganglionic nicotinic receptors (Marder and Paupardin-Tritsch, J. Exp.Biol. 1980, in press). It is interesting that the properties of τ of these muscle ACh channels also bear similarities to the ganglionic channel τ. In addition, we have examined both ACh and Glu current fluctuations on muscle gm6b, which receives glutamatergic innervation while displaying extrajunctional ACh receptors. Glu opens channels of larger conductance (20-30 pS) and different voltage dependence than those activated by ACh on this muscle.

CL and AA are MDA post-doctoral fellows; supported by NSF grant BNS78-15399(to E. Marder) and PHS-NS07464(to J. del Castillo).

253.1 ATTENUATION OF THE PRESSOR RESPONSE TO CENTRALLY ADMINISTERED PROSTAGLANDIN E_1 BY PROGESTERONE. K. M. Skoog* and Nancy J. Kenney, Dept. of Psychology, University of Washington, Seattle, WA 98195.

Progesterone attenuates the pressor effect of various peripherally administered hypertensive agents, e.g., norepinephrine and desoxycorticosterone. Progesterone's effect on centrally mediated pressor responses has not yet been reported.

In this study, changes in mean arterial blood pressure (MABP) following intracerebroventricular (IVT) injection of two well-known pressor agents, angiotensin II (AII) and prostaglandin E_1 (PGE_1) were studied in ovariectomized (ovx) and ovx,progesterone-treated Long-Evans rats. Progesterone (5mg/rat/day) or its seseme-oil vehicle (0.1ml) were injected subcutaneously for 10 days beginning the day after ovariectomy. Blood pressure changes following IVT injections of either 100ng PGE_1 or 5ng AII and their respective carrier solutions were measured by means of indwelling aortic catheters on the last two days of progesterone or oil treatment.

Baseline MABP was unchanged by progesterone treatment. Average basal MABP was 101.1 $\pm$ 2.9 mm Hg for the ovx, progesterone-treated rats and 100.0 $\pm$ 0.8 mm Hg for the oil-treated controls. Progesterone treatment had no effect on the increase of MABP to IVT AII. Ten minutes following the AII injection MABP for the progesterone-treated rats had an average of 9.2 $\pm$ 0.8 mm Hg over baseline levels while that of controls had increased an average of 11.2 $\pm$ 3.1 mm Hg ($t(5)=0.396$, $p > .20$).

The pressor response following IVT PGE_1 injection was markedly attenuated by progesterone treatment. MABP of control animals increased an average of 17.0 $\pm$ 1.5 mm Hg 10 min following the PGE_1 injection while that of progesterone-treated rats rose only an average of 1.6 $\pm$ 4.3 mm Hg ($t(5)=2.920$, $p < .05$).

Progesterone has been reported to block the effects of the E prostaglandins in various peripheral organs. Since progesterone readily crosses the blood-brain barrier, this steroid may act either centrally or peripherally to attenuate the hypertensive response resulting from increases in central PGE levels.

Supported by funds from the Graduate School of Arts and Sciences of the University of Washington and AM-22024 to NJK.

253.2 EVIDENCE THAT THE VENTRAL SURFACE OF THE BRAIN STEM IS THE SITE WHERE MUSCIMOL ACTS TO PRODUCE HYPOTENSION AND BRADYCARDIA. D.J. Williford, B.L. Hamilton, K. Yamada,* and R.A. Gillis. Departments of Pharmacology & Anatomy, Georgetown University, School of Medicine & Dentistry, Washington, D.C. 20007.

Earlier reports from this laboratory have indicated that stimulation of GABA receptors in the CNS with muscimol (M) causes withdrawal of sympathetic outflow resulting in dose-related reductions in blood pressure (BP) and heart rate (HR). M produces this effect when administered into the 4th ventricle (4V), but no effect is observed when M is restricted to the lateral and 3rd ventricles. M injected into the 4V could be acting in any one of 3 general brain areas: 1) the dorsal surface of the brainstem, 2) the ventral surface of the brainstem, or 3) the spinal cord. The present study was designed to locate the brain area(s) in which M acts to lower BP and HR. Experiments were performed in 6 anesthetized cats and consisted of selectively perfusing either the cisterna magna or the spinal cord with M. M produced no effect on BP or HR when the spinal cord was perfused with a dose of 32 ug M over 10 minutes. A similar perfusion of the cisterna magna however, produced falls in BP and HR of -55 $\pm$ 8 mmHg and -40 $\pm$ 6 beats/min, respectively. These results are comparable to those observed following 4V injection of a dose of 16 ug M (-58 $\pm$ 12 mmHg and -44 $\pm$ 9 beats/min). In each experiment perfusion of the cisterna magna with dye indicated that the ventral surface of the brainstem was heavily stained and no flow of dye occurred from the cisterna magna into the 4V. We conclude that M appears to lower BP and HR by acting in the region of the ventral surface of the brainstem and that BP and the HR changes obtained with injection of this agent into the 4V were most probably due to flow of drug through the Foramen of Lushka to the ventral surface.

253.3 CENTRAL CARDIOVASCULAR EFFECTS OF THE GABA MIMETIC AGENT, THIP. D. W. Snyder, L. J. Macklem* and W. H. Severini*. Squibb Institute for Medical Research, Princeton, New Jersey 08540.

Intracerebroventricular (ICV) administration of the GABA agonist 4,5,6,7-tetrahydroisoxazolo [5,4-c]-pyridin-3-ol (THIP) produced dose related decreases in arterial blood pressure in chloralose anesthetized cats. ICV infusion of THIP in total doses of 4, 15 and 40 µg/kg over a 10 min period lowered mean arterial pressure 18±7%, 37±10% and 55±6%, respectively. The onset of the fall in blood pressure occurred within 2 min, and was maximal at the end of the infusion. ICV infusion of THIP also caused changes in heart rate and renal nerve discharge. Similar to the blood pressure response, a fall in heart rate was evident within 2 min of the initiation of infusion at all doses of THIP. The maximal response in heart rate was seen 10 to 15 min after termination of the infusion. The magnitude of the fall in heart rate (15-25% reduction) appeared to be related to the level of resting heart rate prior to THIP administration. Renal nerve discharge was inhibited at the highest dose of THIP (40 µg/kg). At lower doses, effects on renal nerve discharge were variable. Recovery from the effects of THIP was dose related. With the highest dose of THIP only a slight return toward control was seen 60 min following the administration of THIP, whereas all parameters had returned to control within 40 min following the end of administration of the lowest dose of THIP. The data suggest that THIP, like other GABA receptor agonists, lowers blood pressure and heart rate through central inhibition of sympathetic nervous discharge, possibly by activation of central GABA-ergic neurons.

253.4 SUPPRESSION OF BRADYCARDIA INDUCED BY GIGANTOCELLULAR RETICULAR NUCLEUS BY CLONIDINE AND MORPHINE IN THE CAT. Julie Y. Hwa and Samuel H.H. Chan. Department of Life Sciences, Indiana State University, Terre Haute, IN 47809.

A cardioinhibitory mechanism was recently identified in the gigantocellular reticular nucleus (GRN) in the medulla oblongata of the cat. Electrical activation of this medullary mechanism elicited a significant reduction in heart rate (HR), accompanied mostly by hypotension. Parallel studies in our laboratory suggested that the antihypertensive agent clonidine may enlist this same medullary mechanism to induce bradycardia and vasodepression. Furthermore, microinjection of morphine directly into the GRN elicited a significant inhibition of the dental pulp evoked jaw-opening reflex, an experimental pain index. Since clonidine and morphine share a common neural substrate in exerting their respective pharmacologic actions and both agents possess suppressive effect on the cardiovascular system, the present study was undertaken to investigate their possible interactions with the GRN-induced bradycardia.

Experiments were performed on chloralose-urethane anesthetized cats. Intravertebral injection of clonidine (0.5-4.0 µg/kg) produced a dose-dependent decrease in HR and arterial blood pressure (ABP). Superimposed on its inherent circulatory action, clonidine also elicited a drastic depression of the GRN-induced bradycardia. For any given stimulus pulse frequency, clonidine blocked the cardioinhibitory effect of GRN in a dose-related manner. On the other hand, the amount of suppression of GRN-induced cardiodepression by clonidine, at any dose, was inversely related to the reticular stimulus pulse frequency and intensity.

Intravertebral injection of morphine (1.0-4.0 mg/kg) promoted a dose-dependent decrease in ABP and no significant change in HR. It is interesting to note that, superimposed on its cardiovascular effect, morphine also induced a suppression of the GRN-induced bradycardia. The degree of blockage was again directly proportional to the dose of morphine and inversely related to the intensity and pulse frequency of the reticular stimulus train.

It should be mentioned that clonidine and morphine, delivered intravertebrally at the same doses, exerted no influence on the cardioinhibition and vasodepression induced by direct stimuli to the cardiac end of a severed vagus nerve, suggesting that the observed blockage by these two pharmacologic agents on GRN-induced bradycardia should take place in the brainstem.

We conclude that clonidine and morphine may utilize the GRN to exert cardiovascular suppressions. Their activation of the GRN may render the reticular neurons less excitable upon subsequent electrical stimulation, resulting in the reduced degree of bradycardia. (Supported in part by the American Heart Asso., Indiana Affiliate).

253.5 Kainic acid-elicited tachycardia: role of dopaminergic, glutamatergic, and peptidergic systems. A. Y. Deutch, L. S. Clark, and L. J. Peacock. Dept. Psychology, Univ. Georgia, Athens, GA.

We have previously reported that kainic acid (KA) administrato the lateral septum (LSN) effects a short latency tachycardia, the occurence of which is dependent upon glutamatergic afferents. We have extended these findings and attempted to characterize the neuronal systems subserving heart rate changes secondary to KA administration. KA (4.7 nM in 1.0 µl buffered saline; barbiturate-anesthetized rats) effected a short latency tachycardia upon administration to the nucleus accumbens (ACB) and nucleus interstitialis stria terminalis (NIST); vehicle had no effect. Since these sites receive dopamine (DA) afferents from the A10 cell group, we examined a possible role for mesolimbic projections in KA-elicited tachycardia. KA administration to the central amygdaloid nucleus and ventral tegmental area (mesolimbic terminal field and origin, respectively) did not effect significant heart rate changes.

The glutamatergic (Glu) projection system originating in the hippocampus/subiculum innervates the LSN, ACB, and NIST, the three sites at which KA elicits tachycardia. In light of the finding that knife cuts of the Glu projection to the LSN block the heart rate increase subsequent to septal KA administration, we administered KA to the mammillary body (MB), which also receives a Glu projection via the fornix from the subiculum. No heart rate changes were noted upon KA injection of the MB, suggesting that Glu afferents, like DA afferents, do not by themselves subserve the tachcardia induced by KA administration.

We are currently assessing a possible peptidergic mediation of the heart rate changes. Thyrotropin releasing hormone (TRH) has been reported to be localized to the LSN, ACB, and NIST, but not the central amygdala, ventral tegmental area, or the MB. Preliminary data indicate that TRH (50µg) administration to the LSN results in a short latency tachycardia, similar to that observed following KA administration. The tachycardia does not reflect emergence of the animal from anesthesia; delivery of noxious mechanical stimulation did not induce transient shortening of the interbeat interval. Wet dog shakes were noted to occur following administration of TRH, with onset at approximately 8 minutes following initiation of administration of TRH. It is interesting to note that intraventricular administration of TRH at 8-10 minutes following initiation of KA administration to the ventricle (i.e., after both tachycardia and seizure onset) did not attenuate the epileptiform discharge (as recorded electocorticographically) that results from KA administration. This indicates that TRH may not potentiate the anticonvulsant properties of barbiturates, as has been previously suggested.

253.6 INDUCTION OF CARDIAC ARRHYTHMIAS BY TRANSIENT BLOOD PRESSURE ELEVATION DURING SLEEP IN CATS. R.B. Trelease*, G.C. Sieck*, R.E. Hall, and R.M. Harper. Depts. of Anatomy, Physiology, and The Brain Research Institute, UCLA Sch. of Med., Los Angeles, CA 90024.

Episodes of sleep apnea in humans, resulting from upper airway obstruction, are accompanied by transient increased arterial blood pressure, slowing of heart rate, and occasional cardiac arrhythmias. We have attempted to simulate the hemodynamic consequences of these phenomena by transiently increasing blood pressure during sleep and waking states in cats. Cats were surgically implanted with electrodes for monitoring physiological parameters and identifying waking and sleep states. Arterial and venous catheters were inserted into the descending aorta and inferior vena cava. Recording sessions began after the animals had recovered for at least one week. At the time of recording, the cat was placed in a chamber in which it could move freely. EEG, EOG, EKG, respiratory activity, and arterial blood pressure were continuously monitored. Respiratory movements were detected using a piezoelectric stain gauge fastened around the lower thorax. During each state, arterial pressure was transiently elevated by infusion of 30 ug phenylephrine (0.3 ml over 2 seconds) through the venous catheter. Possible non-specific drug effects were controlled by transiently elevating arterial pressure with inflation of a balloon-tipped (Swan-Ganz) monitoring catheter placed in the descending aorta. Various cardiac arrhythmias accompanied periods of increased blood pressure. While the fundamental pattern of reflex bradycardia was obtained with all stimuli in every state, responses to elevated pressure could be divided into four types based on the accompanying cardiac rhythm changes. The first type (normal response in most cases) consisted of a transient sinus bradycardia accompanied by state specific changes in the magnitude of respiratory-related heart rate variation. The second type of response included a transient pulsus alternans (paired long-short interbeat intervals) of sinus origin. A third type was an A-V nodal escape arrhythmia, which apparently occured when sinus rate fell below the rate of spontaneous A-V nodal pacemaker discharge. Transient ventricular arrhythmia characterized the fourth type of response to elevated arterial pressure. Although arrhythmias could be occasionally elicited during waking, the incidence of these arrhythmias was higher during sleep states. We conclude that transient elevation of blood pressure during sleep, such as that associated with obstructive sleep apnea, can cause cardiac arrhythmias.

Research supported by grant HL-22418-02 from the NIH.

253.7 CARDIOVASCULAR RESPONSES TO TRANSIENT BLOOD PRESSURE ELEVATION DURING SLEEP AND WAKING IN CATS. R.M. Harper, R.E. Hall, G.C. Sieck*, and R.B. Trelease*. Depts. of Anatomy, Physiology, and The Brain Research Institute, UCLA Sch. of Med., Los Angeles, CA 90024.

A variety of somatic reflexes are attenuated during sleep. The activity of visceral reflexes, such as the sinoaortic baroreflex, may not be affected in a similar fashion. It has been suggested that baroreflex activity is maintained across sleep and waking states, serving to "buffer" cardiovascular alterations, in particular those associated with REM sleep. The purpose of this study was to compare baroreflex gain during different sleep and waking states. Cats were surgically instrumented with electrodes for recording EEG, EOG, EKG, hippocampal and lateral geniculate activity. Arterial and venous catheters were introduced via the femoral vessels and advanced to the descending aorta and inferior vena cava. Recordings were initiated following one week of recovery from surgery. Recordings were obtained while the animals were unrestrained in a sound attenuated chamber. Sleep states were assessed using standard physiological criteria. During each state, arterial pressure was transiently elevated by bolus injection of phenylephrine (ca. 10 ug/kg, 0.3 ml in 2 sec.) through the venous catheter. To elevate blood pressure nonpharmacologically, the balloon of a double-lumen (Swan-Ganz) catheter was inflated in the descending aorta. Baroreflex gain was calculated in two ways: Absolute gain ($\Delta HR/\Delta BP$) and relative gain ($(\Delta HR/\overline{HR})/(\Delta BP/\overline{BP})$). Mean heart rate and systolic blood pressure values were derived from 5 second intervals immediately preceeding pressure elevation. Periods which included cardiac arrhythmias were excluded from the calculations. Elevation of arterial pressure pharmacologically or by balloon inflation produced progressive bradycardia in all states. The pressure increase in response to phenylephrine was comparable between states, although this elevation was sustained for a longer period of time during quiet sleep. Both absolute and relative baroreflex gains were slightly decreased during sleep states as compared to wakefulness. Therefore, unlike somatic reflexes, the sinoaortic baroreflex is not as markedly influenced by sleep states.

253.8 INCIDENCE OF CARDIAC ARRHYTHMIAS IN NORMAL AND DECEREBRATE RATS AFTER ACUTE SUBARACHNOID HEMORRHAGE. Priti S. Lacy* and A. M. Earle. Dept. of Anatomy, Univ. of Nebraska Med. Center, Omaha, NE 68105.

An anatomical and functional relationship exists between the supramedullary vasomotor regions of the cortex, hypothalamus, mesencephalon and the medullary vasomotor center. The present study was undertaken to determine the role that supramedullary vasomotor regions and the brainstem play in generating different types of electrocardiographic abnormalities after an acute experimental subarachnoid hemorrhage was induced in rats. Rats were divided into two groups and in both groups a subarachnoid hemorrhage was experimentally induced by the introduction of 0.2-0.5 ml of heparinized rat blood into the subarachnoid spaces over the region of the circle of Willis through a burr hole in the frontal bone. The femoral artery was cannulated for measurement of systemic arterial pressure and EKG was monitored from lead II. Both parameters were recorded in both groups of rats before inducing a subarachnoid hemorrhage and group II was then electrolytically lesioned at the midcollicular level. Blood pressure and EKG were recorded after lesioning animals in group II. Animals of both groups were subjected to a subarachnoid hemorrhage when bradycardia and a variety of electrocardiographic abnormalities were seen. Systemic arterial blood pressure either rose slightly or not at all in both groups of animals. After bradycardia ensued, blood pressure decreased and continued to decrease till death in decerebrate rats. Thirty-eight (38) percent of the control rats of group I showed premature ventricular contractions which failed to occur in decerebrate rats. Bradycardia, junctional rhythms, and changes in the shape and size of T waves were of common occurrence in both the control and decerebrate rats which suggests that a sustained elevation of intracranial pressure (Lacy and Earle, Anat. Rec. 196:106A, 1980) after a subarachnoid hemorrhage may through ischemia or deformation activate the vasomotor center in the brain stem. The premature ventricular contractions that failed to occur in decerebrate rats were probably mediated through supramedullary vasomotor centers in control rats of group I.

254.1 ELECTROCHEMICALLY STIMULATED (ECS) LUTEINIZING HORMONE (LH) RELEASE AND NUCLEAR CATECHOLAMINE (CA) CONTENT AFTER HYPOTHALAMIC KNIFE CUTS. C.P. Phelps, S. Saporta and D.M. Nance, Dept. of Anatomy, College of Medicine, Univ. of South Florida, Tampa, Florida 33612

Retrochiasmatic knife cuts that interrupt frontal (FC) or lateral frontal (LFC) neural connections of the rat mediobasal hypothalamus (MBH) respectively reduce or abolish the increases in plasma LH seen in sham (S) cut animals after ECS of the medial preoptic area (MPOA). However, these cut effects on LH release appear to be time dependent, for when the length of the postoperative (postop.) survival period is increased from 21 to 75d LH response to ECS of MPOA was improved in LFC rats (Phelps and Sawyer, Brain Res. 131:335). The present report concerns an examination of female rat response to ECS of MPOA 180d after FC, LFC or S cuts and high performance liquid chromatography with electrochemical detection to assay selected brain regions at 7,21,60 and 180d postop. for norepinephrine (NE), dopamine (DA) and epinephrine (E). Vaginal smears were monitored before and after cuts. At 170d postop. rats were ovariectomized (OVX) and 1 wk later received estradiol benzoate (EB,1µg/75gbw/day at 10:00 hr) x2d. Animals subsequently received pentobarbital (35mg/kg IP) 76 hr after the first EB injection, followed by bilateral ECS 1 hr later in MPOA (20µA anodal DC x 60s, bipolar concentric electrodes, anode positive). Blood was removed by venipuncture at 0,40,80,120 and 160 min after ECS for estimation of plasma LH by RIA. Sham surgeries had no effect on estrous cycles, FC produced constant estrus and polyfollicular ovaries, while LFC rats had variable vaginal cytology and atrophic ovaries. Both FC and S rats showed similar significant increases in plasma LH levels (FC,353±117; S,259±58ng/ml), at 40 min after ECS, which remained elevated at 80 and 120 min. There was no significant change in LH at 40 min (56±37ng/ml) or later in LFC rats. Hypothalamic nuclear NE levels (pg/µg protein) in MPOA, arcuate (ARC) and ventromedial (VMN) nuclei of EB-primed, OVX rats increased 2 and 3-fold above preoperative levels at 7 and 21d after FC and S, but returned to preop. levels at 180d after surgery. LFC resulted in a sharp decline in NE content of the paraventricular nucleus (preop., 38.1±10.8; 21d:4.7±0.3; 180d: 2.8±1.3pg/µg) while E was approximately doubled (7d) and then returned to preop. levels (180d). LFC also increased DA content of ARC from 10.2±2.8pg/µg to 33.9±5.3pg/µg (7d postop.) and 25.4±4.1 pg/µg (180d). Histological examination revealed that all cuts were complete. We conclude that hypothalamic knife cut effects on ECS release of LH and hypothalamic CA content will vary not only with cut location and dimension, but also with survival time.

254.2 IMMUNOCYTOCHEMICAL ANALYSIS OF CHANGES IN HYPOTHALAMIC LHRH DISTRIBUTION FOLLOWING NEONATAL ADMINISTRATION OF MONOSODIUM GLUTAMATE (SPON: E. Boyd), C. A. Bennett-CLARKE*, M. A. Romagnano, S. A. Joseph* and W. H. Pilcher*. Neuroendocrine Unit, University of Rochester, Rochester, N.Y. 14642.

The immunocytochemical distribution of LHRH was examined in control and MSG lesioned mice, using the unlabeled antibody enzyme method of Sternberger. MSG was administered to neonatal mice, in increasing doses according to the injection protocol of Pilcher et al. (1980), while control animals received similar injections of 0.9% saline. Experimental and control mice were intracardially perfused with Zamboni's fixative. Frontal and sagittal sections of brain were serially sectioned at 50µ on an Oxford Vibratome and cytochemically stained for LHRH with antiserum B4305 (supplied by Dr. Sternberger). Control dishes of the same brain were stained with anti-ACTH antiserum, 531 (supplied by Dr. Joseph). Following incubation in primary antiserum, the sections were stained according to previous described immunocytochemical procedures. Correlative radioimmunoassay, to determine content of these peptides in brain, was performed on lesioned and control animals. Neonatal administration of MSG has been shown to destroy 80-90% of the neurons of the arcuate nucleus including those cell bodies which form the bed nucleus of the opiocortin system. In this study, the extent of the MSG-induced arcuate nucleus lesion was determined by routine nuclear staining as well as by *ACTH immunocytochemistry*.

The distribution of LHRH neurons and fibers in both experimental and control animals was similar to that previously described in thick vibratome sections in the rat (Bennett-Clarke & Joseph, 1980) with the exception of the area of the arcuate nucleus. No LHRH neurons were observed in this area in either the lesioned or control animals, however, LHRH fibers were observed projecting along the ventral portion of the third ventricular wall and through the arcuate nucleus along the course of tanycyte processes to the portal capillaries in the control mice. In MSG lesioned animals, the similar portion of the ventricular wall as well as the arcuate nucleus was devoid of immunoreactive LHRH fibers.

(Supported by RCDA Grant HD 00230A to S.A.J., HD 07926, and Program Project Grant NS 15345.).

254.3 THE DISTRIBUTION OF SOMATOSTATIN IN THE MOUSE BRAIN FOLLOWING NEONATAL ADMINISTRATION OF MSG. M.A. Romagnano, C.A. Bennett-Clarke*, S.A. Joseph* and W.H. Pilcher*. Neuroendocrine Unit, University of Rochester, Rochester, NY 14642.

The distribution of somatostatin (SRIF) was examined using the unlabeled antibody enzyme method of Sternberger on brains of control and monosodium glutamate (MSG) treated mice. Neonatal administration of MSG was given in increasing doses according to the injection protocol of Pilcher et al. (submitted to Nature, 1980) which produced a 80-90% cell loss within the arcuate nucleus of the hypothalamus. Control animals were injected with 0.9% saline. Adult mice were perfused through the heart with Bouin's fixative. Brains were removed and 50µ coronal and sagittal sections were cut on a Vibratome. Sections were incubated in Joseph's anti-SRIF "Charlie 8" at a dilution of 1:1000. Only animals with complete lesions as determined by staining for the ACTH component of the opiocortin system were used for the experimental animals. We have shown that the bed nucleus of ACTH-containing cells in the region of the arcuate nucleus is destroyed by the neonatal administration of MSG (Pilcher et al.'80). In addition, the presence or absence of cell bodies in the arcuate nucleus was examined in counterstained cresyl violet sections.

The distribution of hypothalamic and extrahypothalamic SRIF-containing cells and fibers in control animals was similar to that described for the rat (Bennett-Clarke et al., Br. Res., 188:473, 1980). It was noted that the arcuate nucleus contained SRIF fibers throughout its entire extent. Mice with with complete arcuate lesions contained SRIF cells and fibers in the same areas as the control animals with one important exception, the arcuate nucleus in the lesioned animal was devoid of fibers. Correlative RIA data has been performed on control and experimental animals. The loss of SRIF fibers from the arcuate nucleus subsequent to MSG administration raises questions concerning the role of SRIF in the arcuate nucleus during development.

254.4 MONOSYNAPTIC PROJECTIONS OF THE AVIAN HYPOTHALAMUS TO BRAINSTEM AND SPINAL CORD. Judith A. Finkelstein and Mitchell L. Berk, Dept. Anat., N.E. Ohio Univs. Col. Med., Rootstown, Ohio 44272.

The mammalian paraventricular nucleus (PVN) of the hypothalamus has direct connections to brainstem and spinal cord autonomic nuclei. We explored the possibility of a similar hypothalamic projection in birds by the use of the autoradiographic and horseradish peroxidase (HRP) techniques.

In the pigeon, iontophoretic injections of ^{3}H-leucine were placed in n. periventricularis magnocellularis (PVM), the presumed homologue of PVN of mammals. Heavily labeled fibers from PVM course ventrolaterally in the lateral hypothalamic area (LHA), approach the supraoptic decussation, and then turn ventromedially to densely innervate both layers of the median eminence. Another prominent bundle of fibers proceeds caudally through LHA, stratum cellulare externum, and then enters the midbrain tegmentum lateral to n. ruber. These fibers continue posteriorly in the lateral mesencephalic reticular formation. At pontine levels, some of the fibers leave the lateral bundle, travel in a dorsomedial direction and appear to terminate lateral to locus coeruleus. The remaining fibers in the bundle continue caudally in the ventrolateral pons, lateral to the superior olivary nucleus, and proceed into the ventrolateral medulla. Some fibers leave the bundle, course dorsomedially, and densely innervate n. intercalatus, which lies ventral to the dorsal motor nucleus of the vagus (DMX). At this level, fibers also surround DMX and lie within the dorsal, ventral, and lateral margins of n. solitarius. At the level of the central canal, the medial part of n. solitarius is most densely labeled. Also, fibers are still present in the ventrolateral bundle at this caudal medullary level.

Additional PVM projections course to the medial and periventricular preoptic areas, hypothalamus, lateral septum, and nucleus of the septal commissure. Other fibers densely innervate the periventricular part of the dorsomedial thalamus. Fibers also extend into the midbrain periventricular gray adjacent to the cerebral aqueduct.

In other pigeons, HRP was injected into the spinal cord at the level of T1. Labeled cells are observed throughout PVM, many with processes extending into the lateral hypothalamus. Unlike HRP injections into the mammalian spinal cord, very few labeled cells are seen in the lateral hypothalamus. Based on all of the above information, the avian PVM is indeed the homologue of the mammalian PVN. Supported by NIH Grant 5 Rol NS 14344, NSF Grant BNS 77-19302 and NIH Fellowship 1 F32 NS06186.

254.5 THE SUPRACHIASMATIC HYPOTHALAMIC NUCLEUS: ULTRASTRUCTURE OF RELATIONS TO OPTIC CHIASM. J.P. Card, J.N. Riley and R.Y. Moore. Department of Neurology, SUNY at Stony Brook, NY 11794.

Recent studies have demonstrated a retinohypothalamic input to neurons other than those of the suprachiasmatic nuclei (SCN) via dendrites which project into the optic chiasm or tracts. Since dendrites of SCN neurons are also known to project into the optic chiasm, these findings have raised the possibility that the SCN itself may receive a more widespread retinal input than previously demonstrated with the autoradiographic and HRP techniques. As a first step toward the resolution of this question we have conducted a systematic analysis of the interrelation of the SCN and the optic chiasm throughout the rostrocaudal extent of the nucleus. Adult female rats were perfused with buffered aldehyde solutions, the brain removed and 100 μm Vibratome sections cut throughout the rostrocaudal extent of tissue containing the SCN and optic chiasm. Following processing of tissue by conventional procedures for ultrastructural analysis, thick and ultrathin sections were cut from the anterior surface of each Vibratome section. This provides a means for quick and reliable sampling of representative areas of the nucleus at standardized levels to allow comparison among animals. Extensive interrelations of the SCN and optic chiasm throughout the rostrocaudal extent of the nucleus are characterized by projections of SCN neuropil well into the dorsal one-half of the chiasm. Longitudinally cut dendrites are evident coursing from the nucleus proper into the densely packed, myelinated axons of the chiasm. These dendrites often extend into large pockets of neuropil deep within the confines of the chiasm. Numerous axon terminals establish synaptic contacts with intrachiasmatic dendrites. Some of these terminals exhibit lucent mitochondria and other fine structural criteria which have been associated with optic boutons in previous TEM studies while others contain large neurosecretory-like dense-core vesicles. Dendrodendritic synapses are also present between SCN dendrites coursing into the chiasm. The extent of the SCN-chiasm interrelationship varies throughout the rostrocaudal extent of the nucleus. At rostral levels, interdigitation is confined primarily to the ventrolateral aspect of the SCN. As one progresses caudally, intermeshing of the SCN neuropil and chiasm becomes more extensive in this ventrolateral region and further interdigitation is evident throughout the mediolateral extent of the SCN-chiasm interface. The present study has demonstrated a consistent and extensive interrelationship between the SCN and optic chiasm. Further studies are in progress to determine if this relationship is indicative of a more widespread retinal input to the nucleus. Supported by USPNS Grants NS-06247 and NS-16304.

254.6 THE SUPRACHIASMATIC HYPOTHALAMIC NUCLEUS: NEURONAL ULTRASTRUCTURE. R.Y. Moore, J.P. Card and J.N. Riley. Department of Neurology, SUNY at Stony Brook, NY, 11794.

The present study was undertaken to analyze the fine structural characteristics of suprachiasmatic nucleus (SCN) neurons. Adult female Sprague-Dawley rats were perfused with buffered aldehyde solutions. In order to provide a means of sampling representative levels throughout the rostrocaudal axis of the nucleus, 100 μm Vibratome sections of fixed tissue were cut through the extent of the optic chiasm prior to processing of tissue. Thick and ultrathin sections were cut from the anterior surface of each specimen thereby providing a means of determining the exact location within the nucleus and standardizing the comparison among rats. At least two morphologically distinct cell types are found at all levels of the SCN. The first of these is characterized by an elongated perikaryon in which the dominant feature is the cell nucleus. The nucleus of these cells filled the majority of the cell body and sometimes exhibited one or two fingerlike invaginations. A dense homogeneous cytoplasmic matrix exhibiting a paucity of organelles forms a thin rim of cytoplasm on either side of the nucleus in the short axis of the cell. Mitochondria, Golgi cisternae, polyribosomes and sparcely distributed individual cisternae of rough endoplasmic reticula (RER) accumulate in the cytoplasm at each pole of the cell. Few axosomatic contacts were noted on the soma which is either ensheathed by fibrous astrocytic processes or directly opposed to the membrane of an adjacent neuron. These neurons are densely packed along the dorsal and medial aspect of the SCN and are separated from the optic chiasm by the second cell type. This, too, is characterized by a nucleus which fills the majority of the cell body. However these cells differ in that the perikaryon is more spherical and the cell nucleus highly invaginated. Additionally, the cytoplasmic matrix is lighter than that of the first cell type and filled with a richer collection of cellular organelles. RER were more numerous, although still scattered throughout the cytoplasm as individual cisternae. This cell type is concentrated in the lateral and ventral SCN and is often observed in aggregations with direct membrane apposition or adjacent to the endothelium of capillaries. Few axosomatic contacts are observed. In conclusion, the present study has demonstrated two distinct populations of neurons in the SCN of the adult rat. Whether either of these cell types can be correlated with the immunocytochemically distinct cell populations (vasopressin and vasoactive intestinal peptide containing neurons) which have been demonstrated in the SCN is presently under investigation. Supported by USPNS Grants NS-06247 and NS-16304.

255.1 DECREASED TSH RESPONSE TO TRH IN MANIA COMPARED TO SCHIZOPHRENIA. I. Extein, A.L.C. Pottash, M.S. Gold. Fair Oaks Hospital, Summit, NJ 07901, and Yale Univ. School of Medicine, New Haven, CT.

We report here a follow-up to our initial observation of a significant decrease in the release of thyroid-stimulating hormone (TSH) from the pituitary after administration of thyrotropin-releasing hormone (TRH) in mania compared to schizophrenia (Extein, I., et al, Am J Psychiat, in press). The ability to differentiate mania from schizophrenia has important treatment implications for the choice of lithium versus neuroleptics. Because manic patients can be psychotic, differentiating mania from schizophrenic psychosis by clinical criteria alone can be difficult. Our results from a large series of hospitalized patients suggest that the TRH test may be a laboratory diagnostic test useful in differentiating these two disorders.

The TRH test was performed in 76 consecutive newly admitted inpatients who met Research Diagnostic Criteria for mania (n=25), schizoaffective disorder, manic type (n=18), or schizophrenia (n=33; 27 undifferentiated, 6 paranoid; all actively psychotic). Patients with thyroid disease, drug or alcohol abuse, OBS, or recent lithium use were excluded. Patients at bedrest after an overnight fast were administered 500 ug of synthetic TRH via an indwelling venous catheter. Blood samples were taken before and 15, 30, 60, and 90 minutes after TRH infusion for measurement of serum TSH in duplicate by radioimmunoassay. Maximum TSH response (Δ TSH) was calculated for each patient by subtracting the baseline TSH from the peak TSH after TRH infusion. Mean Δ TSH ± SEM of 6.47 ± 0.64 in mania was significantly lower than that of 9.57 ± 0.84 in schizophrenia ($p < .01$ by 2-tailed t-test), and this was not explainable by differences in age, sex, baseline thyroid function or neuroleptic use. The mean Δ TSH of 8.50 ± 1.25 in the schizoaffective group did not differ significantly from either other group. 15 of the manics (60%),9 of the schizoaffectives (50%), and 10 of the schizophrenics (30%) had a Δ TSH ≤ 7.0 *(mania different from schizophrenia, $p < .05$ by Chi-Square)*

Release of the tripeptide TRH from the hypothalamus is inhibited by serotonin and stimulated by norepinephrine and dopamine. Thus the blunted TSH response to TRH in mania may reflect changes in monoaminergic transmission, or reflect changes in endogenous TRH that have been hypothesized to play a role in mood disorders (Prange, A.J.,et al, Lancet 2:999, 1972). The findings reported here suggest that in cases in which it is difficult to distinguish mania from schizophrenia clinically, the TRH test may aid in diagnosis and choice of treatment. Further research is needed to determine if the results of the TRH test predict outcome or response to lithium versus neuroleptics in manic,schizoaffective, and schizophrenic patients

255.2 OPIATE - ENDORPHIN TEST DYSFUNCTION IN MAJOR DEPRESSION. M.S. GOLD, A.L.C. Pottash, D.A. Martin* and I. Extein. Fair Oaks Hospital and Psychiatric Diagnostic Laboratories of America, Summit, NJ 07901, and Yale Univ. Sch. of Medicine, New Haven, CT 06510

There are anecdotal reports from the pre-psychopharmacology era of the efficacy of opiates in periodic and idiopathic depression. The discovery of stereospecific opiate receptors and endogenous morphinomimetic opioid peptides in the brain have again suggested the possible involvement of opioid systems in major affective disorders. The limbic and hypothalamic distribution of opiate receptors and endorphins and the suggestions of a neuromodulatory role of endorphins for noradrenergic and dopaminergic systems suggest that opioid peptides are widely distributed in areas and systems which are involved in the pathophysiology and pharmacotherapy of depression.

As a preliminary in vivo test of the hypothesis that major depression may be accompanied or etiologically-related to a functional decrease in limbic opioid peptide activity, we utilized the opiate-induced serum prolactin (PRL) elevation. We administered 5 mg of morphine sulfate intravenously through an indwelling venous catheter to fifteen patients with a major depressive disorder by RDC criteria and ten normal, age - and sex-matched controls. All subjects gave written informed consent and were medication-free for at least one week prior to the provocative test. All were at bed rest after an overnight fast for the placement of an indwelling catheter (800h) and intravenous administration of morphine (900h) over 60 seconds. Blood was taken through the catheter at 0,30,60,90,120, and 180 minutes for the measurement of serum PRL in duplicate by RIA (1). The maximum PRL response ΔPRL was calculated by subtracting the baseline from peak PRL.

There were no significant differences between groups for age, sex, or baseline PRL. The mean PRL response was significantly decreased at all time points for the depressed group. Mean ΔPRL levels were significantly different ($p < 0.01$) between groups.

Endogenous and exogenous opiates have been demonstrated to be potent stimulators of PRL secretion in man, nonhuman primates,and rodents possible by activation of opiate receptors on dopaminergic neurons (1). The blunted PRL response reported here may be consistent with an opiate receptor abnormality, presence of an endogenous opiate antagonist, or may be another manifestation of deranged hypothalamic-pituitary function in patients with major affective illnesses. As endorphins and ACTH-corticosteroids have a common precursor these endorphin test response data may relate to the vast body of ACTH-cortisol abnormality data reported for patients with major depression. These data offer some support for a hypothesized role for endorphins in pathological mood states and the reported antidepressant efficacy of B-endorphins.

MS Gold, et al. Endocrinology 105:284, 1979.

255.3 HYPOPHYSECTOMY INDUCED HYPERSENSITIVITY TO APOMORPHINE: SUPPRESSION BY ESTROGEN. K.O. Perry*, B.I. Diamond, J.H. Gordon, Dept. of Pharmacology. The Chicago Medical School, Chicago, IL 60612.

Recent reports have suggested that the ability of estrogen to suppress dopamine agonist potency was dependent upon an intact or functioning pituitary. The present series of experiments was designed to test this hypothesis utilizing both apomorphine-induced stereotypy and ^{3}H-Spiroperidol (^{3}H-SPIRO) binding to striatal membranes. Hypophysectomized (HYPOX) or sham HYPOX (SHAM) and ovariectomized rats were purchased from Hormone assay labs, Chicago. The HYPOX and the SHAM animals received either estradiol benzoate (EB; 10 µg/kg/day x 3) or Sesame oil (0.25 ml/kg/day x 3). All animals were challenged with apomorphine on the 4th day of the experiment, 20-24 hours after the last dose of EB or Oil, and the intensity of the stereotypy scored during the 10-20 min following the apomorphine injection. The ED_{50} for apomorphine-induced stereotypy was calculated following probit-log dose transformation. The HYPOX + oil were more sensitive to apomorphine than the SHAM + oil (ED_{50} = 0.24 and 0.45 mg/kg respectively). Treatment weth EB resulted in a significant shift to the right of the dose response curves for both the HYPOX and the SHAM groups. The ED_{50} of the HYPOX + EB = 0.62 mg/kg and SHAM + EB = 0.93 mg/kg. The intensity of the apomorphine-induced stereotypy in the various groups was indistinguishable at doses of 1.6 mg/kg or greater. The separation of the dose response curves was readily apparent as doses below 1.2 mg/kg.

All animals received an injection of EB or oil on day 4 of the experiment following the behavioral test. Animals were sacrificed 24 hours later and the striatum utilized for ^{3}H-SPIRO binding. No significant change in the K_D was noted in any of the experimental groups. The B_{max} values were indistinguishable for the SHAM + oil, SHAM + EB and HYPOX + EB groups, however, the B_{max} of the HYPOX + Oil group was significantly increased (54%) relative to all other groups, at 7 days post-HYPOX. By 28 days post-HYPOX the B_{max} of the HYPOX animals was increased by 94% relative to the SHAM animals. The HYPOX induced sensitivity could be enhanced by chronic haloperidol treatment and withdrawal (193% increase in B_{max}). The haloperidol induced increase in apomorphine stereotypy and ^{3}H-SPIRO binding could be antagonized by EB treatment during the withdrawal from the chronic haloperidol treatment. The data indicate that the pituitary can modulate the sensitivity of the animal to dopamine agonists, but that the presence of the pituitary is not required for estrogen to suppress the efficacy of dopamine or dopamine agonists, thus indicating the probability of a direct CNS effect of estrogen on dopaminergic mechanisms. (This work was supported in part by USPHS Grant RR-5366 and BNS-782-0025.)

255.4 MODULATION OF DOPAMINE AGONIST POTENCY BY ESTROGEN: DOSE AND TIME DEPENDENT EFFECTS. J.H. Gordon, K.O. Perry* and B.I. Diamond. Dept of Pharmacology, The Chicago Med. School, Chicago, IL 60612

Previous reports have presented data which indicates that estrogen can either suppress or enhance the potency of dopamine and/or dopamine agonists.

Female Sprague-Dawley rats were ovariectomized (OVX) or sham operated under ether anesthesia and were allowed two weeks to recover prior to behavioral testing. All rats received either oil (sesame oil) or estradiol benzoate (EB) for three days between 8 and 10 a.m. Three doses of EB were administered to separate groups of rats (10, 50 and 100 µg/kg/day). Animals were tested for apomorphine-induced stereotypy at 24, 48 and 96 hours after the last dose of EB or oil.

At 24 hours after the last dose of EB the results of the apomorphine-induced stereotypy test were indicative of a dose related suppression of apomorphine potency by estrogen. The stereotypy scores of the 10 µg/kg/day dose of EB were suppressed at 24 hours, but were indistinguishable from controls (OVX+oil or sham+oil) during the 48 and 96 hour tests. At 48 hours after the last dose of EB the apomorphine-induced stereotypy, following a 1.0 mg/kg dose of apomorphine, was increased over control values in the OVX animals that had received 100 µg/kg/day of EB. During the 96 hour test both the 50 and 100 µg/kg/day treated animals displayed an enhanced response to the behavioral effects of apomorphine.

These data indicate that estrogen can suppress dopamine and/or dopamine agonist potency 24 hours after the last dose of EB, thus indicating the possibility that the role of endogenous estrogen is to suppress dopaminergic transmission. However, the data are also indicative of an enhanced sensitivity to apomorphine when the drug sensitivity is determined at 48 hours or more after the last dose of EB. The time delay and the dose dependence of the enhanced response to apomorphine following EB is indicative of a "withdrawal" phenomenon. Thus if one uses pharmacologic doses of estrogen (i.e., greater than those needed to maintain uterine weight or treatment for a prolonged period of time), then the withdrawal or discontinuation of these types of treatments will result in a rebound supersensitivity similar to that seen with chronic neuroleptic treatment and withdrawal.

In conclusion, both suppression and enhancement of dopamine and/or dopamine agonist potency can be seen following estrogen treatment, however the data support the conclusion that endogenous estrogen acts to suppress dopaminergic function.

255.5 EFFECTS OF ESTROGEN ON THE DEVELOPMENT AND EXPRESSION OF DOPAMINE RECEPTOR SUPERSENSITIVITY. J.Z.Fields, M.F. Callahan*and John H. Gordon. Dept. Pharmacol.,Chicago Med. Sch.,Chicago IL 60612

Dopamine receptor(DAr) supersensitivity has been implicated in tardive dyskinesia, L-DOPA induced dyskinesias and schizophrenia by both direct and indirect evidence and in both humans and animal models. Agents that reverse or prevent the development of DAr supersensitivity may prove useful in either treating these disorders, or in yielding clues as to their underlying pathophysiological mechanisms. One such agent, we have observed, is estradiol benzoate(EB).

When rats were treated with EB(8 to 10 µg/kg/day) during the period of withdrawal from chronic haloperidol(HAL: 0.5 mg/kg X 3 weeks), the appearance of the characteristic DAr supersensitivity was inhibited. This inhibition affects both the increase in apomorphine(APO: 0.25 mg/kg) elicited stereotype behavior and the increase in specific, striatal (3H)spiroperidol binding to DAr.

For HAL treated animals, the cumulative scores, based on a hierarchy of stereotype activities (locomotion, rearing, head bobbing, sniffing, gnawing) increased over 200% relative to saline treated controls; the same APO dose response curves indicated that about one half as much APO was needed to elicit any particular level of stereotypy. The stereotypy score decreased almost to control levels when EB was given during withdrawal. Similarly, the number of striatal (3H)spiroperidol binding sites increased about 30%(high affinity site) after HAL, and decreased to control values when EB was used. No changes in affinity were observed.

The molecular mechanisms of this down-regulation of DAr are not clear since co-administration of EB with HAL(only saline given during withdrawal) did not inhibit the development of DAr supersensitivity. Subsequent experiments suggested that the hypothalamic/pituitary axis is not involved. The possibilities that chronic HAL can produce supersensitive limbic DAr and that EB can down-regulate limbic DAr are currently being studied.(Supported by grants from N.I.H.(RR-5366) and NSF(BNS-782-0025)).

255.6 FLUROTHYL-INDUCED CONVULSIVE SHOCK DELAYS ONSET OF SEXUAL MATURATION IN THE FEMALE RAT. M. Wilkinson and J. A. Pincock*. Dept. of Physiology and Biophysics and Dept. of Chemistry, Dalhousie University, Halifax, Nova Scotia, B3H 4H7, Canada.

Electroconvulsive shock therapy (ECT) is an empirical but effective treatment for refractory depressive symptoms. At present there is no satisfactory explanation for its effects. Recent studies emphasize the importance of central monoamines, and in this regard ECT has something in common with other anti-depressants such as MAO inhibitors. Chronic anti-depressant drugs or convulsive shocks (CS) decrease noradrenaline-stimulated adenylate cyclase as well as the density of β-adrenergic receptors in rat brain. These changes in synaptic activity are possibly widespread within the nervous system and it would be surprising if adverse effects of CS were not observed on the hypothalamic control of endocrine status in laboratory animals and in man. We report here our initial studies on one such neuroendocrine control system, sexual maturation in female rats. The functional integrity of monoaminergic synapses is crucial to this developmental process.

Expt. 1: CS was given once per day to immature Sprague-Dawley female rats (age 25 days; weight 60 gm) by exposing them to the convulsant Flurothyl (F). F was used in preference to ECT since this ether gives results identical to ECT but does not reduce body weight. After 10 days, 60% of control rats exhibited vaginal opening (VO) ("puberty") whereas only 20% of CS rats had VO.

Expt. 2: Using animals of the same age but with lower body weights (45 gm), CS was given on consecutive days until all the control rats showed VO. Rats were inspected daily for VO. When VO was observed, ovaries, uterus, adrenals and pituitary were dissected and weighed. After 18 days all control rats had VO (mean age VO 39.0 ± 1.0 days) whereas none of the CS rats had ovulated. There were no differences in body weight between treated and control rats. CS rats were killed at day 42; organ weights, mg per 100 gm body weight, were: ovaries 17.3 ± 0.8 (control, C: 30.4 ± 1.7; $p < .001$); uterus 79.4 ± 13.5 (C: 124.4 ± 10.7; $p < .02$); pituitary 3.8 ± 0.2 (C: 4.1 ± 0.4; N.S.); adrenals 25.5 ± 0.6 (C: 26.1 ± 1.0 N.S.). We conclude that maturation of the female reproductive system is sensitive to CS treatment and therefore in clinical terms, could well be susceptible to disruption by other, routine, anti-depressant treatments.

258.1 EVIDENCE OF TWO CONTROL SCHEMES FOR MOTOR UNITS.
C.J. De Luca, A.P. Xenakis*, R.S. LeFever* Dept. of Orth. Surg., Children's Hosp. Med. Ctr., Harvard Med. Sch., Boston, MA. 02115.

The discharge pattern of concurrently active motor units has been investigated in the first dorsal interosseous and deltoid muscles of 13 normal adult subjects. Both constant-force and force-varying (positive ramp followed by a negative ramp) contractions were studied. The subjects were asked to visually track a constant line and a triangle with the force generated by their muscle. The firing patterns were obtained by a technique reported at the 8th Annual Meeting of the Society for Neuroscience (R.S. LeFever and C.J. De Luca).

When the constant-force contractions were executed, the force output of both muscles was not constant. They contained random fluctuations (greater than 1 Hz) about the desired value. The concurrent firing rates of the motor units contained similar fluctuations. Correlation values of 0.65 were obtained between the force output and the firing rate of one motor unit. Furthermore, the fluctuations of the firing rates of all the concurrently detected motor units (ranging from 3 to 8) were highly correlated; at times with a correlation value of 0.85. When the triangular force patterns were executed, it was observed that the firing rates of the motor units would begin to decrease before the force output would reverse (at the peak of the triangle). It was also noted that the earlier recruited, faster firing, motor units began decreasing their firing rates before the later recruited, slower firing, motor units. It is well known that the earlier recruited motor units tend to have relatively long time duration twitches with progressively recruited motor units at higher force having shorter time duration twitches. Therefore, it appears that the observed scheme is necessary to provide precision in the force output of a muscle. These observations were consistent in both muscles of all the 13 subjects.

We postulate that there exists at least two control schemes for motor units. Compensatory force variations consisting of relatively rapid (greater than 1 Hz) low amplitude fluctuations are accomplished by a simultaneous change in the firing rates of most (if not all) the motor units. Slower, higher amplitude intended force variations, that determine the accuracy with which a muscle may generate a desired force value, are regulated by an elegant control scheme which acts individually upon each active motor unit (or pools of motor units). This latter scheme implies the existence of a direct relationship between the CNS and each motor unit (or pools of motor units) in a muscle. (Supported in part by NIAMDD Grant #AM 19665, and The Insurance Institute for Highway Safety).

258.2 CONTROL OF FOREARM POSITION: INFORMATION TRANSMITTED BY THE ACTIVITIES OF THE MUSCLES ACTING ON THE ELBOW JOINT.
B. Sakitt, F. Lestienne* and T. Zeffiro, Department of Psychology, Massachusetts Institute of Technology, Cambridge, MA 02139.

We applied the concepts of Information Theory to visually triggered extension and flexion movements of the forearm. Human subjects were required to rotate the forearm about the elbow joint so as to point to a visual stimulus, without sight of the limb. The trajectory, final position, and electromyographic (EMG) activities of the triceps and biceps were recorded. The number of visual targets in each session was fixed at either 2, 3, 5, 9, 16 or 17. On each trial only one target was lit and presentation was random with replacement. An Information Theory (Shannon, 1948) analysis of the data yielded the result that the arm could only transmit slightly more than 3 bits of Information. This is equivalent to the forearm having only 9 independent positions, even though the range tested covered about 75% of the physiological limits. These results lend support to the hypothesis that one of the processes underlying voluntary movements involves a shift in the equilibrium between the agonist and antagonist muscles (Fel'dman, 1966; Bizzi et al, 1976). Such a motor program would be feasible with either a lookup table or a computation since the numbers involved are surprisingly small.

The Information transmitted by the ratio of the EMGs of the triceps and biceps was almost the same as that transmitted by forearm position. In contrast, the Information transmitted by either the triceps or biceps individually was consistently less than that transmitted by the ratio. Since the variance of independent quantities is additive, this suggests that the ratio of the alpha innervations to the agonist and antagonist muscles is programmed more directly than either innervation separately.

The ratio of the EMGs has previously been shown to play a specific role with regard to final position. Lestienne, Polit, and Bizzi (1978) found that for movements which varied with speed and direction, the final position correlated with the ratio of the EMGs. Sakitt (1980) using an equilibrium spring model of the arm predicted that the ratio of the alpha innervations usually determines joint angle. The present results show that the quantitative relationship between joint angle and the ratio of the EMGs is in good agreement with the theoretical prediction for the range of joint angles tested. Taking these together, this provides evidence that the equilibrium final position is programmed by setting the ratio of the alpha innervations to the agonist and antagonist muscles.

258.3 INTENDED REACTIONS TO EXTERNAL DISPLACEMENT STIMULI IN THE LABIAL MUSCULATURE OF MAN, J.H. Abbs* and K.C. Cole* (SPON: T. Imig) Speech Motor Control Labs., Univ. of Wisconsin, Madison, Wisc. 53706

Several recent studies have revealed short-latency (50-70 msec.) "intended" responses to displacements applied to the limbs. These responses have been interpreted as pre-programmed motor subroutines released by appropriate sensation of movement and developed through learning. The mechanisms underlying this response capability have been suggested variously to involve spindle, cutaneous, and/or joint afferents apparently mediated through cerebellar-cortical pathways. The major controversy in these studies has been in separating the observed responses from long loop "reflexes," inasmuch as the displacement stimuli often have involved loading or unloading a contracting muscle in a manner that disturbs the intended limb position.

In the present study, the intended reaction paradigm was modified in an attempt to (1) reveal the potential independence of these response mechanisms from segmental, brain stem, or long loop reflexes, and (2) determine if motor systems lacking spindles and joint receptors (Viz. the lips) are endowed with comparable response capabilities. Unanticipated displacements were applied to the corner of the mouth with the lips pre-postured for generation of the vowel "ah." Upon sensation of the stimulus, subjects were instructed to respond "as soon as possible" with a rapid, forceful lip closure, as in the generation of a "b" consonant. This configuration provided a situation where the displacement stimulus (25 msec. duration) did not constitute a disturbance to the ongoing sustained gesture nor to the requested response. Further, this stimulus did not elicit a perioral reflex, hence greatly simplifying data interpretation re: potential reflex contamination. EMG was observed in m. orbicularis oris, a muscle that is quiescent during "ah" and phasically active in generating bilabial closure. Between 400 and 700 responses were obtained for each of four young adult male subjects. Interstimulus intervals were determined randomly under on-line computer control from a table of 11 values.

Minimal response latencies, measured from stimulus onset to muscle contraction onset in individual response records, ranged from 45-55 msec. for all subjects. As reported in limb studies of intended reactions, the labial responses showed latency and waveform variability of reaction time-like responses while at the same time displaying certain characteristics that indicated "automatic" or unconscious mediation.

258.4 RECRUITMENT ORDER AND FIRING PATTERNS OF IDENTIFIED CAT HINDLIMB MOTOR UNITS DURING UNRESTRAINED TREADMILL WALKING.
J. A. Hoffer, M. J. O'Donovan*, C. A. Pratt and G. E. Loeb. Laboratory of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Physiological and histochemical studies of muscles, done mostly on cat hindlimb extensors, have demonstrated distinct motor unit types. We are investigating whether the pattern of activation and usage of such units during normal activity are consistent with distinctly different functional roles for the unit types. Using chronically implanted electrodes (Hoffer et al., Neurosci. Abstr. 5:1248, 1979) we recorded firing patterns from intact L5 ventral root fibers in normal cats walking on a treadmill. Muscles of destination were identified from spike-triggered, averaged records of EMG. Axonal conduction velocity was determined from averaged unitary records on two adjacent sets of femoral nerve cuff electrodes. Mechanical parameters, and hence unit type, could sometimes be determined from averaged records of tension obtained from an implanted strain gauge on the patellar ligament, elicited by microstimulating the axon in isolation through the recording microelectrode.

Records obtained from 80 motoneurons, of which 22 projected to quadriceps or sartorius, can be summarized as follows:

1) Individual motor units were reliably recruited when the rectified, smoothed parent muscle EMG crossed a reproducible level for each step.

2) Once recruited, most units exhibited appreciable modulation of their firing rates. The frequencygram for a given unit closely resembled the envelope of the parent muscle EMG. Mean firing rates for individual units were higher at faster walking speeds. Peak rates typically reached 25-60 pps. This is in contrast to earlier observations in decerebrate cats (Severin et al., Biofizika 12:660, 1967; Zajac & Young, Neural Control of Locomotion, 1976, p.789; Jordan et al., Neurosci. Abstr. 5:2445, 1979) where unit firing rates were reported to plateau at fairly low values.

3) Initial doublets (interspike interval < 25 ms), reported to occur commonly in decerebrates, were rare in normal cats. Occasional doublets occurred during fast walking and trotting.

4) EMG bursts during both stance and swing in sartorius demonstrated the complex mechanical action of this muscle. In contrast, individual sartorius motor units fired either during stance or during swing, indicating that sartorius is comprised of 2 or more functionally different populations of motor units.

5) Identified units active during walking were all type S (slow twitch) or type FR (fast twitch, fatigue resistant).

258.5 PROGRAMMED RESPONSES OF ELBOW EXTENSORS AFTER JUMPING. P.A. Reback*and J.L. Smith. (SPON: R.D. Lindsay). Neuromotor Control Lab., UCLA, Los Angeles, CA 90024

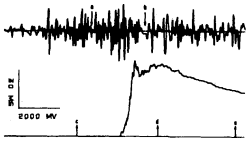
During landing from a fall, hindlimb extensor EMG is not predetermined centrally on the basis of a prediction of height of fall (Prochaska, et al, J. Physiol. 272:705, 1977). During voluntary jump downs, motor programming is necessary and smooth landing may depend more on an interaction between peripheral reflexes and central programming.

Five adult cats were trained to jump down onto a force plate from a platform placed at heights of 1.0, 0.8 and 0.6 m. Ground reactive forces and EMG of the lateral triceps (LT) were coordinated with 16mm high speed film (100 fr/s).

The figure below illustrates the typical three burst pattern and ground reaction forces of landing. Contrary to the hindlimb fall data, the onset latency of the initial burst is related to jump height. After the forepaw leaves the platform the onset latency, on average, is 206 ms at 1.0 m, 185 ms at 0.8 m and 135 ms at 0.6 m. Peak extension velocity (arrow c) occurs soon after. The duration of the initial burst, 40-50 ms, is unrelated to jump height, and it is followed by a short (14-20 ms) reduction or pause (arrow a). The second burst precedes landing by 30-40 ms, and the peak amplitude of the rectified-averaged EMG is correlated with the height of the jump. The second burst is also followed by a period of reduction (arrow b) that coincides with an unloading of the reactive force. This pause occurs 15-20 ms after landing prior to which the torque at the elbow is maximal. This period of inhibition, similar to that described by Laursen et al (Acta Physiol. Scand. 102:462, 1978), may be due to homonymous tendon organ (Ib) inhibition. Up to maximal elbow flexion (arrow e), the EMG during the remainder of the landing is less than the prelanding or contact EMG, and there is little evidence for a landing stretch reflex of the magnitude of that observed by Prochaska, even during peak flexion velocity (arrow d).

During landing the angular displacement and peak flexion velocity at the elbow joint was nearly constant for a given animal across the three jump heights. This data suggest that muscle stiffness was preset and depended on jump height.

Supported by NIH grant 104230-06.



258.6 BIDIRECTIONAL NEURONAL DISCHARGE IN CEREBELLAR NUCLEI AND MOTOR CORTEX DURING SLOW HOLD-RAMP-HOLD TRACKING. Marc H. Schieber & W. Thomas Thach. Dept. Anat. & Neurobiol., Wash. U. Sch. Med., St. Louis, MO 63110.

Trained monkeys made flexion and extension wrist movements guided by a visual pursuit display to track a slow, predictable, hold-ramp-hold target trajectory. Parameters of the trajectory were varied between blocks of trials as extracellular neuronal activity was recorded. EMG activity of the muscles producing these movements was related to load, wrist position, and, although minimally correlated with movement velocity, was clearly related to movement direction. During the movements, agonist and antagonist muscles did not cocontract (Soc. Neurosci. Abstr. 5:585, '79).

In motor cortex, during flexion and extension slow tracking movements, some wrist-related units discharged in a directionally reciprocal manner. In contrast, other wrist-related units were bidirectional: their discharge frequency increased sharply during slow tracking movements in both directions, flexion and extension. The firing frequency of directionally reciprocal units studied thus far was related to load and/or to wrist position, but not to movement velocity. The firing frequency of bidirectional units, however, was related to load, was unrelated to position, but usually increased with increasing velocity in both directions.

In the cerebellar dentate and interposed nuclei, almost all units related to slow tracking movements were bidirectional. In one monkey, several features confirmed that bidirectional neurons were related to movement at the wrist: i) directionally reciprocal activity related to self-paced, alternating movements; and, in interpositus only, ii) reciprocal responses to oppositely directed torque pulses and iii) activity coupled to a fortuitously present tremor. The discharge of these bidirectional neurons was not systematically related to load or position, but did increase with the magnitude of velocity in both directions.

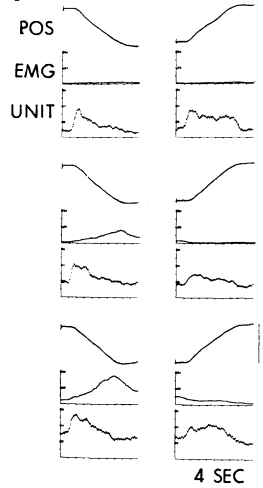
Spindle afferents from forearm muscles were also active bidirectionally, and from their activity we inferred that α-γ linkage was flexible (see companion abstract). These results suggest that, during slow precisely controlled movements, there is functional dissociation of two parallel motor subsystems. One subsystem consists of some motor cortex neurons and of α motoneurons whose discharge remains reciprocal to produce oppositely directed movements. The other subsystem consists of cerebellar nuclear neurons and of other motor cortex neurons, whose discharge under these conditions becomes bidirectional.This subsystem may receive spindle information, control γ motoneurons, or both. It may maintain the constancy of spindle feedback in the face of different conditions (Kuffler, Hunt, & Quilliam, J. Neurophysiol. 14:52,'51): this constancy may be needed for control of slow, precise movement.

Supported by NIH GM 07200 and by 5 R01 NS 12777.

258.7 BIDIRECTIONAL SPINDLE AFFERENT DISCHARGE DURING SLOW TRACKING MOVEMENTS: EVIDENCE FOR ALPHA-GAMMA DISSOCIATION. W. Thomas Thach & Marc H. Schieber. Dept. Anat. & Neurobiol. Wash. U. Sch. Med., St. Louis, MO 63110.

A trained monkey made flexion and extension wrist movements guided by a visual pursuit display to track a slow, predictable, hold-ramp-hold target trajectory. Parameters of the trajectory were varied between blocks of trials as extracellular neuronal activity was recorded from the C7 and C8 dorsal root ganglia.

Spindle afferents thus far studied (N=5) from forearm muscles discharged bidirectionally. The figure shows activity of a spindle afferent from the wrist extensors: the left column shows extensions (parent muscle shortening); and the right, flexions (parent muscle lengthening). In the top row, flexors are loaded (parent muscle relaxed); in the middle row, no load; and in the bottom row, extensors are loaded (parent muscle active). Can spindle stretch and α-γ coactivation explain the results shown? Spindle stretch might explain afferent discharge during all flexions (right column); but even greater discharge might have been expected during flexion under extensor load (bottom right) if the linkage of γ and α motoneuron activity were rigid. Coactivation might explain spindle discharge when extensors were active both under load (bottom row) and during unloaded extension (middle left), yet it does not explain the different time/amplitude profiles of spindle discharge and EMG. But neither stretch nor coactivation can explain the spindle discharge when the parent muscle was relaxed and passively shortening (extension under flexor load, top left). For these reasons we infer, in addition to stretch and coactivation, a third factor: that α-γ linkage is adjustable to the point that γ MN's may drive spindle afferent discharge without coactivation of homonymous α MN's.



Gamma activation of spindles in a quiescent muscle could retrieve information that would otherwise be lost. Furthermore, the observed bidirectional activity of spindle afferents could account for bidirectional units found in motor cortex and cerebellar nuclei (see companion abstract). These higher level neurons may receive spindle feedback, control gamma motoneurons, or both.

Supported by 5 R01 NS 12777 and NIH GM 07200.

258.8 EFFECTS OF A SENSORY CONFLICT ON HEALTHY HUMAN STAIR DESCENT. R. L. Craik and W. Freedman. Rehabilitation Engineering Center #2, Moss Rehabilitation Hospital, Philadelphia, PA 19141.

The occurrence of lower limb muscle activity (emg) prior to step contact marked the beginning of investigations into the motor programs used during stair descent (Melvill Jones and Watt, 1971). Subsequent studies have focused on the role that various sensory systems play in the initiation or modification of this anticipatory muscle activity. Healthy human subjects participated in this experiment designed to characterize the manner in which altered visual input modifies the voluntary motor behavior seen during stair walking.

Fourteen subjects walked down three steps whose height was randomly varied to be 20.3, 30.5, or 40.6 cm. The steps were surrounded by a room 2.77 m high and 0.7 m wide which was connected through a servo system to the vertical position of the subject. Subjects were asked to walk down the three steps while a surface electrode placed over the gastrocnemius-soleus complex recorded muscle activity, a potentiometer measured sagittal plane ankle motion, switches registered bilateral foot-ground contact and release, an accelerometer recorded vertical acceleration and a transducer in the second step measured the force with which it was hit. Anticipatory muscle activity and the ease of landing were examined only on the first two steps. The emg signal was integrated within 10 ms bins over the entire first swing interval (toe off to toe strike) and ease of landing was described by the angular velocity which occurred at the ankle and the rate at which load was applied with contact on the second step. Control performance was compared to that recorded under the following conditions: blindfolded with audition masked and unaware of stair height; aware of stair height and wearing a collar which masked stair height during descent; aware of stair height and wearing a collar while the room moved up, down, or not at all.

Anticipatory muscle activity was diminished and landing was harder for each of the experimental conditions but performance was significantly different between test conditions. These results imply that there is adequate time for a sensory perturbation which occurs during the swing phase to alter the subsequent landing. These data suggest that the visual information predominates when there is a conflict between visual and other somatosensory information as evidenced by the manner in which the subjects contacted the second step. To date, the visual, vestibular and tactile sensory systems have each been demonstrated to modify the anticipatory muscle seen during human stair descent. Additional research is necessary to examine the interaction among these systems.

259.1 AFFERENT CONNECTIONS OF THE PARVOCELLULAR RETICULAR FORMATION IN THE RAT. W. R. Mehler and J. A. Rubertone* NASA-Ames Research Center, Moffett Field, CA 94035 and Dept. of Anatomy, Univ. of Calif., San Francisco, CA.

The parvocellular reticular formation (PC) is a bilateral cylindroid of grey matter in the dorsal lateral tegmentum of the brain stem extending from the level of the pons through the medulla oblongata into the upper cervical spinal cord. Nauta method studies of regional lesions in PC revealed extensive bilateral ascending and descending pathways that interconnect trigeminal, facial, glossopharyngeal, vagal and hypoglossal motor nuclei which in various combinations participate in cardiovascular control, food intake and expulsion (emetic) mechanisms and concomitant control of respiration (Holstege and Kuypers, Brain 100:239, 1977).

Extensive bilateral corticobulbar connections were the first PC afferents to be described. In 1963 Mehler found a system of collaterals from degenerating axons of the mesencephalic root of the trigeminus (Mes. V) that descended in the ipsilateral PC and issued terminal branches into PC from MoV levels to the obex. Comparative studies of cerebellofugal fibers (Mehler, '67) revealed a unique, ipsilateral descending branch of the brachium conjunctivum in the rat that also distributed throughout PC. Cajal ('03) had discovered this pathway in the rat but his contemporaries, working on non-rodents, rejected the idea. Silver studies also showed an extensive commissural system between the two PC regions.

Iontophoretic injections of horseradish peroxidase (HRP) in different regions of PC in rats (see Rubertone and Mehler, this volume) labels cells in both MesV and, primarily the dorsolateral "hump" of the interpositus crebellar nucleus ipsilaterally confirming the earlier studies cited. Scattered labeled cells appear in the upper PC region and in the contingent supratrigeminal and parabrachial regions ipsilaterally and in greater numbers in the contralateral PC. The latter cells appear at, or caudal to, the level of the injection. Some HRP+ cells also appear in the ipsilateral spinal trigeminal nucleus. Labeled cells in the central nucleus of the amygdala appear to confirm Hopkins and Holstege's (1978) anterograde evidence of an amygdalo-PC connection. The results of larger injection and longer survival times, relative to the location of the cells of origin of corticobulbar-PC afferents will be discussed.
NASA-Task 199-05-02-07.

259.2 INDEPENDENCE OF ASCENDING SOMATIC SENSORY PATHWAYS IN THE CAT AND MONKEY. K.J. Berkley. Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306.

Double-labeling experiments using autoradiographic and degeneration orthograde tracing methods in the cat indicate that fibers from the dorsal column nuclei (DCN), lateral cervical nucleus (LCN) and spinothalamic tract (ST) form their densest terminations on different groups of neurons in the ventrobasal complex (VB) and surrounding regions of the thalamus. In the monkey, the same relative terminal arrangements exist; that is, although the precise locations of the terminations of the three pathways in the monkey's thalamus differ from those in the cat, the DCN, LCN and ST fibers form their densest terminations on different small groups (or clusters) of neurons that often are adjacent to each other, particularly within VB. Thus, individual clusters of neurons within VB and its surrounding regions in both the cat and monkey appear to receive their input predominantly from one of the three ascending pathways and relatively little input from either or both of the other two pathways.

Retrograde tracer experiments using the transport of horseradish peroxidase and ^{3}H-inactivated horseradish peroxidase in the cat indicate that the neurons within DCN which project to the thalamus form a morphologically homogeneous population. Neurons within LCN that project to the thalamus, however, form a morphologically heterogeneous population. When these two retrograde tracers are used together in a double-labeling paradigm, it also becomes evident that the DCN neurons which project to the thalamus do not appear to send collateral fibers to the tectum, whereas many of the LCN neurons which project to the thalamus do send collaterals to the tectum. These results suggest that the functional properties of the DCN neurons which project to the thalamus may be different from those of the LCN neurons which project to the thalamus.

The results of these orthograde and retrograde tracing experiments are consistent with the conclusion that individual clusters of neurons within VB (and surrounding regions) may receive input from fibers in different pathways with different response properties. When this conclusion is considered together with experiments by other investigators which have demonstrated a precise and discrete topography in the connections between clusters of neurons in VB and the cerebral cortex, it appears that there exists a structural mechanism from the periphery to the cortex for the maintenance within the somatic sensory system of multiple, and possibly functionally independent, lines of projection.

259.3 SEGREGATION OF NEURONS HAVING SPECIFIC SUBMODAL PROPERTIES WITHIN SOMATOTOPICALLY ORGANIZED REGIONS OF THE THALAMIC VPL AND VPI NUCLEI OF THE SQUIRREL MONKEY (Saimir; Sciureus). R.W. Dykes, M. Sur, M.M. Merzenich, J.H. Kaas and R.J. Nelson. Depts. of Surgery, Neurology and Neurosurgery, McGill University, Montreal; Psychology & Anatomy, Vanderbuilt University, Nashville, Tenn.; Physiology & Otolaryngology, Univ. of California, School of Medicine, San Francisco, Calif.

While studying the detailed topology of the body representation in the ventroposterior (VP) thalamus of the squirrel monkey, we observed restricted regions within this nucleus which received a predominant input from specific kinds of receptors.

Adult squirrel monkeys were anesthetized with ketamine hydrochloride, their skulls fixed in a stereotaxic device and a craniotomy performed. Platinum-iridium microelectrodes were advanced through the thalamus along all three cardinal axes of the Horsey-Clark coordinate system. At 50 μm intervals, multiunit responses were characterized in terms of (i) receptive field (RF) location, (ii) modality (skin or deep), and (iii) probable receptor type: slowly adapting (SA), rapidly adapting (RA) and Pacinian. Histological sections stained with cresyl violet were searched to identify the electrode tracks and to relate the functional data to particular thalamic regions.

Modality changes were closely correlated with nuclear boundaries. The deep responses stopped abruptly at the upper border of VP. Upon entering VPL, neuronal responses were elicited by cutaneous stimuli and this remained the adequate stimulus mode until the ventral border was crossed. Within VPL the first responses encountered were frequently cutaneous RA responses which may have been activated by convergence from several cutaneous RA fibers. Below this, cutaneous SA responses were encountered. These regions appeared to receive a predominant input from cutaneous slowly adapting afferents. In the ventral portion of VPL, cutaneous RA responses were often encountered. In this region the responses suggested a predominant input from non-Pacinian cutaneous RA fibers.

As the electrode left the VP region and entered the VPI nucleus the neurons became most responsive to Pacinian-like stimuli and the neurons in the VPI appeared to receive a predominant input from this receptor class.

Further, we observed (i) abrupt shifts of RF locus, (ii) long sequences of RF's serving one body site and (iii) regular, gradually-shifting sequences of RF's within VP. These data suggest that there are discrete, submodality-specific regions within VP which are topographically organized in a manner far more complex than earlier studies have suggested.

259.4 RECEPTIVE FIELD SEQUENCES IN SOMATOSENSORY CORTEX OF THE CAT. D. Sretavan* and R.W. Dykes (SPON: J. Commissiong). Microsurgical Laboratory, Departments of Surgery and Physiology, McGill University, Montreal, Quebec, Canada.

Recently, electrophysiological mapping experiments have demonstrated the presence of several representations of the body within primary somatosensory cortex of cats and monkeys. Despite detailed characterization, a general principle of organization underlying these maps is still to be defined. One description of the internal organization of the maps proposes that within each map, separate body regions such as the digits, wrist and forearm are each served by a distinct island of cortex and that each representation of the body consists of the aggregate of these islands or 'composites'. An essential requirement for this 'composite' organization is that RF loci should shift abruptly at the edge of the composite as the RF locus jumps to the next body part. The identification of the abrupt RF shift at the edge between two composites is therefore crucial to this theory.

An alternative view is that there are few or no boundaries within each map and that each map is a continuum or smooth sequence of gradually shifting RF loci. This latter hypothesis has certain genetic and developmental advantages over one with many boundaries at the edges between cortical maps. We chose to test these two alternatives in nembutal anesthetized mongrel cats with glass microelectrodes. We made vertical and tangential penetrations through one of the several maps in somatosensory cortex and carefully recorded RF size and locus at 50 μm intervals. Thionin-stained 50 μm frozen sections were used to identify each electrode trajectory and relate it tothe cytoarchitecture.

Results from vertical penetrations document the degree of variability in RF locus found within a vertical path through the cortex and set the degree of variability in RF locus which can be found at a single cortical site. Any shift in RF locus which is to be taken as the boundary of a composite must be larger than the variability found in vertical penetrations. During penetrations tangential to the cortical surface, the sequence of RF loci encountered reflects both the variability seen at any one cortical site plus the shift due to the lateral displacement of the electrode towards another cortical site. Results from tangential penetrations show that the progression of RF was smooth and continuous.

In a few experiments however, abrupt shifts in RF locus were found. The histological data and submodality changes showed that these abrupt RF shifts usually occurred at the edges between cortical maps and not within boundaries of a given map. These results suggest that in the cat, the body surface is represented as a continuum within each cortical map.

259.5 QUANTITATIVE ANALYSES OF THALAMOCORTICAL SYNAPSES ON IDENTIFIED NEURONS IN MOUSE SmI CORTEX. E.L.WHITE, M.P.ROCK* AND S.M.HERSCH*. Dept. Anatomy, Boston U. Sch. Med, Boston, MA. 02118.

A broad variety of neuronal types in mouse SmI cortex (specifically in posteromedial barrel subfield cortex) synapse with thalamocortical (TC) axon terminals (White,E.L., J.Comp.Neur. 181:627, 1978). Although preliminary data suggest these cell types differ in the amounts of TC synapses they form, it is uncertain if particular neuronal types consistently receive specific proportions of their synaptic input directly from TC afferents. Here we report current efforts to answer this question by ascertaining the amounts of TC and other synapses in which different neuronal types are involved. Lesion induced degeneration is used to label TC axon terminals because previous work suggests this method reliably demonstrates all TC afferents in layer IV of mouse PMBSF cortex. Elements postsynaptic to TC axons are labeled by the Golgi/gold-toning method or by the retrograde transport of horseradish peroxidase (HRP). In a third approach, some non-spiny neurons have been identified by their appearance in serial thin sections and in 3-dimensional reconstructions. Analyses of synapses onto a gold-toned layer IV spiny stellate cell show its dendrites to receive 9% of their synapses from the thalamus, whereas dendrites of a layer IV non-spiny stellate cell in the same preparation receive 16% of their synapses from the thalamus. Dendrites of a gold-toned layer V non-spiny stellate cell receive 2.9% of their synapses from the thalamus, whereas in the same PMBSF barrel, neighboring dendrites of a layer IV non-spiny bitufted cell receive 17.3% of their synapses from TC afferents. These results indicate that neurons occurring even within the same thalamic terminal projection field may receive markedly different amounts of their synaptic input from the thalamus. Furthermore, counts show all dendrites examined in these studies pass through neuropil where 18% of the synapses are made by TC afferents and so the observed differences would seem not to be due to differences in the concentration of TC synapses in the fields through which the dendrites pass. Analyses of the synapses of neurons labeled by the retrograde transport of HRP injected into the vibrissal region of ipsilateral MsI cortex show dendrites of layer III and IV pyramidal cells consistently receive only few TC synapses. Further investigation should disclose if superficial pyramids projecting elsewhere receive different amounts of TC synapses.

259.6 CURRENT SOURCE DENSITY ANALYSIS OF THE EVOKED POTENTIAL IN THE SOMATOSENSORY CORTEX OF THE CAT. P.B. Hoeltzell* and R.W. Dykes (SPON: G. Kostopoulos). Microsurgical Laboratory, Departments of Surgery and Physiology, McGill University, Montreal,PQ, Canada.

The sequence of potential changes following a brief punctate tactile stimulus was studied in primary somatosensory cortex. Each cat was anesthetized with sodium penobarbital. Tracheal and venous cannulae were inserted, a pneumothorax was performed and the animal was mounted in a stereotaxic device. Expired CO_2 was kept near 3% and body temperature near 37°C. After a craniotomy a low-impedance glass microelectrode was inserted in the forearm region of SI cortex and a biological transducer was positioned over the center of the receptive field which activated that cortical site. Fixed-amplitude, o.1s stimuli were delivered to the arm every 2s. These stimuli produced action potentials at the cortical focus in the depths from 500 to 1200 μm. The evoked potentials were amplified with conventional recording equipment, filtered to exclude DC and action potentials and digitized with a small laboratory computer.

Preliminary experiments were done to demonstrate stationarity of the potential under these experimental conditions and to calculate the maximum lattice spacing which could be used for sampling without spatial aliasing.

In subsequent experiments the cortical focus was identified and then the microelectrode was withdrawn and used to make a series of penetrations in rostrocaudal or mediolateral rows passing through or parallel to this site. In each penetration evoked potentials were recorded every 50 to 100 μm through the cortical depth. The penetrations were spaced either 100 or 200 μm apart. These potentials were then processed to compute current sources and current sinks in that cortical volume.

The results illustrate that the surface evoked potential is a reflection of neural activity in the upper cortical layers and that the surface maximum is not situated immediately over the site where the maximum thalamic afferent volley arrives, but some distance away where it reflects other, related neural events.

The spatial organization of the evoked potential appears to involve several populations of neurons at more than one cortical depth and more than a single cortical site. Interpretation of this data requires a detailed knowledge of the synaptic relationships among neurons in the somatosensory cortex as well as knowledge of the temporal sequence of activity in the afferent terminals ending in different cortical layers.

259.7 SELECTIVE NEURO-DEGENERATIVE CHANGES IN THE RAT SOMATOSENSORY CORTEX FOLLOWING TREATMENT WITH METHYLAMPHETAMINE, P-CHLORO-AMPHETAMINE BUT NOT 6-HYDROXYDOPAMINE. G. Ricaurte*, R.W. Guillery, L.S. Seiden, C.R. Schuster*. Dept. of Pharmacol. and Physiol. Sciences, Univ. of Chicago, Chicago, IL. 60637.

In a previous Fink-Heimer study (Ricaurte et al., 1980, submitted for publication) signs of neuronal degeneration were found in the somatosensory cortex of rats treated four days previously with high dose regimens (12.5 or 50.0 mg/kg x 3, 8 hours apart, s.c.) of methylamphetamine, a potent psychomotor stimulant drug. The affected neurons were located primarily in laminae III and IV of somatosensory cortical area 2, as defined by Krieg (J. Comp. Neur. 84: 221, 1946); this includes the region of the cortical "barrels" (Woolsey et al., J. Comp. Neur. 164: 79, 1975). These neurons were commonly pyramidal, had darkly-staining shrunken perikarya and argyrophilic dendrites which were frequently fragmented; their nucleus (when discernable) was pyknotic, argyrophilic and often eccentrically displaced. Further, silver sections counter-stained with cresyl violet revealed glial cells closely surrounding (as if phagocytizing) many of these argyrophilic neurons.

We now report that similar neuro-degenerative changes occur in the somatosensory cortex of rats treated four days previously with the serotonergic neurotoxin p-chloroamphetamine (PCA) (10 mg/kg, i.p.). In contrast to this, rats treated with the catecholaminergic neurotoxin 6-hydroxydopamine (6-HDA) (100 ug., i. vent.) do not display comparable neuropathological changes either when 6-HDA is given alone (Hedreen and Chalmers, Brain Res. 47: 1, 1972), or when it is given 45 minutes after a desmethylimipramine (25.0 mg/kg, i.p.) and pargyline (50.0 mg/kg, i.p.) pretreatment, as it was in this study.

Since 6-HDA generally destroys catecholamine-containing cells, the above observations suggest that the somatosensory cortical neurons affected by the amphetamines are not dopaminergic or noradrenergic. This is consistent with the fact that catecholamine producing cell bodies have not been identified in the cerebral cortex. Although the transmitter substance produced by the damaged somatosensory neurons remains to be determined, the fact that they are sensitive to the toxic actions of methylamphetamine and PCA, drugs with known serotonergic neurotoxic properties (Sanders-Bush et al., J. Pharmacol. Exp. Ther. 192: 33, 1975; Ricaurte et al., Brain Res. in press, 1980), suggests that they may be serotonergic or closely related.

260.1 EVIDENCE FOR THE RELEASE OF ENKEPHALINS BY TYROSINE-ARGININE (KYOTORPHIN). Anita Rackham, Paul L. Wood, Roger L. Hudgin*. Merck Frosst Labs., Dept. of Pharmacology, P.O. Box 1005, Pointe Claire-Dorval, Quebec, H9R 4P8, Canada.

The endogenous dipeptide tyrosine-arginine (kyotorphin) has been reported to have naloxone reversible analgesic effects. A proposed mechanism for the analgesia seen after intracerebroventricular administration of this and related peptides is release of enkephalins rather than direct activation of opiate receptors. Unlike enkephalins and standard opiate agents, kyotorphin and related peptides do not inhibit the binding of either [^{3}H]naloxone, [^{3}H](D-ala^2-D-leu^5)enkephalin, or [^{3}H]ethylketocyclazocine at concentrations up to 1000 nM. Using neurochemical (GC-MS) techniques to monitor changes in dopamine (DA) and its metabolites in the rat striatum, the present study further supports the enkephalin-release hypothesis for the action of kyotorphin. At analgesic doses, 50 to 200 µg intracisternally in the rat and mouse tail flick and hot plate assays, the effect of kyotorphin and various dipeptides on DA metabolites was found to be similar to that of morphine and opioid peptides. Significant increases were seen in striatal levels of dihydroxyphenylacetic acid (DOPAC) (90% increase) and homovanillic acid (HVA) (60% increase) while no effect was seen on DA or 3-methoxytyramine (3-MT) levels. Also the kyotorphin-related peptides and standard opiates were found to have similar attenuating effects on cortical and hippocampal acetylcholine turnover (TR_{ACh}), with decreases of 50 to 75% in TR_{ACh} in both the cortex and hippocampus. These data show that the action of kyotorphin and related dipeptides on DA and TR_{ACh} parallels that of standard opiate receptor agonists, but the lack of direct effect on opiate receptors suggests stimulation of enkephalin release may be a possible mechanism of analgesic action.

260.2 EFFECTS OF MORPHINE AND OPIOID PEPTIDES ON THE ELECTRICALLY EVOKED RELEASE OF ENTERIC SUBSTANCE P. Alan R. Gintzler* (Spon: C. Noback), Dept. of Anatomy, Columbia Univ., P&S, New York, 10032.

Previous studies have demonstrated that naloxone-precpitated enteric withdrawal is mediated via 2 neuronal pathways. One involves the release of acetylcholine (ACh) and the activation of smooth muscle muscarinic receptors. The other involves the release of enteric serotonin which then acts through the enteric nervous system to release substance P (Gintzler, A.R., Brain Res., 182:224, 1980). The involvement of substance P in precipitated gut withdrawal suggests that acute administration of narcotics might also be effective in modulating release of substance P in naive preparations. Stimulation of naive ilea (20 Hz) produces an atropine-resistant contracture that can be blocked by pretreatment with tetrodotoxin (TTX; 10^{-6}g/ml) or by desensitization to substance P. This desensitization is highly specific; contractures in response to histamine, ACh, KCl, or 0.1 Hz electrical stimulation are not affected. The magnitude of the atropine-resistant contracture evoked by 20 Hz stimulation therefore, can be used as an indication of the release of substance P. Morphine (5×10^{-6}M) as well as the opioid peptides FK33-824 (9×10^{-7}) or D met^{2}pro^{5}enkephalin (3×10^{-7}M) can significantly reduce the magnitude of the atropine-resistant 20 Hz contracture without altering responses to exogenous substance P. This inhibition is stereospecific and is blocked by naloxone (10^{-6}M). Pretreatment with the nicotinic cholinergic receptor blocker, hexamethonium reduces by about 30% responses to 20 Hz stimulation but has no effect on the inhibition produced by morphine. Thus, although a portion of the electrically evoked release of enteric substance P is dependent on the release of ganglionic ACh, the inhibition of release produced by morphine does not involve a cholinergic mechanism. Furthermore, pretreatment of a naive preparation with naloxone significantly enhances the magnitude of responses to 20 Hz stimulation suggesting that endogenous opioid peptides can also modulate release of enteric substance P. (Supported by NIMH Grant #DA01772).

260.3 ß-ENDORPHIN-INDUCED INCREASE IN CENTRAL SYMPATHETIC OUTFLOW: INHIBITION OF ADRENOMEDULLARY RESPONSE BY INTRACEREBRAL SOMATOSTATIN. Nathan M. Appel and Glen R. Van Loon. Departments of Medicine and Physiology, University of Toronto, Toronto Canada M5S-1A8.

Endorphins have been characterized as peptides with opiate-like biological activities present in brain and pituitary gland. A variety of effects including sedation, catalepsy, analgesia, hypothermia and regulation of pituitary hormone secretion has been attributed to central nervous system actions of endorphins. Evidence for aminergic neuronal modulation of some of these endorphin effects has been provided. The present study was undertaken to examine the possibility that endorphins might alter central sympathetic outflow. That is, we examined the possibility that brain endorphins might alter peripheral release of catecholamines, thus altering plasma catecholamine concentrations. We examined the effects of intracisternal (ic) synthetic human ß-endorphin on plasma concentrations of dopamine, norepinephrine and epinephrine in unanesthetized, freely moving rats bearing a chronic intraarterial cannula. ß-endorphin produced major, prolonged increases in plasma concentrations of all three catecholamines when compared with the responses to ic saline. The increase in plasma epinephrine was much greater than the increases in plasma dopamine or norepinephrine, supporting greater stimulation by ß-endorphin of sympathetic outflow to adrenal medulla than to sympathetic nerve endings. Prior intraarterial administration of naloxone blocked these ß-endorphin-induced effects, supporting mediation by opioid receptors. Systemic naloxone did not alter plasma catecholamine responses to ic saline. Acute systemic administration of guanethidine blunted the plasma norepinephrine response to ic ß-endorphin, suggesting that a considerable portion of the ß-endorphin-induced increase in plasma norepinephrine is derived from sympathetic nerve endings. A variety of putative neurotransmitters may interact with endorphins in modulating central sympathetic outflow. Somatostatin has been implicated as a neurotransmitter in the central nervous system. Simultaneous ic administration of somatostatin together with ß-endorphin markedly inhibited the plasma epinephrine response to ß-endorphin while decreasing the dopamine response to a much lesser degree and decreasing the norepinephrine response nonsignificantly. In conclusion, endorphins increase central sympathetic outflow to both adrenal medulla and to sympathetic nerve endings. In addition, somatostatin neurons appear to interact with endorphin neurons to selectively block endorphin-mediated stimulation of sympathetic outflow to adrenal medulla, without affecting outflow to sympathetic nerve endings.

260.4 CALCIUM SENSITIVITITY OF ENKEPHALIN RESPONSE IN THE HIPPOCAMPAL SLICE. S. M. Bawin*, W. R. Adey, S. Lin-Liu* and M. D. Mahoney*. Research Service, VA Hospital, Loma Linda, CA 92357

Electrophysiological responses such as long-term hyperpolarization, long-term potentiation, and epileptogenic activity in the hippocampal slice, are critically dependent on the calcium concentration in the bathing medium, and are impaired at calcium levels lower than 1mM. Enkephalins have recently been shown to increase spontaneous activity and amplitude of population spike response to Schaffer collateral stimulation in CA_1 pyramidal cells. Therefore, the effects of low (1mM) and high (4mM) calcium concentrations on these excitatory effects were studied, using rat hippocampal slices.

The slices (450 µm) were continuously perfused with warm (33-35C) oxygenated physiological solutions at a rate of 2 ml/min. A double valve system allowed perfusion with either control or treatment solutions without interrupting the flow. Bipolar stimulating electrodes and 4M NaCl micropipettes were positioned in the Schaffer collaterals and the CA_1 pyramidal cells, respectively. Twenty minutes perfusion with 1mM calcium solution induced a progressive decrease in the evoked response, while 4mM calcium solution induced large increases in population spike amplitude. Perfusion with control (2mM Ca) solution containing 200nM (D-Ala^2, Met)-enkephalin resulted in large (50-70 percent), long lasting but reversible increases in spontaneous and evoked cell activity, as described by others.

The enkephalin response was weaker (20-40 percent increase) during perfusion with either high or low calcium concentrations. Furthermore, the induced activity was not maintained beyond the first 10 min of perfusion with enkephalin. Calcium has been shown to antagonize opioid effects in the brain, and could similarly antagonize enkephalin excitation in the CA_1 cells during perfusion with 4mM calcium solution. The decreasing response in low calcium medium could reflect loss of synaptic responsiveness. (Funding: DOE DE-AI101-79ET29078, FDA RO1-FD00963-03, and Southern California Edison Company.)

260.5 ROLE OF β-ENDORPHIN ON CALCIUM FLUXES IN SYNAPTOSOMES. S. Lin-Liu*, S. M. Bawin* and W. R. Adey (SPON: M. A. Baker). Research Service, VA Hospital, Loma Linda, CA 92357

It has been suggested that β-endorphin regulates release of neurotransmitters by inhibition of Ca^{2+} influx into the nerve terminals but does not affect Ca^{2+} release. The present study was aimed at studying the effect of β-endorphin on Ca^{2+} uptake during excitation by K^+ stimulation and further to determine whether Ca^{2+} efflux per se is affected.

Synaptosomes prepared from cerebri of rats according to Cotman and Matthews were suspended in 0.32M sucrose with 5mM Hepes buffer (pH 7.5) and preincubated at 32°C for 5 min. An equal volume of a 32°C. incubation solution I_1 (low KCl) or I_2 (high KCl) containing $^{45}Ca^{2+}$ 0.1 μCi/ml was added and incubation continued for 10 min. $^{45}Ca^{2+}$ uptake was ended by rapid filtration of synaptosomes through millipore filters (0.45 μm pore size). For uptake study, the filters were washed four times with 2.5 ml of stopping solution S_1 (normal NaCl) or S_2 (no NaCl). Radioactivity remaining on filters was assayed by liquid scintillation counting. Results between incubation with and without β-endorphin and between high and low K^+ were compared. The difference between normal- and no-Na^+ washing was interpreted as Na^+-sensitive intracellular Ca^{2+}.

In efflux studies, the filters were perfused continuously with Kreb's saline at 32°C at 2 ml/min. β-endorphin (10 μM) was injected into the perfusion line at 20 μl/min at 1 to 5 min intervals during perfusion. Results were compared with injection of deionized water. In low KCl incubation, β-endorphin decreased calcium uptake 15-20 percent, confirming the findings of others. In the absence of β-endorphin, high KCl stimulated calcium uptake by 30 percent, but with β-endorphin the stimulation was about 17 percent. This 10 percent inhibition by β-endorphin may arise from not only a reduction of K^+-stimulated Ca^{2+} influx, but also from increased Ca^{2+} release from bound pools for the following reasons. First, in both situations, the percentage of Na^+-sensitive Ca^{2+} are the same, suggesting a possible reduction in all Ca^{2+} pools. Second, with low K^+ incubation, while β-endorphin decreased total Ca^{2+} uptake, it increased the percentage of Na^+-sensitive Ca^{2+}. Third, when perfusing with a calcium-free solution, β-endorphin increased $^{45}Ca^{2+}$ in the perfusate. These results demonstrated a regulator role of β-endorphin during neural excitation and suggest that β-endorphin inhibits Ca^{2+} influx and enhances Ca^{2+} efflux at the same time. (Funding: DOE DE-AI101-79ET29078, FDA RO1-FD00963-03, and Southern California Edison Company.)

260.6 BOVINE CHROMAFFIN CELLS IN CULTURE ARE A MODEL FOR THE SYNTHESIS AND RELEASE OF THE ENKEPHALINS AND PUTATIVE PRECURSORS. J. Rossier, B. Livett†, J. Trifaro‡, D. Dean†, R. Lee‡, R. Lewis°°, S. Udenfriend°° Physiologie Nerveuse, CNRS, Gif-sur-Yvette, France, °Dept. of Pharmacol.,Mc Gill Univ.,Montreal, †Dept. of Neurology, Montreal General Hospital, °°Roche Inst.,Nutley,New Jersey.

10^6 Chromaffin cells freshly isolated from the adrenals contain per cells: .9 ng of oxidized Met-enkephalin, .6 ng of Met-enkephalin-Arg^6, 2.2 ng of Met-enkephalin, .8 ng of Leu-enkephalin, 2.5 ng of Met-enkephalin-Arg^6-Phe^7 and more than 100 ng of various putative enkephalin precursors. These putative precursors have M_r ranging from 3000 to 22000. Cells in culture maintain similar levels of enkephalins and putative precursors for more than a week. Biosynthesis: After 8 days in culture, cells were incubated with ^{35}S-Methionine for 2 hrs. An acid extract of the 105,000 g x 1 hr supernatant was separated by gel filtration on a Sephadex G-75 column. Fractions containing the 22,000 M_r enkephalin precursor were incubated with trypsin. The trypsin digest was separated by HPLC and the fractions corresponding to Met-enkephalin-Arg^6 and Met-enkephalin-Lys^6 were immunoprecipitated with a serum specific for the N-terminus of the enkephalin molecules. No radioactivity was precipitated in the tubes corresponding to Met-enkephalin. The 22,000 M_r precursor incorporated into the sequences Met-enkephalin -Arg^6 and -Lys^6 at least .04 % of the radioactivity found in the 105,000 g supernatant. Fractions containing M_r compounds below 1000 were analysed by HPLC. After the 2 hrs pulse, no radioactivity was found in the HPLC fractions corresponding to Met-enkephalin and Met-enkephalin-Arg^6-Phe^7. Six hrs after the pulse, these two HPLC fractions did contain .05 % of the radioactivity found in the 105,000 g extract. By immunoprecipitation it was confirmed that all the radioactivity associated with the two fractions containing Met-enkephalin and Met-enkephalin-Arg^6-Phe^7 respectively corresponded to these molecules. The specific radioactivity of Met-enkephalin was three times greater than that of Met-enkephalin-Arg^6-Phe^7 indicating a slower turn-over of this latter molecule. Release: Studies were carried out with chromaffin cells in culture for 6 days. Nicotine ($5x10^{-6}$ M, 5 min) stimulated the release of catecholamines along with enkephalins and their putative precursors. A single stimulus released 21 % of the total cellular content of noradrenaline, 10 % of adrenalin, 8 % of Leu-enkephalin and 5 % of the putative enkephalin precursors. Various concentrations of nicotine were tested. Dose response curves for the catecholamines and the enkephalins were completely parallel with a maximum for a nicotine concentration of $1x10^{-5}$ M. These results and other cytological evidences indicate that the catecholamines and the enkephalins are stored in, and released from the same vesicles. J.R. is Chargé de Recherche INSERM.

260.7 CHARACTERIZATION OF ENKEPHALIN DEGRADING ENZYMES. Charles Gorenstein and Solomon H. Snyder. Dept. of Pharmacol. Johns Hopkins University School of Medicine, 725 North Wolfe Street, Baltimore, Maryland 21205

Degradation of enkephalins can occur by a variety of peptidases. In an effort to determine which if any are concerned with the physiological breakdown of enkephalins, we have characterized several membrane bound brain peptidases. DEAE chromatography of Triton solubilized membranes resolves several enzymatic activities. Two enzymes, dipeptidylcarboxy peptidases A_1 and A_2 were separated. Identification as dipeptidylcarboxy peptidases was based on formation of tyr-gly-gly by thin-layer chromatography. Both enzymes are metallo-peptidases have an isoelectric point of 4.8 and are clearly resolved from angiotensin converting enzyme. Enkephalinase A_1 has been purified 1500 fold to apparent homogeneity.

A novel membrane bound dipeptidyl aminopeptidase designated enkephalinase B generates tyr-gly and can also cleave a series of basic dipeptides beta-Naphthylamide derivatives (lys-ala β-NA, arg-arg-β-NA). This enzyme has been purified to apparent homogeneity.

Of these enzymes, enkephalinase A_1 shows a regional distribution closely paralleling that of opiate receptors.

260.8 IN VIVO AND IN VITRO ENZYMATIC DEGRADATION OF DYNORPHIN-(1-13) AND STRUCTURAL ANALOGUES. F.M. Leslie* and A. Goldstein (SPONS: B.M. Cox) Addiction Research Foundation, 701 Welch Road, Palo Alto, CA 94304.

Dynorphin-(1-13), a recently synthesized opioid peptide, has been shown to be rapidly degraded by rat brain enzymes both in vivo and in vitro (Goldstein et al., Proc. Nat. Acad. Sci. 76: 6666 (1979)). In order to more fully characterize the pharmacology of dynorphin-like peptides, it is important to synthesize structural analogues which are completely resistant to enzymatic attack under the conditions in which they are studied. The present study investigates in vitro and in vivo enzymatic cleavage of ^{125}I-dynorphin-(1-13) and compares the relative stabilities of several ^{125}I-labelled structural analogues. Degradation was assessed by gel permeation, thin layer and high pressure liquid chromatography, using a combination of systems in which all potential radiolabelled dynorphin-(1-13) metabolites could be identified.

When incubated in vitro with well-washed rat brain membranes (50mM Tris-HCl buffer, pH 7.4), ^{125}I-dynorphin-(1-13) (20-100nM) was degraded by a combination of aminopeptidase and carboxypeptidase activities. At 22°C, in the absence of added ions, carboxypeptidase removal of the terminal lysine residue was the most prominent degradative process. At 37°C, or in the presence of Krebs ions, aminopeptidase activity was greatly increased. High concentrations (1mM) of enzyme inhibitors such as phenanthroline and bacitracin, or incubation at 0°C, attenuated but did not completely inhibit this degradation. Addition of a methyl ester group at the carboxy terminus protected the peptide to some extent from both carboxypeptidase and aminopeptidase attack. Substitution of a D-ala group at position 2 and amidation of the carboxy terminus further increased dynorphin-(1-13) stability in this system.

In vivo degradation was assessed 10 min after lateral intraventricular injection of radiolabelled peptide. Dynorphin-(1-13) (10 and 100 nmoles) was rapidly broken down in intact rat brain by aminopeptidase activity. An analogue, D-Ala^2-dynorphin-(1-11), was considerably more resistant to in vivo enzymatic attack, although there was still significant breakdown at the 10 nmole dose.

260.9 A NOVEL AMINOPEPTIDASE FOR ENKEPHALIN DEGRADATION.

K.-S. Hui,* K.-P. Cheng*and A. Lajtha. Center for Neurochemistry, Ward's Island, New York 10035 U.S.A.

Enkephalins, the endogenous opioid peptides, are inactivated primarily by aminopeptidases, as demonstrated by the release of Tyr with brain homogenate and cultured human endothelial cells. Four peptidases were identified as being responsible for enkephalin degradation, three particulate enzymes, 1) aminopeptidase, 2) enkephalinase A, and 3) enkephalinase B, and 4) a soluble aminopeptidase. Enzymes 1 and 4 split the Tyr-Gly (1-2) bond; 2, the Gly-Gly (2-3)bond; 3, the Gly-Phe (3-4)bond. In the brain, the degradation of enkephalin from the amino terminus is 3-4 times higher than the activity of the other enkephalinases. We purified a soluble aminopeptidase from rat brain using enkephalin as substrate. The post-mitochondrial fraction was precipitated with $(NH_4)_2SO_4$ between 40 and 70% saturation and submitted to permeating chromatography, ion-exchange chromatography, and adsorption chromatography. The enzyme activity was assayed measuring the degradation of enkephalin by the disappearance of UV absorption at 210nm after the separation by high-pressure liquid chromatography equipped with a μBondapak C_{18} column. The enzyme degraded enkephalin only by release of the tyrosine; the disappearance of enkephalin and the appearance of des-Tyr-enkephalin was in 1:1 ratio; it did not split the des-Tyr-enkephalin. Compared to other known aminopeptidases, the enzyme was less active against aminoacyl β-NA: Tyr β-NA, Arg β-NA, Pro β-NA, or γ-endorphin. Disc gel electrophoresis revealed that the enzyme preparation contains 5 protein bands; only one of these was active when gel slices were incubated with enkephalin, and the R_f of the active band was different from that of other aminopeptidases. We observed differences between the breakdown of Met and Leu enkephalins. Bestatin, a potent aminopeptidase inhibitor, inhibited both Met and Leu enkephalin breakdown. SQ14225 had no effect on Met-enkephalin; however, it promoted Leu-enkephalin breakdown. Mn^{++} activated Met-enkephalin degradation but had no effect on Leu-enkephalin degradation. The aminopeptidase is a sulfhydryl enzyme. The effect of metals, inhibitors, the substrate specificity, and other characteristics demonstrate that this enzyme is different from leucine aminopeptidase, arylamidase, amino-peptidase, aminopeptidase A, aminopeptidase B, and aminopeptidase M. The enzyme was stable at 4°C for months but not after freezing and thawing. Its MW is 100K; the pH optimum is 7-7.5. Our results indicate that there exists in the brain a novel aminopeptidase specific for enkephalin, which has hitherto not been reported in the literature.

261.1 THE EFFECTS OF ANESTHESIA ON THE METABOLIC RESPONSE TO CORTICAL SPREADING DEPRESSION IN THE GERBIL. A. Mayevsky, N. Zarchin* and U. Rosenshein*, Life Sciences Dept., Bar-Ilan Univ., Ramat-Gan, ISRAEL.

The present study was aimed at describing the effects of deep anesthesia on the metabolic responses to a large energy demand in the brain of gerbils. Metabolic responses were evaluated by monitoring the oxidation-reduction state of NADH by surface fluorometry in the awake or anesthetized gerbil. A large energy demand was induced by exposing the cortex to complete depolarization-spreading depression (epidural application of 0.3-0.5M KCl solution). The gerbil Meriones unguiculatus (50-60 gr) was anesthetized by Equi-Thesin (a mixture of Pentobarbital, Chloral hydrate, Magnesium sulfate, Propylene glycol and Alcohol) for the duration of the operation (0.3 ml/100 gr). The skull was exposed and drilled for the location of a light-guide holder, push-pull cannula (KCl application) and for ECoG electrodes. After cementation, the animal was connected to a DC fluorometer/reflectometer for the continuous monitoring of NADH redox state. The animal was exposed to 1 min N_2 breathing as a standard test for the state of the brain (Mayevsky, A., Brain Res. 140, 217, 1978). The response to spreading depression (SD) was measured at three stages: 1) 20-30 min after the end of the operation, while the gerbil was still anesthetized; 2) in the fully awake gerbil (2-3 hr after operation); and 3) after reanesthetizing the gerbil with Equi-Thesin or Pentobarbital. The results show a different response to SD in the anesthetized brain as compared to the awake state. The response to SD in the awake gerbil was a state 4 to 3 transition, which appeared as an "oxidation cycle", as was described for the rat brain model. Under deep anesthesia, the response to SD was a "reduction cycle", as was also described in the ischemic rat or gerbil brain (Mayevsky, A., Brain Res. 140, 217, 1978; Mayevsky et al., Neurol. Res. 1, 213, 1980). The effects of anesthetics were found only in the gerbil, but not in the rat, even when very deeply anesthetized. From our study we concluded that deep anesthesia in the gerbil decreases the ability of the cerebral circulation to compensate for the extra oxygen usage during SD, so that a reduction of NADH was recorded. In other studies (Freidli, Mayevsky and Mela, unpublished results) we found that under deep anesthesia induction of SD led to the re-uptake of K^+ from the extracellular space concomitant with the "reduction cycle".

261.2 DECREASED INFLUX OF β-HYDROXYBUTYRATE INTO VARIOUS BRAIN STRUCTURES AFTER PORTACAVAL ANASTOMOSIS. A.M.Mans*, J.F.Biebuyck* and R.A.Hawkins, Depts. of Anes. and Physiol., The Penn State Univ., Coll.of Med., The M.S.Hershey Med.Ctr., Hershey, PA 17033

During hepatic failure in the rat, there are alterations in the blood-brain barrier transport mechanisms for neutral amino acids, leading to increased influx throughout the brain (1). The transport of substrates by other carriers may be differently affected, e.g. the brain uptake index of some monocarboxylic acids was decreased three weeks after a portacaval shunt (pcs) operation (2), while that of glucose was unchanged (3). The location of these changes to brain structures is important for a better understanding of the physiology of the blood-brain barrier in both health and disease. Therefore we have studied the influx of β-hydroxybutyrate, which is transported by the monocarboxylic acid carrier, into the brain of rats 7 weeks after pcs or sham-operation (control). The method used was modified from an autoradiographic technique previously used to study amino acid transport, and which enables measurement of influx into virtually any brain region in vivo. We found a decrease in influx in all 32 brain areas studied ranging from 40 to 50%. The mean values (± SEM) for some regions are shown in the table.

	Influx (nmol.min^{-1}g^{-1})		
	Control(6)	Pcs(6)	% decrease*
Frontal cortex	6.07 ± 0.60	2.54 ± 0.56	58
Parietal cortex	5.88 ± 0.63	2.54 ± 0.52	57
Amygdala	4.54 ± 0.56	1.98 ± 0.52	56
Hippocampus	3.88 ± 0.59	2.10 ± 0.51	46
Hypothalamus	3.64 ± 0.49	1.46 ± 0.45	60
Anterior thalamic nuclei	5.24 ± 0.72	2.84 ± 0.60	46
Medial geniculate	4.81 ± 0.86	1.99 ± 0.56	59
Interpeduncular	5.11 ± 0.59	2.41 ± 0.33	53
Superior colliculus	6.06 ± 0.76	3.21 ± 0.73	47
Inferior colliculus	5.78 ± 0.94	2.39 ± 0.61	59
Cerebellar gray	3.92 ± 0.70	1.64 ± 0.49	58
Cerebellar vermis	5.36 ± 0.65	2.13 ± 0.62	60

*$p<0.05$

The concentration of β-hydroxybutyrate in the plasma was not altered (control:222 ± 16 nmol/ml; pcs:272 ± 51 nmol/ml). Since other plasma substrates for this carrier were also unchanged at 7 weeks after pcs, the decrease in influx indicated an alteration in the characteristics of the transport carrier which occurred throughout the entire brain. These findings, together with other studies, indicate that very specific changes in blood-brain barrier transport occur during hepatic failure.

261.3 AGE-ASSOCIATED DECREASE IN LOCAL CEREBRAL GLUCOSE UTILIZATION (LCGU) IN THE BEAGLE. A.S. Garden*, M. Ohata*, S.I. Rapoport and E.D. London. Lab. of Neurosciences, Nat'l. Inst. on Aging, GRC, Balto. City Hosp., Baltimore, MD 21224.

The ^{14}C-2-deoxy-D-glucose (DG) method of Sokoloff et al. (J. Neurochem. 28:897,1977) allows measurement of local cerebral glucose utilization (LCGU) within individual brain regions. Using the DG method, we showed that LCGU in the brain of the Fischer 344 rat increases between the ages of 1 and 3 mo, decreases between 3 and 12 mo, and remains unchanged between 12 and 24 mo and 24 and 34 mo (London et al., J. Neurochem., in press). In the present investigation, we studied LCGU in the beagle at the ages of 1 yr and 10-11 yr. We chose to study the dog because it shows senescence-associated neuropathology similar to that seen in man (Wisniewsky et al., Lab. Invest. 23: 287, 1970); age-associated neuropathology in the rat is minimal.

DG (50 μCi/kg) was injected i.v. in conscious dogs that were adapted to a harness. Radioactivity in timed arterial plasma samples was measured by liquid scintillation spectroscopy. After 45 min, the brain was removed and dissected into 24 regions for which radioactivity was also measured by scintillation spectroscopy. LCGU was calculated with the kinetic constants for transport and metabolism of DG in the rat (Sokoloff et al., 1977) and with a lumped constant of 0.558 for the beagle (Duffy et al., Trans. Am. Soc. Neurochem. 10:171, 1979). Between the ages of 1 and 10-11 yr, LCGU decreased in every brain region assayed. Most striking decreases were in some white matter areas (corpus callosum excluding the genu, anterior commissure, internal capsule), where LCGU fell by 50-60%. Other white matter areas showed smaller decreases (genu of corpus callosum, 29%; cerebellar white matter, 11%). LCGU fell by approximately 40% in the geniculate nuclei and inferior colliculus, by 20-30% in the superior colliculus and cortex on either side of the calcarine fissure, and by 22% in the olfactory bulb. These decrements may be related to a loss of sensory function with age. Structures involved in limbic function, such as the hippocampus, cingulate cortex, temporal tip, and amygdala, showed decreases in LCGU of approximately 25-30%, but the decline in the mammilary body was 14% and that in the pyriform cortex was only 4%. In gray matter areas involved in motor function, such as the caudate nucleus and cerebellar flocculus, decrements were 25-35%. Other regions which showed decreases in LCGU are: the hypothamus (24%), thalamus less geniculate bodies (31%), midbrain basis and tegmentum (30%), pons (37%) and medulla (22%). Thus, although there is an overall decrease in LCGU with age in the beagle brain, this decrease is not uniform but has a regional distribution that probably is associated with regional deficits in brain function.

261.4 AGE-ASSOCIATED ALTERATIONS IN REGIONAL CEREBRAL BLOOD FLOW IN THE FISCHER-344 RAT. M.Ohata*, U.Sundaram*, W.R. Fredericks*, E.D. London and S.I. Rapoport. Lab. of Neurosciences, Nat'l. Inst. on Aging, GRC, Balto. City Hosp., Baltimore, MD 21224

Regional cerebral blood flow (rCBF) is related to cerebral metabolism and is a measure of neuronal functional activity. rCBF was measured in specific brain regions of the conscious unanesthetized Fischer-344 rat at the ages of 1 mo, 3 mo, 12 mo, 24 mo or 34 mo. ^{14}C-Iodoantipyrine was infused i.v., and radioactivity in timed arterial blood samples was measured by liquid scintillation spectroscopy. The brain was removed and dissected into 14 regions for which radioactivity was also measured by scintillation spectroscopy. rCBF was calculated by applying the Kety-Schmidt analysis to the data (Sakurada et al., Am. J. Physiol. 234, H59, 1978; Ohno et al., Stroke, 10, 62, 1979). In 1 mo old rats, the mean rCBF in 9 anterior brain regions was 92 ml·100g^{-1}·min^{-1}. It was 76 ml·100g^{-1}·min^{-1} in 4 posterior brain regions. rCBF increased significantly ($P < 0.05$) in the 9 anterior regions between 1 and 3 mo of age, and continued to increase after 3 mo to a mean of 132 ml·100g^{-1}·min^{-1} at 12 mo, but did not change significantly in the posterior brain regions between 1 and 12 mo. rCBF tended to decline between 12 and 24 mo, more consistently in the posterior than anterior brain regions. White matter rCBF did not change with age. The findings indicate that rCBF increases during development and maturation of the anterior portion of the rat brain, between 1 and 12 mo. The posterior part of the brain, which is more mature than the anterior brain by 1 mo, shows no significant changes in rCBF between 1 and 12 mo. The decline in rCBF in some brain regions after 12 mo of age may reflect some of the degenerative changes that occur within the brain from 12 mo to death at 36 mo.

rCBF does not follow the same temporal pattern during maturation and aging of the rat brain as does local cerebral glucose utilization (LCGU). LCGU increases as does rCBF between 1 and 3 mo, but then falls by 24% between 3 and 12 mo while simultaneously rCBF continues to rise (London et al., J. Neurochem., in press). The parallel courses of rCBF and LCGU between 1 and 3 mo probably are related to developmental changes in the rat brain, which is not fully mature until 4 mo of age. However, the simultaneous rise in rCBF and fall in LCGU between 3 and 12 mo are unexplained. They may be due to an altered coupling relation between rCBF and cerebral metabolic rate of oxygen consumption. The dissociation between the time courses of rCBF and LCGU during maturation and aging of the rat brain, which is reported here for the first time, suggests that rCBF and LCGU are not indices of the same functional parameters.

261.5 EFFECT OF OXOTREMORINE, A MUSCARINIC AGONIST, ON LOCAL CEREBRAL GLUCOSE UTILIZATION (LCGU) IN THE RAT. D. Dow-Edwards, J.M. Peterson*, P. Mahone*, S.I. Rapoport and E.D. London. Lab of Neurosciences, Gerontology Research Center, National Institute on Aging, Baltimore City Hospitals, Baltimore, MD 21224.

The distribution of specific muscarinic receptor binding sites in the rat brain has been described with the use of radioligand binding and autoradiographic techniques (Yamamura and Snyder, P.N.A.S. 71:1725, 1974;Kuhar and Yamamura, Brain Res. 110:229, 1975; Rotter, A. et al., Brain Res. Rev. 1:141,1979). In order to assess the functional significance of these binding sites, we employed the autoradiographic ^{14}C-2-deoxy-D-glucose (DG) technique of Sokoloff et al. (J. Neurochem. 28:897, 1977) to study local cerebral glucose utilization (LCGU) in the conscious rat. Oxotremorine (OXO), a potent muscarinic agonist, was given i.p. (0.75 mg/kg) 2 min before i.v. DG (125 µCi/kg) and the rats were killed 50 min after DG administration. Although many regions showed no changes in LCGU following OXO, LCGU was increased significantly ($p < 0.05$) in the sensory-motor and parietal cortices, the hippocampus, globus pallidus, caudate nucleus, nucleus accumbens, medial and lateral septal nuclei, olfactory bulb, and cerebellar gray matter. Several diencephalic nuclei showed increased LCGU; these include the ventral and anteroventral thalamic nuclei, the lateral geniculate nucleus and the lateral habenula. In the mesencephalon, the red nucleus and superior colliculus showed 2-fold increases in LCGU, and a 50% increase was noted in the substantia nigra pars compacta. In every region where OXO caused an increase in LCGU, this increase was blocked by the antimuscarinic drug scopolamine (2.5 mg/kg, i.p., 10 min before OXO) but not by atropine methylbromide (1 mg/kg, s.c. 20 min before OXO), which does not readily penetrate the blood-brain barrier. Scopolamine (2.5 mg/kg i.p.) without oxotremorine had no significant effect on LCGU. These findings indicate that increased LCGU in response to oxotremorine requires stimulation of central muscarinic receptors and is not dependent upon peripheral muscarinic stimulation.

We note no simple correlation between the magnitude of increase in LCGU following OXO administration and the reported densities of high affinity muscarinic binding sites. Thus, LCGU following specific pharmacologic stimulation depends on the presence of relevant receptors for the administered drugs and on the neuronal circuitry of that brain region.

261.6 **NEURAL ACTIVITY DURING HIBERNATION: APPLICATION OF THE ^{14}C DEOXYGLUCOSE TECHNIQUE.** **T.S. Kilduff, F.R. Sharp and H.C. Heller*. Dept. Biol. Sci., Stanford University, Stanford, CA 94305 and Dept. Neurology, Univ. Calif. Med. Cntr., San Diego, CA 92103.**

Knowledge of neural activity during hibernation is derived from EEG recordings from a limited number of brain areas. We have utilized the ^{14}C deoxyglucose technique of labelling tissues according to their glucose utilization to provide a more global perspective of brain function during deep hibernation and arousal from hibernation. Golden-mantled ground squirrels (Citellus lateralis) were implanted with chronic jugular catheters and polyethylene re-entrant tubes; some animals were also prepared with thermodes straddling the hypothalamus. The re-entrant tubes enabled introduction of a thermocouple subcutaneously to measure body temperature during experiments. The ^{14}C deoxyglucose was injected through the catheter (15uCi/100g body wt) during deep hibernation, arousal from hiberation, euthermia, and with thermogenesis stimulated by cooling of the skin or hypothalamus. After an incubation time appropriate to the particular experiment, brains were removed, sectioned in a cryostat and exposed to X-ray film. The optical density of 83 neural structures represented in the resultant autoradiographs was measured and these values were compared to the density of a white matter structure such as the optic tract. Analysis of this relative measure of glucose utilization revealed decreases during deep hibernation compared to euthermic controls in all gray matter structures examined except the lateral septal area and the paraflocculus; the greatest decreases of relative glucose utilization were found in the inferior colliculus (63%), cerebellar nuclei (54%), and mammillary body (50%). The predominant band of activity thought to be lamina IV in the auditory, somatosensory and visual cortex in the euthermic animals was not evident in deep hibernation. Areas showing little or no decrement in relative activity during deep hibernation include the cochlear nuclei, superior colliculus, nucleus of the olfactory tract, suprachiasmatic nucleus and, as mentioned above, the lateral septal area. As animals aroused from hibernation, an increase in relative activity was noted in the medullary reticular formation and dorsal horn of the spinal cord. A distinct lamina IV was evident by the time body temperature had reached 15°C. In addition, structures such as the habenula and mammillary body showed an unusual pattern of glucose utilization, suggestive of discrete regions of activity.

261.7 ADENINE NUCLEOTIDE PROTECTION AGAINST LETHAL HYPOXIC HYPOXIA IN RODENTS. B.J. Kraynack, L.L. Kraynack*, J. Hinshaw*, J. Gintautas. Anesthesiology Research Laboratories, Texas Tech University Health Sciences Center, 3601 4th Street, Lubbock, Texas 79430.

Adenosine Triphosphate (ATP) (200/mg/kg) intraperitoneally (IP) administered significantly increased survival time (ST) in mice exposed to an otherwise lethal hypoxic atmosphere. Survival time increased 794%. Here, we compared the effects of the adenine nucleotides, nucleoside, base and cyclic nucleotide on ST. Male Swiss white mice (25-30gm) were injected IP with a constant volume of 0.9% saline while treatment groups received an IP injection of ATP (50, 100, 200 or 400 mg/kg); or one of the following drugs (200 mg/kg): 1) adenosine diphosphate (ADP), 2) adenosine monophosphate (AMP), 3) adenosine, 4) adenine phosphate, 5) dibutyryl cyclic AMP, and 6) phosphocreatine. Thirty minutes later, mice were exposed to 5% oxygen at room temperature. The interval between the introduction of the hypoxic mixture to the chambers and the last respiratory effort was measured for each animal and defined as the ST. The hypoxic observation period was truncated at 30 minutes. The percentage increase of ST for AMP, ADP and ATP are shown in Table 1. The other agents were ineffective. ATP (200 mg/kg) increased ST by 775% and was the most effective dose (and agent) tested. In rats, centrally administered ATP, ADP and AMP (500 µg) significantly increased ST. Although the physiological mechanism by which the adenine nucleotides promote resistance to lethal hypoxia remains undefined, these findings suggest that protection may not be related to an energy transfer mechanism. Moreover, while we can not entirely exclude a peripheral mechanism, the data indicate that the nucleotides probably exert their effect directly on the central nervous system.

Drug	% Increase ST over Saline
Saline	---
AMP	439
ADP	491
ATP (50 mg/kg)	178
(100 mg/kg)	188
(200 mg/kg)	775
(400 mg/kg)	399

261.8 RESPONSES OF CEREBRAL OXYGEN WAVES TO CHANGES IN BLOOD PRESSURE IN RABBIT. Jack P. Douglas; George J. Niemirowski*; Scott Hall; Robert G. Grossman. Division of Neurosurgery, UTMB, Galveston, Texas 77550.

Cortical oxygen tension, measured continuously using polarized platinum electrodes, has previously been observed to oscillate rhythmically. These oscillations are thought to be produced by rhythmic contraction and dilation of the cerebral vasculature, and may play a role in control of blood flow (Folkhow, 1962). We propose that the cerebrovascular network contains intrinsically oscillating series and parallel vascular elements that rhythmically control the amount of blood flowing through a given volume of tissue. We have investigated the changes in reactivity and participation of the various elements along the vascular tree following changes in mean systemic blood pressure (MSBP) in awake and anesthetized rabbits. Two platinum disk electrodes were implanted over the cortical surface of each hemisphere in homologous zones to monitor oxygen availability (aO_2) and for measurement of cerebral blood flow (CBF) using H_2 clearance. At least two weeks were allowed to pass prior to experiments to allow CBF and aO_2 to stabilize. In the awake, unmedicated animal oxygen was found to fluctuate in a complex yet sinusoidal fashion, sometimes very regularly. Power spectral analysis (PSA) showed dominant frequency peaks at each location which, in the resting state, were stable over time. Characteristic peak frequencies ranged from 0.15 to 0.20 Hz. Wave amplitudes were less than 5% of resting oxygen levels. Increases in MSBP, produced by infusion of angiotension II, decreased amplitude, increased peak PSA frequency and desynchronized the signal. CBF autoregulated up to the highest blood pressure obtained (MSBP=145 mm Hg). Hypotension produced by blood removal, on the other hand, caused a significant slowing of the dominant wave frequency, often by 50% from normotensive conditions, and increased wave amplitude. Waves often became more regular at low arterial pressures with ipsilateral and then bilateral wave synchrony occurring. At MSBP near 45 mm Hg, waves abruptly disappeared, and reappeared when pressure slowly increased. If pressure remained low for longer than five minutes, waves remained inhibited for periods up to 30 minutes. These observations suggest multiple vascular pacemaker sites which participate in a differential response to changes in blood pressure. Enhanced bilateral synchrony suggests large basal vessels dominate in responding to lowered pressure, possibly because arterioles are already maximally dilated, while all elements participate at elevated pressures. In addition, waves abruptly collapse at pressures near or lower than those pressures where CBF autoregulation is maintained.

261.9 MERCURY VAPOR TOXICITY IN THE CENTRAL NERVOUS SYSTEM OF RODENT. Yam S. Tong* and Chakwan Siew. Res. Inst., Amer. Dental Assn. Hlth. Fdn., Chicago, IL 60611.

Elemental mercury (Hg) toxicity is generally believed to be associated with the central nervous system (CNS). Ethanol, one of the most commonly used CNS affecting drugs, was employed to probe the effect of Hg vapor on mice. Male Swiss-Webster mice were exposed to mercury vapor (0.2 mg/m^3, 24 hr/day, 7 days) in specially designed chambers. Ethanol sleep time was determined prior to and post Hg exposure. The results indicate that chronic low-level Hg exposure prolongs significantly the ethanol sleep time (Hg exposed mice, 45.7±2.2 vs. control 24.7±2.2 min $p<0.05$). However, there was no signfiicant difference between the two groups in blood ethanol levels which were measured when the mouse awoke. The brains of the exposed mice were then homogenized in 5mM Tris-HCl, pH 8.6. After centrifugation at 100,000 x g for one hour, the majority of the Hg was found bound to the soluble protein(s). The supernatant was exhaustively dialyzed against the same buffer before being chromatographed on a Sephadex G-200 column. The gel filtration column yielded two Hg peaks. The major one was eluted right after the void volume and overlapped with a major protein peak. The second Hg peak came out at a much later volume. The profile obtained from Hg-exposed Sprague/Dawley rats is very similar. When an aliquot of the dialyzed supernatant was brought to 2% sodium dodecyl sulfate (SDS) and then dialyzed against 0.1% SDS, no significant decrease in the Hg content of the sample was detected. This equilibrium dialysis study indicates that the Hg is most likely covalently bound to protein. The biotransformation of metallic Hg to ionic Hg, a form most commonly involved in specific binding with proteins, may possibly depend on the action of the enzyme catalase, which has been suggested to be responsible for an oxidation-reduction cycle of Hg in mammalian tissues. The nature of the binding as well as the identity of the Hg-bound protein(s) are being investigated. (Supported in part by grants from BRSG, RR 05889 and American fund for Dental Health.)

261.10 COLCHICINE: UPTAKE INTO BRAIN AND LONG-TERM MEMORY. E. Bennett, M.H. Alberti*, and J.F. Flood*+. Lab.Chem.Biodynamics, Lawrence Berkeley Lab., Berkeley, CA 94720 and Dept. of Psychology and Psychiatry, UCLA, Los Angeles, CA 90024.

Numerous experiments have shown that inhibitors of protein synthesis including anisomycin (ANI) and cycloheximide impair long-term memory formation in a variety of species. It has been suggested that microtubules may be involved in the transport of essential protein from the cell body to synaptic and dendritic endings. These transported proteins then produce long-lasting changes in membrane structure or cell morphology which are presumed necessary to establish long-term memory. Under training conditions where neither inhibitors of protein synthesis nor inhibitors of axoplasmic flow alone produce amnesia, we have shown that the combined peripheral administration of ANI and Colchicine, vinblastine, or podophyllotoxin will impair long-term memory formation in mice [Amer. Soc. Neurochemistry, Trans., 10, 220 (1978)]. The initial objective of the biochemical experiments reported here was to estimate the amount of colchicine entering mouse brain under the conditions of the behavioral experiments. When [ring A-4-^{3}H]-colchicine (2 µg) was administered, approximately 5% of the radioactivity was found in liver, but less than 0.01% was found in brain. About 40-50% of the radioactivity in brain was precipitated by vinblastine. This uptake into brain was considerably less than was anticipated based upon a report concerning the uptake of methoxy-labelled colchicine into rat brain by Stewart and Rose [J. Neurochem., 30, 595 (1978)]. We therefore compared the effect of species and position of radioactive label upon brain uptake of colchicine. A large species influence on uptake into rat or mouse was not found, but a major effect of label position was observed. Much more radioactivity was found in brain after administration of [ring C-methoxy-^{3}H]-colchicine than after administration of [ring-A-4-^{3}H]-colchicine. Most of the radioactivity in brain after administration of methoxy-labelled colchicine was not precipitated by vinblastine and appeared to be metabolic water. Experiments have now shown when ANI is administered prior to training and as little as 30 pg of colchicine is injected bilaterally into caudate shortly after training, that amnesia for active avoidance training is obtained in a significant proportion of the mice. This (30) pg is approximately equivalent to the amount of colchicine entering the brain after subcutaneous administration of 2 µg of colchicine. Taken together, these experiments lend support to the above hypothesis that structural alterations in synapses brought about by recently synthesized protein transported down the axons of dendrites may be an essential process for long-term memory formation.

262.1 DIFFERENTIAL EFFECTS OF LOCAL AND SYSTEMIC ETHANOL ON RAT CEREBELLAR PURKINJE NEURONS: EVIDENCE FOR A LOCUS COERULEUS INVOLVEMENT. S.M. Sorensen, D. Carter*, J. Marwaha, R. Baker* and R. Freedman*. Alcohol Research Center, Univ. of Colorado Health Sciences Center, Denver, CO 80262, and Denver VA Hospital.

Ethanol (E), applied directly to Purkinje (P) cells using micropressure ejection, produces a dose-dependent inhibition of cell firing. When P cells were monitored continuously after an intraperitoneal injection of E (1 mg/Kg), a biphasic response was seen. An increase in firing rate to 130% of control within 12 minutes of injection is followed by a slow decline to control or below control firing rates at 30 min. (See figure below). The early excitation of the P cell following parenteral E was not seen in rats which had been pretreated with 6-hydroxydopamine to eliminate the noradrenergic (NA) afferents to the cerebellum. The excitation was also blocked by the β-adrenergic antagonist propranolol. In both these cases, after the NA input to the cerebellum is eliminated, only depression of the P cells was observed. These results suggest that the early excitation of P cells, seen after systemic E, may be due to a reduction of the tonic inhibitory input from the locus coeruleus, the source of the NA input to the cerebellum. The biphasic nature of the P cell response to parenteral E may therefore be due to an initial disinhibition followed by a direct depression of the P cell itself.

262.2 COMPARISON OF THE EFFECTS OF ETHANOL, TETRAHYDROISOQUINOLINES (TIQs) AND OPIATES ON NEURONAL ACTIVITY IN BRAIN: AN IONTOPHORETIC AND MICRO-PRESSURE STUDY. E.D. French*, T.W. Berger, G.R. Siggins, T.W. Shier*, and F.E. Bloom. Alcohol Research Center and A.V. Davis Center, Salk Institute, La Jolla, CA 92037.

Iontophoresis of opioid peptides predominantly depresses the discharge of neurons of most brain areas, whereas hippocampal pyramidal cells are usually excited (Nicoll et al. Proc. Natl. Acad. Sci. 74:2586, 1977). These actions are naloxone sensitive. This spectrum of actions was used as an initial comparative model to test two hypotheses: 1) that ethanol effects are mediated by an opiate-like mechanism, and; 2) that formation of acetaldehyde-catecholamine condensation products (TIQs) might contribute to some actions of ethanol. All drugs were applied to single neurons by electroosmosis or micro-pressure. Ethanol (1-3 M in the pipette) weakly inhibited most neurons of the cerebellum, caudate nucleus and parietal cortex, while 55% of presumed HPC pyramidal neurons (N=31) were markedly excited. Tetrahydropapaveroline (3 mM in the pipette) inhibited the spontaneous and glutamate- or acetylcholine (ACh)-induced firing of most (60-100%) neurons in all these regions. In contrast, salsolinol and 7-Me-salsolinol (3 mM in the pipette) excited 73 and 56%, respectively, of HPC pyramidal neurons, while depressing the activity of most parietal cortical neurons. Iontophoretic or systemic naloxone antagonized the excitatory actions of ethanol (75% of tested cells) and salsolinol (89% of tested cells) on HPC pyramidal cells, without change in the basal firing rate. The doses of naloxone used also blocked excitatory responses of HPC pyramidal cells to methionine-enkephalin; however, ACh-induced speeding was also antagonized in 1/3 of tested cells. Conversely, the antimuscarinic agent scopolamine antagonized the excitatory actions of salsolinol, but not those of met-enkephalin, in some HPC pyramidal cells.

These results show that acutely applied ethanol or salsolinol elicits a spectrum of neuronal effects in brain similar to that for opiates; namely inhibition of activity in several tested brain areas, but excitation in hippocampus. A fair percentage of these excitatory effects are antagonized by naloxone. However, the occasional non-specific effects of naloxone and the puzzling antagonism of the ethanol- or salsolinol-induced excitations by scopolamine cast doubt as to the opiate-like actions of these substances. Also, intracellular studies in the HPC slice (Pittman and Siggins, this volume) indicate that ethanol mechanisms are far more complex than for activation of opiate receptors. Supported by NIAAA (AA-03119 and AA 03504).

262.3 ETHANOL HAS MULTIPLE ACTIONS ON ELECTROPHYSIOLOGICAL PROPERTIES OF HIPPOCAMPAL (HPC) PYRAMIDAL NEURONS IN VITRO. Q.J. Pittman and G.R. Siggins. A.V. Davis Center and Alcohol Research Center, The Salk Institute, La Jolla, CA 92037.

The sequelae of alcohol ingestion indicate interactions with the CNS. This possibility is supported by reports of ethanol (EtOH)-induced alterations of EEG and single-unit activity in several brain regions, including HPC. However, dose-response relationships have not been forthcoming from in vivo work and field potential studies in HPC slices have not revealed significant direct EtOH actions at doses below those that would be fatal in vivo. To clarify this discrepancy we used intracellular recording to determine if directly-applied EtOH might selectively affect individual neurons in the HPC slice.

Hippocampi were quickly removed from 100 g rats and 400 μm transverse slices were cut and placed in a perfusion chamber where they were continuously perfused over both surfaces with warmed (35° C), oxygenated artificial CSF. The inflow system permitted introduction of drug-containing solutions without interrupting the flow of the perfusate.

Slices demonstrating large amplitude, stable field potentials in response to stratum radiatum (SR) stimulation were selected for further investigation. Stable intracellular recordings of 1-4 hrs duration were obtained from 20 CA1 neurons. In 10 of these, EtOH (10-400 mM) caused a slight but repeatable hyperpolarization (1-5 mV) whereas 4 other cells displayed weak depolarizations. Although changes in input resistance (measured by current injection) often accompanied these potential changes no obvious relationship was seen between these two properties. Also no clear relationship emerged between the concentration of ethanol and changes in membrane potential or resistance. The amplitudes of recurrent IPSPs evoked by SR stimulation were decreased in the presence of EtOH in 5 of 10 tested cells and increased in 2. SR-induced EPSPs increased in amplitude in 5 of 12 tested neurons; 3 of these increases were associated with increased input resistance and 2 with a decrease in resistance. Three of the 12 cells displayed decreased EPSP amplitude.

Many cells showed reproducible responses in membrane and synaptic properties to low EtOH concentrations (10-40 mM); nonetheless, many cells did not respond at much higher concentrations. These findings indicate that individual hippocampal neurons display marked differences in their sensitivity and responses to ethanol. This could account for the apparent insensitivity to EtOH shown by field potential studies of the HPC slice. Supported by grants from NIAAA (AA-03119 and AA-03504) and MRC (Canada).

262.4 EFFECT OF ETHANOL DEPENDENCE AND WITHDRAWAL ON GABA RECEPTOR BINDING IN RAT BRAIN. L. Volicer and T. M. Biagioni*. Edith Nourse Rogers Memorial Veterans Hospital, Bedford, MA 01730.

Altered binding of neurotransmitters to their receptors participates in mechanism of action of several psychoactive drugs. Since there is considerable evidence indicating that ethanol affects GABA-ergic system, we investigated the effect of chronic ethanol administration on GABA receptor binding.

Ethanol dependence was induced by administration of ethanol three times a day (6-12g/kg/day, per os) for 7 days. Control rats were intubated with water and the ethanol-treated rats were sacrificed 1 hour (dependent) or 16 hours (withdrawn) after the last ethanol dose. Synaptosomal membranes were prepared by differential centrifugation and were frozen and treated with Triton X-100 prior to assay. The membranes were suspended in a sodium free buffer, incubated with ^{3}H-GABA in the presence and absence of mM GABA, and separated on Whatman GF/B filters.

In the cerebral cortex specific GABA binding, determined at 13nM ^{3}H-GABA concentration, was lower in withdrawn rats than in control or dependent animals. This lowering was due to decreased receptor affinity (K_D = 22.41 ± 0.86 vs 12.65 ± 0.60 nM, p <0.001) and was prevented by repeated incubation of synaptosomal membranes with Triton X-100. It occurred also in some dependent rats which exhibited partial withdrawal syndrome between ethanol intubations. Low affinity binding was similar in control and withdrawn rats, but lower in dependent animals. This lowering was due to decreased number of low affinity receptors (0.695 ± 0.175 vs 1.565 ± 0.085 p moles/mg. of protein, p <0.005). In the cerebellum GABA binding, at 13nM ^{3}H-GABA concentration, was not significantly different in control, dependent or withdrawn rats. However, rats which were minimally affected by ethanol administration had higher binding than control or affected rats. In contrast to the ethanol intubation, feeding of rats for 7 or 20 days with a liquid diet containing 35% calories in the form of ethanol did not induce ethanol dependence and did not affect GABA receptor binding determined at 13nM ^{3}H-GABA concentration.

These results indicate that chronic ethanol administration affects both low and high affinity sodium-independent GABA binding. In the cerebral cortex the number of low affinity sites is decreased shortly after ethanol administration and returns to normal during withdrawal. Withdrawal decreases affinity of the high affinity sites possibly by increasing the amount or the binding of an endogenous inhibitor of GABA binding. Changes of GABA binding in the cerebellum indicate that compensatory changes of GABA binding might modify expression of ethanol withdrawal. (Supported by the Veterans Administration)

262.5 ALTERATION OF BRAIN BIOGENIC AMINE LEVELS AFTER CHRONIC ALCOHOL AND LITHIUM ADMINISTRATION. P.A. McGinley* and E.B. Truitt* (Spon: D.C. Riccio), Northeastern Ohio Universities College of Medicine, Rootstown, Ohio 44272

Clinical studies have shown lithium to possibly be effective in reducing recidivism and depressive symptoms in alcoholism accompanied by depression (Kline et. al., Am. J. Med. Sci. 268: 15, 1974 and Merry et. al., Lancet 2:481, 1976). In an effort to find a neurochemical explanation for the observed lithium induced behavioral changes in rats maintained on chronic ethanol, brain area levels of norepinephrine (NE) and dopamine (DA) were measured in rats treated chronically with lithium chloride (1.0 and 1.5 mEq/kg) and ethanol (Lieber-DeCarli liquid diet). Following three weeks of daily injections of lithium chloride or sodium chloride (equimolar concentration; electrolyte control), the animals were maintained on the ethanol diet for seven weeks. Comparisons were made between the lithium-ethanol treated groups and those receiving lithium chloride only, sodium chloride plus ethanol and no treatment. Brains were removed and dissected according to the method of Glowinski and Iverson (Neurochem. 13: 655-69, 1966) into six major areas; cortex, corpus straitum, cerebellum, medulla, hippocampus and midbrain-hypothalmus. Each brain area was analyzed for NE and DA concentration using high pressure liquid chromatography with electrochemical detection (HPLC-EC). Significant changes in NE levels in the corpus straitum and midbrain-hypothalmus were found in the animals treated with lithium and ethanol when compared to all controls. These results corrleate with lithium-induced changes previously found in amphetamine or apomorphine-induced stereotypical behavior and reduction of audiogenic withdrawal seizures (Truitt et. al., Alc. Clin. Exp. Res. 4:231, 1980). These results suggest that lithium may alter the pattern of chronic ethanol-induced behavior and monoamine changes in the brain.

262.6 HISTAMINE ANTAGONISM OF PENTOBARBITAL NARCOSIS AND HYPOTHERMIA. P.W. Kalivas*and A. Horita* (SPON: L.M. Halpern). Depts. of Pharmac. and Psychiat., Univ. of Wash., Sch. Med., Seattle, WA 98195

While a precise physiological function for central histamine (HA) is not defined, data has accumulated indicating that this biogenic amine has neurotransmitter-like qualities. Based upon EEG alterations and circadian fluctuations of central HA, a function in arousal mechanisms has been hypothesized. The pentobarbitalized rat was used to test this hypothesis. Prior to testing, male S.D. rats were bilaterally implanted with guide cannulae in the lateral ventricles. At least 7 days following surgery, animals received 45 mg/kg pentobarbital (PB), given i.p. Twenty min later animals received intraventricular (icv) injections of HA dissolved in buffered saline (pH 6.0-7.0) or buffered saline alone. Doses of 5-25 ug significantly shortened the duration of PB narcosis. Doses as low as 0.1 ug caused a significant attenuation of PB hypothermia. These effects of HA were not associated with changes in brain or plasma levels of C^{14}-PB or its metabolites. While neither H_1 nor H_2 antagonists blocked the analeptic response when given alone, 10^{-7}M cimetidine plus 10^{-7}M chlorpheniramine given icv 10 min prior to $3.4X10^{-8}$M HA (5 ug) were effective. In addition, a number of brain sites were examined for sensitivity to microinjection of HA. While the medial hypothalamic injections (5 ug/0.5 ul/60 sec) elicited the greatest analeptic response, a number of medial diencephalic and septal injection sites demonstrated sensitivity. Interestingly, the interpeduncular nucleus was very sensitive to HA antagonism of PB hypothermia, but insensitive to HA induced arousal.

262.7 INTERACTION OF BARBITURATES WITH BRAIN MEMBRANES. R. Adron Harris and F. Schroeder. Truman V.A. Hospital and Department of Pharmacology, University of Missouri School of Medicine, Columbia, Missouri 65212.

Effects of barbiturates on the physical properties of synaptic plasma membranes (SPM) and myelin prepared from mouse brain were studied after incorporation of fluorescent probes. Absorbance-corrected fluorescence output (CO), polarization of fluorescence (P) and membrane absorbance (AB) were determined (JBC 251:6747, 1976; BBA 511:356, 1978). Diphenylhexatriene (DPH) was used to monitor the hydrophobic membrane core while 1-aminopyrene (1-AP) was used to probe the membrane surface. In vitro addition of pentobarbital (0.1 to 1.0 mM) decreased the polarization (P) of DPH in SPM but did not affect P of DPH in myelin. Lipids were extracted from SPM and phospholipids were separated by silicic acid chromatography. Vesicles prepared from the total lipid extract of SPM were not affected by pentobarbital. However, the P of DPH was increased by pentobarbital in vesicles prepared from SPM phospholipids. Membrane rigidity, as determined by P of DPH, followed the order: intact SPM>total lipid>phospholipid. These results suggest that barbiturates fluidize the more rigid membranes (or membrane domains) yet increase the rigidity of very fluid membrane areas. This postulate was supported by results from experiments in which membrane fluidity and barbiturate effects were altered by changes in temperature. The fluorescence of 1-AP bound to SPM was not affected by pentobarbital, indicating that the predominant effect of the drug involves the hydrophobic core of the membrane. The effect of barbiturates on P of DPH in SPM was stereoselective as the R(+) isomers of pentobarbital and secobarbital were more potent than the S(-) isomers. P was decreased by R(+)-pentobarbital at concentrations as low as 45 μM. Barbiturates also decreased CO of DPH and membrane AB. These effects were not stereoselective and were found with both myelin and SPM. These effects probably reflect changes in membrane physical properties other than fluidity (e.g. polarity, refractive index, membrane thickness). In summary, barbiturates appear to fluidize the hydrophobic inner core of synaptic membranes. This effect is stereoselective and is not found with myelin membranes. Barbiturates also alter other membrane properties, but these effects are not selective for synaptic membranes or for the optical isomers. The fluidization of synaptic membranes by barbiturates, which is similar to that produced by ethanol (Fed. Proc. 39:745, 1980), may produce alterations in synaptic transmission which are ultimately expressed as barbiturate intoxication. (Supported in part by funds from the Medical Research Service of the Veterans Administration, the National Cancer Institute (CA24339), and the American Heart Assoc.(78-734)

262.8 THE EFFECT OF LESIONS IN THE DORSAL AND MEDIAN RAPHÉ NUCLEI ON THE DEVELOPMENT OF TOLERANCE TO ETHANOL-INDUCED HYPOTHERMIA. A.D. Lê*, J.M. Khanna, H. Kalant* and A.E. LeBlanc*. Dept. of Pharmacology, Univ. of Toronto, Toronto, Canada M5S 1A8, and Addiction Research Foundation of Ontario, Toronto, Canada M5S 2S1.

Previously we have reported that general manipulation of whole brain serotonin (5-HT) plays a role in the development of ethanol tolerance (Psychopharmacology, 67:143-146, 1980). In this study, we examined specific 5-HT pathways to further elucidate the role of 5-HT in ethanol tolerance. Electrolytic lesions were made in the median (n = 18), the dorsal (n = 18) and the dorsal plus median (n = 18) raphé nuclei of rats. A fourth group (n = 18) of sham-operated animals was also prepared. After one week of recovery from surgery, each group was tested with a standard test dose of ethanol (3 g/kg). Rectal temperatures were determined by means of a telethermometer fitted with a YSI recorder. The temperature was monitored at 0, 30, 60 and 90 min with a probe inserted 5 cm into the rectum. The maximum fall in temperature (ΔT max) was used to quantify the ethanol effect. The animals in each main treatment group were then divided into two subgroups matched on the basis of their maximum hypothermic response, and were designated to receive either daily treatment with ethanol (5 g/kg, p.o.) or calorically equivalent amount of sucrose. Tolerance to the ethanol-induced hypothermia was assessed at intervals of 5 days for 30 days.

Lesions of the dorsal raphé nucleus produced a negligible effect on the development of ethanol tolerance. Lesions of the median raphé nucleus delayed the development of tolerance. Combined lesions of the median plus dorsal raphé nuclei did not significantly increase the effect produced by the lesions of the median raphé nucleus alone. Biochemical analysis confirmed the differential depletion of 5-HT by the various lesions. These results indicate that the 5-HT pathway originating from the median raphé nucleus is important in the development of tolerance to ethanol.

262.9 DISCRIMINATIVE STIMULUS PROPERTIES OF ETHANOL: THE ROLE OF ACETALDEHYDE AND THP. Shippenberg, Toni S.*, Amirian, James H.*, Altshuler, H. L. Department of Neuropsychopharmacology, Texas Research Institute of Mental Sciences and Department of Pharmacology, Baylor College of Medicine, Texas Medical Center, 1300 Moursund, Houston, Texas 77030.

Ethanol (ALC) serves as a discriminative stimulus (DS) for rats in a double lever drug discrimination (DD) paradigm at doses of 0.6 gm/kg or greater. Our previous studies demonstrate that animals trained to discriminate intraperitoneally (IP) administered ALC from IP saline (SAL) are unable to perform that discrimination following central administration. This study evaluated the contribution of acetaldehyde and a tetrahydroisoquinoline (TIQ), tetrahydropapaveroline (THP) to the DS properties of ALC. 95 male Sprague Dawley rats ranging in weight from 300-450 gms. were subjects in these studies. The animals were shaped to perform ALC-SAL DD in a double lever discrimination paradigm on a DRL-10 reinforcement schedule following either intraperitoneal (IP) or central intraventricular (ICV) dosage. ICV testing of the DS properties of ALC confirmed our previous finding that ICV ALC (1.0 - 1500 μg) does not serve as a DS in rats trained to discriminate IP ALC from IP SAL. Further acetaldehyde (AcALD) administered either centrally (0.05 - 10.0 mg) or peripherally (1.0 - 50.0 mg) does not generalize to ALC in animals trained with IP ALC. A second group of rats were trained to discriminate centrally administered ALC from centrally administered SAL. Although 250 μg ALC is an effective DS, these experiments revealed that the period of training required to establish ALC as a central DS exceeds the usual functional life of the intraventricular cannula. The results of central training were highly variable. The stimulus properties of THP were assessed in IP ALC trained rats. THP was not found to be an effective DS in that group, although the results were highly variable. The results of these studies confirm our earlier studies that the DS cue associated with ALC does not appear to be mediated centrally. These data strongly suggest that the DS property of ALC is a peripheral phenomenon resulting from the irritating effects of ALC following IP dosage.

263.1 PURIFICATION OF CALMODULIN FROM MAMMALIAN NERVE. Z. Iqbal and S. Ochs. Dept. of Physiology and Medical Biophysics Indiana University School of Medicine, Indianapolis, IN 46223 USA

Calmodulin, a calcium-binding protein, has been shown to activate a wide range of enzymes with low levels of Ca^{2+} present. These include cyclic nucleotide metabolizing enzymes, protein kinases and Ca-Mg-ATPase. It participates in the dissociation of microtubules and could be involved directly in the mechanism underlying axoplasmic transport. It is present in mammalian nerve (Iqbal and Ochs, J. Neurobiol. 11:311-318, 1980) and it activates tubulin associated Ca-ATPase (Ochs and Iqbal, These Proceedings). In this communication we describe a simple procedure for the purification of calmodulin from mammalian nerve. Frozen dog nerves were boiled and homogenized in a 10 mM Tris HCl-buffer at pH 7.5 containing 0.1 mM each of 2-mercapto-ethanol and ethylene glycol-bis-(B-aminoethyl ether) N,N'-tetra acetic acid (EGTA) (buffer A). The heat stable proteins remaining in the supernatant after centrifugation at 50,000 x g for 30 min were subjected to 50% saturation with $(NH_4)_2SO_4$. The proteins soluble in 50% saturated $(NH_4)_2SO_4$ were separated by centrifugation and brought to a pH of 3.5 with acetic acid and the contents centrifuged to isolate precipitated proteins. The pellet was solubilized by dilution and by increasing pH to 7.5 and dialyzed extensively against buffer A. Final purification of the calmodulin was performed by affinity chromatography on Sepharose-4B columns using 2-chloro-10 (3-aminopropyl) phenothiazine hydrochloride (CAP) as a ligand employing the procedure of Jamieson and Vanaman (Biochem. Biophys. Res. Commun. 90:1048, 1979). Calmodulin binds to CAP in the presence of Ca^{2+} and it can be eluted from the column with EGTA containing buffers. The identification of the calmodulin in the various fractions eluting from the column was performed by the activation of calmodulin-dependent cyclic nucleotide phosphodiesterase (PDE) isolated either from cat brain or dog nerve. The yield of calmodulin obtained after affinity column chromatography was determined by protein estimation (Lowry's method) to be approximately 1 mg/100 g of frozen dog nerves. Purification of the calmodulin was shown by a single protein band on 12.5% acrylamide gels containing SDS and by thin layer isoelectrofocusing on acrylamide gels. Submicromolar concentrations of the purified calmodulin were able to activate PDE to half maximum level and the activation was prevented by trifluorperazine, also in submicromolar levels. Supported by NIH RO1 8706-11, NSF BNS 79-14029 and the MDA.

263.2 N-METHYLATION OF CALMODULIN IN BRAIN EXTRACTS. A. Sitaramayya*, T.J. Murtaugh*, L.S. Wright* and F.L. Siegel. Depts. of Pediatrics and Physiological Chemistry, University of Wisconsin, Madison, WI 53706.

Calmodulin (CaM) has considerable amino acid sequence homology with troponin C (TnC), but whereas TnC is not methylated CaM contains a simple residue of trimethyllysine (TML), and has also been reported to undergo carboxymethylation; the significance of calmodulin methylation is not known. Brain extracts incubated with S-adenosyl-L-(^{3}H-methyl)-methionine methylate several peptides, the major products having molecular weights of 17K and 35K daltons. Electrophoresis in SDS and native gels in the absence and presence of 2mM EGTA confirm the identity of the 17K peptide as calmodulin. Treatment of the in vitro methylation products with base prior to assay removes carboxymethylase groups, allowing one to estimate N-methylation. The enzyme responsible for the N-methylation of calmodulin has been partially purified and characterized; trimethyllysine has been shown to be the amino acid residue of CaM formed by the action of this enzyme, calmodulin lysine N-methyltransferase (CLNMT). CLNMT is present in brains of all mammals studied but is absent in both electroplax of E. electricus, a tissue particularly rich in CaM, and in other primitive animals and plants. Supported by NS 11652.

263.3 EVIDENCE THAT ACTIN-LIKE PROTEIN 'C' IS PHOSPHORYLATED PRESYNAPTICALLY. R. Hofstein* and M. Hershkowitz. Isotope Department, The Weizmann Institute of Science, Rehovot, Israel.

An actin-like protein named protein 'C', was identified in synaptosomal plasma membranes and found to be phosphorylated under control of calcium and magnesium (Hershkowitz, M., Biochim. Biophys. Acta, 542: 274, 1978; Hofstein R., et al. Biochim. Biophys. Acta, in press). It was proposed that the phosphorylation of protein 'C' is a step in neurotransmitter release. To test this possibility we investigated whether during development, there is correlation between the appearance of presynaptic terminals and the phosphorylation of protein 'C'. On the first day of life, protein 'C' is already present in synaptosomal plasma membranes but it does not undergo detectable phosphorylation until the third day of life. Its maximal phosphorylation is evident by the second week of life. 6-hydroxydopamine (6 OHDA) was used to test whether protein 'C' is localized presynaptically. Intraventicular injection of 6 OHDA into adult rats led to a selective reduction of the phosphorylation of protein 'C' by 30% and 20% in hippocampus and cortex, respectively.

Subcutaneous injections of 6 OHDA into neonatal rats, led to the following changes in the hippocampus: a) reduction by 90% of ^{3}H-noradrenaline (NA) uptake; b) enhancement by 90% in the binding of ^{3}H-dihydroalprenolol (DHA); and c) specific reduction of 60% in the phosphorylation of protein 'C'.

On the other hand, in the brain stem the following changes were observed: a) increase by 16% in the uptake of ^{3}H-NA; b) decrease by 20% of the binding of ^{3}H-DHA and c) increase in the phosphorylation of protein 'C' by 30%.

These results indicate that the phosphorylation of protein 'C' is correlated with the appearance of presynaptic terminals and with their integrity.

263.4 INCORPORATION OF ^{3}H-AMINO ACIDS INTO AXONAL PROTEIN OF DECENTRALIZED AND INTACT AXONAL FIELDS OF GOLDFISH RETINAL EXPLANTS. E. Koenig and P. Adams*. Div. Neurobiology, Dept. Physiology, SUNY/Buffalo, N.Y. 14214.

The goldfish retinal explant system, developed by Landreth and Agranoff (Brain Res., 118:299-303, 1976), is a favorable in vitro system to study the question of endogenous protein synthesizing activity of regenerating vertebrate axons. The explant produces retinal ganglion cell axon fasicles free of ensheathment and non neural cells that extend several mm out from the explant. Incorporation of ^{3}H-amino acids into axonal protein can be assessed in either isolated decentralized fields or in axons retaining their central connections. Protein content of individual axonal fields was determined by direct quantitative microanalysis, and tritium radioactivity was measured in a low background system (< 1 cpm) after combustion of microsamples. A mixture of ^{3}H-amino acids was used to assess endogenous axonal protein synthesis. ^{3}H-amino acids are incorporated into axonal protein of decentralized fields and the incorporation is inhibited 90% by cycloheximide (1 mM). The presence of unlabelled amino acids at the time axons are severed from the explant suppresses subsequent incorporation for 2-3 hrs. Ca^{++} present in the medium at the time of axotomy, diminishes the rate of protein synthesis progressively. Gel microelectrophoresis of axonal proteins shows evidence of proteolytic breakdown in axons 3 hrs after decentralization. Axons decentralized with Ca^{++} present exhibit much more degradation. On the basis of various agents that block axoplasmic transport, radioactive products from ganglion cells do not begin to appear in axonal fields for at least 2 hrs. Preliminary studies with the intact explant system show that Co^{++} (1.8 mM) blocks incorporation into retinal ganglion cells (90%), without affecting incorporation into axonal protein significantly. These studies indicate that optic nerve axons of the goldfish regenerating in culture are capable of endogenous protein synthesizing activity in both the intact and decentralized states.

Research was supported by grants NS 04656 and BNS 77-24886.

263.5 THE PREPARATION OF BIOLOGICALLY ACTIVE MESSENGER RNA FROM HUMAN POSTMORTEM BRAIN. J.M. Gilbert, B.A. Brown,* P. Strocchi,* E.D. Bird and C.A. Marotta. Laboratories for Psychiatric Research and The Lowell Laboratories, Mailman Research Center, Harvard Medical School, McLean Hospital, Belmont, MA 02178.

Messenger RNA (mRNA) was extracted from two specimens of human postmortem brain tissue by alkaline phenol extraction of polysomes followed by oligo (dT)-cellulose chromatography. The mRNA preparations stimulated protein synthesis in a cell-free system containing wheat germ homogenate. The products of protein synthesis were analyzed by one- and two-dimensional gel electrophoresis. These analyses indicated that numerous polypeptides were synthesized by the human mRNA including tubulin subunits and actin isomers. The molecular weight range of polypeptides synthesized by human mRNA fractions from two brains were identical; and analysis by two-dimensional gel electrophoresis indicated qualitatively similar products. The yield of mRNA extracted per gram of human tissue was less than the yield obtained with rat forebrains from animals sacrificed immediately before brain removal and mRNA purification. A decrease in the amount of polysomes isolated from human tissue relative to rat brain tissue was a major factor contributing to the low yield. The molecular weight distribution of polypeptides synthesized by human and rat brain mRNA fractions was similar; thus, there was no indication for selective breakdown or inactivation of high molecular weight mRNA species in the human tissue. Our studies indicate that it is possible to utilize postmortem tissue for molecular biological investigations of human brain mRNA.

263.6 CHANGES IN GENE EXPRESSION DURING CEREBELLAR DEVELOPMENT IN THE RAT. S.L.BERNSTEIN*,A.E.GIOIO*,and B.B.KAPLAN. Dept. Anatomy, Cornell University Medical College, New York, NY. 10021

The cerebellum (Cb) of the Norway rat, Rattus norviegicus, was selected as a model for development of the central nervous system. Alterations in gene expression during postnatal development were evaluated by RNA driven hybridization of radiolabeled single-copy DNA to (a) total cellular poly(A+)RNA, reflecting the complexity of poly(A+)hnRNA (b) poly(A+)mRNA, and (c) polysomal poly(A-)RNA. Total poly(A+)RNA from whole brain was used as an internal hybridization standard.

Total cellular RNA from adult whole brain and Cb at several ages was isolated by the guanidinium thiocyanate/CsCl method (Kaplan, et.al. Biochem. J. 183,184.1979). Polysomes were obtained by sedimentation through 2.0M sucrose, and residual hnRNA contamination subsequently removed by velocity sedimentation in sucrose density gradients. Polyadenylated RNA was obtained from all RNA fractions by affinity chromatography on oligo(dT)-cellulose.

Whole brain total poly(A+)RNA hybridized to 12.6±0.8% (±S.E.M.) of the single-copy DNA, a value consistent with that reported by Kaplan, et.al. (Biochemistry 17, 5516. 1978). Assuming asymmetric transcription, the sequence complexity of total poly(A+)RNA was $4.8X10^6$ nucleotides (nt), a value equivalent to 106,000 different hnRNA transcripts 4500 nt in length. The percentage single-copy DNA expressed as total poly(A+)RNA declined from 12.6±0.7% in the neonate Cb to 10.5±0.4% in the adult ($p<0.05$). Data from mixing experiments containing 3d and 60d total poly(A+)RNA reveal extensive homology (>90%) in the sequences present in these RNA populations. Hybridization values of poly(A+)mRNA from neonate and adult Cb declined from 4.8±0.2% to 4.1±0.2%, respectively ($p<0.01$), a loss equivalent to 15,000 different poly(A+)mRNAs 1800 nt in length. Polysomal poly(A-)RNA was hybridized to R_ot values $> 1.0X10^5$ M Sec. The percentage of single-copy DNA expressed by this RNA class reflects the sequence complexity of the nonadenylated mRNAs (Chikaraishi,D.M.,Biochemistry 18,3249.1979; Van Ness, et.al. Cell 18, 1341.1979). Values for neonate and adult poly(A-)mRNA were 3.4±0.2% vs 3.6±0.2%, respectively. Hybridization to R_ot values $>2.5X10^5$, generated by longer incubation times (>7d) or higher RNA concentrations (>28mg/ml) did not increase apparent saturation values.

The results of this study indicate that (1) the base sequence complexity of cerebellar poly(A+)hnRNA and poly(A+)mRNA decrease significantly during postnatal development, and (2) the age-related alterations appear restricted to specific RNA populations.

(This work supported by NIH grant HD11392.)

264.1 URINE INDUCES CHANGES IN CONCENTRATIONS OF LH-RH AND CATECHOLAMINES (CA) IN THE ACCESSORY OLFACTORY BULB OF FEMALE PRAIRIE VOLES. D. Dluzen, S. Carter-Porges, L. Getz and V.D. Ramirez. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

We previously demonstrated that in rat and vole olfactory bulb, LH-RH is preferentially localized in the accessory (AOB) compared to the main (MOB) olfactory bulb. It was, therefore, of interest to measure concentrations (pg/mg) of LH-RH, dopamine (DA) and norepinephrine (NE) in these structures of female prairie voles (Microtus ochrogaster) following stimulation with conspecific male urine. Approximately 200 µl of urine from sexually experienced males or distilled water was applied onto the upper lip of females (N=7/group) who were decapitated at 1, 30, or 60 min following stimulation. Olfactory bulbs were removed, divided into main and accessory components and unilateral halves were either extracted in 0.1N HCl for LH-RH RIA or in 0.1N $HClO_4$ for CA radioenzymatic assay. In addition, blood was collected for LH RIA. In both urine and water treated females a significantly ($p<.001$) greater concentration of LH-RH was obtained in the AOB (16.4±1.5) vs MOB (5.9±0.4). A slight increase in LH-RH at 30 vs 1 min and a significant ($p<.05$) increase at 60 min limited to the AOB was obtained in urine stimulated females (13.1±1.3, 16.3±3.5, 25.3±5.6). No significant changes were obtained from MOB extracts of these females at 1, 30, or 60 min (6.7±1.3, 6.1±0.8, 8.1±1.5) nor did water treated females demonstrate time dependent changes in either the MOB (4.5±6.1, 4.2±0.3, 5.5±2.1) or AOB (16.9±4.5, 12.5±1.4, 14.3±2.9). One minute following urine or water stimulation NE concentrations in the AOB of both groups were higher than those of the MOB (170±16, 167±12 vs 116±32, 98±16, respectively). A significant ($p<.05$) time effect on NE concentration was observed in the urine stimulated group and limited to the AOB, with maximal depletion of 44% at 60 minutes. No difference between AOB and MOB DA concentrations were obtained, nor did DA in either structure vary as a function of time following stimulation. Using 50 µl samples, no detectable serum LH values were obtained at any interval for water treated females, while 43%, 29%, and 0% of the females treated with urine demonstrated detectable LH levels at the 1, 30, and 60 minute intervals, respectively. These results confirm that olfactory bulb LH-RH in the female vole is preferentially localized in the AOB and demonstrate a time dependent and stimulus specific response to conspecific male urine limited to the AOB. Similarly, a time dependent and stimulus specific response for NE, also limited to the AOB was observed, while DA fails to demonstrate this phenomenon. It would appear that olfactory/gustatory cues contained in male urine capable of producing changes in female serum LH levels may be mediated by direct stimulation of AOB LH-RH neurons possibly under NE control.

264.2 ANTAGONISTIC ANALOGS OF LHRH: SUPPRESSION OF LORDOSIS BEHAVIOR IN RATS. C.A. Dudley*, W. Vale, J. Rivier, R.L. Moss. Department of Physiology, Univ. of Texas Southwestern Med. Sch., Dallas, Tex. 75235 and Neuroendo. Dept., Salk Institute, 10010 N. Torrey Pines Rd. La Jolla, CA 92037.

Peptide analogs of luteinizing hormone-releasing hormone (LHRH) which have a variety of characteristics including extended duration of action, higher potency and antagonistic activity, may provide a tool for investigating the physiological role of LHRH as a modulator of extra-pituitary function. The present experiment was designed to test the effect of two antagonistic analogs as well as an antibody to LHRH on estrogen-progesterone induced mating behavior. A total of 60 female rats were ovariectomized and implanted with 23 guage stainless steel cannulae positioned in the third ventricle. The animals were primed with estrone (E; .20 mg) and progesterone (P; 2.5mg) and tested for lordosis behavior prior to entering the infusion stage of the experiment (mean lordosis-to-mount ratio (L/M)=.91±.08). Subsequently, the animals were randomly divided into two groups, primed with E at 0 hr, and then at 43 hr simultaneously primed with P and infused with either µl saline (S) or one of the following experimental drugs: 1)(D-pGlu; D-Phe^2, D-Trp^{3,6}) LHRH antagonist ($LHRH_1$) 50 ng in 1µL saline; 2) An antibody to LHRH (LHRH-Ab) 1µL diluted 1:10 in saline; 3) (Ac-dehydro-Pro^1, pCl-D-Phe^2, D-Trp^{3,6}) LHRH antagonist ($LHRH_2$) 100 ng in 1µL saline. Animals were tested for lordosis behavior at 48 hr. Ten days elapsed between infusion tests so a period of 60 days was required for the animals to receive S paired with each experimental agent in counterbalanced order. The L/M ratios of the S and drug-treated groups were compared by matched-pair t-tests.

LHRH-Ab had no effect on lordotic responding. This result may indicate that insufficient amounts of LHRH were bound up by the antibody, enabling the remaining LHRH to exert an effect. However, both of the antagonists suppressed lordotic behavior as compared to their S controls. $LHRH_1$ yielded a mean L/M of .45 ± .05 while the mean for the S controls was .60 ± .06 ($t=2.52$; $v=52$, $p<.02$). The decrement in mating behavior produced by $LHRH_2$, a long-acting antagonist, was even more dramatic. The mean L/M for this antagonist was .41±.05 while the S infused animals produced a mean of .88±.03 ($t=8.47$; $v=35$, $p<.01$). Thus, antagonistic analogs of LHRH, which act at the pituitary level to block gonadotropin release and ovulation, were also successful in blocking a CNS-mediated behavioral event, namely, lordosis responding. These results provide additional evidence for the role of endogenous LHRH as a physiological modulator of sexual receptivity.

264.3 THE SUPPRESSION OF COPULATORY BEHAVIOR IN MALE RATS WITH ECTOPIC PITUITARY GRAFTS: ROLE OF PROLACTIN. P.C. Doherty*, A. Bartke* and M.S. Smith*. (SPON: V.F. Williams). Depts. of Anat. and Ob./Gyn., University of Texas Health Science Center, San Antonio, TX 78284, and Dept. of Physiol., University of Pittsburgh, School of Medicine, Pittsburgh, PA 15261.

We have recently reported that hyperprolactinemia induced by grafting whole pituitaries under the kidney capsules suppresses copulatory behavior in male rats and mice (Svare et al., Biol. Reprod., 21:529, 1979). Whole rather than anterior pituitaries were used because it has been reported that they produce higher serum prolactin (PRL) levels (Aguado et al., J. Endocrinol., 72: 399, 1977). Numerous studies have indicated that ectopic pituitaries may produce significant amounts of hormones other than PRL and this may be especially true of whole pituitary grafts. Thus we decided to determine whether the suppressive effects of pituitary grafts on copulatory behavior are the result of high circulating levels of PRL. Adult sexually experienced male CD-F rats were given four whole pituitary grafts, four anterior pituitary grafts, or were sham-operated. Adult females of the same inbred strain served as pituitary donors. Tests of copulatory behavior were begun two and one half weeks after surgery. Males were placed in observation chambers with ovariectomized females made receptive by injection of estrogen and progesterone, and were scored for mount latency, number of mounts, intromission latency, number of intromissions, ejaculation latency, and number of ejaculations. Each test lasted thirty minutes. Both groups of grafted animals exhibited suppressed copulatory behavior patterns, but these effects were more striking in the animals which received only anterior pituitary grafts. Whole pituitary grafted animals had significantly longer latencies to mount ($p < 0.05$) and to intromit ($p < 0.01$) than the sham-operated controls, while the anterior pituitary grafted animals differed from the sham-operated controls in latencies to mount ($p < 0.05$) and to intromit ($p < 0.01$), as well as in the number of mounts ($p < 0.05$) and intromissions ($p < 0.05$). Treatment of sexually experienced male CD-F rats with ovine PRL (400 µg, 2X daily in a 50% polyvinylpyrrolidone-saline vehicle) also resulted in deficits in copulatory behavior. The oPRL treated animals showed a significant decrease in the number of intromissions ($p < 0.02$) as compared to the vehicle treated control animals. The intromission latency was also increased in the PRL-treated group to twice the value of the control group, however this did not prove to be significant ($0.10 > p > 0.05$). In summary, despite possible release of other behaviorally active compounds from the whole pituitary grafts, the behavioral deficits observed in grafted animals are probably the result of chronically high PRL levels. (Supported by HD-12671).

264.4 SEXUAL BEHAVIOR AND DECIDUALIZATION OF THE FEMALE ZUCKER RAT. A.M. Chelich* and E.S. Edmonds. Northwest Center for Medical Education, Indiana University School of Medicine, Gary, Indiana 46408.

The female genetically obese Zucker rat has been described as uniformly sterile (Zucker and Zucker, J. Hered., 52:275-278, 1961). It has been reported (Saiduddin et al., Endo., 93:1251-1256, 1973) that obese females become pseudopregnant following reserpine treatment but not following cervical stimulation, that uteri of pseudopregnant obese females do not decidualize in response to uterine trauma, and that obese females do not lordose. We have previously found that cervical stimulation does induce pseudopregnancy in obese females. To determine whether cervically stimulated pseudopregnant obese females decidualize, 0.1 ml of sesame oil was introduced into the lumen of one uterine horn on the fourth day of pseudopregnancy in five obese and six lean Zucker rats. Uteri were examined and weighed on the ninth day of pseudopregnancy. All obese and lean rats decidualized. The mean weight of the decidualized horns was 1639 ± 319(SEM) and 1449 ± 165 mg and the control horns weighed 232 ± 10 and 151 ± 16 mg for obese and lean rats respectively, except for the control horn of one obese rat which spontaneously decidualized and weighed 490 mg. Sexual behavior was tested twice in eight fat and nine lean females, 2 to 7 months of age. Proestrus obese females were placed with intact males and proestrus lean females with vasectomized males for 20 minutes or until ejaculation occurred. Solicitation (darting and hopping) occurred in all sessions with lean rats and in 12 out of 16 sessions with obese rats. Lean rats did not exhibit rejection (kicking or rolling over) but fat rats rejected in 2 out of 16 trials. In lean rats, lordosis occurred in all sessions with a lordosis quotient of 100%. Contrary to the literature, obese females also exhibited lordosis. All fat rats lordosed during at least one session. Lordosis was observed in 12 out of 16 sessions and occurred during 100% of the mounts except in one trial when it occurred with 68.7% of the mounts. Ejaculation occurred in all trials with lean females but in only 3 out of 16 trials with obese females even if the obese females were left overnight with the males. Of the three successful trials two resulted in pregnancy and one in at least pseudopregnancy. These results suggest than an inability to decidualize (prepare the uterus for implantation) is not a factor contributing to the reduced reproductive capacity of the obese female Zucker rat. Our data also indicate that sexual behavior is inadequate to insure ejaculation but that it is not inadequate because of an absence of solicitation or lordosis.

264.5 EFFECTS OF STEROID ANTAGONISTS ON RAT SEXUAL BEHAVIOR. I.T. Landau. Dept. Psychology, Oakland Univ., Rochester, MI 48063

An initial series of experiments assessed whether the ability of the anti-estrogen, CI-628, to inhibit estrogen stimulated lordosis in ovariectomized adult rats depends upon its interference with the synergistic effects of estrogen with progesterone (P). Thus, the ability of CI-628 to inhibit lordosis was contrasted in ovariectomized rats brought into estrous by (a) a single injection of estradiol benzoate (EB) (2 µg) followed by a single injection of P (500 µg) 48 hours later vs. (b) a series of 4 daily EB injections (without any P). CI-628 (2 mg) substantially and equally effectively antagonized lordosis responding in both conditions, demonstrating an effect of CI-628 in the absence of exogenously administered P. Related studies suggested that CI-628's effectiveness was not dependent upon the subsequent daily EB injections acting as a progestin mimic or upon the influence of progesterone of adrenal origin. Implications of these results for attempts to inhibit androgen-stimulated male sexual behavior by CI-628, and the importance of androgen to estrogen metabolic conversions (aromatization), are discussed.

In a subsequent experiment, possible facilitatory effects of the aromatization inhibitor, 1,4,6-androstatriene-3,17-dione (ATD), on male sexual behavior were evaluated. ATD is typically proposed to antagonize the effect of testosterone propionate (TP) on sexual behavior, by inhibiting the behaviorally significant metabolic conversion of androgen to estrogen. In this study, castrated male rats were treated with daily injections of either ATD or the control vehicle, in combination with TP (50 µg), EB (25 µg), or sesame oil, for four weeks after castration, receiving weekly tests of sexual behavior with a receptive female. It was found that a high dose (10 mg) of ATD alone was sufficinet to maintain precastration levels of sexual behavior, equaling or exceeding scores of the TP controls. This dose of ATD also did not inhibit the stimulatory effect of TP on sexual behavior. This was true despite a lack of either a facilitatory or antagonistic effect of ATD on seminal vesicle weight. Results are discussed in terms of implications for the "aromatization hypothesis," possible central nervous system action of ATD, and possible qualitative differences in the mediation of androgenic effects in neural vs. peripheral target tissues. Related studies evaluated the interactive effects of CI-628 and the non-steroidal antiandrogen, flutamide, in the inhibition of androgen-stimulated male sexual behavior.

264.6 ECLOSION HORMONE: DEVELOPMENTAL TITERS AND ITS ROLE IN ECDYSIS. P. F. Copenhaver*, N. Tublitz*, P. M. Taghert*, and J. W. Truman (SPONS: T. Kennedy). Dept. of Zool, Univ. of Washington, Seattle, WA 98195.

Eclosion hormone (EH), an 8500 dalton peptide hormone which triggers adult emergence in Manduca sexta, has also been found to initiate pupal ecdysial behavior in this species (Truman, Taghert, and Reynolds (1980) J. Exp.Biol. in press). Recently we have been interested in the role of EH in the initiation of larval ecdysis behavior. EH injections into late fourth instar larvae successfully elicits premature ecdysial behavior in a dose and time dependent manner analogous to that seen under similar conditions in pupal ecdysis. An analysis of the blood of ecdysing larvae has demonstrated the presence of EH in significant levels shortly before the onset of ecdysial behavior, paralleling the time course of blood titres of EH in ecdysing pupae. In addition, measurements of the concentrations of EH in the brain and abdominal nerve cord (ANC) of pre- and post-ecdysis animals, using a biological assay, show a significant depletion of EH from the ANC while no similar change in brain concentrations is seen.

Since this evidence suggests that the release of EH is the critical trigger for both larval and pupal ecdyses as well as adult eclosion, we have measured the EH content of the brain and ANC throughout the life cycle of Manduca to determine its synthesis and release profile. Our results suggest that during development there appears to be a coordinated synthesis of these two pools of EH. However, release appears to be independently regulated. On the basis of gel filtration and isoelectric focusing, EH isolated from the brain is indistinguishable from that found in the ANC. Our data indicate that the strictly developmental events of larval and pupal ecdyses are triggered by the release of the peptide from the ANC, whereas adult eclosion, which is strongly gated by a circadian oscillator, is initiated by EH released from the endocrine center of the brain. Thus, there is an apparent correlation between the site of EH release and type of control over the ecdysial event.

264.7 NEUROENDOCRINE AND HISTOLOGICAL EVIDENCE FOR DIFFERENT ADRENAL GLAND RESPONSE PATTERNS IN DOMINANT AND SUBORDINATE JAPANESE QUAIL. D. L. Ely, F. S. Orcutt,* Jr., and F. Sadri.* Dept. of Biology, University of Akron, Akron, OH 44325.

In a previous study we have found that dominant colony mice have predominantly a sympathetic adrenomedullary response pattern to environmental stimuli, whereas subordinate mice respond with a pituitary adrenocortical pattern (Hor. and Behav., 10: 156-169, 1978). Using this model we replicated the study in Japanese quail (Corturnix corturnix japonica). Thirty male quail (4-8 months) were housed 5 nonsiblings to a group in 6 hardware cloth (1/2") cages (63 x 63 x 43 cm) in an environmental chamber (24-25°C, 14 hrs L, 10 hrs D). Behavior was observed 3x/week for each group for 30 min., and a ratio was calculated for pecks given/pecks received per bird for dominance determination. Subordinate animals showed significantly higher levels of plasma corticosterone during weeks 1 and 2 as compared to dominants (21 ug% vs. 14 ug%, $p<.01$, and 22 ug% vs. 11 ug%, $p<.05$). Dominant animals showed significantly higher ratios of adrenal chromaffin cells (CC) to steroidogenic cells (SC) ($p<.02$). Also the dominant males showed higher levels of seminiferous tubule activity ($p<.05$) and less myocardial fibrosis ($p<.05$) as compared to subordinate males. There were no differences in tissue weights or cloacal gland area between dominant and subordinate animals. Between colony comparisons showed that the more socially stable colonies had twice the adrenal weights of the unstable colonies. The stable colonies showed a peak corticosterone response the first week which declined until the 5th week whereas the unstable colonies showed a peak corticosterone response the 2nd which declined to the 6th week. There were no between colony histological differences with regards to CC/SC, heart fibrosis, or seminiferous tubule activity. The results suggest that dominant quail respond to social stimulation with a chromaffin cell proliferation similar to a sympathetic adrenomedullary response in mammals. Subordinate quail respond to social stimulation with an adrenal steroidogenic cell proliferation and increased plasma corticosterone similar to a pituitary adrenocortical response in mammals. (Supported in part by Akron University Faculty Research Grant #566).

264.8 STRESS, CORTISOL, TESTOSTERONE AND DOMINANCE RANK IN FREE-RANGING OLIVE BABOONS (PAPIO ANUBIS) R Sapolsky* (SPON: M Krieger) Rockefeller Univ. NY, NY 10021

Studies have shown that variability in baseline or stressed levels of glucocorticoids & androgens is associated with behavioral status. Generally, subordinate rodents & primates have elevated baseline corticosterone & enlarged adrenals while dominants have greater corticosterone responses to stress. Baseline testosterone, studies suggest, is highest in dominants; all subjects show suppression of testosterone by stress. Because behavioral nuances are lost in the laboratory, examination of these questions with feral animals would be fruitful.

Stress responses were studied in adult males of a troop of baboons living in the Mara Reserve, Kenya. Subjects have been observed for 5 years; rank is based on copulations & consortships with adult estrus females in the 6 months preceding the study. Animals were stressed by darting intramuscularly with an anesthetic syringe of Sernylan. Subjects were clearly stressed, showing agitation before becoming unconscious within 5 minutes. Blood samples were then taken at 5,10,15,30 & 60 mins. Darting was done over 2 weeks at 0800 each day; subjects were unaware they were to be darted. RIAs were conducted for cortisol & testosterone.

Cortisol: a stress response was shown, cortisol initially surging, declining by 10 or 15 minutes & then rising gradually thereafter. It is impossible to determine true maximal levels (since in some it occurs before the first sample at the 5 min. mark) or baseline in these stressed subjects; thus it is impossible to determine whether dominants have larger cortisol responses to stress than do subordinates. However, dominants have faster responses: in subordinates (ranks 5,8-12.5; $\bar{m}$= 8.9) cortisol is low at 5 min, surges at 10 & declines by 15. In dominants, (ranks 104,6,7; $\bar{m}$ = 3.8) levels are already their highest at 5 mins. & decline by 10. Baboons with these two different patterns are significantly different & non-overlapping in rank.

Testosterone: marked suppression of testosterone was shown 10 min. after stress; levels rose thereafter. There were several significant rank-related trends in the stress response. Dominance was correlated with high levels of testosterone (measured by the mean & maximum levels of the 5 sera samples taken from each individual). These measures must be considered the best approximations of baseline obtainable under these conditions. In addition, the relative degree of testosterone suppression following stress is significantly rank-related; dominants show the smallest suppression of testosterone by stress. Thus dominant individuals respond to stress with the most rapid secretions of cortisol. In addition, dominants, seemingly with higher baseline testosterone, show relatively less testosterone suppression by stress than do subordinates. (Supported by NIMH Grant MH-27934).

265.1 PERMEABILITY OF ACETYLCHOLINE-ACTIVATED POSTSYNAPTIC CHANNELS IN SYMPATHETIC NEURONS. Doju Yoshikami. Dept. of Biology, Univ. of Utah, Salt Lake City, UT 84112.

The ionic conductance channels involved in the fast, nicotinic, postsynaptic potentials of principal neurons in sympathetic ganglia of frogs were examined. These acetylcholine (ACh)-activated channels are permeable to a number of different positively charged organic amines. Permeability was measured electrophysiologically and by uptake of ^{3}H-labeled amines. In electrophysiological tests, the reversal potentials (E_{rev}'s) of intracellular responses to iontophoretically applied ACh were measured when the Na^+ in the bathing Ringer's solution was replaced by various amines. An $E_{rev} > E_{K^+}$ was used as an indication that the amine could permeate the ACh-activated synaptic channel. In uptake studies, ganglia were exposed to low concentrations of the ^{3}H-amines either in the presence, or absence, of the ACh analog carbachol. A primary amino group in the labeled compound allows it to be histologically fixed in situ by glutaraldehyde so that uptake could be measured by autoradiography as well as by liquid scintillation counting of the ganglia.

These tests show that the ACh-activated channels which are permeable to Na^+ and K^+ are also permeable to various small primary amines including those having an alcohol, guanidinium, or amide moiety. Thus these neuronal postsynaptic channels appear to be relatively non-selective, cation-specific pores, and in this regard resemble their counterparts in skeletal muscle.

The use of radiolabeled amines in conjunction with autoradiography provides a novel means for the direct visual identification of individual neurons that have been been synaptically active. This provides a potentially powerful tool to probe the functional activity of other neuronal synapses.

265.2 CHANNEL LIFETIME AT INHIBITORY CHOLINERGIC SYNAPSES IS PROLONGED BY ESERINE. Roy L. White* and Daniel Gardner. Dept. of Physiology and Biophysics, Cornell Univ. Med. Coll., New York, N.Y. 10021.

At cholinergic synapses of Aplysia buccal ganglia, inhibitory postsynaptic currents (IPSC) show single exponential decay, implying that a single rate-limiting step (RLS) determines duration. Gardner and Stevens ((1980) J. Physiol. 304) showed that this RLS is unlikely to be either slow transmitter release or transmitter removal by diffusion or hydrolysis. They suggested instead that a conformational change, which closes open synaptic channels with exponentially-distributed lifetime τ, is the RLS determining IPSC decay. Acetylcholine fluctuation (ACh noise) spectra are consistent with this hypothesis. However, as in other cholinergic synapses, the anticholinesterase physostigmine (eserine) prolongs exponential decay of IPSCs, implying an additional action of eserine on the channel complex.

We now report that examination of IPSCs and ACh noise spectra with and without eserine is consistent with a direct eserine action on channel lifetime. IPSC decay follows single-exponential kinetics during and after eserine wash-in, showing that eserine alters an existing RLS, rather than slowing an additional, formerly fast process and thereby substituting a new RLS. Eserine 10^{-4} g/ml lengthened IPSC τ from 18±3 msec (n=7) to 38±5 msec (n=5). Without eserine, ACh was applied using pressure ejection, yielding double Lorentzian ($1/f^2$) spectra with corner frequencies f_1=8.1±0.6 Hz and f_2=60±5 Hz (n=16). If the 8.1 Hz noise process represents synaptic channel lifetime, and if eserine prolongs lifetime, then eserine should correspondingly lower f_1 to 4.2 Hz. In eserine, we recorded spectra with f_1=4.4±0.4 Hz (n=10), consistent with the hypothesis. In 4 cells, both IPSC and ACh noise were each recorded before and after eserine. Eserine lengthened IPSC τ from 16±2 to 37±5 msec; $1/(2\pi f_1)$ calculated from noise shifted correspondingly from 18±3 to 34±4 msec in eserine. The lack of any additional decay processes seen during eserine treatment, and the parallel effects on IPSC τ and noise f_1 provide further confirmation that τ indeed reflects the average channel lifetime, and imply that eserine directly modifies that lifetime.

265.3 SINGLE ACETYLCHOLINE CHANNELS IN CULTURED HUMAN MUSCLE. M. B. Jackson,* H. Lecar,* V. Askanas and W. K. Engel (SPON: R. E. Taylor). N.I.H, Bethesda, Md. 20205.

Single channel ionic current fluctuations were recorded in cultured adult human skeletal muscle obtained by biopsy. A small open-ended extracellular patch electrode containing a dilute solution of the agonist suberyldicholine was used to record the current through a 1-2μ^2 patch of cell membrane. Cells were held at hyperpolarized membrane potentials of between -90 and -100 mV at temperatures of 22 to 26°C. Records of single channel jumps were made from muscle cells in cultures established by the technique of Askanas and Engel (Neurology, 25:58-67, 1975). The measured unit conductance was 47 pS and showed little variation for different cultures. That result is close to the value found with cultured embryonic rat muscle by the same technique (Jackson and Lecar, Nature 282: 863-864, 1979).

In contrast to the conductance measurements, the preliminary experiments did not give a single estimated value of the mean channel open-time. Duration distribution histograms show variability in the kinetics of channel closing. Analysis of these histograms shows that there are channels with mean open-times ranging from approximately 2 to 20 msec. Whether this reflection of varying rates of channel closing is a function of more than one population of channels and/or of developmental stages of the fibers, or of other factors, is not yet known. (Non-synchronous maturation is typical of adult human muscle in cultures). The present study establishes that this technique can be used to investigate such factors.

265.4 CHARACTERIZATION OF ENDPLATE CONDUCTANCE IN TRANSECTED FROG MUSCLE AND ITS MODIFICATION BY ATROPINE AND TUBOCURARINE. J.J. Lambert,* N.N. Durant,* L.S. Reynolds,* R.L. Volle and E.G. Henderson. Dept. of Pharmacol. Univ. of Conn. Health Ctr. Farmington, CT 06032.

Cutaneous pectoris muscles of Rana pipiens were transected distal to the innervated region. Within 10 mins, membrane potentials (E_m's) of -33±2.5mV and endplate potentials (e.p.p.s) (3-15mV) were recorded unaccompanied by muscle action potentials or twitch. The fall in E_m was associated with a net loss of $[K^+]_i$ and a net gain of $[Na^+]_i$. Although the input resistance fell by 50% and the space constant was slightly reduced in the transected muscle fibers, endplates could be adequately voltage-clamped with two microelectrodes. Endplate currents (e.p.c.s) with rise times of 350 to 700μsec were recorded as a function of holding potential (V_m). The current-voltage relationship of peak e.p.c.s over the range of -70 to +20mV was linear and the reversal potential (-6.6±2.2mV) was not different from that found for intact muscle fibers. The decay phase of e.p.c.s could be described as a single exponential at all V_ms and had a voltage (H=-140±14mV) and temperature (Q_{10}= 3.79±.20) dependence similar to that described for e.p.c.s of glycerol-treated muscles. Tubocurarine, ≥ 0.3μM caused a significant decrease in the time constant (τ) of e.p.c. decay and e.p.c. amplitude. The depression of e.p.c. amplitude by tubocurarine was partially reversed by 4-aminopyridine while the decrease of τ was not. Atropine (10^{-4}M) caused a monotonic shortening of e.p.c.s at a V_m of -90mV but e.p.c.s recorded at +50mV were biphasic(τ_{fast}= 0.44±0.02: τ_{slow}=4.03±0.46 msec). The transected muscle has utility for the study of conductance kinetics of the endplate uncomplicated by the presence of drugs or ions to eliminate contraction. (Supported by NS07540 and NS12563)

265.5 EFFECTS OF α-NEUROTOXINS FROM VARIOUS SNAKE VENOMS ON TRANSMISSION IN AUTONOMIC GANGLIA. V.A. Chiappinelli, J.B. Cohen and R.E. Zigmond. Dept. Pharmacol., Harvard Medical School, Boston, MA 02115

The pharmacology of nicotinic transmission in autonomic ganglia has been studied in vitro in intact ganglia by recording the compound action potential from postganglionic nerves following preganglionic nerve stimulation. Previously, we have reported that several, but not all, commercially available lots of α-bungarotoxin block transmission in ciliary and choroid neurons of both pigeon and chicken ciliary ganglia at a concentration of 10 μg/ml (1.2 μM), while having no effect on the rat superior cervical ganglion (Proc. Natl. Acad. Sci. USA 75: 2999 (1978)). This blockade is antagonized by preincubation with 100 μM d-tubocurarine. Two additional experiments were performed to test the postsynaptic nature of the blockade seen with this toxin. 1) Exposure to the toxin (1.2 μM) completely blocked the depolarization of ciliary ganglion cells produced by the cholinergic agonist carbachol (500 μM). 2) A solution of the toxin (1.2 μM) was incubated with membranes purified from Torpedo electric organ containing an excess (3 μM) of α-neurotoxin binding sites. After subsequent centrifugation to remove the Torpedo membranes, the solution was no longer capable of blocking transmission through the ciliary ganglion.

A high-affinity binding site for ^{125}I-α-bungarotoxin (K_D = 1 nM) was characterized in the chicken ciliary ganglion. However, since it is labelled equally well by lots of α-bungarotoxin which block transmission and those that do not, this site does not appear to be involved in the blockade of transmission.

Several α-neurotoxins from snakes other than Bungarus multicinctus were examined for ganglionic blocking activity. α-Cobratoxin (from Naja naja siamensis) and L.s. III (from Laticauda semifasciata) produced a partial blockade of transmission through the pigeon ciliary neurons, while having no effect on transmission through the chicken ciliary neurons or through choroid neurons in either species. Two other α-neurotoxins from Laticauda semifasciata, erabutoxin a and erabutoxin b, had no effect on these cell populations at similar concentrations (1.2 μM).

None of the α-neurotoxins tested had any effect on transmission in either the rat superior cervical ganglion or the rat pelvic ganglion at concentrations up to 100 μg/ml (12 μM). Collagenase treatment of these ganglia, in an attempt to increase access of the toxins to ganglion cells, did not alter these negative results.

265.6 HISTRIONICOTOXIN BINDING TO TORPEDO NICOTINIC POST-SYNAPTIC MEMBRANES. Daniel C. Medynski* and Jonathan B. Cohen. Dept. of Pharmacology, Harvard Medical School, Boston, MA 02115.

The equilibrium binding of [^{3}H]-perhydrohistrionicotoxin([^{3}H]-H_{12}HTX) to nicotinic post-synaptic membranes isolated from Torpedo electric tissue has been studied by ultracentrifugation. The non-specific interaction of this ligand with the membranes is characterized by a partition coefficient, P=200 nmoles/g protein per nmole/ml. In the presence of 10μM carbamylcholine(carb) to occupy all cholinergic receptor binding sites, [^{3}H]-H_{12}HTX binds to a number of sites equal to one half(0.48±.09) the number of α-bungarotoxin sites(α-BgTx) with a K_{eq}=0.5μM. When d-tubocurarine or α-BgTx fully occupies the cholinergic sites, the K_{eq} of H_{12}HTX equals 0.8μM and 5μM respectively, while this alkaloid binds to the same number of sites but with a K_{eq}=5μM in the absence of cholinergic ligands. Thus the affinity of the HTX binding site is regulated by the ligand which occupies the acetylcholine(AcCh) binding site. A twenty-fold excess of non-radioactive H_{12}HTX displaces [^{3}H]-H_{12}HTX bound at equilibrium in the presence of carb on the hour time scale($t_{1/2}$=3 hrs.). There is no evidence that [^{3}H]-H_{12}HTX binds to the AcCh binding site, in contrast to the quaternary aromatic amine non-competitive antagonist, [^{14}C]-meproadifen, which interacts at the AcCh binding site directly in the absence of carb(Krodel et al., Molec. Pharm. 15, 294(1979)). Meproadifen displaces [^{3}H]-H_{12}HTX in a dose dependent manner in the absence(IC_{50}(-carb)=20μM) or presence(IC_{50}(+carb)=1.5μM) of 10μM carb, and non-radioactive H_{12}HTX reduces the binding of [^{14}C]-meproadifen in a manner compatible with competitive interaction at a common site.

The pharmacology of the HTX binding site is defined by the ligands that displace [^{3}H]-H_{12}HTX. The tertiary analogues of meproadifen, proadifen(IC_{50}(+carb)=0.6μM, IC_{50}(-carb)=4μM) and adiphenine(IC_{50}(+carb)=10μM), the aromatic amine, lidocaine(IC_{50}(+carb)=2.4mM, IC_{50}(-carb)=20mM), and the fluorescent ligands ethidium bromide(IC_{50}(+carb)=0.7μM, IC_{50}(-carb)=85μM) and quinacrine(IC_{50}(+carb)=50μM, IC_{50}(-carb)=400μM) all displace [^{3}H]-H_{12}HTX in a dose-dependent manner, exhibiting greater potency in the presence than in the absence of carb. Tetracaine displaces [^{3}H]-H_{12}HTX with greater potency in the absence of carb(IC_{50}(+carb)=100μM, IC_{50}(-carb)=0.35 μM).

265.7 EFFECT OF BOTULINUM TOXIN ON END-PLATE CURRENTS IN THE RAT. L.C. Sellin* and S. Thesleff* (SPON: J. Nyquist) Department of Pharmacology, University of Lund, Lund, Sweden.

Local blockade of evoked transmitter release was produced by sublethal injection of botulinum toxin type A (BoTx) subcutaneously above the anterior tibialis muscle of adult male rats. At 7 days after injection, a time when extrajunctional receptors are present, the extensor digitorum longus nerve-muscle preparation was excised and end-plate currents (e.p.c.) were analysed by dual microelectrode voltage clamp. Control muscles were obtained from untreated rats. In order to facilitate the recording of e.p.c.s. without muscle contraction, the muscle fibers were crushed on both sides of the end-plate region leaving an intact area of about 1-1.5 cm. After this procedure, resting potentials ranged from -20 to -40 mV. In the BoTx-treated muscles and in some control muscles, transmitter release was enhanced by the addition of 2.5 μM 4-aminopyridine (4-AP) to the bathing medium. Data from e.p.c.s. were considered acceptable when the maximum membrane potential variation was less than 2% of the clamped voltage.

The relationship between current amplitude and voltage was linear and the reversal potential was about 0 mV in both the BoTx-treated and the control muscles. An analysis of the decay phase of the e.p.c. indicated that it could be characterized by a simple exponential function in both preparations. However, the decay phase of the e.p.c. was prolonged in the BoTx-treated muscles at 23°C, as indicated by an increase in the time constant (τ). This difference was more pronounced at hyperpolarized voltages than at depolarized voltages. When the rate constant ($\alpha, \alpha = 1/\tau$) of the decay phase of the e.p.c. was plotted logarithmically as a function of the clamped voltage, the BoTx-treated muscles showed an increased voltage sensitivity compared to normal muscles. Low concentrations (1 μM) of 4-AP increased the amplitude of e.p.c.s. without affecting the decay phase. At higher concentrations (5 μM), the time constant of the decay phase increased, but there was no effect on the voltage sensitivity.

These data suggest that alterations in the properties of the end-plate membrane occurs as a result of the paralysis produced by botulinum toxin. It is unlikely that BoTx had a direct effect, because similar changes were not observed at 2 days after toxin injection, although there was complete paralysis. (Supported by N.I.H. fellowship 3F32NS05935-02S1 and the Swedish Research Council).

265.8 **LOCAL ANESTHETIC BLOCK OF THE ENDPLATE CHANNEL IN HIGH EXTERNAL SODIUM.** **G. A. Redmann. Dept. of Physiology & Biophysics, University of Texas Medical Branch, Galveston, Texas 77550.**

The decay time constants and peak amplitudes of inward miniature endplate currents in varying concentrations of the quaternary lidocaine derivative QX-222 and external Na were examined in two microelectrode voltage clamped frog cutaneous pectoris muscle.

$[Na]_o$ (115 mM NaCl with added Na-glutamate) concentrations of 115, 230, and 345 mM gave peak currents of 3.1 ± 0.8 nA, 5.2 ± 0.6 nA and 5.6 ± 0.8 nA (±SD) respectively at -80 mV. Negative abscissal intercepts on double reciprocal plots of this data yielded a K_{Na} of approximately 400 mM at -80 mV, decreasing with hyperpolarization. The control decay rate constant decreased by about 60% in 345 mM Na. The slow to control exponential decay time constant ratios, $\tau s/\tau c$, plotted against varying (0-100 μM) concentrations of QX-222 showed a negative abscissal intercept that decreased with hyperpolarization with an e-fold change for about 60 mV and for a given voltage doubled in going from 115 to 345 mM $[Na]_o$, i.e., K_{QX} was about 40 μM at -80 mV in 115 mM Na, and about 90 μM in 345 mM Na at -80 mV. The amplitude ratios of the fast and slow exponential components of mepc decay, A_f/As, in the presence of 50 and 100 μM QX-222 were respectively 1.2 ± 0.5 (n = 6) and 2.0 ± 0.4 (n = 8) in 115 mM Na at -80, and 0.6 ± 0.2 (n = 4) and 0.9 ± 0.3 (n = 8) in 345 mM Na. A similar dependence of A_f/As on $[Na]_o$ was seen at hyperpolarized potentials. Reciprocal τ fast was a linear function of QX-222 concentrations. The slope of this relation decreased with increasing $[Na]_o$, being 2 x $10^7 M^{-1}s^{-1}$ in 115 $[Na]_o$, and 1 x $10^7 M^{-1}s^{-1}$ in 345 mM $[Na]_o$. The K_I for Na from competitive inhibition of the QX-222 channel block is in reasonable agreement with K_{Na} over the voltage range examined. Making the normal Ringer hypertonic with 460 mM sucrose reduced the mepc amplitude at -80 mV to 1.8 ± 0.9 nA and reduced α by about 30%, but did not change τ_s/τ_c as a function of QX-222 concentration.

The above data are consistent with the idea that both sodium and QX-222 compete for an intrachannel binding site. However, ionic strength effects on surface potential must also be considered. Supported by NS-14920 to P. Adams.

265.9 PROTECTION BY Mg^{++} OF ACETYLCHOLINE ACTIVATED IONIC CHANNEL BLOCKADE BY LIDOCAINE AND LOBELINE IN TRANSSECTED FROG MUSCLE.
E.G. Henderson, J.J. Lambert,* and L.S. Reynolds* (Sponsored by Linda Quenzer). Dept. of Pharmacol. Univ. of Conn. Health Ctr. Farmington, CT 06032.

We have previously shown that Mg^{++} (13mM) protected the Ach activated ionic channel from blockade by lobeline ($5X10^{-5}M$) in intact muscle fibers (Soc. for Neurosci. Abst. 1979:5,483.). In the voltage clamped transected cutaneous pectoris muscle lobeline ($1X10^{-5}M$) and lidocaine ($5X10^{-5}M$) caused a 32% and a 30%, respectively, decrease of the time constant of decay (τ) of e.p.c.s at a holding potential (V_m) of -90mV. After treatment of endplates with Mg^{++} (4-6 mM) lobeline and lidocaine, at the same concentrations, caused only a 16% and a 2%, respectively, decrease in τ. Mg^{++} by itself had no significant effect on τ, nor was the addition of Mg^{++} to the muscles treated with either lobeline or lidocaine able to reverse the block. Tubocurarine ($1.5X10^{-6}M$), atropine ($2X10^{-5}M$) and QX314 ($5X10^{-5}M$) caused a 25±2% decrease of τ which was unaffected by either pretreatment of the muscles with Mg^{++} (4-6mM) or the addition of Mg^{++} to the muscles already exposed to the blocking agent. In view of the possibility that the protection by Mg^{++} of the effect of lidocaine was associated with the degree of ionization at pH 7.4, an approximately equiactive concentration of QX314 ($2X10^{-5}M$) was also examined. As with the higher concentration, Mg^{++} did not protect. A quaternary derivative of lobeline is currently under investigation. These results suggest the possibility of multiple allosteric binding sites in the Ach activated receptor-channel complex. (Supported by NS 07540 and NS12563)

265.10 EFFECTS OF GUANINE NUCLEOTIDES ON THE BINDING OF CHOLINERGIC ANALOGUES TO THE MUSCARINIC RECEPTOR.
F.J. Ehlert*, W.R. Roeske* and H.I. Yamamura (SPON: T. Reisine). Department of Pharmacology, University of Arizona Health Sciences Center, Tucson, AZ 85724.

Guanine nucleotides have been shown to selectively reduce the binding of agonists to several neurotransmitter and hormonal receptors while producing only minimal effects on antagonist binding. Recent studies have demonstrated that guanine nucleotides also regulate muscarinic receptor binding in a manner which resembles the effects of guanine nucleotides on other neurotransmitter receptors. In this study, we have investigated the regulatory influence of guanine nucleotides on the binding of a series of cholinergic analogues and have found a correlation between the effects of guanine nucleotides and the efficacy of cholinergic drugs.

Muscarinic receptor binding assays were carried out on homogenates of the longitudinal muscle of the rat ileum using the specific antagonist affinity label, [^{3}H]quinuclidinyl benzilate ([^{3}H]QNB). In the absence of guanine nucleotides, the carbachol /[^{3}H]QNB competition curve was much flatter than a simple Langmuir isotherm and could be rationalized in terms of two major binding sites (high and low affinity) and a third minor binding site (superhigh affinity). In the presence of the nonhydrolyzable GTP analogue, guanyl-5'-yl imidodiphosphate (Gpp(NH)p), the carbachol/[^{3}H]QNB competition curve shifted to the right and became steeper, demonstrating that guanine nucleotides convert a heterogenous receptor population into a more homogeneous one of lower overall affinity. The greatest effect of guanine nucleotides on ligand binding was observed with the highly efficacious agonists, carbachol and oxotremorine, whose IC_{50} values increased by a factor of 10 in the presence of Gpp(NH)p (100μM). Somewhat smaller increases (five fold) in the IC_{50} values of the partial agonists, pilocarpine and pentyltrimethylammonium, were observed. In contrast, Gpp(NH)p only produced a minimal increase in the IC_{50} value of the antagonist, atropine. Other cholinergic analogues were examined, and a correlation between the effect of Gpp(NH)p and the efficacy of the drug was observed.

The potency of Gpp(NH)p for reducing agonist binding was investigated using the agonist affinity label, [^{3}H]cis methyl dioxolane ([^{3}H]CD). Gpp(NH)p caused a dose dependent inhibition of [^{3}H]CD binding in the heart and ileum, with the IC_{50} for this effect being 1.5 and 25μM, respectively. In contrast, Gpp(NH)p caused a dose dependent enhancement of [^{3}H]QNB binding in the heart and ileum, with the IC_{50} for this effect being 0.2l and 1.0μM, respectively. These data demonstrated reciprocal effects of guanine nucleotides on muscarinic agonist and antagonist binding.

266.1 FORMATION OF TRANSIENT AND STABLE CONNECTIONS BETWEEN ADULT MOLLUSCAN NEURONS. Andrew G. M. Bulloch and Stanley B. Kater. Dept. Zoo., Univ. Iowa, Iowa City, IA 52242.

Traditionally the processes of neuritic growth and synapse formation have been associated with embryonic nervous systems. However, recent studies of adult nervous systems have demonstrated dynamic properties of mature neurons which can cause functional alterations of neuronal circuitry. Here we report the formation of both transient and stable electrical connections between identified buccal neurons of Helisoma trivolvis.

Previous studies of the dynamic capabilities of adult Helisoma neurons demonstrated that proximal nerve crush causes the generation of neurites both within the neuropil and at proximal axon stumps (Murphy and Kater, Brain Res. 186: 251-272). In the case of neurons L and R 5, which normally project only into ipsilateral nerve trunks, some centrally derived neurites enter foreign terrain by traversing the commissure between the paired buccal ganglia. Such sprouting underlies the formation of the novel, stable 5-5 electrical connection observed in the present study.

Isolated buccal ganglia with proximal crushes of Esophageal trunks were cultured in vivo for periods of 1-40 days as described previously. After 1 day of culture, 5-5 coupling was observed in 25% of preparations tested (n=12), whereas at 2 days all preparations (n=11) exhibited this novel connection. The synapse is apparently stable since it was found in >95% of ganglia after 3-40 days of culture (n=40). It is also thought to be highly specified, since neuron 5 was not found to be connected to any other neuron tested (n=32) in preparations 3-40 days of culture.

In contrast to the stable 5-5 connection, a transient electrical synapse forms between neuron 5 and neuron 4. Measurable coupling was detected between these neurons in 75% of preparations (n=8) after 1 day of culture. However, this connection is very weak at 2 days and no longer detectable by 7 days of culture (n= 6).

It is concluded that neuron 5 possesses a latent coding to form a stable connection with its homologue. The mechanism of 5-5 coupling may involve transient formation of a number of "inappropriate" connections with subsequent stabilization of the 5-5 synapse.

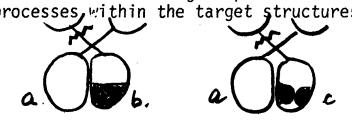
266.2 EVIDENCE FOR THE ROLE OF TARGET-PRODUCED DIFFUSABLE FACTORS AND AXONAL REMODELING IN THE REINNERVATION OF A CAUDAL TECTAL ISLAND BY OPTIC AXONS IN GOLDFISH. M. A. Edwards, S. C. Sharma and M. Murray. Dept. Anatomy, The Medical College of Pennsylvania, Philadelphia, PA and NY Medical College. Introduced by J. Prendergast.

A regenerating optic nerve will establish a compressed retinotopic projection upon a rostral half tectum. If in addition a caudal tectal island is preserved, a compressed pattern will be established which spans both rostral half and caudal island (Murray and Sharma, 1977). The innervation of the island is achieved by the formation of a single prominent bundle which crosses the gap. This successful reinnervation could be accomplished by: (1) non-selective axonal outgrowth from the edge of the rostral tectum plus loss of axons unsuccessful in finding a tectal target; (2) non-selective outgrowth, stimulated by presence of a deafferented tectal island, followed by loss of grossly inappropriate axons; (3) selective outgrowth stimulated by tectal island. We examined the caudal border of the rostral half tectum in half tectal (b) and island (c) fish using EM and HRP. No organized bundles of axons emerge from the caudal border in the half-tectal fish. One or a few bundles of axons, usually closely associated with glial cells, were seen between the meninges and underlying cerebellum or tegmentum, in island preparations. The presence of the island then appears to stimulate this organized outgrowth from the rostral half-tectum. Normal density of boutons and normal appearing optic terminals, stained by orthograde HRP, are seen in the island. The location of retinal ganglion cells whose axons form the bundle projecting to the island was compared following HRP injection into the island (c) or into a comparable caudal site in control tecta (a). Labeled cells in control animals are confined to a small focus in nasal retina. Labeled cells in island fish, injected 1-2 mo. p.o., are distributed over ¼-½ nasal retina. At later stages (> 5 mo. p.o.) labeling is more restricted but still more extensive than normal. Axon outgrowth therefore appears to be stimulated by the presence of the island and presumably by diffusable factors emanating therefrom but outgrowth is somewhat non-selective. With time, the more inappropriate axons appear to be withdrawn. The extent to which aberrant synaptogenesis occurs remains unknown. The data are consistent with the view that precise topographical projections arise through a process of local remodeling of axonal processes within the target structures. (Supported by NS13768).



266.3 SIMULTANEOUS GENERATION OF MOTONEURONS AND INTERNUCLEAR NEURONS IN THE RABBIT ABDUCENS NUCLEUS: A HYPOTHESIS FOR NEURONAL DIFFERENTIATION. Marjorie D. Shaw* and Keith E. Alley (SPON: R. Spetzler). Dept. of Anat., Case Western Reserve University, Cleveland, Ohio 44106.

The rabbit abducens nucleus contains internuclear neurons that project to the oculomotor nucleus, as well as motoneurons that project to the lateral rectus muscle of the eye. These two cell types are fairly evenly mixed throughout the nucleus, and resemble each other so closely that only their axonal projections distinguish them.

By combining ^{3}H-thymidine autoradiography with retrograde transport of HRP, we determined the time of origin of each cell type. In one series of experiments, HRP was injected into the lateral rectus muscle of newborn rabbits which had been injected with ^{3}H-thymidine in utero. Motoneurons were defined as those cells containing HRP. Neurons without HRP were presumed to be internuclear neurons. In a complementary series of experiments, HRP was injected into the oculomotor nucleus of young adult rabbits which had been injected with ^{3}H-thymidine in utero. Internuclear neurons were then defined as those containing HRP granules, while motoneurons did not.

Both motoneurons and internuclear neurons originate over gestation days 9-12, with by far the greatest numbers arising on day 11. No differences could be detected in the generation times of these two populations.

We inferred from the anatomical arrangement of the two cell types and from direct histologic study of embryos, that both cell types originate in the same area of the germinal epithelium. Each has the potential to become either a motoneuron or an internuclear neuron. Not until the cell has migrated into the abducens nucleus primordium does the cell become determined as one type or the other. Within the nuclear primordium, local structural features, such as intercellular ependymal channels (Silver and Sidman, 1980), may guide the growing axons towards one target (oculomotor nucleus) or the other (lateral rectus muscle). By leading the axons to experience different environments, local features of the environment may determine the course of the cells' differentiation.

266.4 SEQUENTIAL GENERATION OF MOTONEURONAL POOLS IN THE OCULOMOTOR NUCLEUS OF THE RABBIT: A THEORY OF NUCLEAR CONSTRUCTION. Keith E. Alley and Marjorie D. Shaw* Dept. Anat., Case Western Reserve University, Cleveland, Ohio 44106.

Motoneurons innervating the same muscle congregate into distinct pools during development. In the oculomotor nucleus five populations of somatic motoneurons are present. These supply four of the eye muscles and the levator palpebrae. This study has analyzed the arrangement of the motor pools in the oculomotor nucleus of the newborn and adult rabbit by means of HRP transport. Their organization was then correlated with the birth dates of the oculomotor neurons as determined with ^{3}H-thymidine autoradiography.

Oculomotor neurons are generated on embryonic days 9 through 12. Plots of the position of labeled cells for each of these days revealed a spatiotemporal gradient of neuron production in the IIIrd nucleus. The sequence of cell formation advances from rostro-ventral to caudal-dorsal; thus the order of neuron origin correlates with its final position in the nucleus. Based on the HRP maps of pool location, this would indicate that the motoneurons innervating the inferior rectus, medial rectus, inferior oblique, and superior rectus muscles are produced in a sequential fashion.

At first, these observations might suggest that the order of neuron origin represents the critical step for forming distinct motor pools through changes in the developmental potential of the germinal epithelium. However, evidence from our investigation of the abducens nucleus would allow another interpretation. Perhaps the environment of the oculomotor primordium consists of a series of compartmentalized microenvironments. Each compartment would be sequentially filled with newly formed oculomotor neurons. Properties of the individual compartments would then specify the proper muscle target for each neuron.

In summary, we propose that motor nuclei are fabricated by the addition of younger neurons onto a base of older neurons. In this way a spatiotemporal gradient is formed. If the gradient covers a single uniform microenvironment, the differentiation of all neurons will be identical. If the gradient covers a series of environmental compartments, compact pools of neurons innervating different muscles will be laid down.

266.5 TRANSITION FROM A CONTINUOUS TO A DISCRETE DISTRIBUTION OF CORTICOSPINAL PROJECTION NEURONS IN THE RAT PARIETAL CORTEX.
Carolyn A. Bates* and Herbert P. Killackey. Dept. of Psychobio., Univ. of Calif., Irvine 92717

In the adult rat, corticospinal projection neurons are found in the medial portion of the parietal cortex. These projection neurons are large pyramidal cells which are located exclusively in layer Vb. Previously, it has been reported that callosal projection neurons which are discretely distributed in layers III and Va in the adult rat are more widely distributed in the neonatal rat (Brain Res., '79, 173:532). The present study was undertaken to see if the corticospinal projection neurons undergo a similar transformation in distribution during the course of maturation.

Forty rats, postnatal days 1 to 14 were injected at the thoracic level of the spinal cord with Sigma VI HRP. The animals were sacrificed 48 hours after injection and processed according to the technique of Mesulam (J. Hist. Cyt., '76).

From the earliest time sampled (PND 3) to PND 6, a continuous band of labeled cells is present along the entire mediolateral extent of parietal cortex (Fig. 1A). The labeled cells are immature pyramidal cells which are destined to reside in layer Vb. By PND 8, the most lateral cells are no longer labeled. The distribution becomes further restricted, so that by PND 11, only the most medial areas of parietal cortex contain labeled cells. At this point, the labeled pyramidal cells have almost reached their mature proportions, and their distribution is very close to that seen in the adult rat. By PND 16 (Fig. 1B), the pyramidal cells have matured and the adult distribution of corticospinal projection neurons is reached.

The present study suggests similarities in the way in which the cortical projection neurons of the different cortical layers develop and that a progressive restriction in the source of efferents from the cortex may be a general feature of cortical development. (Supported by NSF Grant #BNS74-00626.)

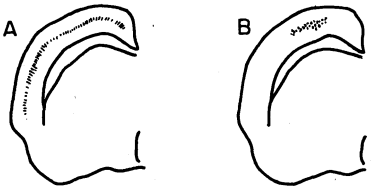


Fig. 1. Distribution of labeled corticospinal neurons at (A) PND 3 and (B) PND 16.

266.6 TRANSITION FROM A CONTINUOUS TO A DISCRETE DISTRIBUTION OF CORTICOTECTAL PROJECTION NEURONS IN THE RAT PARIETAL CORTEX.
G.O. Ivy and H.P. Killackey. Dept. of Psychobiology, Univ. of Calif., Irvine 92717.

We have previously demonstrated a developmental transition from a continuous to a discrete distribution of callosal projection neurons in the rat parietal cortex (Brain Res., '79, 173: 532). We decided to explore the generality of this developmental phenomenon by investigating the distribution of cortical neurons which project to the tectum.

Rat pups of various postnatal ages were injected in the tectum with a 50-60% solution of Sigma VI HRP via a glass micropipette attached to a 1 µl Hamilton syringe. Survival times varied from 6 to 30 hours. The tissue was processed according to the technique of Mesulam ('76).

We have found that in the adult rat, the corticotectal projection neurons are large pyramidal cells located in layer Vb in restricted portions of the parietal cortex (Fig. 1B). In contrast, from the day of birth (postnatal day 0, PND 0) until at least PND 4 (Fig. 1A) these neurons form a continuous band which extends throughout parietal cortex mediolaterally. This band is located in layer Vb, and individual neurons which have filled with the reaction product can often be identified as large pyramidal cells with apical dendrites extending to the pial surface. By PND 7, the band in layer Vb has lost some of its continuity; stretches of layer Vb are often devoid of labeled cells or may contain a few cells which are only lightly labeled. By PND 15, the discontinuous adult distribution pattern is established.

Thus the present findings, in conjunction with our previous findings on the callosal projection neurons and those of Bates and Killackey (this volume) on spinal projection neurons, indicate that the transition from a continuous to a discrete distribution of corticofugal neurons may be a general developmental phenomenon in the neocortex. (Supported by NSF #BNS74-00626).

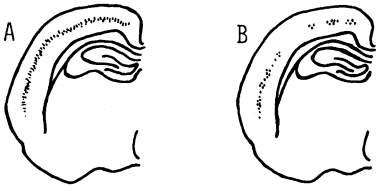

Fig. 1. Distribution of labeled corticotectal neurons at (A) PND 4 and (B) in the adult.

267.1 PERIPHERALLY ADMINISTERED PHLORIDZIN ALTERS SHORT-TERM FOOD INGESTION IN THE RABBIT. D. A. VanderWeele, P. J. Geiselman, and J. D. Sanderson*. Psychology Department, Occidental College, Los Angeles, CA 90041 and Psychology Dept. and Brain Research Inst., UCLA, Los Angeles, CA.

Intact, female New Zealand rabbits were infused with 10 cc of a 2.5 x 10^{-3}M solution of phloridzin or isotonic saline through cannulae entering the hepatic portal system or the upper duodenum and observed for feeding. Infusions were made in both the light and dark portions of the circadian cycle, but the results were virtually identical for both periods, and night results only will be presented. Duodenal administration of phloridzin significantly increased feeding during the first two hours following infusion. Hepatic portal infusion also significantly increased first half-hour feeding; over the first half-hour, food intake was 94% greater for duodenal phloridzin and 117% greater for portal phloridzin than following saline administration via the same routes, $t = 3.01$, $df = 17$, $p<.05$. Hepatic portal infusions, however, produced prolonged periods of anorexia following the immediate enhancement of feeding. The anorexia was not seen after duodenal infusion and lasted 2-3 hours. Duodenal administration produced hyperglycemia, presumably attributable to liver glycogenolysis, while portal infusions produced mild hypoglycemia, probably attributable to renal glucose transport blockade as glycosuria developed, followed by mild hyperglycemia. These results indicate again the lack of importance of absolute levels of glycemia in determining feeding, as both hyperglycemia and hypoglycemia were accompanied by strong feeding responses. We hypothesize that duodenal and portal phloridzin enhanced immediate food ingestion because the drug inhibited liver absorption of glucose and activated glycogenolysis. Phloridzin may, however, interfere with glucose transport into and out of the liver (Goresky & Nadeau, 1974) and, hence, allow liver stores to remain repleted after portal infusion promoting the anorexia observed. Duodenal infusion of phloridzin does not allow significant amounts into the venous system to affect liver or kidney function, as was observed in the present study, and therefore, no anorexia was seen. Alternatively, the blockage of renal reabsorption of glucose by hepatic portal phloridzin could activate sympathetic-mediated, compensatory muscle glycogenolysis which postpones further food intake. The latter hypothesis was suggested as preliminary results with hepatic-portal infusion of phloridzin in subdiaphragmatically vagotomized rabbits shows no immediate enhancement of food ingestion but these animals do show the prolonged anorexia following normal intakes over the first half-hour postinfusion.

267.2 BRAIN REGIONAL SEROTONIN DEPLETION IN HYPOTHALAMIC OBESITY: LESION VS. OVEREATING AS CONTRIBUTORY FACTORS. D.V. Coscina, J.J. Warsh, and G.H. Anderson*. Sects. Biopsychol. and Biochem. Psychiat., Clarke Inst. Psychiat., and Dept. Nutrit. and Food Sci., Univ. Toronto, Toronto, CANADA.

Research into brain monoamine systems which mediate overeating and obesity suggests that impaired serotonin (5HT) metabolism may be one causative factor. Past work from our laboratories has supported this notion in that lesions of the medial hypothalamus (MH) in rats has consistently produced hyperphagia and obesity in association with depleted forebrain 5HT. However, other data from the Biochemical Nutrition literature suggests that overconsumption of protein can itself modify brain 5HT levels. In keeping with this possibility, we have recently obtained behavioral (1) and biochemical (2) evidence that brain 5HT depletion in obese MH-lesioned rats may be a consequence rather than a cause of overeating. To test this hypothesis further, the present study determined 5HT content in 6 discrete brain regions from MH-lesioned rats who either overate food or ate normal amounts of food. Subjects were 30 female rats weighing 230-250 g at surgery. Of these, 18 received bilateral radiofrequency heat lesions (55°C for 1 min per hemisphere) and 12 received sham surgery. All except 9 lesioned rats were allowed unrestricted access to food for 2 weeks. The hyperphagia of these 9 lesioned rats was curtailed by restricting intake to control levels during this time. Analyses of terminal plasma samples showed that hyperphagic rats had lower ratios of tryptophan to other neutral amino acids than sham-operated or restrained-lesioned rats, the latter two not differing from each other. Hypothalamic 5HT was depleted 13-16% ($p < .05$) in lesioned rats regardless of feeding condition. However, hippocampus showed less depletion after restricted feeding (-33%) vs. overeating (-41%; $p < .05$ difference). Thalamus and midbrain were not depleted unless rats overate (-22% and -30%, respectively, $ps < .05$). Neocortex and neostriatum were unaffected by lesion or feeding condition. These data show that overeating after MH injury substantially enhances the lesion-induced depletion of brain 5HT. As such, our findings suggest that overeating must be controlled in experiments designed to elucidate brain 5HT changes associated with this behavior as excessive intake confounds interpretation of other treatment effects.

267.3 MIDBRAIN KNIFE-CUTS WHICH SPARE FOREBRAIN SEROTONIN NEURONS DO NOT BLOCK HYPOTHALAMIC OBESITY. V.M. Dewan and D.V. Coscina. Sect. of Biopsychol., Clarke Inst. Psychiat., and Dept. of Psychol., University of Toronto, Toronto, CANADA.

Previous work from this laboratory (1) has shown that female rats with 70% depletion of forebrain serotonin (5HT) following dorsal and median raphe lesions show little overeating or bodyweight (BW) gain following medial hypothalamic (MH) lesions. This suggests a role for intact 5HT neurons in the expression of hypothalamic obesity. However, the possibility exists that this blockade is not due to 5HT depletion, but instead to disruption of fibers of passage along the midbrain axis. The present study tested this hypothesis by determining if coronal knife cuts (KCs) placed caudal to the raphe nuclei so as to sever such fibers, but leave 5HT afferents to the forebrain intact, would block overeating and obesity following subsequent MH lesions. Subjects were 20 adult female rats: 10 received 3 mm wide, 4 mm deep coronal KCs 0.55 mm behind the raphe nuclei; 5 received sham cuts wherein the knife guide was lowered into brain but the wire knife was not extruded; 5 served as normal controls. Following surgery, BW plus food and water intakes were measured daily for the first week, then weekly for 2 remaining weeks. Six weeks after surgery 5 of the KC rats plus the 5 shams were sacrificed for forebrain assays of 5HT and histologic assessment of KC loci. The remaining 5 KC rats plus 5 normals all received bilateral radiofrequency MH lesions. BW and intake measures were taken as before. One week after KC surgery, cut rats lost 22 g BW compared to 6 g for shams ($p < .05$). However, by the end of the second week, both groups had recovered and were comparable in BW to normal controls. KCs produced little (-14%) depletion of forebrain 5HT compared to sham surgery. BW change 3 weeks after MH surgery was equivalent for KC (+ 149 g) and normal (+ 165 g) rats, reflecting the equivalence of their hyperphagia (32 vs 39 g consumed/day, respectively). The results of this study suggest that the blockade of MH hyperphagia and obesity which follow severe 5HT depletion due to midbrain raphe lesions (1) is not due to transection of rostro-caudal fibers running through the midbrain axis at the level of these raphe nuclei. As such, these data continue to support the possibility that expression of MH hyperphagic requires intact forebrain 5HT systems.

267.4 THE ROLE OF ENDORPHINS IN REGULATORY EATING AND DRINKING: NARCOTIC-INDUCED HYPERPHAGIA AND HYPERDIPSIA. A. Riley, M. Ortuno, K. Hoffman, M. Siemon, and M. Heft. Psychopharmacology Laboratory, The American University, Washington, D. C. 20016.

Although the endorphins have primarily been examined in relation to analgesia (Riley, Zellner, & Duncan, Neurosci. Biobeh. Rev., in press), these endogenous opiates have recently been implicated in the regulation of eating and drinking. This view is based on the suppression of food and water intake by narcotic antagonists (Holtzman, Life Sci., 24: 219-226, 1979) and on elevated endorphin levels in genetically-obese mice and rats (Margules, Moisset, Shibuya, & Pert, Science, 202: 988-991, 1978). If endorphins are mediating consumption, it would be expected that endorphin agonists, e.g., morphine, would produce hyperphagia and hyperdipsia.

Groups of animals were injected daily with distilled water, 20, 40, or 80 mg/kg morphine sulfate for 28 consecutive days. Food and water consumption, as well as body weight, were monitored 1, 3, 6, 12, and 24 hr post injection.

While morphine initially had no differential effects on consumption, with repeated injection (Days 8-14) a significant dose-related hyperphagia and hyperdipsia occurred 3-6 hr post morphine injection. With further injections (Days 15-28) morphine-induced eating and drinking continued to increase and occurred earlier following the morphine injection, i.e., 1-3 hr. That the morphine induced increases in consumption are delayed post injection and develop over injections suggest that morphine may produce several effects, e.g., catatonia and hyperphagia and hyperdipsia, and it is the interaction of these effects that determine the likelihood of consummatory changes following morphine administration. Initially, the morphine-induced catatonia limits changes in consumption. With the development of tolerance to the catatonic effects the morphine-induced changes in consumption can occur. Body weight increases paralleled the drug-induced changes in consumption.

These data parallel the aforementioned effects of narcotic antagonists on consumption and are consistent with the suggestion that endorphins may in part mediate regulatory eating and drinking.

267.5 AMPHETAMINE-INDUCED ANOREXIA IN GENETICALLY OBESE(obob) MICE: CORRESPONDENCE WITH HYPOTHALAMIC NOREPINEPHRINE DEPLETION.
R. Olsauskas and G.A. Oltmans. Dept. Pharmacol., Chicago Medical School, Chicago IL 60612

Genetically obese mice with the obob mutation have elevated hypothalamic(HT) levels of norepinephrine(NE)(Lorden et al., Brain Res., 1975; Feldman et al., Hormone Res., 1979). The relationship of this NE excess to the hyperphagia of the obob mouse is not known. In the current study the effects of amphetamine (AMPH) on food intake and HT NE content were studied in obob mice.

In the initial studies, female mice were adapted to a restricted 6 hour food access schedule and then treated chronically with 3 or 10 mg/kg of AMPH. Saline-treated obob mice ate significantly more and had significantly higher HT NE levels than saline-treated lean mice. AMPH-treated lean or obob mice demonstrated a dose dependent decrease in both food intake and HT NE levels during the initial 3 hrs following drug treatment. Furthermore, the food intake and HT NE levels were no longer different in lean and obob mice treated with the same dose of AMPH. Thus, when HT NE levels in obob mice were similar to those in lean mice, the food intake of the obob mice no longer differed from that of lean mice.

Preliminary studies indicated that the administration of AMPH on a mg/kg basis produced brain AMPH levels in obob mice which were approximately twice those in lean mice. Consequently, obob mice were administered 5 mg/kg AMPH and compared to a group of lean mice administered 10 mg/kg AMPH. The food intake of the 5 mg/kg group of obob mice was significantly decreased, but remained significantly higher than that of lean mice treated with the 10 mg/kg of AMPH. Furthermore, the HT NE levels of these obob mice were intermediate to those of the saline and AMPH-treated lean mice. Thus, equilibrating brain AMPH levels did not produce comparable food intake or HT NE levels in lean and obob mice.

In summary, the AMPH-induced decreases in food intake corresponded to the degree of depletion of HT NE. These results indicate that the decreases in food intake in the obob mice may be functionally related to the HT NE depletion. Thus, it appears that activated release of the NE stores can suppress feeding in this mutant. This may mean that the elevated HT NE levels reflect an abnormal release mechanism in the obob mouse which is related to the hyperphagia of this mutant.(Supported in part by a grant from NINCDS # RO 1 NS15600)

267.6 INCREASED CARBOHYDRATE PREFERENCE IN THE RAT AFTER INJECTION OF 2-DEOXY-D-GLUCOSE AND CLONIDINE. S.E.Fahrbach*, J.R.Tretter*, P.F. Aravich*, J.McCabe* and S.F.Leibowitz (SPON: N.Miller). The Rockefeller Univ. NY 10021 and Brooklyn Coll. NY 11210.

Feeding in the rat can be produced by stimulation of α-adrenergic receptors within the hypothalamic paraventricular nucleus (PVN) and by glucoprivation. There is evidence that hypothalamic catecholamine (CA) neurons may participate in the feeding response to glucoprivation. We further examined this hypothesis by testing the impact of 2-deoxy-D-glucose (2DG) and clonidine (CL) on preference for specific dietary constituents. The experiments reported use a self-selection feeding paradigm. Subjects were adult male rats. Diets varying in carbohydrate, protein, and fat content were compared, including chow-based sugar vs fat diets and dextrin vs casein. Insulin(7U/kg), 2DG(600mg/kg) and CL(50ug/kg) were injected intraperitoneally; in separate experiments CL(10μg) was injected into the PVN in brain-cannulated rats. Food intake was recorded 2,4,6, and 24 h post-injection.

In an attempt to show that chow diets (40% sucrose, 20% corn oil) could provide a sensitive measure of preference, intake after insulin injection, known to stimulate carbohydrate intake, was recorded. The ratio of sugar diet to total intake significantly increased from.59 after vehicle to .85 after insulin.Tests with 2DG showed a change from .57 to .76. CL, tested in the same paradigm, also produced an increase in food intake and a shift in preference to the sugar diet. To further elucidate the mechanism of action of CL, this drug was injected into the PVN, the most sensitive site for α-adrenergic induction of feeding. Intake of dextrin (non-sweet starch) and casein was compared in addition to intake of the chow-based diets. In both cases CL increased preference for the carbohydrate diet, indicating that sweet taste is not important. Thus, CL, presumably acting as a central α-adrenergic agonist, and 2DG, acting through intracellular block of glycolysis, produce similar behavior with respect to nutrient selection. These findings are consistent with the recent evidence of Tretter & Leibowitz (this meeting) that PVN injections of NE selectively enhance carbohydrate intake and the report of Leibowitz & Brown (Br.Res. 1980) that midbrain lesions of the dorsal NE bundle projecting to the PVN impair glucose intake and eating to glucoprivation. We suggest that these data corroborate a role for hypothalamic CA neurons in regulation of carbohydrate intake.

267.7 HINDBRAIN CATECHOLAMINE PROJECTIONS TO THE PERIFORNICAL HYPOTHALAMUS: THEIR ROLE IN THE MEDIATION OF DRUG-INDUCED ANOREXIA AND HYPERPHAGIA. J. McCabe*and S. F. Leibowitz. (SPON: J. Orbach). The Rockefeller University, New York, New York.

Dopaminergic and adrenergic stimulation of the perifornical region of the hypothalamus (PFH) is known to suppress food consumption in hungry rats. When injected directly into the PFH, via chronically-implanted cannula, the neurotransmitters dopamine (DA) and epinephrine and the classic anorectic amphetamine (AMPH) each reduce food intake. The DA receptor blocker chlorpromazine (CPZ), however, when injected centrally or peripherally results in a hyperphagic food intake response. In the present study the role of various catecholamine (CA) fiber systems, previously defined in histochemical studies, were disrupted at several levels of the neuraxis using primarily the wire knife-cut (KC) technique. Food intake of deprived KC animals and sham-operated animals were compared after administration of DA, AMPH, or CPZ.

Results may be summarized as follows: 1). Electrolytic lesions of the proposed PFH receptor area, at the level of the ventromedial nucleus, resulted in a loss of the anorectic response seen after intracranial (IC) and intraperitoneal (IP) AMPH, and a diminished CPZ hyperphagic response. 2). A coronal KC immediately caudal to the proposed PFH receptor area, which severed the most medial fibers of the medial forebrain bundle, produced a loss of anorexia from IC and IP AMPH. The effect of IC injection of DA to the PFH, however, was actually potentiated by the KC, as was the hyperphagic response to CPZ, suggesting the development of denervation supersensitivity in PFH receptors. 3). Moving the cut further caudally into the midbrain tegmentum produced effects that depended on the dorso-ventral extent of the cut. When the KC was more ventrally placed, just dorsal to the medial lemniscus, an attenuated AMPH response was seen to both IC and IP injection. In contrast, if the KC was moved 2 mm dorsally, just lateral to the central grey, it generally failed to disrupt the IP AMPH anorexia, and actually potentiated IC AMPH anorexia. Both midbrain cuts attenuated CPZ hyperphagia. This evidence indicates the importance of the ventral CA fibers in the mediation of AMPH anorexia, while both dorsal and ventral fibers appear to mediate CPZ hyperphagia. Further experiments with KC at the level of the pons are currently in progress.

267.8 PHARMACOLOGICAL AND LESION MANIPULATIONS OF THE HYPOTHALAMIC PARAVENTRICULAR NUCLEUS (PVN): EFFECTS ON EATING ELICITED BY ELECTRICAL BRAIN STIMULATION AND TAIL PINCH. Ronnie Halperin, Christine L. Gatchalian* and Sarah F. Leibowitz. The Rockefeller Univ., New York, NY 10021.

Eating elicited by central norepinephrine (NE) injection, electrical brain stimulation (EBS), and tail pinch (TP) show behavioral similarities and have been explained in terms of forebrain catecholamine mediating mechanisms. Through the use of pharmacological and brain lesion manipulations, the present studies investigate the possible interaction, at the hypothalamic level, of the systems underlying these three elicited eating responses.

Pharmacological Studies. Eleven rats were each chronically implanted with a drug-injection cannula aimed at the PVN and with a bipolar stimulating electrode aimed at the ipsilateral lateral hypothalamus. Rats were satiated and then centrally injected with NE (0.4 to 40 nmoles), the α-adrenergic receptor blocker phentolamine (PHT) (40 to 60 nmoles), or vehicle just prior to a 20-min test session in which eating in response to EBS, TP, or no stimulation (drug alone) was tested. Current thresholds for eating in response to EBS, and eating responsivity to TP were unaltered by a preceding PVN injection of NE. The effects of NE and EBS, and of NE and TP on food intake appeared to be additive, suggesting that these effects may be mediated by independent mechanisms. Furthermore, PHT, which blocked eating in response to NE injection, did not alter eating thresholds in response to EBS or eating in response to TP.

Lesion Studies. To further assess a possible role for the PVN in the mediation of TP-elicited eating, we tested this response in 6 rats before and after bilateral PVN or sham lesions. PVN lesions did not disrupt feeding elicited by TP and, in fact, TP-elicited eating appeared facilitated as measured by response latency and duration. These data indicate that the PVN is not a necessary component in the mediation of TP-elicited eating and that it may actually exert an inhibitory influence on TP-elicited eating.

At the level at which we are studying these responses, the hypothalamic system mediating eating in response to NE injection appears to be independent of the system(s) mediating eating in response to EBS and TP, responses which may be mediated via extrahypothalamic catecholamine systems. The apparent lack of interaction suggests that these systems may be involved in different aspects of the feeding process. 267.9 EFFECTS OF CENTRAL CATECHOLAMINE DEPLETION ON THE FOOD INTAKE AND BODY COMPOSITION OF THE DIABETES MOUSE (db/db). Joan F. Lorden and Mary Ann Pelleymounter*. Dept. of Psychology, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

The diabetes mouse (C57BL/Ks-db) is genetically obese, hyperphagic, hyperglycemic and hyperinsulinemic. Central nervous system involvement in the syndrome is suggested by the observation that this mutant has elevated levels of hypothalamic norepinephrine (NE) in comparison with lean littermate controls. Furthermore, reduction of central NE has been shown to reduce body weight and blood glucose in the db/db (Lorden, J.F., J. Comp. Physiol. Psych. 1979, 93, 1085-96). Studies were undertaken, therefore, to assess the effects of central catecholamine depletion on both the size of the fat stores and also on food intake, activity and body temperature in an attempt to determine the means by which central lesions alter energy balance in this mutant.

Female db/db mice and their lean controls received 80 nmol infusions of the neurotoxin 6-hydroxydopamine (6-OHDA) dissolved in a .9% saline-.02% ascorbic acid vehicle. The 6-OHDA was delivered in a 2 µl volume through a 30 ga cannula stereotaxically aimed at the third ventricle. Additional groups of lean and diabetes mice received injections of the vehicle solution alone.

At sacrifice 100 days after surgery, large decreases in both hypothalamic and telencephalic NE and dopamine were noted in all 6-OHDA treated groups. Body temperature measured at 23°C was decreased in all 6-OHDA treated groups. Activity levels were not significantly altered by the lesions except in the homozygous lean group. These mice decreased their activity in comparison with vehicle treated animals of the same genotype. The 6-OHDA lesions reduced food consumption by 33% in the db/db mice but did not alter food intake in the lean controls. Blood glucose levels were also reduced in diabetes mice treated with 6-OHDA.

Food deprivation was sufficient to reduce both the body weight and blood glucose of vehicle treated db/db mice to the levels of 6-OHDA treated db/db mice. However, in the vehicle treated mice it was necessary to decrease food intake by over 60% to achieve this effect. Body fat was also decreased in both 6-OHDA and food restricted db/db mice in comparison with free-feeding vehicle treated mice. Food restriction and 6-OHDA treatment differed, however, in that food restricted mice also had a reduced lean body mass in comparison with the 6-OHDA treated group. No effects of the lesions were noted on the body composition of the lean control mice. Thus, in the diabetes mouse central catecholamine depletion produces decreases in body fat which are attributable only in part to a reduction in food intake. Since there was no evidence of increased energy expenditure through thermogenesis or activity, the lesion may also alter some as yet unspecified metabolic factor. (Supported by NINCDS grant 14755-02)

268.1 NEURAL ORGANIZATION PREDICTS STIMULUS SPECIFICITY FOR A RETAINED ASSOCIATIVE BEHAVIORAL CHANGE. Joseph Farley*, Dept. Psychology, Princeton Univ., Princeton, NJ 08544 and Daniel L. Alkon, NINCDS, NIH, MBL, Woods Hole, MA 02543.

Complementary behavioral and neurophysiological studies examined stimulus specificity for an associative behavioral change exhibited by the nudibranch Hermissenda. Paired, but not random, presentations of a light step (30 sec duration, intensity 4.6 x 10^3 ergs.cm^{-2}.sec^{-1}) with rotation-produced stimulation of caudal hair cells (94 rpm; 2.24 g) produced a significant increase in response latency for the animals' movement towards a test light. This associative behavioral change did not occur when cephalic, rather than caudal, hair cells were those stimulated by rotation. Indeed, response latencies were faster for animals receiving paired vs. random presentations of light and cephalic hair cell stimulation, and, in some instances faster than original baseline latencies. Intracellular recordings from type B photoreceptors in the isolated nervous system indicated the enhancement of a long-lasting membrane depolarization (LLD, Alkon and Grossman, 1978; Alkon 1979) under stimulus presentation regimens paralleling those involved in training of intact animals. A single pairing of light and rotation-produced excitation of caudal hair cells was sufficient to produce an average 3-4 mV depolarization of type B cells, detectable some 60 sec after the offset of light. Depolarization increased with a second pairing to a cumulative level of 7 mV. Unpaired presentations of light and rotation, as well as light-alone presentations, did not result in an enhanced LLD or a cumulative depolarization. Similarly, paired presentations of light and cephalic hair cell stimulation did not produce an enhanced LLD. Indeed, a slight hyperpolarization (1 mV) was obtained. This sensitivity of cumulative photoreceptor depolarization to the quality of hair cell stimulation derives from the differences in synaptic effects of hair cells upon type B photoreceptors for caudal vs. cephalic hair cell stimulation (Alkon, 1979). The magnitude and duration of type B depolarization following light paired with rotation-produced stimulation of caudal hair cells is enhanced by two sources: increased synaptic excitatory input from the ipsilateral optic ganglion and facilitated disinhibition (from caudal hair cells) of the type B photoreceptor. Turning the circumesophageal nervous system 180° with respect to the center of rotation results in the failure of B cells to receive this synaptic excitation and disinhibition and hence enhancement of the light-induced LLD. This cumulative depolarization specific to stimulus pairing can be expected to result in persistent depolarization ($\geq$3 days) which has been observed for these animals which undergo persistent associative behavioral changes (Crow & Alkon, 1978, 1979).

268.2 IN VITRO CLASSICAL CONDITIONING OF THE GILL WITHDRAWAL REFLEX IN APPLYSIA CALIFORNICA. Ken Lukowiak* and Chris Sahley, Division of Medical Physiology, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada and Department of Biology, Princeton University, Princeton, New Jersey. (SPON: L. Boyarsky)

The neural mechanisms mediating 2 types of non-associative learning (habituation and sensitization) of the gill withdrawal response (GWR) have been extensively studied in the siphon, mantle, gill and abdominal ganglion preparation (SMGA) of Aplysia californica. However, associative learning in this preparation has not been demonstrated. We now present evidence which shows that the gill withdrawal reflex (GWR) in this in vitro preparation can be classically conditioned. Previously, Lukowiak and Jacklet (1972, 1974) demonstrated that light (photic) stimulation to the siphon evoked a siphon withdrawal response. In contrast, the photic stimulus does not result in a gill withdrawal reflex. In our experiments, we pair photic stimulation of the siphon (conditioned stimulus, CS) with strong tactile stimulation of the gill (unconditioned stimulus, US). Tactile stimulation of the gill always evokes a GWR. Following 60-80 paired CS-US presentations, a GWR was observed on a CS alone test trial in 6 out of 9 preparations. A GWR to the CS was never observed in separate control preparations which received either CS alone presentations, US-CS presentations, or random CS, US presentations. The GWR to the CS, then, depended upon the CS-US pairing and, thus, we conclude is the result of associative learning.

Extinction of the learned response is observed following 3 CS alone trials. No systematic study has yet determined the duration of the learned response. Further experiments are being undertaken to determine the neural pathways and changes in neural activity or connectivity which underlie associative learning in this in vitro preparation.

268.3 DOPAMINE MODULATION OF APLYSIA GILL REFLEX BEHAVIORS ACTS PRIMARILY VIA PERIPHERAL TERMINATIONS OF L_7. P. Ruben* and K. Lukowiak* (SPON. C. Beiswanger). Medical Physiology, University of Calgary, Calgary, Alberta, Canada T2N 1N4.

The gill withdrawal reflex (GWR) and its habituation, evoked by tactile stimulation of the siphon, are mediated by the integrated activities of the central and peripheral nervous systems. The GWRs are at least 35% of the amplitude of a spontaneous gill contraction. The CNS is capable of modulating (suppressing or facilitating) the reflex according to the central state of the animal. The facilitated state results in reflexive contractions well in excess of the amplitude of spontaneous contractions, and an absence of habituation or a retardation of its rate, despite normal synaptic decrement to central gill motor neurons. No environmental factors or whole animal behaviors have been correlated with the facilitated GWR. However, we have found two manipulations which can produce physiological mimicry of the facilitated state. First, stimulation of the gill motor neuron L_9 facilitates the GWR and prevents its habituation. Second, these same effects are achieved by the perfusion of dopamine (DA; 10^{-7}M - 5×10^{-7}M) through the gill. DA perfusion prevents habituation despite the decrement of evoked activity in central gill motor neurons which normally accompanies habituation. This demonstrates that DA induced facilitation is being exerted in the periphery. DA could be acting upon elements of the PNS and/or at the terminations of central efferent neurons. It appears that DA modulation of the GWR involves the peripheral terminations of central efferents, as its effects are ablated when the CNS is removed. Furthermore, motor neurons with their axons in the ctenidial nerve are most affected by DA perfusion through the gill. DA fails to exert a facilitatory influence when the ctenidial nerve is cut. DA acts primarily upon the endings of L_7. Hyperpolarization of L_7 to inhibit its contribution to the GWR prevents the facilitation due to DA perfusion. Hyperpolarization of other gill motor neurons does not reduce the facilitation. Repetitive firing of L_7 at 10-12 spikes per second once every 30 seconds produces a decrement of the evoked movement. In addition to its effects on the GWR, DA also facilitates the L_7 evoked movement and prevents its habituation. Preliminary experiments suggest that the ctenidial nerve radiations of L_7 are involved. These data show that dopamine, which may be the neurotransmitter responsible for the naturally occurring state of facilitation, acts to presynaptically or postsynaptically enhance the efficacy of L_7's neuromuscular transmission. These data lead us to favor the presynaptic hypothesis. (Supported by the MRC.)

268.4 PUNCTATE TACTILE GILL STIMULI EVOKE ACTIVITY IN CENTRAL GILL AND SIPHON MOTOR NEURONS IN APLYSIA. J. Goldberg* and K. Lukowiak* (SPON: L. Vaughn). Div. Med. Physiol., Fac. of Med., Univ. of Calgary, Calgary, Alberta T2N 1N4

The gill withdrawal reflex (GWR) can be evoked by tactile stimulation of the siphon or gill. The peripheral nervous system (PNS) mediates the GWR, while the central nervous system (CNS) exerts modulation over reflex behaviors. It has been suggested that tactile gill stimulation of moderate intensity does not send afferent input into the CNS. Brief punctate stimuli did not evoke an excitatory response in central gill motor neuron L_7, while strong shearing stimuli evoked only sub-threshold excitation (Kupfermann et al., 1971; 1974). It was therefore concluded that the PNS within the gill is functionally independent of the CNS. The subsequent demonstration that habituation of the GWR evoked by repetitive gill stimulation transfers its suppression to the GWR evoked by siphon stimulation, and vice versa, contradicts this conclusion since the transfer is mediated by both the CNS and PNS (Goldberg and Lukowiak, 1979). In these present experiments, the question of whether gill stimulation sends afferent input to the central motor neurons is re-evaluated. Brief punctate stimuli of varying intensity (200 mg to 2000 mg) were presented to the siphon and gill, with the CNS intact and removed. With the CNS intact, measurements of reflex latency and latency of excitation recorded in central gill and siphon motor neurons were taken. With the CNS removed, only measurements of GWR latency were taken. The results show that tactile gill stimulation at intensities as low as 200 mg evokes a short latency depolarizing excitatory response in both central gill and siphon motor neurons. The magnitude of excitation is usually slightly less than that evoked by siphon stimulation. The latency of excitation, for both siphon and gill stimulation, decreases sharply as the stimulus intensity is increased from 200 mg to 1000 mg. Upon further increases in stimulus intensity, there is little change in the latency of excitation. Behaviorally, the latency of the GWR evoked by siphon stimulation also decreases as the stimulus intensity is increased from 200 mg to 1000 mg, after which there is little change. The latency of the GWR evoked by gill stimulation is shorter than that evoked by siphon stimulation and decreases more gradually as the stimulus intensity is increased. For siphon and gill stimulation with the CNS removed, the GWR latencies are also short, and decrease only gradually as the stimulus intensity is increased. These data show that: 1) Brief punctate gill stimuli evoke excitation in central gill motor neurons; 2) The CNS controls the latency of the GWR when evoked by siphon stimulation, but not gill stimulation.

Supported by the MRC of Canada.

268.5 DENTATE SINGLE UNIT AND FIELD POTENTIAL ACTIVITY DURING NM CONDITIONING IN RABBIT. D. J. WEISZ*#, G. A. CLARK*#, B. Y. YANG*§, P. R. SOLOMON*¶, T. W. BERGER° and R. F. THOMPSON#, #Dept. Psychobiol., Univ. California, Irvine, CA 92717, §Dept. Biol., Fudan Univ., Shanghai, P.R.C., ¶Dept. Psychol., Williams Coll., Williamstown, MA 01267, °Dept. Psychol., Univ. Pittsburgh, Pittsburgh, PA 15260.

Previous research has demonstrated an early, substantial, and persistent conditioned increase in hippocampal cell activity during classical conditioning of the rabbit nictitating membrane (NM) response. A much smaller conditioned increase in cell activity was seen in the part of entorhinal cortex (layers II and III) which contains cells afferent to the hippocampus and dentate gyrus. In the present two studies we examined the possibility that the conditioned increase in entorhinal cortex was amplified at the perforant path-granule cell synapse and/or relayed through dentate to the rest of hippocampus.

In one study we analyzed the responses of single cells from dentate gyrus recorded during classical conditioning of the NM response. Cells that demonstrated short latency activation following perforant path stimulation were identified as granule cells. The response patterns of identified granule cells during paired CS-US presentations were much different from the patterns of entorhinal and hippocampal CA1 and CA3 cells. During paired conditioning, granule cells exhibited short latency responses to the tone. Unlike patterns of entorhinal, CA1, and CA3 cells, those of granule cells did not form a temporal model of the conditioned NM behavior. Rather, many granule cells responded to the tonal CS with a rhythmical bursting pattern (burst frequency was approximately 8 Hz). During unpaired CS and US presentations, the dominant response of granule cells was a decrease of firing rate. While responses of entorhinal, CA1, and CA3 cells have been typically time-locked to the conditioned NM behavior, granule cell responses were temporally linked to the stimuli.

In a second study, monosynaptic field potentials from dentate gyrus were elicited by perforant path stimulation during NM conditioning. Granule cell excitability during the CS period was higher in the paired conditioning group than in the unpaired control group. A decrease in excitability was seen following tone presentations in the unpaired group.

These findings strongly suggest that the previously observed learning-dependent increase in entorhinal unit activity is not amplified at the perforant path-granule cell synapse nor relayed through dentate granule cells during acquisition of the conditioned NM response. The data do suggest a role in processing of stimuli for the dentate granule cells.

268.6 EXCITABILITY INCREASES IN FACIAL MOTONEURONES OF THE CAT AFTER SERIAL PRESENTATION OF GLABELLA TAP. M.Matsumura* and C.D.Woody. Depts. of Anatomy and Psychiatry, Mental Retardation Research Center, UCLA Medical Center, Los Angeles, CA 90024.

Neuronal plasticity of facial motoneurones was investigated in awake cats after serial delivery of taps to the bridge of the nose (glabella). The effects of these stimuli which were used as unconditioned stimuli (US) in the production of conditioned blinking were assessed by intracellular recording and stimulation. Cats were classified into three groups: 1) "Conditioned" group: the cats were classically conditioned to eye blink by repeatedly presenting a click as conditioned stimulus (CS) followed by glabella tap as US; 2) "US-only" group: only glabella tap was presented; (This group did not exhibit an overt conditioned response when click was delivered). 3)"Naive" group: they were not given presentations of the CS or US.

Intracellular recordings were obtained using glass microelectrodes filled with 3M KCl (resistances 15 to 30MΩ), and inserted through a previously implanted guide tube oriented stereotaxically toward the facial nucleus. Facial motoneurones were identified by their response to stimulating the zygomatic branch of the facial nerve with single or double shocks every 500 msec. as well as by collision test. Of 47 neurons tested, 27 responded antidromically to facial nerve stimulation and 20 responded orthodromically. Resting potentials averaged -56 mV, while spike amplitudes averaged 30 mV. There were no significant differences in resting potential or spike amplitude among the three groups of cats or between antidromic cells and orthodromic cells.

Intracellular depolarizing current pulses were applied in each neuron to induce spike generation. The minimum current which repeatedly produced spike activity was taken as the threshold current for excitation. The threshold currents were distributed widely and evenly up to 7 nA in the "Naive" group. However, the distribution was shifted toward the lower values in the "Conditioned" and "US-only" groups. The mean threshold currents of neurons in the "Conditioned" group were 1.2 ± 1.2 nA; those in the "US-only" group were 1.0 ± 1.0 nA; and those in the "Naive" group were 3.5 ± 2.2 nA. The differences between "Conditioned" and "Naive" and between "US-only" and "Naive" groups were significant ($p < 0.01$). Besides the changes in threshold currents, membrane resistances of neurons from "Conditioned" and "US-only" groups were higher than those from the "Naive" group.

The results indicate that excitability changes may be produced in motoneurones by a US regardless of whether or not a CS is associatively paired. These changes could support the latent facilitation of motor behavior that occurs subsequent to presentation of US alone and has been identified previously by behavioral studies (supported by USPHS HD05959).

268.7 PLASTICITY OF A STARTLE-LIKE RESPONSE ELICITED ELECTRICALLY FROM THE ACOUSTIC STARTLE CIRCUIT IN THE RAT. Thomas Parisi and Michael Davis. Dept. Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06508.

The acoustic startle response has proven to be an excellent model system with which to study phenomenon such as habituation, sensitization, and reflex modification caused by antecedant stimulation (pre-pulse modification). Recent evidence suggests that the primary acoustic startle circuit in the rat consists of the auditory nerve, ventral cochlear nucleus, nucleus of the lateral lemniscus, nucleus reticularis pontis caudalis, spinal cord, and muscle (Gendelman & Davis, Neurosci. Abst., 5, 1964, 1979). Startle-like responses can be elicited from various points along this circuit by brief, single-pulse electrical stimuli. The purpose of this study was to evaluate how variables that are known to alter acoustic startle would alter 'startle' electrically elicited from selected structures.

Rats were implanted with chronic bilateral electrodes in either the ventral cochlear nucleus (VCN), or ventral sites in the nucleus reticularis pontis caudalis (NRPC). During testing, startle was elicited electrically by bilateral, single, cathodal pulses (1 msec, .05-.2 mA) to each site.

Similar to acoustic startle, electrically elicited 'startle' amplitude at both sites was directly related to stimulus intensity and inversely related to interpulse interval over a range from 0.5 to 32 sec (temporal recovery process). In a pre-pulse modification paradigm, a weak noise burst (70 db, 20 msec) with a lead time of 10 msec produced marked facilitation of 'startle' amplitude elicited from the VCN but only weak and non-significant facilitation of 'startle' amplitude when elicited from the NRPC. On the other hand, at 80 or 120 msec lead times, the pre-pulse depressed startle amplitude elicited from either site by about the same amount. These results suggest that pre-pulse facilitation, reported for acoustic startle, may be mediated primarily by an action on structures in the acoustic startle circuit prior to the NRPC, whereas pre-pulse inhibition may be mediated by an action on the NRPC or structures beyond.

Like acoustic startle, repetitive elicitation of electrical 'startle' from the VCN using interpulse intervals of 30 sec resulted in an initial increase in 'startle' amplitude (sensitization) followed by a gradual decrease in amplitude (habituation). In contrast, these same procedures resulted in a marked increase in amplitude across the session (sensitization) when 'startle' was elicited from the NRPC. These results suggest that under these conditions, habituation may be mediated by effects on structures prior to the NRPC whereas sensitization may be mediated by actions on the NRPC or structures beyond.

268.8 THE EFFECTS OF SENSORY DEPRIVATION ON SPATIAL RESPONSES OF HIPPOCAMPAL NEURONAL ACTIVITY IN RAT. P. J. Best and A. J. Hill. Dept. of Psychology, Univ. of Virginia, Charlottesville, VA 22901.

In rat, the activity of hippocampal cells is related to the animal's position in space. Maximum rates occur only within certain "spatial fields", specific for each hippocampal cell. In normal animals, if the field of a cell is determined in an open radial maze, and the maze is rotated, the field persists relative to the fixed surroundings and does not shift with the maze. Entorhinal lesions disrupt this spatial persistence and impair performance of a spatial task on the maze.

Neuroanatomical studies have indicated that entorhinal cortex is the primary source of sensory afferents to hippocampus. The present study investigates the effects of sensory deprivation on spatial firing in hippocampus. Rats were made deaf by chronic injection of neomycin sulfate and blindfolded with an opaque rubber mask. Fields of place cells were determined as rats ran on an elevated 6-arm radial maze for sucrose solution. The maze was rotated and place fields again determined. In 10 out of 13 cases, spatial fields did not persist, but followed the maze. In the 3 cases in which spatial firing persisted, rats were spun rapidly at the same time the maze was rotated again. The procedure disrupted the persistence of these cells as well. The same animals were tested in a spatial task on a 17-arm radial maze. Although these animals did not perform quite as well as controls, their scores did not differ significantly from those of controls.

Although loss of auditory and visual cues effects hippocampal cellular activity in a manner similar to entorhinal lesions, the cue deficit has less of a debilitating effect on behavior.

268.9 POST-REINFORCEMENT SYNCHRONIZATION IN THE EEG IS A CORRELATE OF LEARNING ABILITY IN CATS, Cynthia M. Harris*, Glenn T. Livezey*, and Thaddeus J. Marczynski, Univ. Ill. Med. Ctr, Chicago, ILL., 60612.

Pavlov postulated that learning requires an internal inhibition of maladaptive and nonreinforced responses and that the inhibition is coupled with phasic suppression of arousal. Clemente, Sterman and Wyrwicka (1964) hypothesized that phasic bursts of alpha-like EEG activity during conditioned behavior reflects the strength of the internal inhibitory process.In agreement with their hypothesis we have postulated that this phenomena will correlate with learning ability in cats.

To test our hypothesis we recorded EEG in cats during and after behavioral training. We inspected the records for occurence and magnitude of alpha-wave like segments of slow high amplitude synchronized EEG activity following rewarded behavior. The correlation between this Post-Reinforcement Synchronization (PRS) and learning ability was subjected to statistical analysis.

We implanted 27 cats with epicortical stainless steel recording electrodes over the posterior marginal and ectosylvian gyri. Each cat was placed in a training chamber where 1 cc. aliquots of milk were presented via remote control by the experimenter observing the animal's exploratory behavior. Exploratory tendencies that led stepwise toward association of the milk reward with lever pressing were partially rewarded by the experimenter to direct the animal's choice of exploratory behaviors. Thus the training proceedure required flexibility of behavior by the animal to suppress actions that were only partially rewarded in favor of those that were more fully rewarded until the animal learned to consistently depress the lever with the paw. Band pass frequency filters and a Grass integrator allowed quantification of the 7-14 c/s EEG frequency characteristic of PRS. PRS magnitude was scored as a ratio of the deflection of the integrator trace during the PRS activity and the deflection during a comparable time period before or after this PRS segment. Learning rate was scored in terms of length of training time required for each cat.

Across the 25 cats which learned to lever-press a significant correlation was found between the mean magnitude of PRS and the time required to learn to lever press ($r=.77$, $P<.001$). Cats with small PRS responses showed a tendency to perseverate in non-effective behaviors and required 3-6 fold greater training periods compared with cats with large PRS responses.

A neural model to account for this correlation between learning ability and PRS magnitude is presented in a companion abstract (Ladien et al.). The model incorporates the notion of PRS involvement in response evaluation and learning consolidation. The model also incorporates behavioral pharmacology data supporting a role for opiate and cholinergic receptors in PRS generation. As both expectation of reward and stimulus reinforcement value are required for PRS manifestation, a neural substrate for a match/mismatch process is discussed.

268.10 AN EXPANDED PARSIMONIOUS MODEL OF THE BRAIN. K. Ladien, T.J. Marczynski, and C.M. Harris, Dept of Pharmacology, Univ. of Illinois Med Ctr., Chicago, IL 60612

Numerous studies have shown that cats develop an alpha-like post-reinforcement synchronization (PRS) centered over their parieto-occipital area during consumption of milk in a bar pressing paradigm. We report in a companion abstract (Harris et al) that slow learning cats after acquisition of response have poorly developed PRS as compared to fast learners. Also, PRS in well-trained cats is blocked in a dose-dependent fashion by naloxone and is augmented by low doses of morphine.*Such observations support the notion that PRS activity and an accompanying Reward Contingent Positive Variation (RCPV) slow cortical potential are dependent both upon expectations and the stimulus reinforcement value. Similarly to Vanderwolf, Lindsley and others, we have observed hippocampal theta rhythms during approach and irregular activity during consumption which may be a necessary, but not sufficient condition for the appearance of PRS. We discuss the role of hippocampal match/mismatch feedback processes within the context of phasic reticular inhibition upon task completion. A circuit diagram accounting for the neuroanatomical substrates of the expectation, reinforcement, and matching processes is presented. It is proposed that task-specific channels are set up between stimulus- and response-sets during learning. Operant behaviors may be mediated by hippocampal spatial and cognitive maps reflected in the convergence of processed sensory inputs via the entorhinal perforant path with reticular and reinforcement information through medial septal-fascia dentate cholinergic tracts. Channels reflect the temporally coherent ensemble activity of multiple areas leading from the selective attention to and categorization of a stimulus to the matching of this stimulus with a particular response. For PRS, hippocampal maps may help couple parieto-occipital, reticular, and endogenous reinforcement pathways which are cooperatively activated depending upon learned associations and expectations. These areas remain coupled until a response is completed. The PRS-RCPV is seen as a cortical correlate of stimulus-response evaluation and may be important both in channel consolidation as well as in preparing the animal to shift attention. Such evaluation effects may also correlate with the P300 activity observed in human evoked potentials during sensory and cognitive discriminations. This work represents an update and elaboration upon a previously presented model of PRS-RCPV and other electrophysiological data (Marczynski, Multidisciplinary Perspectives in Event-Related Brain Potential Research, D. Otto, ed, EPA, 1978).

* Enkephalinergic projections between and within the amygdalar nuclei and the bed nucleus of stria terminalis may partially underlie these morphine-related reinforcement effects.

269.1 MONOCULAR DEPRIVATION AFFECTS CELL MORPHOLOGY IN LAMINAE C AND C_1 IN CAT LATERAL GENICULATE NUCLEUS. D. M. Murakami* and P. D. Wilson (SPON: J. Myerson).

Monocular deprivation leads to reduced cell growth in the binocular segment of the deprived A-laminae of the cat lateral geniculate nucleus (LGN). However, in order to measure the effect of monocular deprivation on cells in the C-laminae, laminae C and C-2 receiving contralateral input must be discriminable from lamina C-1 receiving ipsilateral input, and this is not possible with only Nissl stained material.

In order to study the C-laminae, kittens monocularly deprived 20-38 weeks received a 25 µl injection of 20% horseradish peroxidase (HRP) in the posterior chamber of either the deprived or experienced eye. After 4 days survival, the animal was perfused with Karnovsky's solution, and 40 µm brain sections were reacted for HRP with TMB and counterstained with neutral red. The presence and absence of HRP reaction product in the optic tract terminals clearly defined all laminae within the LGN.

Soma sizes were measured at 1000x for over 100 cells in each lamina, with care taken to measure only cells clearly within the boundaries of a lamina and only those profiles containing a clear nucleolus and Nissl substance. A significant reduction in cell size was found in laminae C and C-1 as well as in the A-laminae. Cells in the deprived laminae relative to those in the non-deprived laminae were reduced 27% for lamina A, 35% for A-1, 25% for C, 28% for C-1, and 3% for C-2, with a significant difference for all laminae except C-2.

Previous reports concerning cells in the A-laminae have shown that Y-type relay cells are more affected by monocular deprivation than X-type relay cells. Since W-type relay cells are found in laminae C (the ventral portion), C-1 and C-2 of the LGN, our results suggest that the soma size of W-cells may also be affected by monocular deprivation (Supported by Biomedical Research Grant, UCR)

269.2 EFFECTS OF MONOCULAR EYELID SUTURE ON THE STRUCTURE OF PHYSIOLOGICALLY IDENTIFIED NEURONS IN THE DORSAL LATERAL GENICULATE NUCLEUS. Michael J. Friedlander, L.R. Stanford* and S. Murray Sherman. Dept. of Neurobiology and Behavior, State Univ. of New York, Stony Brook, NY 11794.

The relationship of neuronal structure to physiological type was investigated in the A laminae of the dorsal lateral geniculate nucleus of cats raised to adulthood with monocular eyelid suture. This was done by intracellularly injecting physiologically described cells with horseradish peroxidase (HRP) for subsequent morphological analysis. Intracellular recording, iontophoresis of HRP, and tissue processing was as previously described in this laboratory[1,2].

Twenty neurons from deprived animals (10 cells each from deprived and nondeprived layers), have been recovered, to date. The morphological properties of these cells have been compared to those of identified X- and Y-cells from normal animals[1,2]. The following similarities to and differences from normal X- and Y-cells have been seen: 1) Nondeprived Y-cells appear physiologically and morphologically normal. 2) Nondeprived X-cells appear physiologically normal. The nondeprived X-cells all have soma sizes at the upper end of the normal X-cell size distribution, but their morphology is otherwise unremarkable. 3) Deprived X-cells appear normal in soma size, but have some morphological dendritic properties usually associated with Y-cells. 4) Finally, deprived Y-cells, some with normal and some with abnormal physiological properties have been recovered. All of these deprived Y-cells have somata smaller than any normal Y-cell previously seen. The physiologically normal, surviving deprived Y-cells are small but otherwise morphologically like normal Y-cells. Some of the deprived Y-cells with unusual physiological properties show dendritic structure not associated with normal Y-cells.

269.3 RETURN OF Y-CELLS IN THE LATERAL GENICULATE NUCLEUS OF MONOCULARLY DEPRIVED CATS. E.E. Geisert, P.D. Spear and A. Langsetmo.* Dept. of Psychology and Neuroscience Training Program, Univ. of Wisconsin, Madison.

Previous studies have shown that removing inputs from the experienced eye of monocularly deprived cats increases the ability of the deprived eye to drive striate cortex neurons. The present experiment investigated whether the loss of Y-cells that occurs in deprived laminae of the lateral geniculate nucleus of monocularly deprived cats also is reversed following removal of the experienced eye. Single cell recordings were made in the lateral geniculate of four groups of animals: normal adult cats; 7 mo. old monocularly deprived cats (MD); 7 mo. old monocularly deprived cats that had the experienced eye removed at 4 mo. of age (MD-DE); and 7 mo. old monocularly deprived cats that had the experienced eye removed and the deprived eye opened at 4 mo. of age (MD-DE-O). From 5-7 cats and 126-155 neurons were studied in each group.

In normal cats, 41.2% of the cells were Y-cells. In agreement with previous studies, monocular deprivation produced a reduction in the proportion of Y-cells encountered: 18.2% were Y-cells in deprived laminae of MD cats, and this is significantly lower than in normal cats (p=0.013, Mann-Whitney test). Removing the experienced eye did not produce an increase in the proportion of Y-cells if the deprived eye remained closed: 17.0% were Y-cells in MD-DE cats. This is significantly lower than in normal cats (p=0.001) but indistinguishable from MD cats. However, removing the experienced eye and opening the deprived eye did produce an increase in the proportion of Y-cells: 40.2% were Y-cells in MD-DE-O cats. This is significantly higher than in both MD (p=0.009) and MD-DE (p=.001) cats, but indistinguishable from normal cats.

The results of this study demonstrate several interesting dissociations. In striate cortex of monocularly deprived cats, the percentage of cells driven by the deprived eye increases when the experienced eye is removed (MD-DE), and this is not altered by opening the deprived eye (MD-DE-O). Therefore, striate cortex shows an increase in the percentage of neurons that can be driven by the deprived eye when there is no change in the percentage of Y-cells in the lateral geniculate nucleus (MD-DE cats), and the return of Y-cells in the lateral geniculate does not have a noticeable effect on the response properties of striate cortex neurons (MD-DE-O cats). Furthermore, in the lateral geniculate nucleus of MD-DE cats, the cells return to nearly normal size, while the percentage of Y-cells remains the same as in MD cats.

269.4 BINOCULARLY MEDIATED INTERACTIONS APPEAR TO MODIFY THE PHYSIOLOGY OF THE ADULT LATERAL GENICULATE NUCLEUS AFTER MONOCULAR PARALYSIS M.G. MacAvoy* and W.L. Salinger. Dept. Psych., University of North Carolina at Greensboro, Greensboro, NC 27412.

Contrary to the traditional view, it has been established that the adult visual system is altered by sensory modifications. For instance, in the lateral geniculate nucleus (LGN) of the adult cat, the relative encounter rate for X-cells (X/Y ratio) is reduced by such perturbations of visual stimulation as chronic monocular paralysis (CHMP;<14 days), acute and chronic binocular paralysis, chronic monocular tenotomy, and reverse monocular deprivation.

To analyze mechanisms responsible for adult neural plasticity we have used the chronic monocular paralysis preparation. As previously reported, the X-cell encounter rate was reduced by CHMP in the three major laminae in the LGN contralateral to the paralyzed eye, even in the lamina which is innervated by the unoperated eye. This reduction of encounter rate for X-cells in the lamina innervated by the unoperated eye led Salinger et al. (1977) to suggest a binocular inhibitory interaction as a mechanism underlying the shift in the X/Y ratio with CHMP. Central to this hypothesis was the assumption that there is a parallel effect of CHMP in the LGN ipsilateral to the paralyzed eye. However, this assumption remained untested for technical reasons. The present experiment provided a test of this assumption by examining the effects of CHMP on the previously unstudied (ipsilateral) LGN.

The change in X/Y ratios in the ipsilateral LGN after monocular paralysis was found to be parallel to that previously reported for the contralateral LGN. Thus reductions were found in all major laminae of the LGN's of both hemispheres, whether the laminae were innervated by the mobile or the paralyzed eye. These findings of parallel effects validate the assumption central to the hypothesis that a powerful binocular inhibitory interaction is involved in the suppression of X-cells during chronic monocular paralysis. These results were particularly striking in light of the traditional picture of the LGN as an entity composed of monocular cells which are subject only to weak, subtle binocular interactions.

269.5 CELL SHRINKAGE IN GENICULATE NEURONS FOLLOWING BRIEF UNILATERAL BLOCKADE OF RETINAL GANGLION CELL ACTIVITY. Baruch Kuppermann* and Takuji Kasamatsu (SPON: D. Van Essen). Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Tonic background activity in visual afferents is indispensable for maintenance of synapses in the adult brain (Lund and Lund, Science, 171, 1971). By brief reversible blockade of tonic retinal discharges, the functional connectivity of geniculo-cortical synapses can be modified in binocular cortical cells of kittens (Kasamatsu, Exp. Brain Res., 26, 1976).

Currently we have studied morphological changes in the dorsal lateral geniculate nucleus (LGN) and physiological changes in the primary visual cortex of kittens induced by monocular blockade of tonic retinal activity. We injected tetrodotoxin (TTX) intraocularly, 10 μg per dose given twice, 3 days apart, to 6-week old kittens. TTX reversibly blocks ganglion cell firing in the retina. Five kittens received unilateral intraocular injections of TTX and were kept either in the light or in a dark room for a week-long period of TTX-induced monocular deprivation. After one week, histological examination of the celloidin-embedded LGN showed cell shrinkage in the deprived laminae in both the animals kept in the light and in the dark. The magnitude of cell shrinkage in deprived laminae of the dark-animals was remarkable despite the brief, one week blockade of tonic retinal discharges. Cell shrinkage in the deprived monocular segment was also observed, as expected with a pure deprivation effect (Hickey et al, J. Comp. Neurol., 172, 1977).

Single unit recordings were made on five kittens subjected to unilateral intraocular TTX (10 μg per dose in two injections 3 days apart) and kept in the light or in a dark room until the recording session. The duration of effects of TTX on ganglion cell firing was determined by physiological recording in the cortex. The end of the effect coincided with reappearance of the pupillary reflex of the injected eye. The period of suppression was found to last from 11 to 13 days. In all recordings a striking loss of binocular cells was observed, with a larger number of cells driven exclusively through the contralateral eye than through the ipsilateral eye.

In summary, we found that total blockade of tonic retinal discharges could induce striking morphological changes in the LGN after only one week of treatment and also resulted in a decrease of the number of binocular cells in the cortex. These changes were found in animals which were kept in the dark as well as in the light throughout the TTX treatment.

269.6 THE EFFECT OF BINOCULAR ENUCLEATION ON LAMINAR DEVELOPMENT IN THE DORSAL LATERAL GENICULATE NUCLEUS. J. K. Brunso-Bechtold and V. A. Casagrande, Depts. of Anatomy and Psychology, Vanderbilt University, Nashville, TN 37232.

In the tree shrew, the dorsal lateral geniculate nucleus (LGN) appears cytoarchitecturally homogeneous at birth. During the first 10 postnatal days, the six layers typical of the adult nucleus gradually become distinct (Brunso-Bechtold and Casagrande, 1980). The object of the present study was to determine the effects of retinal input on the development of LGN layers by removing both eyes of tree shrews on the first postnatal day. The animals were allowed to survive for several intervals up to maturity (3 mo.) and then sacrificed, the brains embedded in celloidin, cut,and stained using standard procedures.

Our main results can be summarized as follows: First, in the adult bilateral enucleate the presence of layers can be distinguished on the basis of cellular morphology and packing density, although such distinctions are not as obvious as in the normal adult nucleus. This suggests that LGN cells can undergo maturation without retinal input. However, comparisons between bilaterally enucleated and normal animals sacrificed on the 8th postnatal day, indicate that the maturation of LGN neurons is slowed by the absence of retinal input. Second, our results show no evidence of clear interlaminar spaces in the absence of retinal input. Since it is unlikely that removal of afferents could prevent cell death, this result would seem to argue that interlaminar spaces form as a result of migration or cell movement rather than cell death. Furthermore, although the interlaminar spaces receive heavy input from superior colliculus and cortex (Casagrande, 1974), their presence in cases with bilateral enucleation demonstrates that these afferents are not sufficient to induce the formation of interlaminar spaces. Moreover, the lack of clear interlaminar spaces after 1, 2, and 3 weeks indicates that the absence of interlaminar spaces at 3 months is not a secondary loss. Finally, bilateral enucleation at birth appears to have a much less profound effect on LGN organization than does unilateral enucleation (unpublished observations). In cases with unilateral enucleation, the deafferented layers can scarcely be distinguished, and the nucleus appears dominated by the layers still receiving retinal input. This suggests that additional factors such as binocular interactions may play a major role in the development of LGN.

269.7 LOSS OF RETINAL X-CELLS IN CATS WITH NEONATAL VISUAL CORTEX REMOVAL. P.D. Spear, L. Tong, R.E. Kalil, and E.C. Callahan*. Depts. of Psychology and Ophthalmology, and Neuroscience Training Program, Univ. of Wisconsin, Madison, WI 53706.

Previous anatomical experiments indicate that transneuronal retrograde degeneration of retinal ganglion cells occurs following neonatal removal of visual cortex in both cats and monkeys. In addition, size measurements and the central projections of the remaining ganglion cells have led to the suggestion that the degeneration selectively affects the X-cell functional class. We tested this possibility directly by recording from retinal ganglion cells in cats that had visual cortex removed neonatally.

Kittens received unilateral lesions of areas 17, 18, and 19 within 24 hours of birth, and they were studied when they were 13-14.5 months old. Recordings were made from single ganglion cell somas using intraocular microelectrodes. Cells were sampled from the nasal retina of the eye contralateral to the lesion; i.e., from the portion of the retina that normally projects exclusively to the hemisphere with the visual cortex lesion. An area of retina spanning 5°-15° from the area centralis and 8° above to 8° below the zero horizontal meridian was sampled systematically. Recordings also were made in normal adult cats using identical sampling procedures. Ganglion cells were classified as X, Y, or W on the basis of a large battery of tests, including the presence of linear or non-linear spatial summation, cut-off velocity, receptive field size, and response latency to optic chiasm stimulation.

Thus far, recordings have been made from four normal cats and three cats with neonatal visual cortex lesions. In normal cats, cell body recordings were encountered on about 40% of the retinal penetrations. Among 85 ganglion cells that have been studied, 50% were X-cells, 33% were Y-cells, and 17% were W-cells. In cats with neonatal visual cortex removal, cell body recordings were encountered on only about 25% of the retinal penetrations. Among 60 ganglion cells that have been studied, only one (1.5%) was an X-cell while 62% were Y-cells and 36.5% were W-cells. It is interesting to note that the decrease in ganglion cell sampling density (% of penetrations in which a cell body recording was encountered) can be accounted for entirely by the decrease in X-cells encountered. In addition, the ratio of remaining Y-cells to W-cells encountered in cats with neonatal lesions is about the same (1.7:1) as that in normal cats (2:1). Therefore, the results indicate that the neonatal visual cortex lesions produce a severe loss of retinal ganglion cells in the X-cell functional class, and that retinal Y-cells and W-cells are unaffected by the lesions.

269.8 RETROGRADE DEGENERATION OF RETINAL GANGLION CELLS FOLLOWING REMOVAL OF VISUAL CORTEX IN THE NEWBORN KITTEN. R.E. Kalil, Dept. of Ophthalmology, Univ. of Wisconsin, Madison, WI 53706.

It is well known that ablation of visual cortex in the adult cat produces retrograde cell degeneration in the dorsal lateral geniculate nucleus. Removal of visual cortex in the newborn kitten also causes retrograde cell changes in the primary visual pathway and these changes appear to be more extensive than those which follow adult lesions. Thus damage to visual cortex in neonatal animals leads not only to cell death in the lateral geniculate nucleus, but also, as the present findings demonstrate, to transsynaptic retrograde degeneration of ganglion cells in the retina.

The degeneration of retinal ganglion cells has been studied quantitatively in cats from which visual cortex had been removed on the day of birth. As adults, the animals were perfused with phosphate buffered glutaraldehyde and a whole mount of the retina from each eye was prepared, and then stained with cresyl violet. The cross-sectional, perikaryal areas of ganglion cells were measured at two locations in each retina. Both locations were approximately 2.5 mm above the area centralis, and either 1.0 mm nasal or temporal to it. In addition, all large ganglion cells (cross-sectional area 800 μ^2 or greater) were counted in a 45 mm^2 area of the upper quadrants of the nasal and temporal hemiretinae of each eye.

Cell size frequency distributions were constructed from the cross-sectional area measurements. The distributions from the temporal and nasal retinae ipsilateral and contralateral, respectively, to the early cortical lesion show a 60% to 70% reduction in the number of medium sized ganglion cells (cross-sectional areas 300 μ^2 to 800 μ^2), but little or no change in the number of small ganglion cells (cross-sectional area less than 300 μ^2). Large ganglion cells appear to be unaffected by early removal of visual cortex insofar as their density and cross-sectional area are not altered.

These results indicate that damage to visual cortex in the newborn kitten leads to specific retrograde transneuronal changes in the ganglion cells of the retina: medium sized cells are reduced in number dramatically, whereas small and large ganglion cells are unaffected. Functionally, these results predict a deficit in X type ganglion cells but not in W- or Y-cells.

Supported by NEI Grant EY01331.

270.1 MECHANISM OF ACTION OF PHENCYCLIDINE (PCP) IN THE CNS: AN IONTOPHORETIC STUDY. S.N. Raja*, and P.G. Guyenet. Univ. of Virginia, Dept. Pharmacology, Charlottesville, VA 22908.

The following electrophysiological experiments were undertaken to determine the effects of PCP on noradrenergic (NE) and dopaminergic (DA) neurons and to examine whether the drug alters the postsynaptic action of ACh, NE, DA, opioid peptides, Glu, GABA and substance P. Single unit recordings were made in chloral hydrate anesthetized rats using single or multi-barrel glass micropipettes. NE neurons were recorded in the locus coeruleus (LC), DA neurons in the substantia nigra pars compacta (SN). The rest of the recordings were obtained for CA1 hippocampal pyramidal cells (CA1 cells) or cerebellar purkinje cells (P cells).

PCP (0.75-1.8 mg/kg i.v.) produced a 55-65% decrease in the spontaneous firing rate (SFR) of all 6 NE neurons tested, lasting for 15-20 min. Iontophoretic PCP (0.2M, pH 4.0, 10-20nA) also decreased the SFR of these cells by 50 to 100%. In the LC, PCP (3-7nA) inhibited the action of three excitatory neurotransmitters (ACh, Glu, subs P) to approximately the same degree while the action of inhibitory substances was unchanged (met-enkephalin, GABA and clonidine). The antagonism by PCP of excitatory transmitters was observed only at doses which also decreased the SFR of LC cells; in contrast, the local anesthetic procaine antagonized the excitation caused by ACh and Glu without altering the SFR.

PCP (1.0-1.8 mg/kg i.v.) increased the SFR of a fraction of DA cells in the SN characterized by a slow (1-3/sec) firing rate (5 cells) and did not alter the SFR of the others (7 cells). PCP pretreatment (5.2-10 mg/kg i.v., 10 min) produced a 2.3 fold increase in the average dose of i.v. amphetamine necessary to inhibit the SFR of DA cells. Iontophoretic PCP (20-40nA) slightly inhibited the SFR of DA neurons and did not alter the inhibitory response to iontophoretic DA. These results demonstrate that PCP is neither a dopaminergic antagonist nor an amphetamine-like drug and suggest that the action of PCP on DA neurons must be indirect, possibly via a decrease in the activity of a striatonigral feedback.

From these and additional experiments conducted with CA1 and P cells the following generalizations could be made: 1) iontophoretic PCP depressed the SFR of all cells recorded 2) PCP antagonized the effects of all excitatory neurotransmitters tested and didnot alter the action of inhibitory transmitters (GABA, opiates, NE at α or β receptors) but its effects were qualitatively different from that of procaine 3) all effects of PCP (i.v. or local) could be mimicked with doses of the related anesthetic ketamine 3 to 10 times larger. Supported by NIDA grant # 1R01DA 02310-01.

270.2 EFFECT OF PHENCYCLIDINE (PCP) ON ELECTROSHOCK-INDUCED SEIZURES AND ON GLUTAMIC ACID DECARBOXYLASE ACTIVITY OF THE MOUSE BRAIN. Marie T. Spoerlein, Christina VanderWende and William Pritchard*. Rutgers University, Coll. Pharmacy, Box 789, Piscataway, N.J. 08854.

Male, Swiss Webster mice were administered various doses of PCP intraperitoneally. The animals were sacrificed by decapitation 35 min. after the injection; the brains were removed and dissected over a bed of crushed ice to isolate the cerebellum, striatum and hippocampus. Glutamic acid decarboxylase (GAD) was assayed by a modification of the method of Lowe, Robins and Eyerman (J. Neurochem. 3: 8-18, 1958) to scale it up to a more macro procedure. Each area was homogenized in 3.0 ml cold distilled water and centrifuged at 1,000 g for 20 min. One half of 1.0 ml was added to 0.5 ml of buffered substrate mixture containing pyridoxal phosphate and sodium glutamate to give final concentrations of 0.5 mM and 25 mM, respectively in 0.1 M phosphate buffer, pH 6.4.

PCP caused a 15 % increase of GAD at 5 mg/Kg and a 27% increase at 10 mg/Kg in the hippocampus, but at higher doses where the animals exhibited increased excitability and seizures, there was no difference from the control. There was no effect of PCP on GAD in the cerebellum or striatum at 10 mg/Kg.

PCP was examined for anticonvulsant activity at doses that caused no seizure activity in themselves. Animals were protected against maximal electroshock-induced seizures at 35 min. after injections in a dose related manner. At 10 mg/Kg, 100% of the animals tested were protected whereas at 5 mg/Kg and 2.5 mg/Kg, 60% and 50% of the animals were protected, respectively.

Although it cannot be definitely concluded from these data, the increase of GAD activity in the hippocampus may relate to the ability of PCP to prevent seizures.

270.3 BUSPIRONE: A MODEL FOR ANXIOSELECTIVE DRUG ACTION. Duncan P. Taylor, Deborah K. Hyslop* and L. A. Riblet. Biologic Research, Mead Johnson Pharmaceutical Division, Evansville, IN 47721.

Buspirone has been shown to be an effective antianxiety agent at the same dose as diazepam in a double-blind placebo-controlled study of psychoneurotic outpatients with a primary diagnosis of anxiety neurosis (Am. J. Psychiatry 136: 1184). Behavioral studies in animals as well as clinical observations have revealed that buspirone possesses an anxioselective pharmacological profile. Specifically, while buspirone shares diazepam's antianxiety properties, buspirone does not elicit sedative-hypnotic, anticonvulsant, or muscle relaxant effects. Further, buspirone exhibits minimal interaction with CNS depressants and does not display any potential for physical dependence or abuse in animal models. In in vitro binding experiments buspirone exhibits minimal inhibition of [^{3}H]-ligand binding at α_1, α_2, β, ACh, glutamate, glycine, H_1, H_2, opiate, 5-HT_1, and 5-HT_2 receptors. Notably, buspirone neither inhibits nor stimulates [^{3}H]-benzodiazepine binding, is without effect on the stimulation of binding by GABA or halide anions, and does not interfere with GABA binding or uptake. Buspirone interacts with reasonable potency only at the dopamine receptor. Buspirone appears to be an antagonist (100 µM GTP produces no shift in K_i) of lower potency (K_i=90 nM) at [^{3}H]-spiperone binding sites (postsynaptic) and as an agonist (a GTP-induced loss of inhibitory potency is present) of higher potency (K_i=18 nM) at [^{3}H]-N-propylnorapomorphine binding sites (presynaptic). Preliminary experiments indicate that the concentration of buspirone in the brain is of the order of 3 nM after therapeutic dose levels. This is consistent with the hypothesis that buspirone interacts at low concentrations at a receptor responsible for the relief of anxiety, and at higher concentrations at receptors responsible for other dopamine-mediated responses. However, unlike spiperone or other postsynaptic dopamine receptor antagonists, buspirone does not cause catalepsy. If presynaptic inhibitory dopamine receptors are located on dopaminergic neurons, stimulation of these receptors should inhibit dopaminergic transmission. If DA receptors are located on synaptic endings of other neurons (NE, ACh, peptides), stimulation of these receptors would alter nondopaminergic forms of neurotransmission. For instance, disinhibition of central noradrenergic transmission might be responsible for the electrocortical activation observed in animals treated with buspirone (Fed. Proc. 39: 752). A dose-dependent biphasic response to buspirone has been observed in vivo which provides pharmacologically revelant support for this hypothesis.

270.4 TOLERANCE FOLLOWING CHRONIC BENZODIAZEPINE TREATMENT: CHANGES IN BEHAVIOR AND IN NUMBER OF RECEPTORS. Howard C. Rosenberg and Ted H. Chiu*. Dept. of Pharmacology, Medical College of Ohio, Toledo, OH. 43699.

Previous reports from this laboratory have shown that intensive treatment of rats with the benzodiazepine flurazepam (FZP) caused an apparent reduction in the number of benzodiazepine receptors (Life Sci. 23:1153, 1978). This is a specific effect since similar treatment with barbital caused no significant change in benzodiazepine binding (Life Sci. 24:803, 1979). The present report describes further research into the time course of change in receptors, and the possible role of receptor modification in tolerance.

FZP was dissolved in a .02% saccharin solution and rats were allowed free access to this as their only liquid supply. Control rats were given saccharin solution to drink. Based on each rat's weight and volume of fluid consumed, FZP was added so that each rat would consume a dose of 100 mg/kg daily for the first week, then 150 mg/kg daily for the remainder of the treatment. Specific ^{3}H-flunitrazepam (^{3}H-FNP) binding to cerebral cortical membranes was studied following different durations of treatment. After 28 or 56 days of treatment, there was a highly significant decrease of 18-22% in the maximal binding capacity (B_{max}). Treatment for 7 or 14 days had no effect on B_{max}. Another series of rats received 28 days of treatment, then undrugged saccharin solution was given for various times before performing ^{3}H-FNP binding assays. B_{max} was reduced up to 12 hrs after the end of chronic treatment, but returned to control value by 24 hrs. There was no significant change in the dissociation constant (K_D) in any group.

The ataxia produced by acute i.p. FZP (20 to 200 mg/kg) was measured in control rats and in rats that had been treated for 28 days with FZP. Ataxia was rated on a scale of 0 (normal gait) to 3 (unable to walk at all). Dose-response analysis showed significant tolerance in rats tested 12 hrs after terminating chronic FZP consumption. However, in rats tested 24 hrs after the end of chronic treatment, tolerance had been lost. Thus, chronic FZP caused adaptation that was seen both as a reduction in the number of benzodiazepine receptors, and as tolerance to FZP-induced ataxia. Both measures returned to control between 12 and 24 hrs. after stopping chronic treatment. This suggests that the ataxia produced by FZP is mediated by specific benzodiazepine receptors, and the observed tolerance is a result of reduction in the number of benzodiazepine receptors.

270.5 A GAS CHROMATOGRAPHIC-MASS SPECTROMETRIC IDENTIFICATION OF FLURAZEPAM AND ITS METABOLITES IN PLASMA AND CEREBROSPINAL FLUID OF THE CAT. C. C. Chiueh, M. Ohata*, S. I. Rapoport, W. Mendelson and D. Greenblatt*. Lab. of Neurosciences, NIA, NIH, Baltimore City Hospitals, Baltimore, MD 21224; Lab of Clinical Psychopharmacology, NIMH, Bethesda, MD 20205; Clinical Pharmacology, Tufts-New England Medical Center Hospital, Boston, MA 02111.

The metabolic fate of flurazepam has been studied in animals and humans by using radioactive tracer techniques, spectrophotofluorometry and gas chromatographic techniques. Most of these studies described the pharmacokinetics of flurazepam in plasma or urine samples and indicate that N_1-desalkyl flurazepam is slowly biotransformed and accumulated during chronic therapy. Because the N_1-unsubstituted metabolite of this drug is pharmacologically active, it may be responsible for the unwanted toxic effects of flurazepam in the elderly following a 30 mg per night dose regime. The present experiments were designed to study the accumulation of lipophilic metabolites in the central nervous system of the cat after i.v. administration of 30 mg/kg of flurazepam. A gas chromatographic-mass spectrometric procedure is used in order to identify flurazepam and its metabolites in cerebrospinal fluid and plasma samples. A positive identification of benzodiazepines by mass spectrometry requires at least 50 to 100 ng per injection of sample into the Hewlett-Packard-5992 gas chromatographic-mass spectrometric system. Results confirm that the major metabolite of flurazepam in the blood was the N_1-desalkyl analogue, which accumulated significantly up to 24 hr after administration of a single dose of flurazepam. A positive identification of unchanged and N_1-desalkyl flurazepam in the cerebrospinal fluid was obtained 60 min after i.v. administration of the drug. There was an accumulation of this N_1-unsubstituted metabolite in the cerebrospinal fluid 24 hr after a single dose of flurazepam. The half life of flurazepam in plasma and cerebrospinal fluid appeared to be less than 2 hr. In summary, after a single i.v. administration of flurazepam, the unchanged analogue disappears quickly in plasma and cerebrospinal fluid while the N_1-desalkyl metabolite is slowly accumulated in blood and cerebrospinal fluid.

270.6 EFFECTS OF PHENYTOIN ON [^{3}H]DIAZEPAM BINDING IN DISSOCIATED PRIMARY CORTICAL CELL CULTURE. D. W. Gallager, P. Mallorga,* K. Swaiman* and P. Nelson. Biological Psychiatry Branch, NIMH and Lab. of Developmental Neurobiology, NIH, Bethesda, MD 20205

Primary cell cultures of fetal mouse cortex were grown in the presence of various concentrations of the anticonvulsant drug phenytoin (DPH). In these cultures, total [^{3}H]diazepam binding successively decreased in a dose-dependent manner, decreasing to 39% of control when maintained for 7 days in media containing 50 µg/ml DPH. Pharmacological characterization of [^{3}H]diazepam binding was accomplished by measuring the ability of a centrally active benzodiazepine, clonazepam (CLON), and a centrally inactive benzodiazepine, RO5-4864 to displace [^{3}H]diazepam binding (see abstract this volume, Mallorga et al.). In DPH-treated cultures, a dose-dependent decrease in CLON displaceable [^{3}H]-diazepam binding was observed decreasing to 6% of control culture binding at the 50 µg/ml dose of DPH. Scatchard analysis of membranes from DPH and control cultures showed that the decrease in CLON-displaceable [^{3}H]diazepam binding was due to a decrease in the total number of binding sites without a significant change in [^{3}H]diazepam binding site affinity. For example, membranes from cells grown in culture with media containing 25 µg/ml DPH had a K_D = 9.6 nM and B_{max} = 478 fmol/mg protein as compared to binding in control cultures with a K_D = 7.2 nM and B_{max} = 645.4 fmol/mg protein. The ratio of 10^{-7} M CLON/10^{-7} M RO5-4864 displaceable binding progressively decreased with increasing doses of DPH from 6.5 in non-DPH treated cultures to 0.15 in cultures treated with 50 µg/ml DPH. These changes can be correlated with DPH dose-dependent decreases in neuronal cell number as documented in a parallel cell culture study (see abstract this volume, E. A. Neale et al.). Decreases in the total number of [^{3}H]diazepam binding sites in fetal cortical cells maintained in culture with DPH are also consistent with decreases in [^{3}H]diazepam binding site number observed in cortical membranes prepared from pups exposed in utero to DPH (Gallager and Mallorga, Science, 208:64, 1980). These data are consistent with the possibility that DPH causes a dose-dependent reduction in developing cortical neurons containing [^{3}H]diazepam binding sites.

270.7 PHENYTOIN INCREASES THE SPONTANEOUS RELEASE OF ^{3}H-GABA IN CRUDE SYNAPTOSOMAL FRACTIONS OF RAT BRAIN. A. D. Vanker and S. J. Prevost*. Information Science Group, Univ. of Missouri, Columbia, MO 65211 and Dept. of Biology, Georgia State Univ., Atlanta, GA 30303.

Sprague-Dawley rats were given daily intraperitoneal injections of phenytoin at 10 mg/kg for 0-28 days. The animals were sacrificed by decapitation and the cerebral cortex divided into hemispheres. Each hemisphere was minced with a razor blade into prisms with sides of approximately 1 mm. One mince was used immediately to obtain a crude synaptosomal fraction for uptake studies using standard methods. The other was placed in a physiological buffer containing ^{3}H-gamma-aminobutyric acid (^{3}H-GABA) at 37°C and incubated under oxygen for 10 min, 'preloading' the various elements of the mince with ^{3}H-GABA. This mince was then used to obtain a crude synaptosomal fraction. Approximately 40 min elapsed between the end of the incubation and the actual release experiments.

Low-affinity and high-affinity uptake of ^{3}H-GABA were not affected in any experimental group; neither was elevated K^+-induced release of ^{3}H-GABA from the 'preloaded' fractions. Spontaneous release of ^{3}H-GABA, however, was significantly increased in all experimental groups except day 0. No significant inter-group differences were observed. It is apparent from our data that phenytoin affects a GABA pool not directly involved in the uptake or depolarization-induced release of GABA. This pool could be synaptosomal, glial, or perhaps even mitochondrial in origin. If it occurs into the synaptic region, the increased spontaneous release of this inhibitory neurotransmitter may be part of the anticonvulsant mechanism of action of phenytoin.

This research was supported by a grant from the Epilepsy Foundation of America.

270.8 EFFECTS OF γ-VINYL GABA ON CHEMICALLY INDUCED SEIZURES IN MICE: CORRELATION WITH BRAIN GABA CONTENT. D.A. Kendall,* D. Fox and S.J. Enna. Depts. Pharmacol. and Neurobiol. and Anat., Univ. Texas Medical School, Houston, Texas 77025

A number of inhibitors of GABA transaminase (GABA-T), the enzyme responsible for the metabolism of this neurotransmitter, have been reported to be effective in attenuating audiogenic or chemically induced convulsions. Curiously, however, while these drugs presumably act by enhancing GABAergic transmission, they tend to be substantially less effective against seizures induced by bicuculline, a GABA receptor antagonist, than against other types of convulsants. In the present investigation, the neurochemical and anticonvulsant effects of γ-vinyl GABA (GVG), an irreversible inhibitor of this enzyme, were investigated in an attempt to better understand the mechanism of action of this agent.

Male mice (Timco) were injected with 1500 mg/kg GVG and the protection against bicuculline (3 mg/kg s.c.), picrotoxin (10 mg/kg s.c.), isoniazid (250 mg/kg s.c.) and strychnine (2 mg/kg i.p induced seizures was determined at 4 and 24 hr after administration of GVG. The characteristics of the seizures induced by these agents differed with regard to severity and latency to clonus and tonus, presumably because of their differences in potency and sites of action. The parameters measured were time to first clonus, loss of righting reflex, onset of tonus and death. At the 4 hr time, significant protection was noted against all convulsants except bicuculline. Surprisingly, at 24 hr, while the degree of protection against picrotoxin, isoniazid and strychnine had substantially diminished, bicuculline-induced seizures were now significantly inhibited. Neurochemical analysis revealed that brain GABA content was elevated 15-fold at 4 hrs, but had declined to 7-fold at the 24 hr time point. In order to determine whether the time after injection or the brain GABA levels correlated best with the apparent selectivity of the anticonvulsant effect, animals were treated with a dose of GVG (1000 mg/kg) which elevated brain GABA 7-fold at the 4 hr time. In this case, bicuculline seizures were inhibited in a manner similar to that seen at 24 hr after the larger dose of GVG.

The results suggest that brain GABA content must be substantially elevated to inhibit chemically-induced seizures. Furthermore, the anticonvulsant effect appears to be somewhat selective in that protection against bicuculline-induced seizures occurs only within a narrow dose range of GVG. Thus, clinically, the antiepileptic dose of GVG may vary, not only with severity, but also with the type of seizure being treated. (Supported in part by USPHS grants NS-13803 and NS-00335).

270.9 THE ACTIONS OF VALPROIC ACID ON DORSAL ROOT FIBERS IN THE FROG SPINAL CORD. John C. Hackman, Robert A. Davidoff and Victoria Grayson.* Neurophysiology Laboratory, Neurology Service, V.A. Hospital and Department of Neurology, University of Miami School of Medicine, Miami, Florida 33101.

Valproate (n-dipropylacetate, DPA), an effective anticonvulsant, is thought to act by increasing CNS GABA levels. But recently it has been shown to augment GABA-induced inhibition of neurons. Our present experiments were designed to evaluate the effect of DPA on GABAergic synapses located on primary afferent fibers.

We used the hemisected frog spinal cord continuously superfused with HCO_3^--buffered Ringer's solution maintained at 15°C. Synaptic and amino acid-induced responses were recorded from dorsal roots (DR) using sucrose gap techniques.

DPA, added to the superfusate in concentrations of 10^{-5}M or greater, usually produced a small depolarization of primary afferent terminals (∿ 0.5mV). This potential change did not appear to result from activation of GABA receptors or Cl^- ionophores since it was not blocked by picrotoxin, bicuculline, piretanide or low $[Cl^-]_o$. Nor did it result from release of transmitter from GABAergic synapses, since DPA did not affect the spontaneous efflux of preloaded [^{3}H]GABA from cord slices. Futhermore, there was no "cross-desensitization" between GABA and DPA.

DPA (10^{-5}M) enhanced the amplitude (130%) and duration of DR depolarizations produced by applications of GABA [and depressed those caused by K^+ (10mM), glutamate and aspartate] in both normal and Mn^{++} (1.5mM)-Ringers. Two processes contributed to the effect: (1) The fading ("desensitization") of GABA-depolarizations seen with prolonged applications of the amino acid was suppressed by DPA; (2) DPA significantly reduced the high-affinity uptake of [^{3}H]GABA by cord minislices (1% of control uptake). The postsynaptic potentiating effect of DPA may not be specific for GABA, since DPA also increased the size of the DR responses elicited by β-alanine and taurine applications.

The anticonvulsant depressed and shortened dorsal root potentials elicited by DR or ventral root stimulation. This effect may be caused by the ability of DPA to reduce (40%, 10 min, 10^{-5}M) the K^+-induced efflux of [^{3}H]GABA from cord slices and to the decreased release of K^+ induced by tetanic DR stimulation (as measured with K^+-sensitive electrodes).

These effects of DPA may contribute to its anticonvulsant properties. (Supported by V.A. funds, MRIS 1769).

270.10 METABOLISM OF L-DOPA AND DEUTERATED L-DOPA IN RAT BRAIN: CONVERSION INTO METABOLITES OF NOREPINEPHRINE. David J. Edwards and Marguerite Rizk*. Dept. of Pharmacology-Physiology, Univ. of Pittsburgh, Sch. Dent. Med., Pittsburgh, PA 15261.

The therapeutic effects of L-DOPA in Parkinson's disease is generally attributed to its conversion to dopamine (DA), thereby overcoming the deficiency of this neurotransmitter in the basal ganglia. However, several studies show effects of L-DOPA on norepinephrine (NE) metabolism in brain, and other studies suggest that NE may play a role in some of the behavioral effects of L-DOPA. We have developed techniques utilizing gas chromatography/mass spectrometry for analyzing the neutral deaminated metabolites of DA, NE and related amines (Edwards, et al., J. Chromatogr. Biomed. Applic. 164, 407, 1979), which we now have applied to studying the effects of L-DOPA and its deuterated analogue in the rat. Urine metabolite studies revealed that the excretion of 3,4-dihydroxyphenylglycol (DHPG), a NE metabolite, was elevated 2.3-fold in male Sprague-Dawley rats (240-300 g) injected i.p. with 150 mg/kg L-DOPA as compared to control animals (22 ± 3 µg/24 hr in experimental vs. 9.4 ± 1.1 µg/24 hr in controls, $p < .01$), but the excretion of 3-methoxy-4-hydroxyphenylglycol (MHPG) was not significantly changed (63 ± 8 vs. 60 ± 8 µg/24 hr in experimental and control animals, respectively). In separate experiments, brain levels of MHPG and DHPG were measured in brain samples of rats injected with L-DOPA. Both MHPG and DHPG as well as the corresponding DA metabolites reached a maximum 1 hr after injection. MHPG and DHPG concentrations in whole brain were increased by 78% ($p < .001$) and 134% ($p < .02$), respectively, 1 hr after an injection of 150 mg/kg L-DOPA. MHPG and DHPG concentrations were also increased in each of the specific brain regions examined. Since the increases in MHPG and DHPG could be due to either an increase in NE synthesis (via conversion from the exogeneously administered L-DOPA) or to an increased turnover of the endogeneous NE content, experiments were carried out using deuterium-labeled L-DOPA (L-DOPA-d3) to distinquish between these two possibilities. MHPG and DHPG and the corresponding d3-labeled analogues were measured in the cerebellum and "rest of brain" of rats injected with either 50 or 150 mg/kg L-DOPA-d3 one hour before sacrifice. The concentrations of unlabeled MHPG and DHPG showed small, but nonsignificant, changes in the two brain parts. MHPG-d3 concentrations in the cerebellum and "rest of brain" of rats injected with 150 mg/kg L-DOPA-d3 were 77 and 80 ng/g, respectively; and DHPG-d3 concentrations were 82 and 61 ng/g, respectively. These amounts of deuterated metabolites in tissues account for almost all of the increases in MHPG and DHPG observed in experiments using unlabeled L-DOPA. Thus, these results demonstrate that the increases in MHPG and DHPG produced by L-DOPA is primarily due to the conversion of L-DOPA to NE. (Supported by grant MH-28340 from NIMH).

270.11 INTERACTIONS BETWEEN HARMALINE(HAR), RESERPINE(RES) AND APOMORPHINE(APO) ALTER CENTRAL AND PERIPHERAL CATECHOLAMINE(CA) METABOLISM. S.G. Speciale*, F.Karoum and R.J. Wyatt(SPON: R.M. Stewart). Dept. Psychiat., U. Tx. Hlth. Sci. Cntr., Dallas, TX 75235 and Lab. Clin. Psychopharm., NIMH, St.Elizabeths Hosp., Wash., D.C. 20032

The mammalian sympathetic ganglion is a useful model of neuronal circuitry and transmitter interaction. It contains cholinergic preganglionics that synapse on noradrenergic (NE) cell bodies (sending postganglionic fibers to target organs) and interneurons, which, in some species, are dopaminergic (DA) and possibly peptidergic. We have used pharmacological approaches to manipulate CA metabolism and compare effects in the celiac ganglion (cg) with several brain regions. We examined the interactions of a monoamine oxidase (MAO) type A inhibitor, HAR (since ganglia contain type A almost exclusively and brain contains types A and B), the DA agonist APO and RES, a CA depletor.

Male Sprague-Dawley rats (200gms) were utilized in all experiments. Drug dosages were adjusted to standardize sacrifice time to 150 minutes. HAR (1mg/kg,ip) elevated NE, but not DA or its metabolite, dihydroxyphenylacetic acid (DOPAC) in the cg. APO (2.5 mg/kg, ip) similarly increased NE without changing DA or DOPAC. RES (1mg/kg,sc) lowered cg NE 75% and DA 56%, while DOPAC rose over 5-fold. APO+HAR combination did not differ significantly from that of HAR or APO alone. RES+HAR resulted in less amine depletion (NE 38% Control (C), DA 76% C) and completely antagonized the RES-induced increase in DOPAC (expected by blocking catabolism).

CA metabolism was also measured in the hypothalamus (hpth) and caudate (cn) of the same animals. In the hpth HAR did not change DA or its metabolites, but reduced NE and its metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG). APO did not alter NE, DA or their metabolites. RES significantly depleted NE (20% C) and DA (7% C), while DA metabolite homovanillic acid (HVA) and MHPG only changed slightly. APO+RES antagonized the CA depletion (NE 56% C, DA 60% C) and metabolites remained unchanged. HAR+RES even further reversed depletion (NE 83% C, DA 139% C), while metabolites were unchanged.

In the cn HAR did not alter CA concentrations but DOPAC and HVA decreased 40%. Apo produced very similar changes. RES alone depleted NE (14% C) and DA (3% C), while DOPAC and HVA increased over 2-fold. As in hpth, HAR+RES increased DA 30% and restored NE levels, however metabolites were significantly reduced (>60%).

Brain and cg CA metabolism responded differently to these drugs. HAR antagonized RES-induced metabolite increase but HAR did not elevate amines greatly in any tissue, as MAO inhibition should do. At these doses HAR and APO had similar actions, alone or combined with RES, in cg and cn, suggesting a common DA-like mechanism, different from MAO inhibition. Decreases in cn DA metabolites without amine changes suggest HAR and APO reduce DA turnover.

270.12 DIFFERENTIAL EFFECTS OF APOMORPHINE ON DORSAL AND MEDIAN RAPHE NEURONS. E.H-Y. Lee* , and M.A. Geyer. Dept. of Psychiatry, Univ. of California at San Diego Sch. of Med., La Jolla, CA 92093.

In an effort to assess the functional inter-relationships between monoaminergic systems in brain, we have used quantitative cytofluorimetry to measure changes in cellular serotonin produced by the dopaminergic agonist apomorphine. A measure of fluorescence fading using a computerized microspectro-fluorimeter enables us to discriminate changes in serotonin from changes in catecholamines and to discriminate intracellular from extracellular amines (Geyer et al., 1978. J. Pharm. Exp. Ther. 207:650-667). Thirty minutes after intraperitoneal injections of saline, 1.0 or 10.0 mg/kg apomorphine, male rats (125-150 gms) were sacrificed, the midbrain raphe area was removed, freeze-dried, treated with formaldehyde, and embedded in paraffin. Microscopic measures were made in both the dorsal (B7) and median (B8) raphe nuclei in 8 micron sections. Both doses of apomorphine significantly increased intracellular serotonin levels in B7, without significantly affecting the cells in B8. This regional difference in apomorphine's effect may be related to the differential amounts of catecholaminergic innervation to these two nuclei. We have reported similar regional difference in the effects of amphetamine on serotonin fluorescence in B7 and B8 (Geyer et al. 1975, Brain Res. 85: 135-139), although amphetamine's effect was to decrease rather than increase serotonin. Apomorphine also produced a dose-dependent increase in the fluorescence outside the cell bodies, particularly in B7. This change appears to be due to increases in both serotonin and catecholamines in the extracellular spaces. Further studies are in progress to clarify the changes in catecholamines within the raphe and to determine the mechanism of apomorphine's effect on the serotonergic cell bodies.

270.13 INHIBITION OF PROTEIN SYNTHESIS IN RAT STRIATUM BY AMPHETAMINE TREATMENT: PARTIAL REVERSAL BY HALOPERIDOL PRETREATMENT. Robert Cohen*, Susan Chung*, and Lawrence Roel (SPON: Mary F. Orr). Dept. of Anatomy, Northwestern Univ., 303 E. Chicago Ave., Chicago, IL 60611.

Previous studies have indicated that intraperitoneal (i.p.) administration of d-amphetamine sulfate causes polysome disaggregation in rat brain (Proc. natn Acad. Sci. U.S.A. 72: 779, 1975) which is accompanied by reduced rates of brain protein synthesis (J. Neurochem. 31: 341, 1978). Doses of amphetamine which are effective in causing whole brain polysomal disaggregation inhibit protein synthesis in all areas of the brain that were investigated.

We now have undertaken studies to determine whether lower doses of amphetamine (subthreshold for producing whole brain polysomal disaggregation) might produce changes in protein synthesis in selective areas of the brain. In the first series of experiments, amphetamine sulfate (1 mg/kg) or an equal volume of saline was administered i.p. to 140 g male Sprague Dawley rats. Seventy five min later, animals were injected intravenously (i.v.) with 20 μCi ^{3}H-lysine, and killed 30 min thereafter. In the second series of experiments, rats were injected i.p. with haloperidol (1 mg/kg) or 0.025 M citric acid diluent, and 1 hr later injected i.p. with 1 mg/kg amphetamine or saline diluent. One hr after amphetamine (or saline) administration, animals were injected i.v. with 20 μCi ^{3}H-lysine and killed 30 min later. Brains were rapidly removed, dissected into striatum, cerebral cortex, hypothalamus, cerebellum, and "rest of brain", and incorporation of ^{3}H-lysine into trichloroacetic acid precipitable protein determined.

Synthesis of protein in striatum is inhibited 25-40% 105 min after administration of 1 mg/kg amphetamine sulfate. At this time after amphetamine administration, protein synthesis did not appear to be altered in cerebellum, cerebral cortex, hypothalamus, or "rest of brain". When haloperidol was administered 1 hr prior to amphetamine injection, the selective inhibition of protein synthesis in striatum was blocked about 50%. Haloperidol treatment alone did not alter protein synthesis in striatum, or any of the other brain regions studied. Supported by a starter grant from Northwestern University (NIH RR05370).

270.14 SPECIFIC INTERACTION OF ATROPINE WITH α-ADRENERGIC RECEPTORS IN RAT BRAIN. Elinor H. Cantor, Shlomo Abraham* and Sydney Spector*
Department of Physiological Chemistry and Pharmacology, Roche Institute of Molecular Biology, Nutley, New Jersey 07110

Several reports in the literature have suggested that the antimuscarinic drug atropine inhibits catecholamine-induced contractions in isolated vascular tissue. We have recently described a hypotensive response to atropine in conscious rats which is apparently mediated by postjunctional α-adrenergic receptor blockade. The present study was undertaken to determine directly if atropine interacts with α-adrenergic sites. Binding of the α-adrenergic receptor ligands [^{3}H]WB-4101 (WB) (0.2 nM) and [^{3}H]prazosin (PRAZ) (0.1 nM) and the α_2-adrenergic receptor ligand [^{3}H]clonidine (CLON) (1.0 nM) was measured in homogenates of brains of Sprague-Dawley rats. Binding was measured in the presence and absence of various concentrations of phentolamine, l-norepinephrine, and atropine. IC_{50} values were determined by linear regression analyses of log-probability plots of the displacement curves obtained with each competitor. K_i values were calculated according to the formula $K_i = IC_{50}/(1 + C/K_d)$, using the following K_i values determined in our laboratory: K_d(WB) = 0.5 nM, K_d(PRAZ) = 0.1 nM, and K_d(CLON) = 5.0 nM. All assays were performed in duplicate and the data are presented as mean ± SEM. Total binding (fmol/mg protein) was 21.3 ± 1.7 (n=11) for WB, 15.6 ± 1.3 (n=7) for PRAZ, and 10.2 ± 2.3 (n=8) for CLON. Phentolamine was the most potent of the agents tested, with K_i values of 2.4 ± 0.5 nM (n=3) for displacement of WB, 2.2 ± 0.3 nM (n=4) for PRAZ, and 9.7 ± 2.4 nM (n=3) for CLON. Norepinephrine was more active in displacing CLON binding (K_i = 24 ± 5 nM, n=3) than WB (K_i = 840 ± 140 nM, n=3) or PRAZ (K_i = 560 ± 40 nM, n=4) binding. Atropine was equally as active as norepinephrine in displacing α_1-adrenergic ligands with a K_i value of 860 ± 90 nM (n=5) for WB binding and 740 ± 50 nM (n=4) for PRAZ, but was essentially inactive against CLON binding (K_i = 200 ± 3 μM, n=4). These data indicate that atropine interacts specifically with the classical postjunctional α_1-adrenergic site as defined by radioligand binding studies. This property is not common to all antimuscarinic drugs as methylatropine and scopolamine failed to displace either α_1- or α_2-receptor ligands at concentrations less than 100 μM. Furthermore, the ratio of the K_i values for displacement of α_1- and α_2-ligands by atropine is of the same order as that generally obtained with α-adrenergic receptor antagonists. These data, together with the observed effect in vivo, suggest that atropine acts as an antagonist at the α_1-site.

270.15 ANTAGONISM OF BEHAVIORAL AND ELECTROPHYSIOLOGICAL RESPONSES TO SEROTONIN BY CLONIDINE. William D. Matthews. Department of Biological Research, Smith Kline and French Laboratories, Philadelphia, PA 19101.

The head shake response in rats after systemic administration of the serotonin (5HT) precursor 5-hydroxytryptophan (5HTP) is a useful model for central 5HT receptor activation (Matthews and Smith, Life Sci. 26:1397,1980). Head shakes induced by 5HTP are particularly sensitive to intraperitoneal administration of known 5HT antagonists. Metergoline inhibited head shakes with an ED_{75}= 0.07 (0.02-0.27) mg/kg as did cyproheptadine, ED_{75}=0.15 (0.09-0.30) mg/kg. Recent studies revealed that clonidine also produced a dose-related antagonism of the head shake behavior, ED_{75}= 0.005 (0.002-0.014) mg/kg. Electrophysiological experiments were then conducted to determine if antagonists of 5HTP-induced head shakes could inhibit responses to 5HT applied iontophoretically to hippocampal neurons.

Rats were anesthetized with urethane and standard electrophysiological techniques used to record the activity of individual hippocampal neurons (pyramidal and granule cells) while applying drugs by microiontophoresis. Hippocampal neurons respond to 5HT in a uniform manner. Ninety-one percent (103 of 113) of all cells encountered were inhibited (≥ 50% reduction in spontaneous firing rate) by iontophoretic application of 5HT (0.05M, pH4, 50-100nA). Metergoline (0.04M, pH4, 20-40nA) applied for up to 5 min had no effect on spontaneous neuronal activity but blocked the inhibitory actions of 5HT in 60% (9 of 15) of the cells tested. Clonidine (0.01M, pH4, 5-20nA) reduced or abolished the inhibitory effect of 5HT in 100% (9 of 9) of the cells studied. Some cells increased their rate of discharge in the presence of clonidine. A clonidine analog (2-3,4-dihydroxyphenylamino) imidazoline (DPI) was also studied in the electrophysiological experiments. DPI (0.01M, pH5, 10-20nA) reduced or abolished the inhibitory response to iontophoretic application of 5HT in all cells examined (5 of 5).

The data suggest that inhibition of 5HTP-induced head shakes by clonidine may result from an interaction between clonidine and 5HT at the level of a central 5HT receptor. Further studies are in progress to definitely characterize the clonidine-5HT interaction.

270.16 NEUROPHARMACOLOGICAL CHARACTERIZATION OF CNS PURINERGIC P_1 RECEPTORS. G. G. Yarbrough and J. C. McGuffin-Clineschmidt*.
Merck Institute for Therapeutic Research, West Point, PA 19486.

Purines exert pronounced influences on the excitability of many types of tissues, including the CNS, and the existence of subclasses of the "purinergic" receptor has been inferred (Burnstock, 1978). While there is a substantial body of literature describing the effects of purines on central neuronal excitability and various biochemical parameters, there is a relative paucity of data concerning the in vivo behavioral effects of adenosine (ADO) and related compounds. Administered intracisternally, ADO, 2-chloroadenosine (CADO), adenosine-5'-cyclopropylcarboxamide (ACC) and adenosine-5'-ethylcarboxamide (AEC) caused dose-related increases in hot plate reaction times in rodents. The rank order of potency was AEC = ACC > CADO > ADO. ADO itself was more potent than AMP, ADP, ATP and several other related compounds of interest. Theophylline and caffeine antagonized the antinocisponsive effect of CADO or ACC. Papaverine (an adenosine uptake blocker) and erythro-9-(2-hydroxy-3-nonyl) adenine (EHNA; an adenosine deaminase inhibitor) potentiated the effect of ADO. EHNA did not potentiate the action of CADO in this procedure. The antinocisponsive effect of CADO was not antagonized by a host of neurally active agents including naloxone, clonidine and RO 20-1724. Time course studies indicated that the antinocisponsive effect of ADO was transient with the peak effect occurring 5 min after injection and disappearing by 60 min, whereas the effect of CADO persisted for up to 4 hrs. Intracisternally-administered CADO also caused a pronounced hypothermia and loss of muscle tone in mice and exerted a hypotensive effect in anesthetized rats. CADO was also active in the mouse writhing test. Taken together, these data demonstrate that purines exert potent in vivo behavioral effects and are consonant with the existence of a central purinergic P_1 receptor which is amenable to selective pharmacological manipulation.

Burnstock, G. (1978) In: Cell Membrane Receptors for Drugs and Hormones: A Multidisciplinary Approach. eds. L. Bolis and R.W. Straub, Raven Press, New York.

270.17 BINDING OF THE ANTITUSSIVE DRUG DEXTROMETHORPHAN TO GUINEA PIG BRAIN. G. L. Craviso* and J. M. Musacchio. Dept. Pharmacology, N.Y.U. School of Medicine, New York, NY 10016.

We have studied the binding of the non-narcotic antitussive drug dextromethorphan (DM) to guinea pig brain homogenates. ^{3}H-DM at a final concentration of 4 nM is incubated with brain tissue for 2.5 hrs at 0°C in the presence and absence of 10 µM unlabeled DM. Bound ^{3}H-ligand is separated from free drug by rapid filtration. The binding of DM is saturable and reversible and displays stereospecificity since levomethorphan is 20 fold less effective than its dextro isomer as an inhibitor of ^{3}H-DM binding. Scatchard analysis demonstrates the presence of two binding components, a high affinity component with a K_d of 30 nM and a low affinity component. Subcellular distribution studies indicate that the low affinity component is localized in the mitochondrial fraction whereas the high affinity component is found in both "microsomal" and "membrane fractions". In regional distribution studies, the greatest proportion of high affinity binding sites is in the cerebellum and lower brain stem.

Various classes of centrally-acting antitussive drugs have been tested for their ability to alter ^{3}H-DM binding. Opiate analgesics and opiate antagonists with antitussive activity (butorphanol) have negligible effects on binding when used at concentrations up to 10^{-5} M. The non-analgesic antitussive drugs (+)-methadone and (-)-propoxyphene produce significant inhibition at 10^{-5} M (73% and 28% respectively) and dextrorphan has an IC_{50} value of 2.5×10^{-6} M. Clonazepam, an antitussive benzodiazepine, does not alter binding at any concentration tested. Noscapine, a phthalideisoquinoline antitussive drug, produces a dose-dependent (10^{-7} M to 10^{-5} M) increase in ^{3}H-DM binding. Saturation studies indicate that this drug increases the affinity of ^{3}H-DM for the high affinity binding sites 3 fold while the low affinity binding component is not affected. The antitussive noscapine analog hydrastine also increases ^{3}H-DM binding but only when used at higher concentrations.

High affinity, stereospecific and saturable binding of ^{3}H-DM has also been detected in liver and other non-neural tissue. However, the high affinity DM binding studied in the liver is not increased by noscapine, suggesting that the nature of the binding sites is different in neural and non-neural tissue.

Whether or not the binding of ^{3}H-DM described is related to the mechanism of action of the drug cannot be determined at this time. The antitussive activity of DM is not naloxone reversible and therefore not mediated by opiate receptors. The results of our binding experiments are consistent with this finding. (Supported by PHS grants #1 RO1 DA02013, MH17785 and a Pharmaceutical Manufacturers Association Predoctoral Fellowship to G.L.C).

270.18 METHOTRIMEPRAZINE, A PHENOTHIAZINE ANALGESIC, LACKS DIRECT ENKEPHALINERGIC ACTIVITY. T. A. Robert, A. N. Hagardorn*, and E. A. Daigneault. Dept. of Pharmacology, East Tennessee State University College of Medicine, Johnson City, TN 37601.

The drug methotrimeprazine (MTM) is unique in that it possesses both clinically useful neuroleptic and analgesic activities. These actions are stereospecific in that the levorotatory isomer is the pharmacologically active specie. Since stereospecificity and potency are characteristics associated with receptor-specific interactions, it was proposed that MTM produces analgesia as an opiate receptor agonist. This hypothesis was tested by in vitro opiate receptor binding studies and in vivo rat prolactin (rPRL) release experiments.

Opiate receptor studies were performed upon crude homogenates of the calf caudate nucleus utilizing tritiated methionine enkephalin, dihydromorphine, and naloxone as ligands at concentrations of 2, 1, and 1.5nM, respectively. Various concentrations of both levorotatory and dextrorotatory MTM were tested for their abilities to inhibit specific opiate receptor binding. Specific binding was defined as the difference between that which occurred in the absence or presence of 1 µM levallorphan. The effects of various test drugs upon rPRL release were determined in groups of five male rats (300 ± 27 g) at 0, 30, and 60 min post treatment. Treatments employed were: saline control (vehicle); chlorpromazine HCl, 10 µmole/kg; morphine sulfate, 10 mg/kg; (-)-MTM, 10 µmole/kg; all administered i.p. Plasma samples from blood obtained by heart puncture under light ether anesthesia were analyzed for rPRL concentrations using the NIAMDD radioimmunoassay kit (supplied by Dr. A. F. Parlow of the Rat Pituitary Hormone Distribution Program).

In all the opiate receptor studies with endogenous or exogenous agonists or the antagonist, MTM failed to show stereospecific inhibition of radioligand binding at concentrations less than 10^{-5}M. Furthermore, the observed release of rPRL induced by (-)-MTM was not significantly different ($P<0.05$) from chlorpromazine or morphine sulfate. These results suggest that (-)-MTM does not interact directly upon enkephalinergic neurons in the central nervous system.

270.19 THE PHARMACOLOGICAL EFFECTS OF NICOTINE IN THE UNANESTHETIZED DOG. S. G. Kamerling, J. G. Wettstein*, and W. R. Martin. Dept. of Pharmacology, University of Kentucky, Coll. of Med., Lexington, Ky 40536.

Six unanesthetized beagle type dogs (weighing 8.5-11.0 kg) participated in a study of the effects of nicotine on heart and respiratory rates, electroencephalographic amplitude and frequency, pupillary diameter, heat evoked skin twitch latency, body temperature and behavior. The release of methionine-enkephalin into ventricular perfusates was also studied in these dogs concurrently and will be reported elsewhere. Each dog participated in three experiments conducted at weekly intervals using a crossover design. The experiments were (1) intravenous nicotine infusion (40 µg/kg/min) for 20 minutes, (2) intravenous saline infusion for 20 minutes, and (3) no treatment. Observations were made at 5 minute intervals for 60 minutes. For statistical purposes, observations were divided into three 20 minute epochs. During the second epoch the nicotine or saline infusion was given. The data were expressed as a percent of the mean of the first epoch for each physiologic parameter. During the nicotine infusion skin twitch latency, heart rate and respiratory rate were significantly increased, while pupillary diameter and EEG amplitude were significantly decreased. The decreased EEG amplitude and pupillary diameter persisted into the third epoch. Nicotine generally produced behavioral arousal, vomiting and moderate degrees of salivation, rhinorrhea, and lacrimation during the second epoch. Nicotine analgesia, as measured by prolongation of the skin twitch reflex latency, was not antagonized by naltrexone (2 mg/kg) or by mecamylamine (1 mg/kg) pretreatment. However, the mecamylamine experiment was confounded by the fact that mecamylamine alone produced a significant degree of analgesia.

270.20 NEUROPHARMACOLOGICAL STUDIES OF THE PARASITIC TREMATODE, SCHISTOSOMA MANSONI, USING ELECTROMYOGRAPHY. T. N. Mellin, R. D. Busch* and C. C. Wang. Dept. of Biochemistry, Merck Sharp & Dohme Research Labs, Rahway, NJ 07065.

A dual in vitro test system was developed which combines a 1 hr. visual motor assay with suction electrode electromyography for quantitation of the electrical activity produced by contracture of the worms musculature. Studies were conducted on adult male and female worms maintained in 50% heat inactivated horse serum/Earles balanced salts at 37°C. This media was buffered at pH 7.4 with 0.02mM Hepes. Surface electrical activity was measured as the absolute integral of positive and negative input signals, obtained by full wave rectification, and expressed in mV seconds. Male worm length was also measured. All changes in motility were confirmed by electromyography.

5-Hydroxytryptamine (5-HT-0.01mM), a putative neurotransmitter in schistosomes, caused a marked increase in motor and electrical activity. Tryptamine (0.1mM) and the 5-HT agonist 2-(p-chlorophenyl)-ethylamine, were equivalent to 5-HT in activity. Acetylcholine (20mM), a putative inhibitory neurotransmitter in schistosomes, and the cholinergic agonist, carbachol (1mM), produced a flaccid paralysis. Worm length was unaffected. The cholinergic antagonists, atropine (muscarinic-0.01mM) and mecamylamine (nicotinic-1mM), increased worm motility and blocked the action of exogenous acetylcholine (10mM). Worm activity was decreased by the cholinesterase inhibitor, neostigmine (1mM). GABA (1mM) and its agonists, piperazine (1mM) and muscimol (0.1mM), had no effect on schistosome activity, nor did the GABA antagonists, picrotoxin (0.1mM) and bicuculline (0.1mM) or the Cl^- channel blockers, Na-penicillin-G (1mM) or pentylene tetrazole (1mM). L-glutamate (1mM), and its agonist, kainic acid (1mM), glycine (1mM) and avermectin B_{1a} (0.01mM) were also without effect. Dopamine (10mM) and apomorphine (10mM) caused little or no decrease in worm activity, but produced 76% ($P<0.01$) and 36% ($P<0.01$) increases in worm length, respectively.

The novel antischistosomals, praziquantel (PZQ-0.001mM) and clonazepam (CLZ-0.025mM), caused a rapid and total loss of motor and electrical activity, with a significant ($P<0.01$) shortening in length. Other benzodiazepines, diazepam (valium-0.1mM) and chlordiazepoxide (librium-0.1mM), were without effect. The activity of PZQ and CLZ was blocked by the Ca^{+2} transport/binding inhibitors, ruthenium red (1mM) and lanthanum (1mM). These inhibitors did not block the spastic paralysis produced by the general cation ionophore, lasalocid (1mM), suggesting that PZQ act by a non-ionophore mechanism.

270.21 INTERACTIONS BETWEEN ANTIDEPRESSANT DRUGS AND β -ADRENERGIC BINDING AND FUNCTION IN NORMAL MOUSE ASTROCYTES. L. Hertz* and J.S. Richardson, Dept. of Pharmacology, University of Saskatchewan Saskatoon, Saskatchewan S7N 0W0 Canada.

The demonstration by Sulser (Trends Pharm. Sci., 1, 92, 1979) that chronic treatment with any type of antidepressant drug leads to a "down-regulation" of β-adrenergic receptor function has led us to study the effect of antidepressant drugs on cyclic AMP level and on the binding of [^{3}H]dihydroalprenolol, a β-adrenergic ligand, in normal mouse astrocytes in cultures; such cells are known to possess β-adrenergic receptors (McCarthy and de Vellis, J. Cycl. Nucl. Res. 4, 15, 1978; Van Calker and Hamprecht, J. Neurochem. 30, 713, 1978). The labeled ligand was bound in large amounts by a saturable, high-affinity binding (K_D approximately 50 nM) which was efficiently displaced by the β-adrenergic blocker propranolol but, peculiarly enough, not by the β-adrenergic agonist isoproterenol. The antidepressant drugs studied were amitriptyline and desipramine (two monoamine uptake inhibitors), tranylcypromine (a MAO inhibitor), and doxepine, inprindole and mianserin, which have little or no effect on these two parameters. All these drugs displaced the labeled dihydroalprenolol. They showed somewhat different potencies but half maximum displacement was in general observed at a concentration of about 5 μM, i.e., a concentration about 10 times the plasma levels observed in patients under chronic treatment with antidepressants. Binding studies were also made of the binding of one of the antidepressants, doxepin, which was bound specifically with a K_D value which likewise was a few μM. This binding could be displaced both by amitriptyline and propranolol.

In accordance with findings by Van Calker and Hamprecht (opus cit.) the level of cyclic AMP in the cultured cells was substantially increased after 10 min. of exposure (at 37°) to the β-adrenergic agonist isoproterenol. This increase was partly (about 50%) blocked by 5 μM amitriptyline, the only drug tested until now. In contrast, amitriptyline had no effect on the level of cyclic AMP in the absence of isoproterenol.

From these studies we conclude that antidepressant drugs show specific binding to cells from the central nervous system, that this binding may interact with β-adrenergic binding sites, and that antidepressants seem to have a beta blocking effect. The experiments were all carried out using astrocytes,and studies are in progress whether similar phenomena also occur in cultured neurons. We are also studying possible chronic effects of exposure of cultured astrocytes to antidepressants in the absence or presence of β-adrenergic agonists.

270.22 EFFECTS OF YOHIMBINE ON DESIPRAMINE INDUCED ADRENORECEPTOR ALTERATIONS IN THE LIMBIC FOREBRAIN. Richard W. Johnson*, N.L. Weich*, R.C. Ursillo* and Henry I. Yamamura. Depts. of Biochemistry, Pharmacology and Psychiatry, Univ. of Ariz. HSC, Tucson, Ariz., 85724 and Merrell Research Center, Cincinnati, Ohio 45215.

Desipramine (DMI), along with several other tricyclic antidepressants, has been shown to be a potent inhibitor of neuronal norepinephrine (NE) reuptake, an effect which has been sugested to constitute its primary mechanism of action. Administration of DMI to rats results in down-regulation of β-adrenergic receptors; this effect is usually manifest only after chronic DMI administration, and has been postulated to be a neurochemical correlate of antidepressant action. The present study was undertaken to determine the effects of yohimbine, an α_2-receptor antagonist which would be expected to disrupt feedback regulation of NE release, on DMI-induced down-regulation of β-adrenergic receptors in the limbic forebrain of the rat. DMI induced alterations of α_2-adrenoreceptors, and the effects of yohimbine thereon, were also investigated in order to determine the involvement of these autoregulatory receptors in the actions of DMI. Our results indicate that after only 4 days [^{3}H]DHA binding to limbic forebrain areas of animals which were treated with DMI plus yohimbine was significantly ($p<.005$) reduced as compared to control (vehicle injected) animals. There was no significant decrease in binding after treatment for this period of time with either DMI or yohimbine alone. The observed reduction of [^{3}H]DHA binding was attributable to a decrease in receptor density (Bmax), with no significant change in affinity. An increase in α_2-receptor density, as measured by [^{3}H]clonidine binding, was also seen after 4-day treatment with DMI plus yohimbine. A similar increase was noted after treatment with yohimbine alone, which may be explicable on the basis of direct α_2-receptor antagonism; however treatment with DMI alone, which has very little affinity for α_2-receptors, also resulted in a significant, though less dramatic increase in α_2-receptor density.

In light of the cotemporality between DMI-induced β-receptor down-regulation and clinically observable reversal of depressive symptoms, the finding that β-receptor desensitization can be accelerated by co-administration of yohimbine suggests that this type of drug combination approach may lead to the development of clinically applicable treatment regimens which exploit this phenomenon to achieve a more rapid reversal of the symptoms of affective disorders. The implications of the observed α_2-receptor increases remain to be elucidated, however the possibility exists that alterations in α_2-receptor density play a role in the mechanism of action of a certain antidepressant drugs. The apparent reciprocity between these α_2 an β-adrenoreceptor alterations is discussed with respect to possible noradrenergic antoregulatory mechanisms within the CNS. Supported by grants from the NIMH.

270.23 [^{3}H] IMIPRAMINE BINDING TO RAT FOREBRAIN AND HUMAN BLOOD CELLS - INHIBITION BY CATIONS. J.L. Steinberg, J.T. Brauchi* and J.D. Lane. Psychiatry Research Unit, Department of Psychiatry, Louisiana State University Medical Center, Shreveport, LA 71130.

Several groups have demonstrated tritiated imipramine binding to rat CNS and human platelets. Our laboratory investigated the specific high affinity binding of this ligand to these membrane preparations and also to membranes from human red blood cells. In addition, numerous cations and anions were added to the incubation media to determine their effects. Total particulate membranes were prepared from rat forebrain, human platelets and human red blood cells by lysing in water or Tris-acetate buffer, with repeated disruption using a Polytron^R and high speed centrifugation. The binding studies were carried out at 50 mM Tris-acetate buffer, pH 7.4. To this buffer were added 0.5-100 mM salts of sodium, potassium, lithium, ammonium, silver, chloride, acetate, citrate, bicarbonate and/or nitrate, and/or 1 mM calcium, cobalt, manganese or magnesium in the presence or absence of 100 μM desipramine. All three kinds of membranes had specific imipramine binding sites (total binding sites: platelets>rat forebrain>red blood cells), with dissociation constants circa 2 nM. Monovalent and divalent cations inhibited specific imipramine binding by as much as 80% (100 mM cations) in a concentration dependent fashion, while non-specific binding was not affected. Numerous anions had no effect on binding. The inhibition was additive if more than one cation was included in the incubation. The effects of guanine nucleotides and displacement of ligand by imipramine metabolites were also investigated. High affinity imipramine binding sites may be similar to opiate, adrenergic, benzodiazepine, and muscarinic cholinergic receptors which also show ion-dependent binding characteristics. (Supported by USPHS Grant #MH-31835)

270.24 COMPARISON OF RADIORECEPTOR AND CHEMICAL ASSAYS IN THE EVALUATION OF THE EFFECTS OF NEUROLEPTICS AND ANTIDEPRESSANTS IN MAN. C.H. Misra, H. Shelat*, J. Sammeta*, D.E. Leelavathi, J.C. Schoolar, and R.C. Smith, Behavioral Neurochemistry, Texas Research Institute of Mental Sciences, Houston, Texas 77030.

Multi-spectrum radioreceptor (RR) assays on the same plasma sample may provide a better correlation with differential clinical and side-effects of a psychotropic drug in man than specific chemical assays. We have been studying the utility of radioreceptor blood level assays in controlled clinical studies. Haloperidol and thioridazine levels in the plasma sample were assayed by displacement of three ligands -- spiperone, QNB and WB-4101. Antidepressants were assayed by displacement of QNB and WB-4101. Drugs were also assayed by specific chemical methods. There was a good correlation ($r = .80 - .90$) between levels of haloperidol obtained by radioreceptor assay of spiperone and GLC assay, although there was considerable interpatient variability. Hydroxy metabolites of imipramine, desipramine, and nortriptyline, as well as the parent drugs, were fairly potent in displacing QNB and WB-4101 (IC_{50} 10^{-5} to 10^{-6} M). Radioreceptor blood levels determined by QNB and WB-4101 displacement correlated highly with some side-effects of the drugs in patients. Detailed studies of the correlation of blood levels determined by RR and chemical assays in relation to clinical response are being analyzed.

270.25 DOPAMINERGIC CHARACTERISTICS OF A NIGRO-STRIATAL SYSTEM MAINTAINED IN VITRO. Catherine Mytilineou, William O. Whetsell and Gerald Cohen. Mount Sinai School of Medicine, New York, N.Y. 10029.

Explants from substantia nigra and striatum from newborn mongrel dogs were grown together in organ cultures for periods up to 2 months. The explants developed fiber outgrowth which connected the substantia nigra with the striatum. Glyoxylic acid histofluorescence demonstrated the presence of catecholamines in several cell bodies in the substantia nigra and in numerous fibers originating from that explant. Fluorescing fibers were also seen reaching and terminating in the striatal tissue. Both the substantia nigra and the striatal explants exhibited an active uptake for ^{3}H-dopamine which was completely inhibited by the specific dopamine uptake inhibitor nomifensine (10^{-5}M). The accumulated ^{3}H-dopamine could be released when the explants were incubated in a medium containing high concentrations of K^+ (50 mM). The synthesis of dopamine could also be followed in the living cultures by measuring the accumulation of homovallinic acid (HVA) into the feeding medium by high performance liquid chromatography with amperometric detection. The amount of HVA which accumulated in the 50 ul of feeding medium bathing the nigro-striatal cultures during 3 to 4 days ranged from 4-24 ng. The accumulation of HVA was inhibited by treating the cultures with 10^{-5}M pargyline. HVA was not present in feeding medium that was not exposed to the nigrostriatal cultures. In addition, there was no HVA present in the feeding medium from cultures that consisted of striatal tissue alone.

Supported by NIH Grant 11631.

270.26 DOPAMINE AGONIST ACTIVITY OF "PARTIAL" ERGOLINE MOLECULES. E. B. Smalstig,* E. C. Kornfeld,* and J. A. Clemens. Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

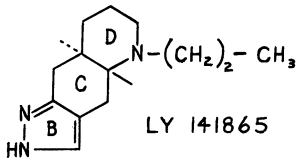
Based on the potent dopamine (DA) agonist activity of ergoline molecules such as lergotrile, pergolide, and bromocriptine, an attempt was made to identify the portion of the 4-ringed ergoline structure which imparts this DA activity. In vivo inhibition of reserpine-elevated serum prolactin was used to assess activity at pituitary dopamine receptors. In vitro dopamine agonist activity was tested in a paired hemipituitary incubation. Central nervous system DA agonism was measured by ability to induce "turning behavior" in rats with unilateral 6OHDA lesions of the nigrostriatal pathway and/or electrolytic lesions of the caudate nucleus. Specific DA receptor blockers (spiperone, haloperidol and pimozide) were used to verify the dopaminergic basis of the observed effects.

A comprehensive series of tri- and bicyclic compounds (containing various portions of the ergoline structure) was synthesized and tested. These compounds included tricyclic benz<cd> indols and tricyclic and bicyclic pyrrols and pyrazols. To avoid rapid metabolism by MAO, most compounds were secondary or tertiary amines with substitution of methyl, ethyl or propyl groups on the nitrogen corresponding to the 6 position on the ergoline molecule.

DA agonism was present in all of the classes of partial ergolines tested. Based on both prolactin inhibition and turning induction data the DA potency of the classes decreases in the following order:

tricyclic pyrazoles=tricyclic pyrroles>tricyclic benzindols>
bicyclic pyrazoles=bicyclic pyrroles

The tertiary amines were always more active than the primary or secondary amines and propyl substituted amines were the most active compounds in each class. The most potent of the partial ergolines was LY141865, a propyl substituted tricyclic pyrazole. The dopamine agonist activity of LY141865 approached that of pergolide in vitro, and in vivo, and could be blocked by spiperone and haloperidol. Isolated smooth muscle testing indicated that LY141865 has none of the serotonin agonist or α-blocking activities seen with many of the ergolines.



LY 141865

These experiments illustrate that the dopamine agonist properties of the ergolines reside in the pyrrolethylamine "substructure" rather than the phenethylamine portion of the molecule.

270.27 AMANTADINE SPECIFICALLY PROTECTS STRIATAL DOPAMINE RECEPTORS FROM HALOPERIDOL INDUCED HYPERSENSITIVITY. R.M. Allen, J.D. Lane, J.T. Brauchi*. Psychiatry Research Unit, Department of Psychiatry, LSU Medical Center, Shreveport, LA 71130.

Amantadine has been shown to present haloperidol induced dopamine receptor hypersensitivity using a stereotyped behavior model (Allen et al, Biol. Psychiatry, 14, 541). In this study we looked at the effects of amantadine on the development of striatal, mesolimbic and hypothalamic DA neuron hypersensitivity secondary to chronic haloperidol administration using both the apomorphine induced stereotyped behavior assay and [^{3}H] spiroperidol binding. Three groups of 18 Fisher rats were treated according to the following protocol for 21 days: Group I saline; Group II haloperidol 5 mg/kg; Group III haloperidol haloperidol 5 mg/kg and amantadine HCl 50 mg/kg; all intraperitoneally. Four animals were selected from each group and challenged with subthreshold apomorphine (.25 mg/kg I.P.) prior to treatment and following treatment and rated for stereotyped behavior at 5,15, and 30 min using a 4 point scale as reported previously (Ibid). The remaining animals were killed by decapitation and the striata, nuclei accumbens, and hypothalami dissected and frozen at -70°C. The areas from each group were separately pooled and membrane preparations made. The [^{3}H] spiroperidol binding technique of Fields et al (Brain Res.,136, 578) was used. The results of the stereotyped behavior assay, which assesses only striatal supersensitivity, revealed a significant reduction in striatal hypersensitivity in the amantadine group compared to the haloperidol alone group (P<.014 using Marin-Whitney single tail t-test). The results of the radioligand assay were similar and consistent for the striatal area-Group I Saline Bmax=748 fmol/mg protein; KDapp 73; Group II haloperidol Bmax=932 fmol/mg protein; KDapp=89 pM; Group III haloperidol and amantadine Bmax 789 fmol/mg KDapp 75 pM. All linear correlations on the Scatchard analysis were greater than 0.997. Because of limited tissue, binding was assayed at 100 pM concentration of [^{3}H] spiroperidol in the nucleus accumbens and hypothalamic areas for the 3 groups with the following results=Group I NA 72.7 fmol/mg protein; hypo. 24.4 fmol/mg; Group II NA 89.6 fmol/mg, hypo. 27.3 fmol/mg; Group III NA 95.4 fmol/mg, hypo. 33.7 fmol/mg. These results show that amantadine protects striatal but not mesolimbic or hypothalamic DA receptors from haloperidol-induced supersensitivity. These results correlated with clinical observations that amantadine is effective in treating neuroleptic induced extrapyramidal side effects without affecting antipsychotic activity (DiMassio et al, Arch. Gen. Psychiatry, 33, 599) and support Allen's hypothesis that amantadine might prevent neuroleptic induced tardive dyskinesia (Curr. Ther. Res., 22, 914).

270.28 ANTAGONISM OF DRUG-INDUCED ACTIVATION OF STRIATAL DOPAMINE SYNTHESIS BY LEVONANTRADOL. B. Kenneth Koe. Central Research, Pfizer Inc., Groton, CT 06340.

Dopamine (DA) synthesis in rat corpus striatum is accelerated in response to (1) the blockade of DA receptors by neuroleptics, and (2) the inhibition of impulse flow by γ-butyrolactone or baclofen. This phenomenon may be used to study agents which exert a modulatory effect on striatal DA neurons. Levonantradol is a novel cannabinoid-related benzo[c]quinoline with potent analgesic properties (Milne et al., The Pharmacologist 20: 243, 1978). I have found that levonantradol (1 μmole/kg s.c.) antagonized the increased synthesis of DA (dopa accumulation) induced by haloperidol (HA) (0.32 μmole/kg s.c.), γ-butyrolactone (8.72 mmoles/kg i.p.), or baclofen (178 μmoles/kg i.p.). Levonantradol itself did not affect dopa accumulation in striatum. This action of levonantradol may be related to the known anticholinergic properties of Δ^9-THC or its recently described GABAergic activity (Revuelta et al., 1979). These authors reported that Δ^9-THC (32 μmoles/kg i.v.) or cannabidiol (64 μmoles/kg i.v.) doubled GABA turnover rate in rat substantia nigra. I found that at these high doses Δ^9-THC, but not cannabidiol, diminished the enhanced dopa accumulation in striatum after HA. Levonantradol was effective at doses down to 0.1 μmole/kg i.v. This effect on HA showed the same stereospecificity that characterizes other pharmacological activities of levonantradol. The inactive enantiomer CP-53,870-1 was 30 times less active than levonantradol. These results suggest that levonantradol may modulate central dopaminergic mechanisms.

270.29 THE EFFECT OF LEVONANTRADOL ON RAT CEREBELLAR CYCLIC GMP LEVELS; POSSIBLE GABA-LIKE ACTION. J.P. Leader and A. Weissman (SPON: R.W. Caldwell). Central Research, Pfizer Inc., Groton 06340.

Levonantradol, a novel phenanthridine, produces stereospecific analgetic activity in animals 9-14 times more potent than morphine and yet does not act at the opiate receptor (Milne et al., NIDA Research Monograph Series 9-46, in press). More recent studies have also demonstrated its ability to block the emesis induced by antineoplastic agents in cats (Borison and McCarthy, The Pharmacologist 21: 205, 1979). Despite its stereospecificity of action, the biochemical mechanisms by which levonantradol produces these effects hasn't been elucidated. We report here that levonantradol alters rat cerebellar cyclic GMP in a manner similar to known GABAergic agents.

There is a known reciprocal relationship between cerebellar cyclic GMP levels and GABAergic activity. In the current experiments rats were sacrificed by microwave radiation two hours after intraperitoneal administration of levonantradol and cerebellar cyclic GMP levels were determined by RIA. Levonantradol decreased cyclic GMP levels by 50% at a dose of 1 mg/kg. In rats GABAergic activity can be decreased pharmacologically by the administration of the glutamic acid decarboxylase (GAD) inhibitor isoniazid, thereby increasing cerebellar cyclic GMP. Under these conditions levonantradol decreased cyclic GMP levels by 50% at a dose of .32 mg/kg. This enhanced potency in decreasing isoniazid-elevated cyclic GMP levels compared to the effect on basal cyclic GMP levels is characteristically seen with GABAergic agents. As reported for analgetic endpoints this effect was stereospecific since the analgetically less active d-isomer, CP-53,870, was ten fold less potent than levonantradol in decreasing cyclic GMP. Δ^9-tetrahydrocannabinol also decreased isoniazid-elevated cyclic GMP, but was one hundred fold less active than levonantradol. Scopolamine had no effect on isoniazid-elevated cyclic GMP levels, suggesting that the potent effect of levonantradol and Δ^9-THC reflects a GABAergic component of activity. In support of this we found that levonantradol protected mice against convulsions induced by the administration of the GAD inhibitor 3-mercaptopropionic acid.

In summary, these biochemical and behavioral studies suggest that levonantradol has GABA-like activity at relatively low doses. The relationship of the GABAergic component of activity of levonantradol to its pharmacologic effects is currently under investigation.

271.1 TRIETHYLTIN INTOXICATION INDUCES SELECTIVE DEFICITS IN SEROTONERGIC AND CHOLINERGIC NEUROTRANSMISSION IN RAT BRAIN SYNAPTOSOMES. J.J. Valdes, R.N. Cory*, G.G. Bierkamper*, A.M. Goldberg and Z. Annau. Division of Toxicology, The Johns Hopkins University, Baltimore, MD 21205.

The alkyltins are highly toxic compounds with widespread industrial applications. The toxicity of alkyltins increases to a maximum as the number of alkyl groups is increased to three, and, since the ethyl-tins are maximally toxic to vertebrates, triethyltin (TET) has been used to study the toxicity of alkyltins in the vertebrate nervous system. Symptoms of TET poisoning include cerebral edema, affective disturbance, and muscular weakness and are suggestive of dysfunctions of serotonergic and cholinergic neurotransmission.

Adult male Long-Evans hooded rats were individually housed and given ad libitum access to food and water. Rats in the acute exposure group received one injection of TET (10 mg/kg, i.p.) and were decapitated 24 hr after injection. Rats in the chronic exposure condition received TET in their drinking water (30 mg/L) and were sacrificed, along with matched controls, at 1, 2, and 3 weeks after initiation of exposure. TET-treated rats developed progressive symptoms of hindlimb weakness, penile erection, and aggressive response to handling. Whole brain P2 synaptosomal pellets were obtained, and high-affinity uptake of tritiated 5-hydroxytryptamine (3H-5-HT) and choline (3H-Ch), and spontaneous and potassium-stimulated release of 3H-5-HT and nonlabelled acetylcholine (ACh) were assessed. Uptake of 3H-5-HT and 3H-Ch were not compromised by either acute or chronic treatment, suggesting that the nerve terminals were functionally intact. Chronic, but not acute, TET intoxication resulted in time-dependent selective debilitation of the release systems, with increases in spontaneous, and decreases in potassium-stimulated, release of 3H-5-HT being the major finding. These data are consistent with the assertion that TET promotes cerebral edema by interfering with serotonergic modulation of cerebrovascular permeability, and suggests the possibility for the pharmacological manipulation of TET neurotoxicity. Rats that survive a normally lethal acute dose, or those that are removed from the chronic TET exposure regimen, show recovery of function over a period of weeks. Experiments are in progress to determine whether the neurochemical deficit recovers as a function of discontinuation of exposure.

Supported in part by grant ES-01580 and ES-07094, ES-00034 and ES-00454

271.2 REDUCED HIGH-AFFINITY ACCUMULATION OF CHOLINE IN CULTURED FIBROBLASTS FROM PATIENTS WITH INHERITED TORSION DYSTONIA AND GILLES DE LA TOURETTE SYNDROME. Donald Kay Riker, Robert H. Roth and Xandra O. Breakefield. Depts. Pharmacology, Psychiatry, and Human Genetics, Yale University School Med., New Haven, CT 06510.

We have examined high-affinity ^{3}H-choline accumulation (HACA) in cultured skin fibroblasts from patients with two inherited movement disorders of unknown etiology: dystonia musculorum deformans (DMD) and Gilles de la Tourette syndrome (GLT). Central cholinergic dysfunction might contribute to the pathognomonic signs in these disorders; for example, intravenous physostigmine can abate the motor tics of GLT (Stahl & Berger, NEJM 302:298, 1980).

HACA in brain synaptosomes (K_T<5μM) has been implicated as the rate-limiting step in the synthesis of acetylcholine in septal-hippocampal neurons. Recently, Na^+-dependent HACA has been demonstrated in avian muscle and human skin fibroblasts (Barald & Berg, Dev. Biol. 65:90, 1978; Riker et al, Soc. Neurosci. Abstr. 5:757, 1979). The K_T of HACA in four control human fibroblast lines ranges from 5-11 μM. In a jewish family with DMD the V_{max} and K_T of HACA was compared in parallel in fibroblasts from an unaffected (16 yrs) and severely affected (19 yrs) sister. We observed (N = 3) a 100% elevation in the K_T of HACA in cells from the affected sister (24.8 μM ± 0.7 SEM) when compared to the unaffected sister (12.4 μM ± 1.4 SEM). The V_{max} of HACA was similiar in these siblings (∿225 pm/mg pro/4 min). A second unrelated dystonia patient (13 yrs) demonstrated a 90% increase in the K_T (18.5 μM), with little change in the V_{max} (+20%), when compared to parallel cultures of an age-matched control (9.8 μM). Finally, the comparison of HACA in a patient with GLT (16 yrs) compared to an age-matched control yielded a 146% greater K_T (19.2 μM ± 2.55 SEM vs. 7.8 μM ± SEM; N = 2) with similiar V_{max}'s (∿275 pm/mg pro/4 min).

These preliminary results in fibroblasts demonstrate a decrease in affinity of the transport carrier for choline in lines from patients with these inherited disorders. Such differences in the K_T for choline might result from a common polymorphism for the transport carrier in the human population, variable ratios of fibroblast cell types, or discrete biochemical alterations of the cell membrane. The concentration of choline in human CSF (∿5 μM) and plasma (∿12 μM) indicates that HACA normally operates near its K_T. Under physiologic conditions a doubling of the K_T would reduce the fractional velocity of HACA to 25% of its V_{max}. This reduction in affinity of the choline transport carrier could impair cerebral cholinergic function in brain regions strongly dependent on reuptake of choline, such as the candate-putamen. (Supported by The Dystonia Medical Research Foundation).

271.3 DIPIPERIDINOETHANE MIMICS KAINATE CONVULSIONS AND BRAIN DAMAGE. J.W. Olney, T. Fuller, R. Collins, T. de Gubareff.* Departments of Psychiatry & Neurology, Wash. Univ. Sch. Med., St. Louis MO 63110.

Levine & Sowinski recently described a pattern of brain damage due to dipiperidinoethane (DPE) intoxication which resembles that we have observed in adult rats treated systemically with kainic acid (KA). We undertook the present experiments to explore possible parallelisms between DPE and KA neurotoxicity.

DPE was neutralized with acetic acid and administered sc in aqueous solution to adult male rats in single doses up to 400 mg/kg or was injected (400 nmoles) directly into several brain regions. In some rats, CNS utilization of 2-deoxyglucose (2-DG) was studied after sc DPE injections (400 mg/kg) and in others, the possibility that diazepam pretreatment (20 mg/kg) might protect against DPE neurotoxicity was explored.

Although Levine and Sowinski did not observe convulsions in their DPE-treated rats, ours exhibited the temporal lobe seizures and status epilepticus typically seen in KA-treated rats; moreover, the type and pattern of brain lesions and of 2-DG utilization induced by DPE appeared remarkably similar to that we have reported in KA-treated rats. Diazepam pretreatment, which protects rats from both the convulsions and brain damage induced by KA, also protected DPE-treated rats against both phenomena. Paradoxically, whereas intra-amygdaloid injection of 4 nmoles of KA results in convulsions and extensive local, as well as "distant" neuronal loss, injection of 400 nmoles of DPE into the amygdala caused neither convulsions nor significant histopathological changes locally or elsewhere in brain over a 24 hr post-treatment interval. Since some of our rats treated sc with DPE developed both status epilepticus and a diffuse pattern of limbic brain damage within 2-8 hrs after treatment, it is possible that DPE owes its convulsogenic and brain damaging properties to an active metabolite generated in the periphery. The molecular structure of DPE is not closely related to KA, but bears some resemblance to tremorine, a putative cholinergic agonist. Thus, studies are needed to assess the possible role of cholinergic mechanisms in DPE or KA neurotoxicity (or both). We suspect that a seizure mechanism (status seizures, not seizures per se) underlies the limbic pattern of brain damage sustained in rats treated sc with either KA or DPE.

Our DPE findings, although quite preliminary, are reported for their implications in relation to epilepsy, epileptic brain damage and unresolved questions regarding the mechanism of KA neurotoxicity. 271.4 ALTERATIONS IN SEROTONERGIC RECEPTOR BINDING IN AN ANIMAL MODEL OF MOVEMENT DISORDER. A.C. Sconzert, S. Gabay, and B. Haber. Marine Biomedical Institute, UTMB, Galveston, TX. and V.A. Medical Center, Brockton, Mass.

The ECC syndrome may be induced in rats by the daily intraperitoneal administration of β-β'-iminodipropionitrile (IDPN; 300 mg/kg) for one week. The symptoms are expressed immediately thereafter and are stabilized within seven days. Once induced, the syndrome is permanent and requires no further injections. The ECC syndrome is a behavioral complex of motor abnormalities which include a heightened level of general excitability, circling, and choreiform head and neck movements. Thus the ECC syndrome is a potentially useful model system in which to explore some of the neurochemical parameters underlying hyperkinetic behavior. We have previously demonstrated alterations in both the GABAergic and the cholinergic neurotransmitter systems in the expression of this syndrome. Results from pharmacological studies utilizing Quipazine (2-(1-piperazinyl)quinone maleate), a 5-HT agonist, (Langlais and Gabay 1977) implicated a possible role of serotonin receptors in the expression of the ECC syndrome. We chose to clarify the role of serotonin receptors in the ECC syndrome by measuring the ^{3}H-5HT binding in various regions of the brain of ECC animals. Female syndromized rats were sacrificed two months post injection of IDPN, and the brains were analyzed for ^{3}H-5HT binding (Bennett and Snyder 1976) on a regional basis (olfactory bulb, frontal cortex, occipital cortex, striatum, hippocampus, hypothalamus, thalamus, cerebellum, pons, and medulla). In IDPN treated rats, levels of ^{3}H-5HT binding are generally decreased, particularly in the pons (37 % of control), striatum (52 % of control), and the frontal cortex (36 % of control). These changes in ^{3}H-5HT binding resemble those reported for post-mortem brains of Huntington Disease patients. The depression of ^{3}H-5HT binding in the striatum can be due to either destruction of terminals originating in the raphe or neuronal cell loss in the raphe per se. These possibilities, in tandem with those alterations in the GABA and acetylcholine systems seen in the striatum of the ECC rat are under further investigation.

271.5 BIOCHEMICAL ALTERATIONS OF DOPAMINE RECEPTOR RESPONSES FOLLOWING CHRONIC TREATMENT WITH DOPAMINE AGONISTS. K. D. Wilner*, I. J. Butler, W. E. Seifert* and Y. C. Clement-Cormier (SPON: V. A. Lewis). Depts. of Pharmacology, Neurobiology, Neurology and Biochemistry, University of Texas Medical School, Houston, Texas 77025.

The effects of chronic dopamine agonist treatment on rat striatal adenylate cyclase and dopamine-receptor binding activities were studied using Sinemet (L-dopa/carbidopa) administered orally at a calculated daily intake of 150 mg/kg or bromocriptine (CB-154) given intraperitoneally (2 mg/kg). A four-fold increase was observed in the EC50 for dopamine on adenylate cyclase activity in homogenates of the caudate nucleus with no change in the maximal level of enzyme activity following Sinemet treatment. Conversely, the bromocriptine group showed an increase in the maximal level of enzyme activity with no change in the EC50. Binding studies using (^{3}H)-spiroperidol, a dopamine-receptor antagonist, revealed a decrease in the dissociation constant from 0.26nM in the control group to 0.069nM in the Sinemet treated group. In addition, the Bmax for (^{3}H)-spiroperidol in these animals increased by 300 fmoles/mg over that observed in the control group. There was no statistically significant change in the dissociation constant for (^{3}H)-spiroperidol binding in the bromocriptine group with only a slight increase in the Bmax. Overall these data reveal a differential effect of Sinemet and bromocriptine on the biochemical properties of the dopamine receptor which may in part explain the effectiveness of their use in combination drug therapy in the treatment of Parkinson's Disease. (Supported by the National Science Foundation 7816003 and the American Parkinson's Disease Association).

271.6 NEUROTRANSMITTER RECEPTOR BINDING AFTER VARIOUS INTENSITIES OF ELECTROSHOCK. A.S. Perumal, G. Connova* & A.I. Barkai. N.Y.S. Psychiatric Institute, New York, NY 10032. Electroshock treatment (EST) is most effective therapeutically for patients with certain forms of affective disorders. When applied to rats at extremely high current intensities (75-150mA) EST has been shown to decrease β-adrenergic receptor (β-AdR) sensitivity in cerebral cortex. However the relationship between the intensity of applied current and modification of receptor sensitivity in cortex and other brain regions have not been investigated. We have studied effects of EST at current intensities ranging from a subconvulsive level of 1-2mA to a seizure producing level of 20-30mA on the sensitivity of β-AdR and apparent dopaminergic receptors in membrane preparations of cerebral cortex and a combined thalamus-striatum-midbrain (TSM) region in rats. Animals were subjected to EST once a day through saline moistened ear-clip electrodes for seven days and sacrificed 1 hour after the last treatment. Specific binding of β-AdR was assessed with H^3-DHA and (-) alprenolol whereas apparent dopamine receptors were evaluated with hot and cold haloperidol. The larger decrease (35%) in β-AdR sensitivity was seen in the cerebral cortex with EST of 6-10mA which is not adequate to produce prolonged tonic-clonic seizures. The lower EST of 1-2mA resulted in 40% increase in β-AdR sensitivity in TSM with a slight (15%) decrease in cortical β-AdR. Haloperidol specific binding was increased nearly two-fold in cerebral cortex at all EST levels while a slight decrease was seen in TSM. These results indicate that changes in receptor sensitivity may be obtained with subconvulsive EST intensities. Hence the hypothesis that a seizure-producing EST exerts its therapeutic effects by modifying catecholaminergic receptors should be re-examined. (Supported in part by a grant from New York State #HRC1715)

271.7 NEUROCHEMICAL AND BEHAVIORAL CORRELATES OF ANTIDEPRESSANT DRUG ACTION. E. Mann* and S.J. Enna (SPON: I.J. Butler). Depts. Pharmacol. and Neurobiol. and Anat., Univ. Texas Medical School, Houston, Texas 77025

Experiments were undertaken on muricidal rats to better understand the neurochemical basis for this behavior and the modification of this activity by psychopharmacological agents. For the study, male Long-Evans rats were housed individually in isolation for 16 weeks, during which time 40% became muricidal. Following this, some animals were sacrificed while the remaining were divided into three separate groups, one of which received atropine (20 mg/kg), one imipramine (20 mg/kg) and the third saline once daily for 15 days, and their muricidal behavior tested at both 1 hr and 24 hr following each injection.

Neurotransmitter receptor binding assays in the cerebral cortical tissue revealed a change only in the 5-HT_2 receptor system, with binding being significantly increased (42%) in the isolated muricidal animals relative to the isolated nonmuricidal controls. No significant difference was noted in β-adrenergic receptor binding in these same animals. With regard to the drug treated animals, muricidal behavior was significantly inhibited in both the atropine and imipramine subjects at 1 hr after treatment, but not at the 24 hr time point during the first 4 days of treatment. Notably, however, there was an extinction in muricidal behavior in the imipramine, but not atropine, treated group at the 24 hr time point, commencing after 4-6 days of treatment and reaching a nadir at 7-9 days. Receptor binding analysis indicated that there was a reduction in both β-adrenergic (33%) and 5-HT_2 (55%) receptor binding in the imipramine treated group during this time compared to saline treated control animals. No change in receptor binding was noted in the atropine treated animals.

The results suggest that the acute (1 hr) response to antidepressants in muricidal animals may be due to the anticholinergic properties of these drugs but that, chronically, they induce changes in receptor sensitivity that cause a longer lasting alteration in behavior. Finally, from these data, it would appear that changes in the serotoninergic receptor system may be responsible for muricidal behavior in rats and their response to antidepressants. (Supported in part by USPHS grants NS-13803 and NS-00335).

271.8 REPEATED ANTIDEPRESSANT TREATMENTS INDUCE DOPAMINE AUTORECEPTOR SUBSENSITIVITY: ARE DAILY TRICYCLICS NECESSARY FOR THERAPEUTIC EFFICACY? S.M. Antelman* and L.A. Chiodo (SPON: G. Werner). Dept. of Psychiatry, Psychobiology Program, University of Pittsburgh, Pittsburgh, PA 15260.

Brain dopamine (DA) systems have received little attention in considering mechanisms which underlie antidepressant therapies. It has recently been proposed that antidepressants can induce a subsensitivity of DA autoreceptors (Serra et al., Life Science, 25, 415, 1979). This hypothesis was tested directly using single unit electrophysiological techniques. We now report that repeated tricyclic antidepressants (TCA), electroconvulsive shock (ECS) and amphetamine (AM, which has a brief antidepressant effect) treatments induce DA autoreceptor subsensitivity.

Male albino rats were anesthetized and single unit DA activity was recorded through micropipettes (2M NaCl, 4-12 megohm). DA autoreceptor sensitivity was determined by the administration of a presynaptic dose of apomorphine (0.004 mg/kg, i.v.). This dose was chosen because it has been shown to preferentially stimulate DA autoreceptors and thereby inhibit DA activity (Skirboll et al., Science, 206, 80, 1979). Animals were assigned to the following groups: two or ten days of either imipramine, amitriptyline or iprindole (10 mg/kg, i.p., twice a day); six days of ECS (105 V a.c., 0.7 sec), and six or fifteen days of AM (4 mg/kg, i.p.). Forty-eight hours later autoreceptor sensitivity was determined.

All treatments (TCA, ECS, AM) resulted in a highly significant attenuation of apomorphine's ability to inhibit the spontaneous discharge of DA neurons. Ten days of TCA treatment resulted in a greater degree of DA autoreceptor subsensitivity than two days of treatment.

Is the progressive autoreceptor subsensitivity seen between 2 and 10 days of treatment dependent on daily drug or the passage of time? To test this we administered imipramine for 2 days and waited 10 days before recording. This group showed an identical subsensitivity as the 10 day treatment group, but significantly more subsensitivity than animals given 2 days of drug followed by only 48 hrs. Similar time dependent changes were seen after only one ECS followed by a 7 day delay.

These findings clearly implicate DA autoreceptor subsensitivity as a potential mechanism underlying the clinical efficacy of a spectrum of antidepressant agents. More importantly, they suggest that the delayed therapeutic effects seen following TCA and ECS may depend on the passage of time rather than repeated treatment. Finally, the ability of pharmacological agents to initiate a process which then progresses in the absence of further treatment may necessitate a reevaluation of the most basic views of drug action.

RSDA-MH-00238, MH-23206

271.9 ENDOGENOUS INHIBITOR OF MONOAMINE OXIDASE (MAO) IN PLATELETS OF NORMALS AND SCHIZOPHRENICS. R.E. Becker,* C. Giambalvo, H. Elboim* and H. Lal* Rhode Island Psychiatric Training and Research Center, Cranston, RI 02920, and Dept. of Pharmacology and Toxicology, Univ. of Rhode Island, Kingston, RI 02881.

The activity of platelet MAO varies among subjects and is suggested to also vary with schizophrenic symptoms (Becker, R.E. and Shaskan, E.C., Am. J. Psychiat. 134: 512-517, 1977). We now report presence of an endogenous inhibitor in the plasma of normal volunteers and of schizophrenics, and this finding might explain the variation in MAO activity. The plasma from low, average and high MAO-activity groups among normal subjects and hospitalized schizophrenics was incubated with platelets obtained from the pooled normal blood using ^{14}C-tryptamine as MAO substrate. There was found a linear relationship between the amount of plasma added in vitro and the inhibition of MAO activity. The plasma inhibitory activity and the endogenous MAO levels were inversely correlated. In the schizophrenics with high MAO, their plasma showed no inhibition of MAO even at the highest amount (500 ul) of plasma tested. However, plasma from lower MAO schizophrenics inhibited MAO significantly. A number of neuroleptic and anti-Parkinsonian drugs tested failed to act as the inhibitors. Previous observations that hallucinations occur with greater frequency among schizophrenics with low MAO were also confirmed. The ability of differential MAO levels and the presently reported inhibitory activity in the plasma to predict clinical course of schizophrenic symptomology or drug therapy is being determined presently.

271.10 PROLONGED ADMINISTRATION OF L-DOPA DOES NOT INDUCE DEGENERATION OF NIGROSTRIATAL NEURONS IN THE MOUSE. E. Melamed, F. Hefti, J. Bhawan*, and R.J. Wurtman, Lab. Neuroendocrine Regulation, M.I.T., 56-245, Cambridge, and Department of Pathology, University of Massachusetts Medical School, Worcester, MA.

Autooxidation of L-DOPA gives rise to several cytotoxic products such as quinones, free radicals and also the catecholaminergic neurotoxin 6-hydroxydopamine (Graham et al., Molec Pharmacol. 14, 633, 1978). Toxic effects of L-DOPA on neuroblastoma and melanoma cells have been demonstrated in vitro. L-DOPA is currently the drug of choice in the treatment of many patients with Parkinson's disease. Theoretically, chronic administration of L-DOPA, its uptake by dopaminergic neurons and intracellular formation of cytotoxic substances, could cause neuronal loss in the nigrostriatal system. Therefore, in parkinsonian patients treated with L-DOPA, such L-DOPA toxicity and the underlying etiology of the illness could have a cummulative effect on the rate of the nigrostriatal degeneration and the progression of parkinsonism would be accelerated. This mechanism might also be involved in the emergence of side effects during long-term L-DOPA therapy, such as declining responsiveness to the drug and the on-off phenomenon.

We tested the hypothesis that prolonged administration of L-DOPA can destroy nigrostriatal dopaminergic neurons in an in vivo animal model. C57 black/6 mice received a diet containing 40 mg L-DOPA per g diet. Control animals were given the same diet without L-DOPA. Mice in both groups ingested approximately 5 g of diet per day and were kept on their corresponding diets for a period of 18 months. L-DOPA-treated mice were then transferred to the control diet containing no L-DOPA to allow complete washout of the drug. Eight days after discontinuation of L-DOPA, animals from both groups were decapitated. Corpora striata were assayed for tyrosine hydroxylase and DOPA decarboxylase activities. Striatal DOPA, dopamine and DOPAC levels were measured using high-performance liquid chromatography with electrochemical detection. DOPA was undetectable in striata of both control and L-DOPA-treated mice at the time of sacrifice, i.e.,8 days after withdrawal of the drug. Indices for the number of striatal dopaminergic terminals and the integrity of the nigrostriatal system, i.e. striatal dopamine and DOPAC concentrations and tyrosine hydroxylase and DOPA decarboxylase activities were equal in corpora striata of control animals and of L-DOPA-treated mice.

Our findings suggest that prolonged oral administration of large doses of L-DOPA (approximately 200 mg per animal per day during a period of 18 months) does not decrease the number of nigrostriatal dopaminergic neurons in the mouse. Therefore, long-term L-DOPA therapy in parkinsonism probably does not accelerate the degeneration of nigrostriatal neurons and the progression of the illness.

271.11 BIOCHEMICAL EVIDENCE OF DECREASED MUSCARINIC CHOLINERGIC NEURONAL COMMUNICATION IN AMYGDALA KINDLING. Richard Dasheiff, Mary Byrne*, Vincent Patrone*, and James O. McNamara Division of Neurology, Duke Univ. and VA Med. Center, Durham, N. C. 27710

Kindling is an animal model of epilepsy induced by periodic electrical stimulation of the brain. Pharmacologic evidence suggests that increased muscarinic cholinergic communication contributes to the development of amygdala kindling. Paradoxically, we have previously found decreased numbers of muscarinic cholinergic receptors in multiple sites of the limbic system of kindled rats. To obtain a more complete biochemical assessment of pre- and postsynaptic muscarinic cholinergic communication, we measured two presynaptic indices, choline acetyltransferase (ChAT) and sodium dependent high affinity choline uptake (SDHACU), the degradative enzyme acetylcholinesterase (AchE) and the muscarinic receptor. Rats were sacrificed one day following completion of kindling (defined as a single Class 5 motor seizure consisting of rearing and falling). Amygdala, dentate and hippocampal gyral tissues were dissected and the above indices measured with radiochemical assays. All three anatomic regions yielded similar results. Muscarinic receptors ([^{3}H] QNB binding expressed as pmol/mg $\pm$ SEM) in the dentate for kindled/control (electrode implanted, unstimulated) were (n = 9): left 893 $\pm$ 27, 1114 $\pm$ 45, right 785 $\pm$ 52, 1006 $\pm$ 24 ($p < .005$, paired t-test). SDHACU (pmol/mg/4 min $\pm$ SEM) in the dentate, K/C, was not significantly increased (n = 7): left 33.0 $\pm$ 2.0, 32.6 $\pm$ 2.7; right, 29.0 $\pm$ 2.6, 33.6 $\pm$ 2.1. The activities of ChAT and AchE were not significantly different from controls. Together these results are consistent with a net reduction of muscarinic cholinergic neuronal communication on the day following completion of kindling.

Measurement of muscarinic receptors at additional times disclosed that the reductions developed late (Class 4) during development of kindling and returned towards normal seven days following completion of kindling. Significant increases of choline uptake were never observed, despite measurements during development of kindling, during kindled seizures, and at multiple times after completion of kindling. This transient reduction of muscarinic cholinergic neuronal communication may represent the biochemical basis of an endogenous inhibitory process developing as a consequence of repeated limbic seizures.

272.1 AMPHETAMINE PRODUCES AN ENDURING RECOVERY OF LOCOMOTOR FUNCTION AFTER MOTOR CORTEX INJURY IN THE RAT D. M. Feeney, A. Gonzalez, H. M. Murray and W. G. Dail Depts. of Psychology & Anatomy, University of New Mexico, Albuquerque, NM 87131

Unilateral ablation of the entire motor cortex of the rat produces a marked contralateral hemiparesis. While the animals are able to locomote on a flat surface they are unable to walk normally on a narrow beam for several weeks after injury. We examined the effects of amphetamine and haloperidol on this recovery of locomotor function. Rats were trained to run a 122 cm long, 2.5 cm wide beam to escape a loud noise. Twenty rats were given three trials per day and within a week all animals were running rapidly. The entire motor cortex was then unilaterally removed by suction ablation. All animals were retested at 24-hours postsurgery and most could not maintain their balance on the beam and none could walk or run on the beam. The limbs contralateral to the injury hung off the beam. The animals were rated on ability to traverse the beam and movies taken of their performance for later blind ratings. The animals were assigned to one of four drug conditions A) 1 mg/kg D-amphetamine B) saline control C) 1 mg/kg D-amphetamine followed in 30 minutes by 0.1 mg/kg haloperidol D) 1 mg/kg D-amphetamine followed in 30 minutes by 0.3 mg/kg haloperidol. The single dose of amphetamine or saline was administered immediately after the 24-hour postsurgery testing. The animals were retested every hour for six hours and retested at 12 hours and every other day for 30 days. By one hour after amphetamine, the locomotor ability of the motor cortex injured, hemiparetic rats began to improve. Animals that previously had been unable to even stand on the beam after amphetamine could locomote the length of the board. This improved performance after a single dose of amphetamine was maintained through the subsequent weeks of testing. The saline control group's performance did not match that of the amphetamine group until three weeks postinjury. The 0.1 mg/kg haloperidol dose had no effect; however, the 0.3 mg/kg dose completely blocked the amphetamine-induced recovery of function. The data suggest that following unilateral motor cortex injury in rats, much of the locomotor deficit and contralateral hemiparesis is attributable to a depression of catecholamine function which can be reversed by amphetamine. This hypothesis is being directly examined using catecholamine histofluorescence and biochemical analysis of injured brain.

272.2 CORTICAL AND HYPOTHALAMIC LESIONS DIFFER IN THE MOVEMENT DYSFUNCTIONS THEY PRODUCE. L. Misantone, M. Suokas*, A. Sassler* and J. Prendergast. Dept. Anatomy, Philadelphia College of Osteopathic Medicine and The Medical College of Pennsylvania, Philadelphia, PA 19131.

Unilateral lesions of either the dorsal cortex or of the lateral hypothalamus result in significant weight loss due to hypophagia and hypodipsia. Our findings suggest that dysfunctions in coordinated movement of forelimb and/or head musculature contributed to these weight losses, and that the 2 groups differ qualitatively in these movement deficits.

Rats (n=12) with unilateral lateral hypothalamic lesions (damaging lateral medial forebrain bundle and medial internal capsule at tuberal level) were compared to rats (n=8) with unilateral lesions of the dorsal aspect of the rostral cortex (sensorimotor fore- and hind-limb areas). Weight losses for both groups over the first 7 days after surgery were significant and equivalent. Subsequently, rats with cortical lesions recovered more quickly, and at 14 days were at their preoperative level, while rats with hypothalamic lesions were still significantly below preoperative. To ascertain the relative contribution of various movement dysfunctions to these ingestive behavior deficits, we examined head orienting responses to probing of the vibrissae and face; proprioceptive (joint deformation) placing and hopping responses, both without visual cues; and forepaw grasping responses. We found that 1 day after hypothalamic lesion, 11 of 12 rats did not orient to probing contralateral to the lesion, and 9 of 12 did not place in the forward direction contralaterally. By day 7 these responses were again present bilaterally, but were more difficult to elicit contralaterally. These two responses were largely unaffected by cortical lesions. On the other hand, backward grasping responses in the paw contralateral to the cortical lesion were nearly completely absent, and remained severely deficient until 7-10 days postoperative. Recovery occurred as a gradual increase of strength that moved from distal to proximal portions of the digits and paw. Alternatively, grasping was present in rats with hypothalamic lesions, and actually appeared initially to be more intense than usual.

Thus, deficits in sensorimotor integregation affecting head (orientation) and forelimb (placing) movements appear after hypothalamic lesions, while deficits in forepaw usage (grasping) appear after cortical lesions. Importantly, while both groups have in common an ingestive behavior deficit, the movement dysfunctions that probably underly the latter deficit differ qualitatively. (Supported by NS16101, EY03360 and NS15893).

272.3 ABNORMAL RELATIONS BETWEEN ISOMETRIC MUSCLE FORCE AND SURFACE EMG IN HEMIPARETIC SUBJECTS. A. Tang* and W.Z. Rymer. BME Program and Physiol. Dept., Northwestern Univ., Chicago, IL 60611.

The decerebrate cat with a dorsal hemisection of the spinal cord is a useful model of human spasticity[1]. A recent study using this model has shown that the slope of the isometric force-emg relation in the decerebrate state is radically increased after dorsal hemisection of the spinal cord. This change was attributed to the lowering of the average motor unit discharge rates following the cord lesion. This lowering of rates has been found in human spastic muscle and it is reasonable to expect that the force-emg relation of spastic muscle should be modified in a fashion similar to that described for the animal model.

Our study compared the force-semg relation of the biceps-brachialis and brachioradialis muscles in normal and spastic limbs of hemiparetic subjects. The muscles on the non-paretic side were used to provide a "control" for the paretic limb. The patient population consisted of subjects with stroke and traumatically induced hemiparesis. Muscular strength of the patients ranged from normal to 25% of normal strength.

Studies were performed on 10 hemiparetics and 7 normal controls. Subjects were seated with the elbow at 90 degrees, the forearm parallel to the floor, and the wrist in a semi-prone position in contact with an immovable handle. This handle was attached to a load cell. Semg was measured using 2 sets of 1 cm dia. platinum electrodes, located over the biceps-brachialis and brachioradialis. Location of the electrodes was identical on each limb. Semgs were amplified, rectified and filtered. The subjects generated a range of static forces, according to a computer-controlled display. Data analysis included plots of mean force vs. mean emg-each calculated over a stationary interval of about 1 sec. Regression lines were fitted to these points by the least squares method.

The relations between isometric force and semg of the biceps and brachioradialis were consistently linear. In 6 of 10 patients, the force-semg slope for the biceps on the paretic side was increased and statistically separable from that of the normal limb's. However, even in those cases where the slopes were not statistically separable, the semg at 2 kg. was usually systematically increased on the paretic side. Results from the brachioradialis were inconclusive. It is concluded that the force-semg relations are modified in the muscles of hemiparetic limbs and second, that this modification probably results from a reduction of motor unit discharge rates in the muscles.

272.4 PSYCHOMOTOR DYSFUNCTION OF PARKINSON PATIENTS. L. Z. Podbros* (SPON: A. Rosen). Dept. of Psych., SUNY at Stony Brook, Stony Brook, New York 11794.

Conventional group studies with parkinson patients have revealed performance deficits on a number of seemingly dissimilar tasks; however relationships among performance on the tasks have not been examined. The present investigation was designed to delineate more precisely some of the parameters operative in these performance deficits. Relationships among 20 clinical/subject variables and performance on a battery of 113 psychomotor measures were examined with 8 idiopathic parkinson male out-patients.

Although each subject shows a variety of deficits, subjects clearly differ from each other in their patterns of performance. After 4 subjects had been tested, Pearson product-moment correlations were computed to identify relationships among clinical and performance variables. Relationships of theoretical interest identified by this method were replicated by recomputation of correlations after each additional subject. Results indicate: 1) differences among subjects in the execution of relatively simple movements (e.g. arm flexion, crossing legs, simple reaction time) clearly relate ($r's \geq .80$) to differences in rigidity and tremor. 2) Rigidity and tremor do not relate as strongly to performance on more complex tasks. 3) Some aspects of psychomotor dysfunction relate strongly ($r's \geq .80$) to proprioceptive factors and other aspects to mnemonic factors; these dissociated deficits may or may not appear in the same parkinson patient. For example, proprioceptive difficulties (e.g. balancing on toes or on one leg) show strong relationships with bead transferring, pursuit rotor and purdue pegboard, as well as with a route-walking task requiring spatial operations. The latter relationship suggests that some of the parkinsonian "cognitive" deficits may be interpreted more parsimoniously than is usually done. However, proprioception can not account for all parkinson "cognitive" deficits. Deficits on a spatial task requiring rotation of stick figures seem to be dissociated from proprioception and related tasks and strongly related to mnemonic factors ($r=-.94$). These results support the role of basal ganglia in functions that involve sensory-motor rather than purely motor components. They also support the view that parkinsonian psychomotor dysfunction involves dissociated impairment of proprioceptive and mnemonic functions.

272.5 THERAPEUTIC EFFICACY OF L-DOPA CHELATES IN ANIMAL MODELS FOR PARKINSON'S DISEASE. K.S. Rajan, B.I. Diamond, R.L. Borison and J.M. Davis. IIT Research Institute, Mt. Sinai Hospital Medical Center, and ILL. State Psych. Inst., Chicago, Illinois.

The pharmacological activities of the Cu(II)- and Zn(II)-L-DOPA chelates were investigated in two different animal models of Parkinson's disease (PD). 6-Hydroxydopamine-lesioned Parkinsonian rats were treated separately with L-DOPA chelates and unchelated L-DOPA. All the chelate-treated PD animals showed significantly larger contralateral rotatory activity than the unchelated L-DOPA-treated PD animals. Experiments on the reversal of reserpine-induced Parkinsonism by L-DOPA and L-DOPA chelate treatments showed a substantial shift of the chelate dose-response curve to the left of the L-DOPA curve indicating substantially increased therapeutic efficacy. Further, treatment with Zn- and Cu-chelate resulted in a four-fold increase of the catecholamine content (DA and NE) in the striatum when compared to that obtained by mere L-DOPA treatment. Treatments with L-DOPA and L-DOPA + carbidopa merely increased striatal dopamine levels, whereas the chelate treatment produced increased levels of norepinephrine and dopamine. The clinical significance of these results is discussed.

272.6 THE EFFECT OF CHRONIC N-n-PROPLYNORAPOMORPHINE ADMINISTRATION ON 6-HYDROXYDOPAMINE LESIONED RATS. P.C. Chen*, R.E. Wilcox, and W.H. Riffee, Dept. of Pharmacology, College of Pharmacy, University of Texas, Austin 78712.

Specific lesions induced by 6-hydroxydopamine (6-OHDA) microinjected into the zona compacta of the substantia nigra (ZCSN) constitute a widely used animal model of Parkinson's disease. N-n-propylnorapomorphine (NPA) is of interest as a potent dopaminergic agonist and as an agent potentially useful in the treatment of various neurological disorders including Parkinson's disease. We have investigated the alteration of both behavioral and biochemical parameters due to 6-OHDA (8µg 6-OHDA base/4µl) induced unilateral lesions of the ZCSN or caudate nucleus (CN) of rats after chronic NPA treatment (5mg/kg i.p. once daily for 4 weeks).

Challenge with 5mg/kg apomorphine (APO) intraperitoneally showed that unilateral lesions of the medial ZCSN resulted in predominant contralateral turning, while lesions of the lateral ZCSN caused predominant ipsilateral turning. Most animals with lesions in the CN showed ipsilateral turning. H^3-DA uptake studies revealed that only rats with 80% or more depletion of dopamine nerve terminals exhibited significant contralateral turning upon APO challenge. After chronic NPA treatment, significant changes in turning behavior were observed in animals with contralateral or ipsilateral turning greater than 4 R.P.M.. H^3-spiroperidol saturability studies indicated that the affinity remained unchanged following chronic NPA administration. The receptor density (Bmax) increased by 70% after 6-OHDA lesions, but decreased by 30% after chronic NPA treatments with the lesioned side retaining more receptors than the unlesioned side. Behavioral alterations may serve as a supplement to neurochemical measures such as uptake and receptor binding to investigate the mechanisms of psychoactive drugs. (Supported in part by NIMH-MH 33443 to WHR and REW and UT-BRSG to REW).

272.7 HYPERTHYROIDISM, PARKINSONISM AND TRI-IODOTHYRONINE RECEPTORS. W. J. Nowack. Department of Neurology, Indiana University School of Medicine, Indianapolis, Indiana 46223.

The clinical association between Parkinsonism and disease of the thyroid has been noted in the past. A fifty four year old lady presented to the Indiana University Medical Center with clearcut clinical evidence of Parkinsonism. One year earlier, when she was seen at a local medical facility for weight loss and nervousness, a minimal tremor of the upper extremities, not thought to be Parkinsonian, was noted. T4 was elevated, a thyroid uptake was within normal limits, a thyroid scan showed cold nodules and nodular nontoxic goiter was diagnosed. Subtotal thyroidectomy was performed and areas of focal lymphocytic infiltration, but no evidence of carcinoma, were found. The patient was on thyroid replacement therapy when she was seen at the Indiana University Medical Center and found to be Parkinsonian. At that time T4-RIA was within normal limits and T3-RIA was elevated. Review of the records revealed no similar cases.

Nuclear receptors specific for tri-iodothyronine have been reported in the brains of rats. This case suggests that pathological stimulation of the tri-iodothyronine receptors in the brain can result in a syndrome clinically identical to Parkinson's disease. Elevations of T3 are usually seen in conjunction with elevations of T4. This case further suggests that the effect of the elevated T4 can mask the Parkinsonian symptomatology and thus, the infrequent observation of the simultaneous occurrence of hyperthyroidism and Parkinsonism may be a direct result of the rarity of isolated T3 thyrotoxicosis.

272.8 SIMILAR ISOELECTRIC PATTERNS OF LIPOAMIDE DEHYDROGENASE IN RAT BRAIN AND OTHER ORGANS. L. Möller*, D. M. Becker, C. Nissenson* and R. A. Pieter Kark. Ataxia Ctr, Reed Neurological & Jerry Lewis Neuromuscular Research Centers, UCLA Sch. of Medicine, Los Angeles, CA. 90024.

Defective activity of lipoamide dehydrogenase (LAD, EC 1.6.4.3) has been associated with inherited neurological disease including Friedreich's ataxia. These studies have largely been carried out in peripheral tissues and the assumption made that the findings may be extrapolated to the nervous system. However, several studies of electrophoretic patterns of LAD from mammalian mitochondria suggest the presence of 2 to 13 distinct bands on the gels, as identified by Coomassie-Blue or the diaphorase reaction. Two bands may represent conformational changes of a single LAD affected by two multienzyme complexes; the others may represent artifacts of partial proteolysis during purification or true distinct protein species. If these are true isoenzymes, and are tissue-specific, defects of LAD in peripheral tissues would not necessarily imply defective LAD in the nervous system. We have previously found a stain for LAD activity in gels dependent upon both dihydrolipoamide and NADH and more specific than diaphorase in identifying partially purified LAD.

In the present study, we investigated the number and pattern of isoelectric bands of LAD from four rat tissues. LAD was extracted from homogenates of brain, skeletal muscle, heart and liver. Extracts were adjusted to equivalent activity of LAD/volume and subjected to isoelectric focusing on a flat-bed, 6% polyacrylamide gel (pH 3-10). Protein was stained with 0.1% Coomassie Brilliant Blue, LAD by our specific method and diaphorase activity by NADH coupled to nitroblue tetrazolium dye.

Fresh samples from brain, muscle and heart had 2 major and 2 minor LAD bands, 4 major and 2 minor diaphorase bands, and over 40 protein bands, while liver had the same plus 4 additional minor diaphorase bands. Additional bands of LAD and yet others of diaphorase activity appeared in tissues after storage for weeks to months. The major bands were identical in all tissues, as were those minor bands that could be detected in each tissue.

The results suggest 1) that the speci(es) of LAD in each of these tissues is the same and 2) that some of the redundant bands may be artifacts arising during preparation and storage.

272.9 KINETICS OF LIPOAMIDE DEHYDROGENASE IN RAT BRAIN AND OTHER ORGANS. M. Jensvold*, S. L. Perlman*, S. Djordjevic*, R. A. Pieter Kark, D. M. Becker, M. R. Budelli*, D. Reeves* and N. Wheeler*. Ataxia Center and Reed Neurological & Jerry Lewis Neuromuscular Res. Ctrs, UCLA Sch. of Med. Los Angeles, CA.90024 & John Hopkins Sch. of Med. Baltimore, MD. 21205.

Abnormalities of lipoamide dehydrogenase (LAD, EC 1.6.4.3) in peripheral tissues have been associated with certain human neurological diseases, especially a recessively-inherited ataxia. The abnormalities appear to breed true in families in a pattern identical to that of the ataxia. However, it is not yet known whether LAD in the nervous system is the same protein species as in peripheral tissues. Kinetic properties can distinguish isoenzymes, and we have studied the kinetics of LAD from brain (B), skeletal muscle (M), heart (H) and liver (L) of 12 rats. To avoid possible selective loss of isoenzymes on purification, assays were in simple homogenates. These were assayed with their own optimal conditions: pH 7.3, 120 μM NADH and 8-12 concentrations of substrate in the range, 60-600 μM lipoamide, both at 30° and 37°.

Kinetic parameters were calculated with reiterative computer analysis by Eadie-Scatchard and Hill methods assuming a) linear and b) non-linear regression on Lineweaver-Burke plots. The two assumptions gave similar values for Km, Hill number and Vmax. Assuming the former, values for Km (in μM lipoamide) at the two temperatures were:

	B	M	H	L
30°	262 ± 37	140 ± 22	192 ± 25	235 ± 16
37°	205 ± 43	332 ± 72	288 ± 67	261 ± 94

Hill numbers ranged from 1.0 to 2.0 at both temperatures, varying with time of storage.

Neither Km nor Hill number varied significantly from tissue to tissue. Vmax values, as specific activity, were consistently high in heart and liver, intermediate in brain, and lowest in muscle ($p<0.005$). By these methods there is no evidence for tissue-specific isoenzymes of LAD in the four tissues of the rat.

272.10 IMINODIPROPIONITRILE NEUROPATHY IN CATS-PHYSIOLOGICAL CONSEQUENCES OF GIANT AXON FORMATIONS. B.G. Gold*, J.W. Griffin*, D.L. Price*, L.C. Cork* and H.E. Lowndes. Dept. Pharmacol., CMDNJ-N.J. Med. Sch. Newark, N.J. 07103 and Depts. Neurol. and Pathol., Johns Hopkins Med. Sch. Baltimore, Md. 21205.

β, β'-iminodipropionitrile (IDPN, 50 mg/kg) given i.p. once weekly for 5 weeks to cats produced a neuropathy manifested by ataxia, hindlimb weakness, swaying, hyperactivity and loss of righting reflexes. Morphologically the neuropathy was characterized by large (often > 100 μm) giant axon formations (GAF) in the proximal internodal region of virtually every spinal motor axon: these GAF remained for the duration of the neuropathy. Smaller GAF appeared more distally in almost all intraspinal axons and spread centrifugally with time. Additionally, scattered multifocal GAF were observed in tibial nerve branches. The consequences of these GAF on motoneuron and motor nerve function were investigated using standard electrophysiological techniques. Soleus (S) motor nerve conduction velocities were decreased an average of 35% 50 days and 49% 100 days after the first dose of IDPN. Renshaw inhibition was reduced from 31% in normal cats to 10.7% in test animals. Amplitudes of spinal monosynaptic reflexes (MSR), evoked by unconditioned (single) stimulation of dorsal roots (DR), S or medial gastrocnemius (MG) nerves were 1.69, 0.540 and 0.365 mV in normal cats but 1.00, 0.137 and 0.027 mV in IDPN-treated cats, respectively. Tetanic stimulation (500 Hz, 15 s) of the same afferents evoked a post-tetanic potentiation of MSR of 82, 111, and 125% in normal cats. Corresponding values in IDPN-treated cats were 157, 236 and 533%. A peculiar, double spike pattern of MSR response was observed in all treated cats, suggested altered spike formation in motoneurons (MN) with GAF. This was confirmed by intracellular recording of antidromically elicited spike potentials in lumbar MN. Spike potentials were normal, exhibited marked premature or delayed depolarizations or fired in doublet or triplet fashion upon single stimulation. These data suggest that IDPN neuropathy in the cat is an excellent model in which to study GAF and their consequences on neurophysiological function.

272.11 IN VIVO AND IN VITRO EFFECTS OF NEUROTOXIC ACRYLAMIDE ON SELECTED ENZYME ACTIVITIES IN RAT BRAIN, SCIATIC NERVE AND LIVER, Ivy L. Vyas*, Richard D. Howland*, and Herbert E. Lowndes (Spon: Henry Brezenoff). Dept. Pharmacol., CMDNJ, N.J. Medical Sch., Newark, N.J. 07103.

Acrylamide causes a "dying-back" type of polyneuropathy characterized pathologically by degeneration beginning in distal portions of axons of large nerve fibers. It has been suggested that the metabolic basis for this type of neuropathy may be an interference with axonal energy metabolism (Sabri, et. al.: Neurotox. 1:285, 1979, J. Neurochem. 32:683, 1979 and Howland, et al.: Brain Res., in press). It is necessary to establish the precise pattern of effects on parameters of metabolism in neural and non-neural tissues if such a metabolic derangement is to be demonstrated for acrylamide and toxic compounds producing a similar type of neuropathy. The effect of acrylamide on activities of glyceraldehyde-3-phosphate dehydrogenase (GAPDH), an enzyme associated with axoplasmic transport in neural tissue, and phosphofructokinase (PFK), an important regulatory enzyme in glycolysis, was investigated in homogenates of rat brain, sciatic nerve and liver. Enzymatic activities were determined from initial velocity measurements in a post-nuclear fraction of tissue homogenates. For in vitro experiments aliquots of brain homogenates were incubated with or without acrylamide. When compared to controls incubated without acrylamide, incubation with acrylamide caused an inhibition of both GAPDH (I_{50}=0.41 mM) and PFK (I_{50}=5mM). For in vivo experiments, rats were treated with acrylamide 50 mg/kg/day i.p. to a cummulative dose of 350 mg/kg or 500 mg/kg. When compared to appropriate controls, activities of GAPDH were decreased by 31.9% in brain, 47.9% in sciatic nerve and 30.2% in liver homogenates from rats given 500 mg/kg and 27.8% in brain in rats given 350 mg/kg.PFK activity was decreased in sciatic nerve (23.2%), slightly decreased in brain (5.25%) but not different from control values in liver homogenates from rats given 500 mg/kg. In brain homogenates from rats given 350 mg/kg PFK activity was 10.8% lower than in controls. These preliminary results suggest that inhibition of GAPDH is a specific effect of acrylamide and occurs in both neural and non-neural tissue. The significance of the decreased activity of PFK in brain and sciatic nerve remains to be determined.

Supported by: USPHS NIH Grants NS-11948 and 5 S07 RR05393 (Biomedical Research Grant).

272.12 NEURONAL AND NON-NEURONAL ENOLASE ACTIVITIES IN PERIPHERAL NERVE AND SKELETAL MUSCLES IN CATS WITH ACRYLAMIDE NEUROPATHY. Richard D. Howland* (Spon: Amos G. Gona). Dept. Pharmacol., CMDNJ, N.J. Med. Sch., Newark, N.J. 07103.

Current investigations of the etiology of acrylamide (ACR) neuropathy have focused on the role of inhibition of certain glycolytic enzymes, viz. enolase (EN), phosphofructokinase (PFK) and glyceraldehyde phosphate dehydrogenase (GAPDH). This laboratory has shown that the activity of the neuron-specific isoenzyme of enolase (NSE) is decreased in sciatic nerve and brain of ACR intoxicated rats (Howland et al. Brain Res., in press). In order to assess the significance of inactivation of NSE in the development of ACR neuropathy, the activity of total EN and NSE was measured in sciatic and tibial nerves of cats intoxicated with cummulative doses of either 150 or 300 mg/kg ACR. In addition, EN, PFK and GAPDH were measured in soleus and medial gastrocnemius muscles. (Enzyme activities are expressed as units where one unit equals the formation of one μmole of product per min. All values are $\bar{x} \pm$ SEM for at least 4 animals).

NSE activity in tibial n. was decreased 39 and 85% of control (0.013 ± 0.002 units/mg prot.) in cats receiving 150 and 300 mg/kg ACR, respectively. Total EN and NSE activities did not differ significantly in control sciatic and tibial nerves indicating no proximal-distal gradient for these enzymes. ACR, at either dose, had no effect on either enolase activity in sciatic n. In soleus m. of ACR treated cats EN, PFK and GAPDH activities were unchanged from control activities of 0.91 ± 0.05, 0.095 ± 0.004 and 1.11 ± 0.07 units/mg protein, respectively. The relative activities of these enzymes in gastroc. m. was much different: 5.97 ± 0.15, 0.004 ± 0.0005 and 6.92 ± 0.46 units/mg protein for EN, PFK and GAPDH, respectively. ACR (150 mg/kg) resulted in a 42% decrease in GAPDH activity and a 15% decrease in EN activity. No change was seen in PFK activity nor did the higher dose alter the results. These data suggest that the neurotoxicity of ACR is dependent upon the susceptibility of certain glycolytic enzymes to inactivation and that the susceptibility is tissue dependent. The data also suggest that the inactivation of NSE may be an initiating event in the development of ACR neuropathy.

272.13 ASSESSMENT OF THE EFFECTS OF THREE NEUROTOXIC COMPOUNDS ON MOTOR FUNCTIONS IN MICE, S. G. Gilbert* and J. P. J. Maurissen. Dept of Rad. Biol. Biophys., University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

Sensorimotor dysfunctions can be induced by a wide range of neurotoxic chemicals. Simple techniques to assess such motor disorders, often expressed as hindlimb weakness, have been developed. Rotarod performance and landing foot-spread were measured before, during and after the course of dosing, and the sensitivity of these techniques compared.

Thirty female BALB/c mice were divided into six groups. Acrylamide (250 ppm), 2,5-hexanedione (5000 ppm) and methylmercury chloride (10, 20 and 40 ppm) were dissolved in distilled water and administered via light-tight drinking bottles. Treatment ceased when the first signs of toxicity became evident.

Baseline data were collected before dosing started. Mice were placed twice weekly on an accelerating rod, and their retention time recorded. In the landing foot-spread test, the experimenter dropped mice from 15 cm on a flat smooth surface once a week. The hindlimb splay was then measured by the examiner. Both experimenter and examiner were unaware of the identity of each group during the testing period.

The effects of acrylamide in rats have been described previously with these two techniques (Kaplan and Murphy, 1972; Edwards and Parker, 1977). Decreased retention time and increased hindlimb splay were observed simultaneously in mice after 12 days of exposure. Recovery followed treatment cessation. Increased hindlimb splay preceded an obvious decline of rotarod performance in the group receiving the 10 ppm methylmercury solution.

Mice receiving the 20 and 40 ppm of methylmercury solutions did not display any changes in these tests before overt signs of toxicity. 2,5-Hexanedione did not produce any clear decline in performance although it induced subjectively observed changes (muscle weakness, reduced motor activity) leading to exposure termination.

Our data show that rotarod and hindlimb splay test in mice have approximately equal sensitivity to the effects of several neurotoxic chemicals. However, these techniques cannot always detect motor function disorders before overt signs of toxicity are apparent.

272.14 PHENYTOIN, METHYSERGIDE, AND PENICILLAMINE IN HEREDITARY MUSCULAR DYSTROPHY OF THE CHICKEN. R.K. Entrikin, G.T. Patterson, and B.W. Wilson. Depts., of Pharmacology, Phys. Med. & Rehabil., and Avian Sciences, University of California, Davis, CA 95616.

Since 1975, improvements in hereditary muscular dystrophy of the chicken have been reported for phenytoin (DPH), methysergide (MES), and D-penicillamine (PEN). It has not been possible to conclude from the published reports which compound is most effective or the duration of treatment required to detect a beneficial drug effect. This is partly due to the fact that different aspects of the dystrophy were evaluated in each study. Even in the case of impaired righting ability, which was used in all the studies, a different method of assessment was used for each drug. Here we report the first direct comparison of these three drugs in a single, standardized test system.

Each drug was evaluated in 3 to 5 short-term trials (25 days duration) and one long-term trial (90 days duration) in male chicks of UC Davis lines 412 normal and 413 dystrophic. Drug doses were similar to those used in the original reports, and were administered i.p., b.i.d., beginning on day 1 ex ovo (PEN was also administered p.o., as originally reported). Righting ability was determined at 10-day intervals using the exhaustion score (ES), the consecutive number of times a chick could rise from the supine position in rapid succession during a single test period. Plasma creatine kinase (CK) activity was determined spectrophotometrically on venous blood.

Mean ES values (± SEM) and 29-day CK values are shown below for normal controls (412C), dystrophic controls (413C), and for one trial with dystrophics treated with DPH, MES, or PEN (n in parentheses).

	Day 15 ex ovo	Day 25 ex ovo	CK (% of 412C)
412C	18.8 ± 1.2 (55)	19.3 ± 1.2 (55)	100.0
413C	3.7 ± 1.2 (31)	1.7 ± 0.6 (31)	3018.2
DPH	7.7 ± 1.1 (9)	6.3 ± 1.9 (9)	1747.6
MES	7.4 ± 1.4 (10)	7.2 ± 2.3 (10)	2188.2
PEN	1.5 ± 0.4 (10)	0.0 ± 0.0 (3)	805.9

These data, as well as those obtained in other trials, confirm the earlier reports that both DPH and MES increase righting ability and decrease plasma CK in dystrophic chicks. As tested here, these drugs appear equally effective. PEN, on the other hand, did not increase righting ability. With respect to duration of treatment required, DPH and MES could be detected as beneficial at the first test period (10 or 15 days ex ovo) in all trials. Although the effects of DPH and MES decreased as the animals aged, both drugs still exerted a slight beneficial effect at 90 days ex ovo. (Supported by the Muscular Dystrophy Association, Inc.).

272.15 THE TURNOVER OF POLYPHOSPHOINOSITIDES IN ERYTHROCYTE MEMBRANES IN MYOTONIC MUSCULAR DYSTROPHY. R. B. Moore*, S. H. Appel and G. A. Plishker* (SPON: A. Coats). Dept. of Neurology, Baylor College of Medicine, Houston, Texas 77030.

Erythrocyte membranes possess a phosphodiesterase which in the presence of calcium cleaves the polar head groups from di- (DPI) and triphosphoinositides (TPI). The products of this reaction are 1,2 diacylglycerol and inositol di- and triphosphates. The diacylglycerol is converted in the presence of ATP by a phosphokinase to phosphatidic acid (PA). Recently, it has been reported that the calcium-dependent PA synthesis is altered in erythrocytes in myotonic muscular dystrophy (MyD) (Grey et al, Fed. Proc. 39:2495, 1980). In our studies calcium-dependent hydrolysis of DPI and TPI in erythrocyte ghosts and ATP depleted erythrocytes of normals and MyD patients was examined. A 40% loss of ^{32}P phospholipids was observed in ghosts incubated at 37° for 10 min. in the presence of 0.3 mM calcium. Thin layer chromatography showed that 94% of the ^{32}P was incorporated into DPI, TPI and PA. The loss in radioactivity resulted from a 70% decrease in DPI and a 30% decrease in TPI. PA remained unchanged. Calcium activation studies at pH 7 in the presence of 1 mM $MgCl_2$ revealed a half maximal hydrolysis of TPI and DPI at 0.8 μM calcium. Strontium was found to be 100 times less effective than calcium and barium was without an effect at 0.1 mM. Over the range of 1.5×10^{-7} to 1×10^{-3} M calcium the amount and pattern of polyphosphoinositide hydrolysis from 7 patients with MyD was normal. The hydrolysis of TPI as compared to DPI was higher in intact ATP depleted cells exposed to the calcium ionophore A23187. Cells incubated at 20° for 30 min with 1 μM A23187 and 3.6 μM free calcium showed a 65% loss in DPI and a 50% loss in TPI. Two patients showed similar patterns of TPI and DPI hydrolysis. In ^{32}P-labeled cells containing ATP more than a ten fold increase in ^{32}P-labeled PA was observed when they were incubated at 20° for 60 min in the presence of 3.6 μM calcium and 1 μM A23187. Half maximal synthesis of PA was observed in the presence of 0.4 μM calcium. A comparison of 7 patients with normal age, sex-matched controls revealed no significant differences in radioactive PA synthesis. A batch experiment demonstrated that the specific activity of the PA was the same for a normal and a myotonic. These results suggest that 1) the hydrolysis of TPI is higher in intact cells than in ghosts; 2) the hydrolysis of DPI and TPI in ghosts and ATP-depleted intact cells is normal in MyD; and 3) synthesis of PA in ATP containing cells is normal in MyD. (Supported by the Muscular Dystrophy Association and by a fellowship to RBM by the Muscular Dystrophy Association of Canada).

273.1 MORPHOLOGICAL AND QUANTITATIVE ANALYSIS OF ACETYLCHOLINESTERASE-CONTAINING NEURONS IN CAT NEOSTRIATUM. J. O'Reilly-Fromentin*, R. Boucher and A. Parent, Lab. Neurobiol., Fac. Med., Laval Univ., Québec, Canada.

The use of the Butcher's pharmaco-histochemical protocol (Butcher et al., '75) for the demonstration of acetylcholinesterase (AChE), which involves pretreatment with di-isopropylfluorophosphate (DFP), has allowed a clear visualization of AChE-producing neurons in cat neostriatum with minimal background staining. A quatitative investigation of these neurons could thus be undertaken with the help of a Zeiss modular system for quantitative digital image analysis. The AChE neurons in cat neostriatum represent only a small percentage of the total striatal cell population: 3-6 cells/mm^2 in caudate nucleus, and 14-15 cells /mm^2 in putamen. In caudate nucleus the strongly-stained AChE neurons were either fusiform with one typical thick process emerging from one pole of the cell body, or multipolar with numerous thinner processes. In putamen the AChE neurons were larger than those of the caudate and had a round or polygonal cell body with innumerable processes branching abundantly. These processes often intermingled with the myelinated fiber fascicles traversing the putamen. Measurements made on 138 caudate cells and 177 putamen cells reveal that the AChE neurons in caudate had a maximum diameter of 33.3 ± 0.7 μm (mean ± S.E.M.) and a surface area of 390.9 ± 0.7 μm^2. The AChE neurons in the rostral half of putamen had a max. diam. of 36.7 ± 0.7 μm and a surface area of 524 ± 15.5 μm^2, whereas those in caudal half of putamen were even larger: max. diam. 41.1 ± 0.6 μm and surface area 662.1 ± 15.1 μm^2. In caudal portion of putamen some AChE cells as large as 60 μm (max. diam.) were encountered. In the hope to find out if some of the AChE striatal cells are output neurons, HRP was injected in the entopeduncular nucleus or in the substantia nigra pars reticulata and retrorubral nucleus, in 4 cats, and the brain sections processed according to the combined HRP-AChE method of Mesulam ('76). After HRP injections a multitude of medium-sized (15-20 μm) labeled cells were found in both caudate and putamen, sometimes closely surrounding the larger AChE neurons. However, HRP granules could not be detected in the striatal AChE neurons themselves.

These findings suggest that, in cat, the AChE neurons of the putamen are morphologically different and significantly larger than those of the caudate nucleus, and support the view that the *striatal AChE cells are not output neurons.*

273.2 COMPUTER-ASSISTED QUANTIFICATION OF DENDRITIC MATURATION IN THE KITTEN CAUDATE NUCLEUS. J.P. McAllister*, M.S. Levine, C.D. Hull, and A.M. Adinolfi. Mental Retardation Research Center, School of Medicine, UCLA, Los Angeles, CA 90024.

Several quantitative analyses have been employed to assess the dendritic maturation of spiny neurons in the kitten caudate nucleus. Tissue from kittens in 4 age groups (see Table) was impregnated using the Rapid Golgi method. Spiny neurons were drawn using a camera lucida and three dimensional analysis performed with a PDP 11/40 computer. Comparisons of mean values indicate: 1) the number of branches per dendrite remains constant, 2) total dendritic length increases approximately 20-25%, 3) branch length (Br), length of each dendrite and dendritic field radius all increase gradually during the first 10 days, then rise sharply between the second-third week to values observed in older animals. Since mean length of the first dendritic segment remains relatively constant at 18-22μm, linear growth occurs along intermediate and distal branches. These relationships were confirmed by comparing the same measurements from only the longest (optimally impregnated) dendrite of each cell, a procedure that corrects for branches that are truncated as they pass out of the section. The decrease in total dendritic length in older kittens may correlate with the finding that loss of primary dendrites occurs sometime after the third week. Counts of dendritic spines drawn at 1000x magnification indicate that these appendages are lost along proximal segments (P) but increase 228% on distal branches (D) with development. A concentric sphere analysis further demonstrates that nearly all dendritic branches (# crossings) are confined within 180μm of the soma origin at 2-3 days of age, but gradually shift to 270μm away by 90-143 days. Likewise, during the first two weeks of age, free endings are clustered between 60 and 150μm from the cell origin, but are distributed evenly up to 270μm in the older kittens. Branch order analysis indicates that the ordering of segments is not rearranged with development, and that with age dendritic branches lengthen uniformly beyond the primary segment. These results illustrate that the dendrites of most caudate neurons exhibit significant increases in length and distal spine density during the early postnatal period without changes in branch numbers, and suggests that apparent dendritic remodeling may be involved in neuronal maturation.

				Mean Length in μm				Spines/μm		
Age	#Cats	Cells	#Dend	Br	Ea.Dend	Radius	Total	P	I	D

273.3 TOPOGRAPHIC ORGANIZATION OF THE HABENULO-INTERPEDUNCULAR PATHWAY IN THE RAT. B.A. Flumerfelt, A. Contestabile* and A.W. Hrycyshyn*. Dept. of Anatomy, University of Western Ontario, London, Canada.

Using the HRP tracing method, the topographic organization of the projection to the interpeduncular nucleus (IPN) from the habenular nuclei (Hb) was investigated in the rat. Hand drawn micropipettes (O.D. 50μm) were filled with 50% HRP by capillarity and the solution was allowed to dry at the tip. The micropipette was then placed stereotaxically in the IPN and left in place for 10-30 mins., producing a discrete locus of HRP activity at the pipette tip. Using this method, HRP was deposited in various locations throughout the IPN in 32 rats. Following post-operative survival times of 2-3 days the animals were sacrificed and HRP activity was demonstrated in frozen serial sections through the brain using tetramethylbenzidine as the chromogen. The following pattern of organization in the Hb-IPN pathway was revealed: The main component arises from the medial Hb and follows a reversed caudorostral pattern, terminating throughout all but the caudalmost part of the IPN. The ventral two-thirds of the IPN receives a much heavier projection such that a large ventrolateral area of the medial Hb projects to the lateral part of the IPN in a completely bilateral way. An additional projection which is predominantly ipsilateral arises from the rostral half of the dorsolateral part of the medial Hb and terminates in the caudal IPN. The medial part of the medial Hb projects preferentially to central areas of the IPN.

The projection from the lateral Hb is quantitatively much smaller but appears to be distributed to the entire length of the IPN following a non-reversed, caudo-rostral arrangement, with the ipsilateral projection predominating. The projections from the medial and lateral Hb to the IPN were confirmed by tracing anterogradely transported HRP as well. No reciprocal connection from the IPN to the Hb could be demonstrated.

Additional observations revealed a small projection to the IPN with a strong ipsilateral predominance from the horizontal limbs of the nucleus of the diagonal band of Broca. Small projections from the premammillary and supramammillary nuclei were also demonstrated. Confirmatory data and some details of organization were also obtained for projections to the IPN from other areas, including the medial and dorsal raphe nuclei, the dorsal tegmental nucleus of Gudden and the adjacent dorsolateral tegmental nucleus. Very small projections from the ventral tegmental nucleus and the locus coeruleus were also found.

273.4 THE INFLUENCE OF DOPAMINERGIC MECHANISMS ON TWO TYPES OF CERVICAL DYSTONIA IN THE CAT. F. Malouin and P. Bédard (SPON: L.J. Poirier). Lab. de neurobiologie, Université Laval, G1K 7P4.

Destruction of the dopaminergic nigro-striatal pathway in cats by injection of the neurotoxine 6-hydroxy-dopamine (6-OHDA) resulted in the appearance of an asymmetric static head position accompanied by spasmodic movements. These movements, which consisted of horizontal deviations of the head to the side ipsilateral to the lesion, were observed by the first post-injection day. In contrast, an electrolytic lesion dorsolateral to the substantia nigra (SN), which interrupted the striato-nigral efferents and destroyed part of the SN pars reticulata produced spasmodic horizontal deviations of the head to the side contralateral to the lesion. The influence of dopaminergic pharmacological agents on the asymmetrical cervical posture and the spasmodic head movements was described by means of concomitant recordings of electrogoniometric measurements of the neck movements and the electromyographic activity from neck muscles.

In the two types of cervical dystonia apomorphine (0.1 mg/kg s.c.), a dopamine agonist, corrected and subsequently reversed the asymmetry of the head, while pimozide (2.5 mg/kg I.P.), a dopaminergic antagonist, increased the spontaneous asymmetry. However while amphetamine (1.0 mg/kg I.M.) a dopaminergic agent increased the asymmetry caused by 6-OHDA lesion, it reversed the asymmetry resulting from the electrolytic lesion.

These results emphasize the role of the dopaminergic system in the modulation of head movements following the interruption of the nigro-striatal and striato-nigral pathways in the cat.

273.5 AXONAL ARBORIZATIONS OF NIGROTHALAMIC AND NIGROTECTAL CELLS: ANATOMICAL AND ELECTROPHYSIOLOGICAL STUDIES. J.M. Deniau*, I. Grofova*, D. Steindler*, S.T. Kitai (SPON: L.I. O'Kelly). Depts of Anatomy, Michigan State Univ., U.S.A., Univ. Oslo, Norway, Lab. Physiol. Ctr. Nerv., Univ P. et M. Curie Paris, France.

Patterns of intrinsic and extrinsic axonal arborizations of rat nigrothalamic and nigrotectal cells were studied by intracellular recording, intracellular HRP labeling and extracellular double labeling techniques.

Intrinsic Collaterals. Monosynaptic IPSPs were recorded in substantia nigra pars reticulata (SNr) following Thalamus (Th) and Superior Colliculus (SC) stimulation. These responses remained after hemitransection of the brain just rostral to Th, eliminating a possible source of inhibitory inputs from forebrain. Since there is no known connections from either Th nor SC to SNr, these monosynaptic IPSPs were considered to be induced by recurrent collaterals. Light microscopic examination of nigrothalamic and nigrotectal neurons intracellularly labeled with HRP revealed that axons of these neurons give off 1-3 collaterals within the SN. These collaterals arborize partly within and partly outside of the dendritic field of the parent cells and also reach the pars compacta. These morphological and electrophysiological observations indicate that intrinsic axon collaterals of SNr neurons are involved in collateral inhibition.

Extrinsic Branching. Previously we have demonstrated that antidromic activation of SNr neurons from Th, SC and Striatum indicate that many SNr cells project at least to two different target nuclei (i.e. Th and SC or Th and Striatum). We now demonstrate anatomically that branched axonal projections arise from SNr cells by the observation of double labeled neurons following conjugated extracellular injections of HRP in Th and tritiated wheat germ agglutinin in the Striatum or SC. Evidence for axonal branching of SNr projection cells is also provided by tracing the axons of nigral cells intracellularly labeled with HRP. An axon of a nigrothalamic neuron was seen to divide in four branches in the ventral mesencephalic tegmentum. One of the branches was followed rostrolaterally until reaching the ventral part of the subthalamic nucleus. The other three branches ran dorsocaudally in the direction of the SC and gave off several branches in the mesencephalic reticular substance. Some of them were of small caliber and arborize locally whereas two thick branches were seen to turn rostrally toward the Th. These observations favor the hypothesis that single SNr neurons may exert a synchronous influence on areas of CNS which are involved in the integration of sensorimotor activities.

273.6 PROJECTIONS OF GLOBUS PALLIDUS NEURONS REVEALED BY LOCALIZED INJECTION OF RADIOACTIVE AMINO ACIDS IN MONKEY. J.L. DeVito and M.E. Anderson, Regional Primate Research Center and Dept. of Neurol. Surg., Rehab Med., and Physiol. and Biophys., Univ. of Wash., Seattle, WA 98195.

The destination and course taken by globus pallidus (GP) axons reaching thalamic and brainstem structures were traced by autoradiography in monkeys in which simultaneous injections of horseradish peroxidase (HRP) allowed the identification of potential afferents to the same pallidal sites.

The borders of GP were determined in 4 awake Macaca mulatta by recording the tonic discharge patterns characteristic of pallidal neurons. A mixture of radioactive amino acids and HRP (0.2-0.3 ul) was injected into GP via a microliter syringe. Survival times were 2-3 days and brain sections were processed with standard autoradiographic techniques. Major projections from the medial pallidal segment (Gpi) were traced to thalamic nuclei, ventralis anterior (VA) and lateralis (VL), the centromedian (CM) the habenula, and the pedunculopontine nucleus (PPN) as described by others. The clear topographic input from striatum into dorsal, central and ventral GPi as determined by retrograde transport of HRP was not reflected in orthograde transport of isotopes to the regions listed above. Efferents from a ventral GPi site extended somewhat more medially and efferents from dorsal GPi somewhat more laterally in the VA and VL thalamic nuclei. There was, however, considerable overlap of projections from the two regions. In contrast to some reports, GPi projections extended dorsally into the pars caudalis region of VL (VLc). This part of VLc seemed to correspond to areas free of degeneration following cerebellar lesions (G.Percheron, J.Hirnforsch, 1977), thus reinforcing the concept that pallidal and cerebellar fibers terminate independently in the thalamus. VLc connections were not observed following an injection centered in the lateral pallidal segment. Intralaminar connections were predominantly to the magnocellular part of CM and lateral part of the parafascicular nuclei. These regions are known to receive fibers from premotor and rostral area 4 cortex. The caudal and lateral parvocellular region of CM, which receives projections from caudal area 4 was only lightly labeled following GP injections. Pallidal axons took multiple pathways through the mesencephalon with the PPN as a major terminus. En route, the pattern of silver grains was suggestive of terminals in the prerubral field. Some fibers in the medial longitudinal fasciculus were also labeled although a final destination apart from the PPN could not be determined. Labeling of these pathways did not depend on involving substantia innominata adjacent to GP as has been suggested.

273.7 THE VESTIBULAR PROJECTION UPON THE INTRALAMINAR THALAMUS AS DEMONSTRATED BY ANTEROGRADE TRANSPORT OF H^3-LABELED AMINO ACIDS. Charlotte M. McGuinness*, Michael Bixler*, and George M. Krauthamer (SPON: A. Hess). Dept. of Anatomy, CMDNJ-Rutgers Medical School, Piscataway, NJ 08854.

The presence of projections from the vestibular nuclei (VN) to the thalamus has been disputed, although electrophysiological responses to vestibular stimuli have been recorded in the intralaminar nuclei (IL), ventrobasal complex, and other areas. Studies using retrograde transport of horseradish peroxidase (HRP), in this laboratory, have indicated a projection from the medial VN and lateral VN to centrum medianum of IL (Brain Res., 1980, 184:255). Several recent autoradiographic studies of VN have not specifically examined the efferents of these two nuclei, and have therefore failed to unequivocally describe this projection.

Multiple small injections of H^3-labeled proline and leucine were made unilaterally in the medial and lateral vestibular n. of cats. Animals survived one week, and brains were processed according to standard procedures.

Autoradiograms of frontal sections taken through the thalamus showed that the injected nuclei project to a restricted portion of IL. Label was found, fairly uniformly, throughout centrum medianum; it was not present in abutting nuclei, nor in more anterior sections through centralis lateralis, indicating that the projection terminates at this level. The contralateral projection exceeded the ipselateral one, confirming our earlier HRP studies. Further experiments will examine possible differences between projection of the medial and lateral vestibular nuclei.

(Supported by NIH Grant NS10922 to G. Krauthamer.)

273.8 GABA IS A PALLIDOTHALAMIC NEUROTRANSMITTER. J.B. Penney* and A.B. Young. Dept. of Neurology, University of Michigan, Ann Arbor, MI 48109.

Research on the movement disorders has focused primarily on the nigrostriatonigral pathways. Much information about this neuronal circuit has become available. Despite the numerous studies, it is difficult to develop any theory of basal ganglia dysfunction based solely on this circuit. We are currently studying the more classical basal ganglia corticostriatopallidothalamocortical circuit in order to more adequately understand the neurochemical correlates of the movement disorders.

One of the major outputs of the basal ganglia is the pathway from medial globus pallidus (MPS) to ventrolateral nucleus (VL) of the thalamus. Neurophysiologic studies indicate this pathway tonically inhibits VL (Geogopoulous, A.P., Neurosci. Abst. 4:43, 1978; Uno, M., Brain Res. 99:377, 1975).

We have injected kainic acid (KA) into the murine counterpart of the MPS, the entopeduncular nucleus (EP), and measured neurotransmitter levels in VL. 1 nmole of KA is injected microelectrophoretically into one EP of anesthetized rats. At 2 weeks, animals are sacrificed, the brain rapidly removed and punches taken from VL bilaterally. Amino acid levels demonstrate a selective 54% decrease in GABA levels on the lesioned side. There are also 46% decreases in both glutamic acid decarboxylase, the rate limiting enzyme in GABA synthesis, and in high affinity synaptosomal uptake of GABA.

Thus, there is strong evidence that the pallidothalamic output of the basal ganglia utilizes GABA as its neurotransmitter. Since the striatopallidal pathway is also GABAergic, the presence of sequential GABAergic pathways may explain the failure of GABA agonists in movement disorders such as Huntington's Disease. Supported by USPHS grants NS00464-01, NS00420-01 and NS15140-02, the United Cerebral Palsy Research Foundation and Michigan Memorial Phoenix project grant 567.

273.9 THE PALLIDO-SUBTHALAMIC PROJECTION IN RAT: ANATOMICAL AND BIOCHEMICAL STUDIES. T. Hattori, Derek van der Kooy, Kathleen Shannak* and O. Hornykiewicz. Dept. Anatomy, Univ. Toronto, Toronto, Ont., M5S 1A8, Human Brain Lab, Clarke Inst. Psych, Toronto, Ont., M5T 1R8, Inst. Biochem. Pharmacol., Univ. Vienna, Austria

Horseradish peroxidase injected into the rat globus pallidus was transported retrogradely to subthalamic nucleus neuronal cell bodies and anterogradely to axon terminals in the subthalamic nucleus. Electron microscopic observations revealed that the labeled axon terminals made symmetrical axosomatic and axo-dendritic synaptic contacts with labeled subthalamic nucleus perikarya and dendrites. Injection of kainic acid in the globus pallidus several days prior to the horseradish peroxidase injection abolished the anterograde but not the retrograde transport of the tracer. This suggested the anterograde labeling observed in the subthalamic nucleus originated from neuronal cell bodies in the globus pallidus.

Kainic acid lesions identical to those employed in the above anatomical studies resulted in a loss of neuronal cell bodies throughout the globus pallidus and caused a drop in glutamic acid decarboxylase and choline acetyltransferase levels in the globus pallidus. Levels of these two enzymes were not changed in the subthalamic nucleus after the globus pallidus kainic acid lesions, but both showed small, statistically significant decreases in the substantia nigra. It was concluded that there is a massive pathway from the globus pallidus to the subthalamic nucleus, which terminates on subthalamic nucleus neurons projecting back to the globus pallidus. Neither γ-aminobutyric acid nor acetylcholine is the major neurotransmitter in the massive pallido-subthalamic pathway.

273.10 SOMA-DENDRITIC MORPHOLOGY OF THE SUBSTANTIA NIGRA PROJECTION NEURONS INTRACELLULARLY LABELED WITH HRP. I. Grofova* J.M.Deniau* and S.T.Kitai. (SPON: M.B.Rheuben) Depts. of Anatomy, Mich. State Univ., U.S.A.: Univ. Oslo, Norway, Lab. Physiol. Ctr. Nerv., Univ P. et M. Curie, Paris, France.

Rat substantia nigra pars reticulata (SNR) neurons were activated antidromically following thalamic or tectal stimulation and subsequently intracellularly labeled with HRP. After fixation the brains were cut in a sagittal or frontal plane, processed for HRP histochemistry, osmicated and flat-embedded in plastic following the method of Wilson and Groves (J.Neurosci. Methods, 1:383-391, 1979).

Light microscopic examination of 25 labeled cells revealed three types of projection neurons. The most frequently encountered was a medium-size cell in the dorsal part of SNR. Three to five thick primary dendrites arise from the elongated cell bodies and immediately branch to form secondary dendrites which course primarily anteroposteriorly and dorsoventrally, but also having a considerable spread in the mediolateral direction. The dendritic fields extend up to 1400μm anteroposteriorly, 700μm mediolaterally, and 500μm dorsoventrally covering almost the entire anteroposterior and dorsoventral extents of SN. Thin beaded branches, spines, and protrusions of various sizes and shapes appear on all dendrites and are more frequent distally. Ventral dendrites terminate in complex arborizations, "thickets", composed of several branches covered by numerous pleomorphic appendages. The medium-size cell lying in the ventral part of SNR has a strikingly different dendritic organization. The dendrites course mediolaterally and anteroposteriorly, and completely remain within the ventralmost part of SN. Distally, the dendrites branch more frequently and are covered by numerous pleomorphic appendages. Some terminal dendrites are varicose, other form complicated thickets. Large cells are characterized by voluminous somata and sparsely branching dendrites which gradually taper toward the end and course mainly anteroposteriorly. The dendritic field is relatively narrow mediolaterally and dorsoventrally. Thin tortuous branches which are often beaded arise from all the dendrites but spine-like appendages and terminal thickets are absent.

The nigrothalamic and nigrotectal cells were intermingled in SNR and their appearance was not related to whether they were identified as nigrothalamic or nigrotectal. On the other hand, the dendritic morphology of medium-size neurons was related to their position within SN. The observations suggest that, regardless of the precise topography of the striatonigral fibers, the nigrothalamic and nigrotectal neurons may receive afferents from wide areas of the striatum.

(Supported by NIH Grant NS14866 to S.T.K. & BRSG RR 0572 to I.G.).

273.11 COMBINED PUSH-PULL CANNULA AND ELECTROCHEMICAL DETECTOR IN CAT CAUDATE. C.R. Freed* and R. Lane. Depts. Med. & Pharmacology, Div. Clin. Pharmacology, U. Colorado Health Sciences Center, Denver, CO 80262; Dept. Chemistry, U. Oregon, Eugene, OR 97403.

To evaluate the specificity of the response of the in vivo electrochemical detector, we have correlated the detector response to actual catecholamine measurements made on the outflow of a push-pull cannula implanted in the same cat. Cats of either sex weighing 4-6 kg were anesthetized with 1-1.5 gm/kg of urethane. A 200 micron carbon paste electrochemical detector electrode was placed stereotaxically in the left caudate. Signal was measured at a fixed potential of 0.7 volts using a model LC-2A amplifier (Bioanalytical Systems). A 1.5 mm O.D. stainless steel push-pull cannula was inserted in the right caudate and the caudate perfused at 25 microliters per minute. The outflow passed through a second electrochemical detector and then to a fraction collector. One-half hour fractions were collected and assayed for catecholamine content by high performance liquid chromatography with electrochemical detection. A drug challenge of L-dopa 200 mg/kg I.P. was given together with the peripheral decarboxylase inhibitor carbidopa 50 mg/kg. Electrochemical signals and push-pull cannula fractions were monitored for 16 hr thereafter. Fractions were assayed for L-dopa, dopamine, DOPAC, HVA and 3-O-methyldopa. Results show that the in vivo electrochemical detector and the detector in the outflow stream of the push-pull cannula gave similar responses over time. Furthermore, the peak shape of the electrical response could be reconstructed from the catecholamine concentration data. The electrochemical detector was most sensitive to dopamine (response = 1.00) and less sensitive to L-dopa (.21), DOPAC (.04), HVA (.03), and 3-O-methyldopa (.03). Because of this differential sensitivity, most of the electrochemical detector response, both in vivo and in the push-pull cannula outflow, was due to L-dopa and dopamine. These data show that the in vivo electrochemical detector set at fixed potential is responding to catecholamines and metabolites that are soluble and that can be eluted from tissue. The electrochemical response correlates well with the concentration time curve for catecholamines assayed from push-pull cannula fractions.

273.14 MOVEMENT DISORDERS ASSOCIATED WITH KAINIC ACID LESIONS IN PARTS OF THE AVIAN "BASAL GANGLIA". Garl K. Rieke. Dept. Anatomy, Texas A&M University, College of Medicine, College Station, TX 77843.

The pigeon paleostriatal complex(PC) is composed of three parts: the paleostriatum augmentatum(PA), the paleostriatum primitivum(PP) and the nucleus intrapeduncularis(INP). The PA may be the avian analogue of the caudatoputamen, while the PP-INP may be analogous to the mammalian globus pallidus. The PP projects to the ipsilateral nucleus spiriformis lateralis(SpL), the nucleus tegmenti pedunculopontinus(TP), the nucleus of the ansa lenticularis(AL) and the nucleus dorsointermedius posterior thalami(DIP) by way of the ansa lenticularis. The SpL may be the analogue of the pars reticulata of the substantia nigra(SNr), and the TP may be the pars compacta of the substantia nigra. The analogies are based upon comparative neuroanatomical, neurohistochemical observations and one recent behavioral study. If the PC and those nuclei that receive inputs from the ansa lenticularis comprise the avian analogue of the mammalian basal ganglia, then can neurochemically induced lesions in the avian brain be associated with movement disorders similar to those induced in mammals by treatment of analogous structures with the same neurochemical agent?

One microliter volumes of kainic acid (KA, 2.5-0.213µg/µL, pH 7.4-7.6) were intracerebrally injected into parts of the avian basal ganglia on one side. Equal volumes of vehicle alone were injected into the opposite side, and the birds were allowed to survive for 17hrs. to 5 days. Unilateral injection of KA into the PC destroyed the large neurons of the PP and reduced the numbers of neurons in the PA. The birds showed unusual postures of the head, irregular arrhythmic movements of the head and rotatory episodes. Birds rotated toward the side of injection as did rats with KA injections in the corpus striatum. Kainic acid destroyed neurons in the SpL, the AL and part of the TP. The birds again demonstrated unusual postures of the head, arrhythmic movements of the head, increased resistance to passive movement of the lower limbs and the neck, and rotatory episodes. Birds rotated away from the side of injection particularly when the SpL was involved in the lesion. The contralateral rotation occurred at frequencies as high as 24 turns/minute. The direction of rotation in birds following SpL lesions was the same as that in rats after KA lesions to the pars reticulata of the SN. Sham controls did not rotate, nor were postural problems present. In conclusion there appears to be a striking similarity in movement disorders in both birds and rats following KA induced lesions of the analogous components of the basal ganglia of the respective brains. The pigeon may therefore serve as another useful experimental model to assess the biochemical, neuropathological and behavioral changes associated with movement disorders.

273.15 FURTHER STUDIES OF THE NIGROSTRIATONIGRAL MECHANISMS AND THEIR ROLES IN MORPHINE SUPPRESSION OF CAUDATE NEURONAL ACTIVITIES. Edward P. Finnerty and Samuel H.H. Chan. Dept. of Life Sciences, Indiana State University, Terre Haute, IN 47809.

A population of substantia nigra zona reticulata (SNR) neurons which appears to play an inhibitory role in the striatonigral feedback pathway was recently identified (Finnerty and Chan, Neurosci. Abst. 4:443, 1978; Eur. J. Pharmacol. 59:307, 1979; Grace and Bunney, Eur. J. Pharmacol. 59:211, 1979). This population of SNR neurons is thought to project to the substantia nigra zona compacta (SNC), and is involved, via an inactivation, in the morphine (MO) suppression of spontaneous caudate nucleus (CN) activities. Based on electrophysiologic evidences, we suggested that the chemical transmitter involved may be glycine (GLY) (Finnerty and Chan, Neurosci. Abst. 5:71, 1979). The present study is a further analysis of the role of the SNC and SNR neurons in the MO suppression of CN activities.

Spontaneous extracellular single-neuron activities were recorded from the SNC and CN by means of stereotaxically placed tungsten microelectrodes in pentobarbital (50 mg/kg, i.p.) anesthetized rats. Direct microinjection to the SN, at a volume of 1 µl, was performed by a stereotaxically positioned 27-gauge syringe needle attached to a microinjection device. Systemic injections were achieved via a cannulated jugular vein or intraperitoneally.

Microinjection of MO (100 µg) into the SN produced a suppression of the spontaneous activities of the CN, coupled with a simultaneous increase in the SNC discharges. The suppressive effect of MO on CN activities was not observed, however, in rats pretreated with the dopamine (DA) receptor blocker haloperidol (HAL, 0.5 mg/kg, i.p.). These results provided confirmation of our previous postulation that MO suppression of CN activities is at least in part produced via a direct activation of the DA-containing nigrostriatal pathway.

Intranigral microinjection of GLY produced an inhibition of the SNC neurons. An excitation of the CN cells, at a parallel time-course, was also observed. GLY microinjected into the SN following HAL pretreatment resulted in only a suppression of the SNC with no effect on the CN units. These data further suggested that GLY may well be the transmitter agent of the inhibitory SNR neurons that are interposed between the CN and the SNC DA-containing neurons in the striatonigral feedback pathway.

273.16 AUTORADIOGRAPHIC OBSERVATIONS ON THE ORGANIZATION OF THALAMOSTRIATAL AND CORTICOSTRIATE PROJECTIONS IN CATS AND KITTENS. J.A. Cospito, M.S. Levine and A.M. Adinolfi. Mental Retardation Research Center; Dept. of Anatomy, UCLA, Los Angeles, CA 90024.

The present study describes the organization of intralaminar thalamic projections within the caudate nucleus and putamen of kittens and cats and contrasts these observations with our earlier findings on the organization of precruciate corticostriate connectivity at comparable ages. Two adult cats and nine kittens (3 each at 2, 6, and 21 days) were used. In each instance, large single or multiple injections (0.2-0.7ul for total radioactive concentration of 5-35uCi) of equal mixtures of tritiated leucine and proline reconstituted in sterile saline filled the intralaminar complex on one side and extended into lateral portions of the mediodorsal nucleus. Animals were sacrificed between 24 hours and 5 days depending on their ages. In adult cats, thalamic projections fill the ipsilateral head of the caudate nucleus and putamen. The clustering or patchy nature of these projections (which has been described by Royce, Brain Res. 146: 145-150, 1978) was seen as irregular zones of density of the transported label within rostral neostriatum. Zones of intense labelling were also seen in the caudate body. In kittens, the organization of thalamic inputs is well-established by 21 days within the rostral neostriatum where the patchy nature of terminal fields is evident but less pronounced than in adults. However, projections into the body of the caudate nucleus were not found in kittens. From earlier studies, we note that the extent and patchy nature of precruciate corticostriate projection fields also becomes evident by three weeks of age. These terminal fields are bilateral and are confined laterally in the caudate head, a small projection into the body, and dorsally in the rostral putamen. In 2 day kittens these projections are bilateral and very prominent throughout the entire neostriatum. These observations suggest that the major inputs from neocortex and intralaminar thalamus differ within the neostriatum and that they become well-established by three weeks of age.

273.17 SUBSTANCE P: LOCALIZATION WITHIN PALEOSTRIATO-TEGMENTAL PATHWAYS IN BIRDS AND REPTILES. Anton Reiner, Harvey J. Karten and Gary E. Korte. Dept. of Neurobiology and Behavior, SUNY, Stony Brook, N.Y. 11794.

Immunohistochemical techniques (indirect immunoflorescence method or immunoperoxidase bridge method) were used to study the localization of substance P (SP) within the paleostriatal complex (PC) and within the projection targets of the PC in pigeon and turtle. Monoclonal antibodies against SP were used (generously supplied by A.C. Cuello). The neuropil of the small-celled zone of the PC (equivalent to the mammalian caudate-putamen) showed heavy SP-like immunoreactivity. Numerous medium-sized neurons containing SP-like immunoreactivity were observed within the more medial subdivision of the small-celled zone of the PC (termed lobus parolfactorius, LPO, in bird and area d in turtle). Fewer neurons containing SP-like immunoreactivity were observed in the more lateral subdivision of the small-celled zone of the PC (termed the paleostriatum augmentatum, PA) and none were observed in the large-celled zone of the PC (termed the paleostriatum primitivum in bird and globus pallidus in turtle).

Two prominent tegmental catecholaminergic cell groups have been noted to receive input from LPO/area d: the ventral tegmental area of Tsai (AVT) and a caudal ventrolaterally situated cell group termed the nucleus tegmentipedunculopontinus (TP) in bird and the substantia nigra (SN) in turtle (Kitt and Brauth, Neurosci. Abs., 1979; Reiner, Neurosci. Abs., 1979). A dense neuropil showing heavy SP-like immunoreactivity that could be eliminated by knife cuts of the efferent outflow pathway of the PC was observed in both AVT and TP/SN.

The present data argue that, as in mammals (Jessel, et al., Br. Res., 1978), portions of the small-celled zone of the basal ganglia (PC) in birds and reptiles may utilize SP as a neurotransmitter or modulator in their projections to tegmental sites. Further, the present data suggest that LPO and PA together in bird and area d and PA together in turtle are to be considered equivalent to the mammalian caudate-putamen and nucleus accumbens. Previous studies had only emphasized the similarity of PA to the mammalian caudate-putamen (Karten and Dubbeldam, JCN, 1973). This research was supported by NS 12078 to H.J.K. and F32 NS 05682 and T32 EY 07039 to A.R.

274.1 RIGHT-SIDE OUTPUT SUPERIORITY EFFECT IN WORD PROCESSING, WITH AND WITHOUT VERBAL EXPECTANCY. Y. Guiard ✱ (SPON : J. Requin). Département de Psychobiologie Expérimentale, CNRS-INP 3, 31, chemin J. Aiguier, 13009 Marseille, France.

In a previous study (Guiard, 1980), it was shown that right-handers display a right-side advantage in motor performance when responding to Stroop stimuli on the basis of the carrier-word, but not on the basis of the colour of ink. Furthermore, this output asymmetry effect of verbal processing was shown to consist both in a right-hand advantage - regardless of the movement parameters - and an advantage of movements towards the right side of space - regardless of the hand involved - (Guiard and Giraudo, 1980).

The present experiment was aimed at estimating the role of verbal expectancy (pre-stimulus processes) as distinct from verbal processing (post-stimulus processes) in the manifestation of this output asymmetry phenomenon. Non-coloured colour names (GREEN or RED) and coloured non-words (crosses printed in green or red ink) were presented in central vision, in random succession. On separate conditions, the probabilities of word processing and colour processing were .75/.25 and .25/.75 respectively. The choice response was a pointing movement either with the left hand towards a left-sided target, or with the right hand towards a right-sided target.

No effect of verbal versus non-verbal expectancy on performance asymmetry was observed. By contrast, the actual processing of the word, as compared with that of the colour, was found to result in a right-sided motor bias exerted in part on reaction-time processes, and in part on movement processes. The results are discussed in terms of the current model of cerebral lateralization of function.

Guiard, Y. Effect of processing mode on the degree of motor asymmetry in the manual Stroop test. To be published in Cortex.

274.2 HEMISPHERIC SPECIALIZATION IN SPLIT-BRAIN MONKEYS. B. A. Vermeire and C. R. Hamilton. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

Split-brain rhesus monkeys were tested for differences in the abilities of their two cerebral hemispheres to process visual stimuli. Tests of visual preferences, i.e., what each hemisphere likes to look at, utilized color photographs of naturalistic stimuli such as monkeys, people, other animals, and outdoor scenes. In general these tests revealed an overall greater preference by the left hemisphere. Furthermore, for some types of photographs the hemisphere with the greater preference correlated with each monkey's handedness; the hemispheric ipsilateral to the preferred hand, possibly equivalent to the human non-dominant hemisphere, showed greater preferences.

The monkeys' ability to make same-different judgments about pairs of sequentially-presented geometrical visual stimuli was also assessed. Overall there was no generalized advantage for either the left or right hemisphere. There was a significant correlation between each monkey's dominance index and handedness, however, which indicated that the hemisphere contralateral to the preferred hand, possibly equivalent to the human dominant hemisphere, learned the task more readily.

These results and other examples of left-right differences and of correlations of hemisphericity with handedness in rats, monkeys, and humans reported in the literature suggest that the basis for hemispheric specialization, particularly in infrahuman mammals, may be quantitative asymmetries in emotional and/or attentional processes.

274.3 BOTH SYNTACTIC AND SEMANTIC FACTORS AFFECT THE TASK-EVOKED PUPILLARY RESPONSE DURING SENTENCE PROCESSING. J. Beatty and M. Schluroff, Human Neurophysiology Laboratory, Dept of Psychology, University of California, Los Angeles, CA 90024

The performance of complex cognitive functions has been shown to elicit widespread momentary increases in sympathetic and decreases in parasympathetic activity that reflect the processing demands imposed by the task. These changes have been interpreted as peripheral signs of activity in the ascending reticular activating system. Orderly pupillary responses have previously been demonstrated during sentence processing. We now report that both syntactic and semantic organization act to reduce information processing load as indexed by the magnitude of the task-evoked pupillary response.

Twenty-four people listened to 3 sets of 12 6-word sentences and repeated them at the rate of 1 word/sec. Standard Sentences were semantically meaningful and varied in syntactic construction. Anomalous Sentences utilized these same syntactic structures but the actual words were exchanged between sentences to minimize meaning. In the third group, Scrambled Sentences, words were randomly ordered to eliminate syntactic structure.

For all sentence types, pupillary diameter increased while listening, dilated markedly before the first word was being repeated, then constricted to baseline by the end of sentence repetition. The magnitude of this response, averaged over the entire period of listening and repeating differed significantly for the 3 types of sentences ($F(2,46)=20.52$; p .001), being largest for the Scrambled Sentences and smallest for the Standard Sentences. A secondary analysis showed that pupillary diameter was significantly larger ($F(1,23)=10.44$; p .001) during repetition than during listening and that this effect interacted with sentence type ($F(2,46)=9.49$; p .001). This means that syntax and semantic structure exert their effects on processing load primarily during sentence production.

A final analysis contrasted syntactically simple and complex Standard and Anomalous Sentences. Both the effect of complexity ($F(1,23)=37.27$; p .001) and its interaction with input vs. output period ($F(1,23)=37.84$; p .001) were significant, indicating that syntactic complexity primarily effects production.

274.4 EVENT-RELATED SLOW POTENTIAL FROM RAT FRONTAL CORTEX IN RESPONSE TO AN AUDITORY CUE PRECEDING ELECTRICAL BRAIN STIMULATION: ALTERATION BY DEXTROAMPHETAMINE. James H. Pirch. Department of Pharmacology and Therapeutics, Texas Tech University Health Sciences Center, Lubbock, Texas 79430.

Negative event-related slow potentials are generated in rat frontal cortex by auditory cues given two seconds prior to delivery of food reinforcement, to extension of a lever which can deliver food reinforcement or to delivery of a discriminative cue which signals food reinforcement. Dextroamphetamine reduces the amplitude of these food-reinforced slow potentials (SPs) (Pharmacol. Res. Comm. 9: 669, 1977; Pharmacol. Biochem. Behav. 6: 697, 1977; Neuropharmacol. 19: 365, 1980). In order to examine the effect of amphetamine on SPs associated with another type of reinforcement, rats were implanted with monopolar stimulating electrodes in the medial forebrain bundle (MFB) as well as SP recording electrodes. The "active" SP electrode was a chlorided silver wire in contact with the dura via an agar-saline bridge. The location was 2 mm anterior to bregma and 1.5 mm to the right of midline, ipsilateral to the MFB electrode. The reference was a similar electrode placed into a bone indentation drilled at the midline immediately behind lambda. SPs were recorded with d.c. amplifiers and analyzed by computer. The warning cue (S^W) was a click and the initial training sequence consisted of 100-150 habituation trials (click only) followed by 30 trials each at S^W-MFB stimulation intervals of 0.5, 1, 1.5 and 2.0 seconds. Trials were presented at variable intervals of 15-50 seconds. During test sessions two sets of 50 trials each were obtained with saline or d-amphetamine injected subcutaneously 15 min before the second set. The SP response to S^W had two negative components; the first wave (N1) reached maximum amplitude (70-130 μV) at 190 to 350 msec and the second (N2) achieved maximum amplitude (80-120 μV) during the last 250 msec of the 2 sec interval following S^W. Amphetamine (0.25, 0.5, 1 mg/kg) produced a dose-related suppression of the SP with a greater effect on N2 than N1. For example, 0.5 mg/kg depressed N1 to 71% and N2 to 38% of the pre-injection amplitudes (saline responses for N1 and N2 were 102% and 101% of preinjection amplitudes respectively; 4 animals). The results indicate that the effect of amphetamine on frontal cortex SPs associated with brain stimulation reinforcement is similar to the effect on SPs associated with food reinforcement. 274.5 EFFECTS OF RESPONSE SPEED ON EVOKED POTENTIALS TO AUDITORY PROBES DURING A VISUAL LETTER-MATCHING TASK. A. J. Nash and C. S. Williams*. Department of Psychology, Florida Atlantic University, Boca Raton, FL 33431.

Evoked potential (EP) paradigms which require reaction time (RT) responses from the subject raise the possibility that non-specific effects of arousal associated with the RT response itself may restrict the reported effects of other stimulus/task variables on the EP to relatively high-arousal states only. In the present study, two groups of seven subjects each were tested in a Posner and Boies paradigm (Psychol. Rev., 78: 391, 1971) consisting of a (primary) visual letter-matching RT task and a (secondary) RT task to an auditory probe stimulus which occurred on 50 per cent of the trials at selected temporal positions within the "Warning Letter/First Test Letter/Second Test Letter" sequence. Probes P-1 and P-2 followed the warning letter by 480 and 680 msec while probes P-3 and P-4 followed the first test letter by 480 and 680 msec respectively. Probes P-1 and P-2 were selected to occur at temporal locations in the trial sequence when the information processing demands of the visual task were low relative to the task demands within the interval containing probes P-3 and P-4. The control group received standard RT instructions to respond as quickly as possible without making errors. The experimental "High Response Speed (HRS)" group received instructions which placed greater emphasis on speed of responding to the visual task.

Baseline measures of EEG activity averaged over the 100 msec intervals preceding each of the auditory probes were in general found to be more negative for the HRS group than for the control group. Baselines also tended to be more negative at probe locations P-2 and P-4 which preceded the first and second test letters respectively. The N100 and P300 amplitudes of the EP to the auditory probes were both greater under the HRS condition but only the P300 showed an interaction between the response speed conditions and the probe locations, the response speed effects being greatest at location P-4, just prior to the second test letter. These effects were attributed to the non-specific effects of arousal associated with the different emphases on RT speed and the varying processing demands within the visual task sequence.

274.6 EFFECTS OF VIGILANCE ON CORTICAL PROCESSING. DD Daly, DM Daly, JW Drane*, JD Frost Jr*, MG Jones*, P Kellaway, Neurol.UTHSCD, Dallas, Tx. 75235; Statistics, SMU; Neurol. Baylor Col. Med., Houston, Tx.

Normal persons significantly deprived of sleep show impaired vigilance (VG) with slowing of motor responses, errors in cognitive processing and defects in recall. Pupillometry measures autonomic correlates of VG in both normals and narcoleptics. We report effects of fluctuating VG on cortical processing using sparse acoustic stimuli, SAS (Drane et al Comput.Biomed.Res. 12:351, 1979).

A 12 year old boy was unable to remain alert while reading, studying or watching TV. A sister, his mother and maternal grandfather were similarly affected. During 4 hrs we recorded EEG and continuously presented various sets of SAS. During intervals of alertness (activated EEG), he classified SAS precisely (G^2=175.6, DF=22) with appropriate variation in reaction times. With declining VG, as indicated by EEG, classifications of SAS with FM components became increasingly homogenous (G^2=85.5, DF=22) and reaction times fluctuated widely. Methylphenidate (MPD) 20 mg sublingually restored and sustained VG for an interval consonant with its $T_{\frac{1}{2}}$, paralleled by activation of EEG and appropriate perception and classification of SAS.

For many years a 50 year old woman had difficulty remaining alert while reading, driving and in social situations. A 14 hr polygraphic study showed normal sleep staging without excessive arousals. Throughout life she had difficulty in perceiving and speaking certain polysyllabic words. Two of 3 sons have impaired VG and 1 also has similar auditory problems. When alert she classified anomalously certain sets of SAS. With declining VG she showed increasingly homogeneous classifications for all sets save vowels. MPD repeatedly restored and sustained VG and stable, even if anomalous, classifications for a time appropriate to $T_{\frac{1}{2}}$.

Alterations in perception involving FM components of SAS and sparing CF are consonant with their representations in auditory cortex (Daly et al J.Neurophysiol. In Press). With declining vigilance, increasing homogeneity, engulfing parametric extremes, in perception of FM components reflects altered cortical activity. Spontaneous fluctuations and pharmacologic reversability demonstrate that VG modulates cortical processing. SAS can be used to monitor continuously cortical states and quantify levels of VG.

274.7 HEMISPHERIC DIFFERENCES IN EVOKED POTENTIALS: SELECTIVE ATTENTION TO THE LEFT AND RIGHT VISUAL FIELD. M. R. Harter,* C. Aine* and C. Schroeder* (SPON: R. Eason). Dept. of Psych., Univ. of North Carolina, Greensboro, NC 27412.

Changes in visual evoked potentials (VEPs) have indicated that selective attention influences the neural processing of visual information; however, it is not clear how early in the processing sequence this influence can occur. It is hypothesized that selective attention effects occur as early as in visual cortex. The fact that the left and right hemispheres of visual cortex are activated by stimulation of the right and left visual fields respectively provides an opportunity to test this hypothesis. This hypothesis predicts that attention to one visual field should selectively enhance the neural response in the hemisphere contralateral to the attended field.

Flashes of either a solid green circle or a white ring (diameters subtending 2.3°) were randomly presented in the left and right visual fields (20° from a central fixation point). The presentation rate was 1/520 msec. VEPs to these flashes were recorded over the left and right regions of occipital (O_1 and O_2) and central (C_3 and C_4) cortex. Attention was directed toward one of the visual fields by making the flashes in that field relevant to a reaction time task.

The results indicate that selective attention to one visual field enhanced a negative potential (onset about 160 msec post stimulation) in VEPs to flashes in the attended, but not ignored, visual field. As predicted, this enhancement was greater in occipital VEPs recorded over the hemisphere contralateral to the attended field. There was an additional tendency for this enhancement to be greater over the left hemisphere (occipital and central regions) regardless of the attended field. These findings were interpreted as indicating that selective attention influences the processing of information in visual cortex and that there is some degree of left hemisphere specialization in selective attention.

274.8 ENHANCED ATTENTION IN THE CONTRALATERAL VISUAL HEMIFIELD INDUCED BY UNILATERAL HYPOTHALAMIC STIMULATION. C. B. Pott* and M. F. Mac Donnell* (Spon: M.J. Weiss) Dept. Biology , Livingston College , Rutgers Univ. , New Brunswick , N. J. 08903

Electrical stimulation of particular areas in the lateral hypothalamus of cats evokes a set of discrete behavioral reactions that culminate in a predatory attack. Previous studies have demonstrated that lateral hypothalamic excitation regulates the utilization of tactile sensory information in the orientation to and capture of prey. The present investigation was undertaken in order to determine the role of the hypothalamus in directing visual attention during predatory behavior.

Ten adult female cats were prepared for electrode placement under Nembutal anesthesia (48 mg/kg ip). Stainless steel monopolar electrodes were placed postoperatively in unanesthetized freely moving cats to establish the behavior at each stimulation point. Biphasic square-wave pulses of 1-msec duration , 60Hz , and .05-0.8ma were delivered to unilateral electrodes , which were advanced in small steps until a well-directed quiet biting attack on a rat was elicited. After electrode placement the cats were painlessly immobilized in a headholder. Following the onset of hypothalamic stimulation a slowly moving visual stimulus (cotton probe) was brought manually into the visual field from either an ipsilateral or contralateral direction. One ipsilateral and one contralateral presentation constituted one trial. Each cat was tested for ten trials.The electrodes were confirmed to be in the lateral hypothalamus by histological examination.

Control trials without hypothalamic stimulation revealed no response to visual stimulation. Introduction of the moving target into the ipsilateral visual field of hypothalamically aroused animals produced no overt behavior. However , the introduction of a target into the contralateral visual field produced dramatic behavioral responses. All ten cats displayed an immediate orienting eye movement as soon as the target entered the field. Furthermore , once visual contact was established , all ten cats continued to follow the target until hypothalamic stimulation was stopped. Nine of the ten cats exhibited "facial following." As the visual stimulus moved toward the peripheral edge of the contralateral field these cats raised their upper lips on the contralateral side ; this effectively directed their whiskers laterally and backwards , keeping them in line with the stimulus.

The results of this study reveal sharply enhanced responses to previously ineffective stimuli moving in the contralateral retinal hemifield during hypothalamic arousal. These responses include saccadic orientation of the eyes , smooth pursuit , visual locking -on and facial movements , which can all be interpreted as promoting maximal sensory contact with a moving target.

274.9 CHARACTERISTICS OF ATTENTION-RELATED CELLS IN PREFRONTAL CORTICAL REGIONS. E. Bakay Pragay*, A.F. Mirsky, C.V. Mirsky* and B.H. Scales*. Lab. of Neuropsychology, Div. of Psychiatry, Boston Univ. Sch. of Med., Boston, MA 02118.

Bakay Pragay et al. (1978) have described attention-related units in the brainstem RF in monkeys working on a go - no go visual attention task. These "Type II" units showed changes either following or anticipating the stimulus in both go and no go trials. In contrast, Type I units showed changes only in go trials.

We are exploring other parts of an attention "system" in the brain. We have found Type II units in the prefrontal cortex. In addition, we varied the reward conditions and the length of the fixed interstimulus interval (ISI) in the basic go - no go task (Bakay Pragay et al., 1978). Units were tested with reward for both correct go and no go trials as well as with non-reinforcement for correct no go trials (NRNG); units were also tested under 3 different fixed ISI intervals: 1 sec., 2 sec. and 3 (or 4) sec. In addition, 2 extra-task conditions were applied: task-stimuli without access to task and reward; delivery of noncontingent reward.

A total of 50 task-related units were studied in the prefrontal cortical region of two monkeys, including the banks and depths of s. principalis as well as more ventral, inferior and caudal areas. The vast majority of units (43 out of 50) were of Type II. In most instances, the increase or decrease of firing rate began well before the end of the trial. Six units showed pre-trial, anticipatory changes in the basic task. Type II units only were tested under several conditions. NRNG: 30 units; ISI: 17 units; extra-task conditions: 34 units. In the NRNG condition, various degrees of loss of the original reinforced response, or the reverse form of response (i.e., from increase to decrease) were seen. In all, 12 units were changed by NRNG. These cells also responded to the noncontingent delivery of reinforcement. Varying the ISI affected 12 of the units tested. Increasing ISI typically increased or induced anticipatory activity. Decrease of ISI to 1 sec. prevented such activity, and in a number of cases disrupted task-related unit behavior. Extra-task administration of the CS usually evoked no systematic change.

Prefrontal units thus respond not only to the delivery of reinforcement (Rosenkilde et al., 1979) but also to CSs presaging reinforcement; and they adapt quickly to changes in reinforcing conditions. Plasticity was especially striking under ISI variations. However, apart from the high proportion of Type II (vs. Type I) cells, prefrontal units do not differ greatly from brainstem RF units in their attention related functions, as described by Ray (1979).

274.10 THE EFFECT OF BISECTING THE SUPERIOR COLLICULI ON THE CAT'S ORIENTATION TO PREY. J.S. Robinson and T.J. Voneida. UCSF, Brain-Behavior Res. Ctr., Sonoma State Hospital, Eldridge, CA 95431.

Sprague, et al. (J. Comp. Neurol., 172:441, 1977) have shown that bilateral removal of cortical areas 17 and 18 may leave the cat's orienting behavior undisturbed; our results show that a minimal strategically placed midline lesion, providing maximal destruction of relevant structures, i.e., commissural and decussating pathways connecting the deep layers of the superior colliculus (SC) with the reticular core (Edwards, S.B., J. Comp. Neurol. 173:23, 1977) may result in significant disruption of such behavior.

Two 4-day (6 min/day) tests of orientation to live mice were made before (T1) and after (T2) a 2 month interval for surgery and convalescence (all cross-midline pathways of the superior colliculi dorsal to the cerebral acqueduct were sectioned in 5 of 11 cats; 6 remained intact. All 11 were good "mousers"). The cats were tested in a semicircular double-walled surround, the inner wall of which was clear plastic. The live mouse prey was confined to a 2 1/2 in. space between the walls, but could move freely along the base of the surround, visible to the cat subject but protected from it by the plastic barrier. Video-taped records were made of the cat's and mouse's behavior and were analyzed to obtain separate scores showing 1) the amount of time a cat spent orienting to the mouse when it was motionless and 2) the time spent orienting to a moving mouse.

There was little change in the orienting behavior of any of the 11 subjects in the 4 test days of the T1 series, and the control subjects were as likely to show an increase as a decrease in orienting in T2 (as compared with the T1 level). There was no apparent qualitative change in the orienting behavior of the cats with the tectal splits, but they did show a quantitative one: there was a significant decrease in orientation to both the motionless and the moving mouse (Wilcoxon W=15, p=.03 for both decreases). A mouse could no longer elicit as much orienting from the most active of the operated animals as it could from the least enthusiastic orienter prior to its surgery.

274.11 STIMULATION OF NOREPINEPHRINE RECEPTORS WITH CLONIDINE BLOCKS DISRUPTION OF SELECTIVE ATTENTION BY APOMORPHINE. MaryLou Cheal. Neuropsychology Laboratory, McLean Hospital, Harvard Medical School, Belmont, MA 02178.

Evidence that amphetamine-treated gerbils responded selectively to a novel object even at a dose that resulted in continuous stereotypy was reported earlier (Soc. Neurosci. Abst., 1978, 4, 487). These animals spent little time actively investigating the object after injection, but a low rate of responding the next day indicated that they remembered the object. Apomorphine-treated gerbils, on the other hand, showed no memory of the object the second day even though they spent 11-12 sec licking, sniffing, or biting the object following an injection of 1 mg/kg (Psychopharmacol., in press). One difference in the actions of amphetamine and apomorphine is that amphetamine is an agonist of dopamine (DA) and norepinephrine (NE), whereas apomorphine is relatively selective to the DA system. To test the hypothesis that relative levels of NE and DA activity are necessary for selective attention and habituation, gerbils were given the NE receptor stimulant, clonidine (0, .01, .03, .3 mg/kg), followed 30 min later by the DA receptor stimulant, apomorphine (1 mg/kg). They were tested 10 min after the second injection in the 24-hour variation of stimulus-elicited investigation. Following adaptation trials, half of each drug group were given one 60 sec, nonreinforced trial in which to investigate a small cup. All of the gerbils were tested again the next day with no further drug treatment.

When gerbils were injected with both clonidine and apomorphine, the locomotor response to apomorphine was potentiated so that the animals were very jumpy and had a very low startle response. In spite of this, the gerbils showed memory the second day. For the gerbils given .03 or .3 mg/kg clonidine plus apomorphine, the responses were confounded because of residual effects of the drugs. Of greater interest, however, are those that received .01 mg/kg clonidine before apomorphine. Gerbils that had seen the object on Day 1 spent significantly less time investigating it than those that had not seen it previously. At this dose, both the exposed and the nonexposed groups of gerbils had approximately the same duration and frequency of responding on Trial 1 as those that received only apomorphine (1 mg/kg), but the Trial 2 responses indicated memory in those receiving clonidine and apomorphine, but no memory following just apomorphine. Thus, the hypothesis that selective attention and habituation are dependent on the relative amounts of NE and DA activity is supported.

274.12 LEAD INGESTION AND ACTIVITY LEVELS IN THE RHESUS MONKEY. N. K. Laughlin*, P. J. Bushnell and R. E. Bowman (SPON: G. W. Kraemer). Primate Lab, University of Wisconsin, Madison, WI 53706.

In Exp. 1 rhesus monkeys were separated from their mothers at birth and maintained on a commercial milk diet and monkey chow. Cloth mother surrogates and regular social interaction with peers were provided during the first year of life.

Pb was administered as lead acetate added to the milk diet daily during the first postnatal year. Doses were adjusted weekly to maintain blood lead levels (PbB) of 90 µg/dl (High Pb, n=3) or 50 µg/dl (Low Pb, n=3). Controls (n=4) were given no added Pb and their PbB levels averaged 5 µg/dl.

Animals were tested for circadian locomotor activity at 12,13, 18, 22, 27 and 37 months of age. At each test, animals were housed singly for 24 hrs in a wire mesh cage quadrasected by 2 photobeams. The number of photobeam interruptions was cumulated at 3 hr intervals beginning at 1000 hrs. Lights in the test room went on at 0700 hrs for 12 hrs. Food was provided once during the test and water was available continuously.

The High Pb group was more active than controls from 18-27 months of age inclusive and the Low Pb group was more active than controls from 18-22 months inclusive. However, this hyperactivity was specific to the circadian test as dose-related locomotor hypoactivity was observed during the social tests with age-mates.

Subsequent experiments have failed to replicate the Pb-induced hyperactivity in the circadian test. These experiments have manipulated Pb dose (Exps. 2 and 3) and milk intake (Exp. 4). In Exp. 1, PbB levels were relatively constant across the year of Pb dosing; those in Exp. 2 rose gradually, reaching peak values of 150 and 70 µg/dl for High (n=4) and Low (n=4) dose groups, respectively. In Exp. 3, early elevated Pb dosing produced transient peak PbB values of 300 µg/dl followed by either chronic Pb intake (n=4) or no subsequent added Pb (n=4). An additional group received only chronic Pb intake (n=4). PbB levels averaged 90 µg/dl in the groups receiving chronic Pb. In Exp. 4, animals were dosed chronically with Pb in the presence of an ad lib milk diet (n=4) or a restricted milk diet (n=4). In all experiments, control monkeys received no added dietary Pb. In these experiments, hyperactivity did not result from early chronic Pb ingestion. The early transient Pb pulse and restricted milk intake each produced hyperactivity at certain ages. We conclude from these experiments that early chronic Pb exposure is not associated with hyperactivity in the rhesus monkey.

275.1 NEUROANATOMICAL FUNCTIONAL MAPPING OF THE VAGAL PRESSOR REFLEX USING THE AUTORADIOGRAPHIC [^{14}C] DEOXYGLUCOSE TECHNIQUE IN THE DOG. D.R. Kostreva and J.P. Kampine. Dept. Anesthesiology and Physiology, Med. Col. of Wis. and VA Med. Ctr., Wood, WI 53193.

The medullary and pontine projections of vagal afferent fibers that elicit a pressor response during electrical stimulation of the left vagus was studied in mongrel dogs (6-9 kg) using the [^{14}C] deoxyglucose technique of Sokoloff, et al. (J.Neurochemistry 28:897-916, 1977). The animals were fasted for 2 days and then anesthetized with sodium pentobarbital (35 mg/kg), intubated and placed on positive pressure ventilation. Systemic blood pressure from a femoral artery and the lead II electrocardiogram were recorded using a Grass polygraph. The cervical vagi were exposed bilaterally and sectioned transversely. The central end of the left vagus was desheathed, and placed on a pair of tungsten carbide electrodes connected to a constant current stimulator. The stimulus parameters were 10 Hz, 0.5 ms pulse width and a current strength of 0.5-10 ma. The current strength was increased until a pressor response of 15-25 mmHg could be elicited repeatedly. 1mCi of [^{14}C] Deoxyglucose (specific activity 57 mCi/mmol New England Nuclear) was injected as a single bolus into a femoral vein. The left vagus was stimulated repeatedly (45 sec stimulation with 15 sec rest) for a total of 45 minutes. The entire brain and part of the spinal cord was then removed and frozen in -40°C isopentane. 20 um sections were made using an AO Cryostat and dried on glass cover slips. The sections were covered with Kodak MR-1 film and stored in X-ray cassettes for 14 days. The autoradiographs were then developed and analyzed for the pathways having the greatest metabolic activity as indicated by the density of photographic emulsion. High cervical cord sections did not show any difference in density from the background activity. Sections in the region of obex revealed a marked increase in density in the left nucleus tractus solitarius and the tractus solitarius which is on the side of the centrally stimulated vagus. These structures could be seen as two distinct entities. The density of the right nucleus tractus solitarius and tractus solitarius was not distinguishable from the background density of adjacent structures on the right side. Also seen in these sections were an increase in density of the emulsion in the area of olivary nuclei bilaterally. Rostral sections continued to delineate the left nucleus tractus solitarius. Sections in the region of the 8th nerve showed a marked density in the nucleus olivarius superior. Sections in the rostral pons and midbrain revealed marked increases in density of the cerebellar peduncles and the interpeduncular nucleus. This study demonstrates that the deoxyglucose technique is useful for studying the central pathways of autonomic reflexes. (This study was supported by NIH Young Cardiovascular Grant HL 21042 and VA Medical Research Service).

275.2 CONVERGENCE OF SOMATIC AND VISCERAL INPUTS ONTO THORACIC NEURONS PROJECTING TO THE MEDULLARY RETICULAR FORMATION. R. Neal Weber,* Robert W. Blair and Robert D. Foreman, Dept. of Physiology and Biophysics, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.

Spinoreticular neurons transmit nociceptive information from lumbar and cervical regions of the spinal cord into medullary, pontine and mesencephalic reticular formation nuclei. It is of interest to know if spinoreticular neurons of thoracic origin might constitute an afferent pathway for nociceptive input that is received from thoracic visceral and somatic receptive fields. The purpose of this study was to identify and characterize spinal neurons which originate in the gray matter of T_1 - T_5 spinal segments and project into the medullary reticular formation, and exhibit convergence of visceral and somatic afferent inputs. Such cells were located, using bilateral antidromic stimulation from the medullary nucleus gigantocellularis and tegmental region just anterior to the obex. Cell activity was recorded extracellularly in the left spinal gray matter of chloralose anesthetized and gallamine paralyzed cats. Of the total number of antidromic cells in the study, 46% exhibited both somatic and visceral inputs. These cells were selected for further characterization. Antidromic stimulation of the reticular formation from the contralateral side activated 61% of the cells, from the ipsilateral side 30% of the cells, and from both sides 9 % of the cells. The average antidromic conduction velocities were 36.3 M/s for contralateral and 25.9 M/s for ipsilateral neurons. Somatic input was determined by natural stimulation of skin and muscle in the cell's receptive field while visceral input was determined by electrical stimulation of the sympathetic chain between the left T_2 and T_3 segments. Ninety-one (91%) per cent of the somatic fields were classified as high threshold with the remainder being wide dynamic range. Of the cells that responded to sympathetic chain stimulation, 48% received C-fiber input as determined by minimum afferent conduction velocity and cell activation threshold. Eight cells out of a total of 20 tested for their response to intracardiac injections of bradykinin increased their discharge rate after an average latency of 10s. Injections of bradykinin into the femoral artery and vein only activated 2 cells that discharged after a longer latency and at a much slower discharge rate. This study demonstrates that sympathetic afferent fibers from the cardiopulmonary region and somatic afferents excite T_1 - T_5 spinal neurons projecting into the medullary reticular formation.

275.3 PRESENCE OF GLUTAMIC ACID DECARBOXYLASE IN HINDBRAIN NUCLEI INVOLVED IN CONTROLLING PARASYMPATHETIC OUTFLOW TO THE HEART. B.L. Hamilton, S.C. Brown*, D.J. Williford, W.P. Norman*, M.J. Iadarola, K. Gale, and R.A. Gillis. Depts. of Pharmacol. and Anat., Schools of Medicine and Dentistry, Georgetown University, Washington, D.C. 20007.

Data has been accumulating to indicate that gamma-aminobutyric acid (GABA) may be an important neurotransmitter for controlling central vagal activity to the heart in cats. Drugs which block CNS GABAergic transmission (i.e. bicuculline, picrotoxin and isoniazid) increase vagal activity, whereas drugs which augment CNS GABA activity (i.e. GABA itself, muscimol, and THIP) decrease vagal activity. These effects appear to occur at nucleus ambiguus (NA). Additionally, we have demonstrated that GABA is present in NA in concentrations 2.5 fold higher than the GABA content in surrounding reticular nuclei. To obtain further evidence for GABA being a neurotransmitter at this site, measurements of the enzyme responsible for GABA synthesis, glutamic acid decarboxylase (GAD), were made and compared with values obtained for other hindbrain nuclei and substantia nigra. GAD activity was measured using the method of Sims and Pitts (1970). Results obtained are summarized in the table.

Brain Region Examined	GAD Activity (umole/g protein/hr) Right	Left
Nucleus Ambiguus (7)	97 ± 11	85 ± 8
Dorsal Nucleus of X (DMV) Plus Nucleus Tractus Solitarius (NTS) (7)	166 ± 5	148 ± 7
External Cuneate Nucleus (4)	45 ± 10	62 ± 7
Lateral Reticular Nucleus (4)	40 ± 5	40 ± 2
Substantia Nigra (4)	630 ± 132	600 ± 151

These results indicate a significant amount of GAD activity in NA as well as in the area encompassing DMV-NTS, and are consistent with the notion that GABA is an important neurotransmitter controlling central vagal outflow.

275.4 ALTERATIONS IN CARDIOVASCULAR REGULATION AND REFLEXES FOLLOWING 6-HYDROXYDOPAMINE LESIONS OF THE INTERMEDIATE NUCLEUS TRACTUS SOLITARIUS MEDIALIS. Healy, D.P.*, T.H. Williams, J. Jew and A.C. Black, Jr. Dept. of Anatomy, University of Iowa, Iowa City, Iowa 52242.

The catecholaminergic innervation of the nucleus tractus solitarius (NTS) has been implicated in central cardiovascular control. Snyder et al. (Circ. Res. 43:662, 1978) have shown that selective destruction of catecholaminergic nerve elements in NTS at the level of the obex using 6-hydroxydopamine (6-OHDA) resulted in increased arterial pressure lability. It has been reported from this laboratory that 6-OHDA lesions of the intermediate portion of NTS medialis (rostral to the obex) produced a bradycardia which persisted throughout 5 days of observation. The bradycardia was reversed by atropine, suggesting an increase in vagal activity following the lesion. We now sought to investigate: 1. whether chronically lesioned animals would also show a reduction in heart rate; 2. whether arterial pressure lability was altered either acutely or chronically; 3. whether the integrity of the baroreceptor reflex was altered; and 4. possible effect of atropine on heart rates of chronically lesioned animals.

24 - 28 hours prior to lesioning, animals were catheterized for recording of arterial pressure (AP) and heart rate (HR) in a conscious, freely-moving condition. 4.0 µg of 6-OHDA chloride in 1.0 µl vehicle was administered bilaterally into NTS medialis, 1.0 mm rostral to obex. Control animals received injections of vehicle. Chronic animals were lesioned as above and catheterized two weeks later. Measurements of AP and HR were taken for a period of a week in both groups. Quantification of the baroreceptor reflex response was carried out by giving graded doses of phenylephrine i.v. After one week animals were perfused and a glyoxlic acid catecholamine fluorescence technique used to verify lesion sites and to evaluate the extent of catecholamine terminal destruction.

1. There was a marked reduction in catecholamine terminals in intermediate NTS medialis. 2. Both acute and chronic animal groups displayed a significant bradycardia which lasted throughout the period of observation, (i.e. up to three weeks). 3. The bradycardia was reversed by atropine. 4. There was no change in arterial pressure lability. 5. The gain of the baroreceptor reflex response was decreased following lesions in both groups.

These results indicate that the catecholaminergic innervation of the intermediate NTS medialis is involved in inhibitory modulation of vagal activity. The decreased gain of the baroreceptor reflex response may be due to the already increased vagal activity observed following lesions. (This work was supported by N.I.H. grants NS11650 and HL21914.)

275.5 GIGANTOCELLULAR RETICULAR NUCLEUS: A COMMON NEURAL SUBSTRATE IN THE MEDULLA OBLONGATA FOR HYPOTENSION, BRADYCARDIA AND ANALGESIA. Samuel H.H. Chan and Julie Y. Hwa. Department of Life Sciences, Indiana State University, Terre Haute, IN 47809.

Investigations in our laboratory on the neural mechanisms involved in the central control of circulation and antinociception, as well as their modifications by antihypertensive and analgesic agents, have identified a common neural substrate for all these processes: gigantocellular reticular nucleus (GRN) in the medulla oblongata. The present communication summarizes the evidences that lead to this intriguing conclusion, based on experiments performed on anesthetized or decerebrate cats.

(1) Electrical stimulation of the GRN induced a significant reduction in heart rate (HR), accompanied mostly by a decrease in arterial blood pressure (ABP). The degree of suppression was related to the pulse frequency and intensity of the reticular stimulus train. Such GRN-elicited bradycardia interacted synergistically with reflex cardioinhibition and antagonistically with reflex tachycardia.

(2) Intravenous injection of the antihypertensive agent clonidine (10 µg/kg) failed to promote a reduction in HR and ABP after the GRN was electrolytically lesioned. Bilateral microinjection of clonidine (1 µl in vol.) directly into the GRN, at an ineffective intravenous dose (0.2-0.5 µg/kg), on the other hand, produced an appreciable cardioinhibition and hypotension.

(3) Intravertebral administration of clonidine (0.5-4.0 µg/kg) elicited a drastic suppression of the GRN-induced bradycardia.

(4) GRN activation invariably produced a suppression of the dental pulp-evoked field potential in the subnucleus oralis of the spinal trigeminal complex (oralis potential) and jaw-opening reflex (JOR), based on a conditioning-testing paradigm. The degree and duration of such inhibition were also related to the reticular stimulus parameters.

(5) GRN stimulation evoked negative potentials in the spinal trigeminal tract at the level of the subnucleus oralis that possessed electrophysiologic characteristics similar to the dorsal root potentials induced by comparable reticular activation in the spinal cord. The time course of these negative potentials paralleled the GRN-promoted suppression of dental pulp-evoked oralis potentials, implicating the possible involvement of a presynaptic inhibitory mechanism in the process.

(6) Microinjection of morphine (10 µg/kg) into the GRN elicited a significant inhibition of the dental pulp-evoked JOR, which was reversed by naloxone (1 mg/kg, i.v.).

It is concluded that the GRN in the medulla oblongata is a common neural substrate for the induction of hypotension, bradycardia and analgesia. (Supported in part by the American Heart Association, Indiana Affiliate).

275.6 BRAIN STEM INTERNEURONS WITH OROPHARYNGEAL AND VAGAL RESPONSIVENESS. D.A. Bereiter, H.-R. Berthoud* and B. Jeanrenaud*. University of Geneva Medical School, Geneva, Switzerland

The early metabolic and hormonal responses to food ingestion, the so-called cephalic phase responses, are dependent on oropharyngeal afferent input and a vagal efferent innervation of abdominal end organs. To study the brain stem organization of neurons possibly involved in such cephalic phase reflexes, we have used single unit recording techniques to identify the location and response characteristics of neurons dually responsive to chorda tympani (CT) and vagus nerve (X) electrical stimulation. Male rats anesthetized with α-chloralose/urethane were used. Oropharyngeal stimulation was mimicked by electrical stimulation (200-900µA, 0.2 ms) of the CT proximal to its junction with the lingual nerve. Cervical X stimulation (200-900µA, 0.2 ms) was applied distal to the superior laryngeal nerve. A total of 79 dually responsive (CT/X) neurons were identified, all responding orthodromically. The mean latency to CT stimulation (11.2 ± 1.2 ms) and to X stimulation (24.7 ± 2.4 ms) was highly correlated ($P < .01$ for this group of CT/X responsive neurons, suggesting that both stimuli activate interneurons at an equal relative distance from the stimulus source.

The location of these neurons fell into two fairly distinct regions : a) lateral nucleus tractus solitarius and b) the nucleus ambiguus region. However, many cells were found in the intermediate dorsoventral region between these two nuclear structures. These results extend previous studies showing lateral hypothalamic-oropharyngeal convergence onto nts neurons (Bereiter et al., Ex. Brain Res., 1980).

These results demonstrate that CT and X input to second-order interneurons show considerable overlap and that both nucleus tractus solitarius and/or nucleus ambiguus may integrate oropharyngeal-vagal information necessary for the expression of cephalic phase reflexes. This is corroborated by the fact that nucleus ambiguus stimulation will evoke a prompt rise in plasma insulin levels (Bereiter et al., 1980).

This work has been supported by NIH grants No. R01 AM 25220-01 and the Swiss National Science Foundation.

275.7 THE VENTRAL MEDULLA: DIRECT PROJECTIONS TO THE INTERMEDIOLATERAL CELL COLUMN AND THE HYPOTHALAMUS IN THE RAT. A.D. Loewy, J.H. Wallach and S. McKellar. Dept. Anat. & Neurobiology, Wash. Univ. Sch. Med., St. Louis, MO 63110

Previous physiological and pharmacological studies have reported that the ventral surface of the medulla is a functionally important region concerned with the regulation of respiration, blood pressure, blood glucose levels and possibly vasopressin release. We have therefore used both autoradiographic and horseradish peroxidase tracing techniques to elucidate the efferent projections of this region.

Injections of ^{3}H amino acids were made in the ventral medulla in rats and after a 5-7 day survival period, the brains and spinal cords were processed by the autoradiographic technique. A very dense area of anterograde labeling was observed bilaterally in the intermediolateral cell column in both normal and 6-hydroxydopamine treated rats. In addition, we found a projection to the cervical and thoracic ventral horn. Ascending labeled fibers were found to course through the reticular formation and entered the central gray matter. A relatively heavy, ipsilateral projection was seen in the posterior and medial parts of the paraventricular hypothalamic nucleus and ventral part of the supraoptic nucleus in both normal and 6-hydroxydopamine treated rats. Furthermore, a few labeled fibers were traced to the lateral hypothalamic area and perifornical region of the hypothalamus.

In other rats, 30-50 nl of a 0.1% solution of horseradish peroxidase-wheat germ agglutinin (HRP-WGA) conjugate was injected into the hypothalamus and after 48 hr. the rats were perfused and brainstem sections reacted by the tetramethylbenzidine procedure. Hypothalamic injections which included the paraventricular and supraoptic nuclei resulted in retrograde cell body labeling in the ventral medulla in an area near the exit zone of the XII nerve, an area dorsal to the lateral reticular nucleus, and in the region of the A1 catecholamine cell group.

These results confirm the existence of a group of neurons in the ventral medulla with direct projections to sympathetic and hypothalamic centers known to be involved in cardiovascular regulation and neuroendocrine control. (Supported by USPHS grant NS12751, NS07071, HL 07275 and a grant-in-aid from the American Heart Association #80-723).

275.8 DESCENDING HYPOTHALAMIC PATHWAYS TO THE MEDULLA OBLONGATA IN THE RAT. J.H. Wallach and A.D. Loewy. Dept. Anatomy and Neurobiology, Washington Univ. Sch. Med., St. Louis, MO 63110

Although it has been previously demonstrated that the paraventricular nucleus of the hypothalamus (PVH) has direct connections with the dorsal medulla, relatively little information exists on the medullary projections of the other hypothalamic nuclei. Considering the importance of the medulla as a major center for cardiovascular, respiratory, and gastrointestinal integration, we have used both anterograde and retrograde neuroanatomical tracing techniques to further delineate direct hypothalamo-medullary connections.

Small (30 nl) injections of ^{3}H amino acids were placed in the dorsomedial (DMH) and perifornical area (PFA) of the hypothalamus, Fields of Forel (FF) and zona incerta (ZI) in 20 rats, and after a 7 day survival period the brains were processed with the autoradiographic method. Injections in the region of the DMH and PFA resulted in anterograde labeling in the magnocellular reticular formation dorsal to the superior olive, nucleus reticularis gigantocellularis pars α (Rgc), nucleus reticularis parvocellularis, nucleus tractus solitarius (NTS), area postrema, and raphe pallidus. After injections in FF, labeled fibers were traced to the nucleus reticularis pontis, central grey matter, nucleus reticularis pontis caudalis (Rpc), and Rgc. Injections in the ZI resulted in labeling in Rpc and Rgc.

Additional experiments were performed in which 30-50 nl of a 0.1% solution of horseradish peroxidase-wheat germ agglutinin (HRP-WGA) conjugate was injected into the NTS, raphe pallidus, and nucleus reticularis gigantocellularis. Following a 48 hr. survival period, the rats were perfused and brain sections reacted by the tetramethylbenzidine procedure. HRP-WGA injections confined to the NTS resulted in retrograde cell body labeling primarily in the PVH and DMH. Labeled cell bodies were also found in the DMH following a small injection into the raphe pallidus. Lastly, HRP-WGA injections in the region of the nucleus reticularis gigantocellularis labeled neurons in the FF, ZI, DMH, and the lateral hypothalamic area.

These results are consonant with physiological studies that suggest an important role of several hypothalamic nuclei in the modulation and/or control of medullary autonomic centers. (Supported by USPHS grant NS07071 and NS12751 and by a Grant-in-Aid from the American Heart Association (#80-723).

275.9 PARABRACHIAL NUCLEUS AS A MEDIATOR OF BRADYCARDIA IN RABBITS. Robert B. Hamilton, Howard H. Ellenberger*, David R. Liskowsky*, Marc D. Gellman* and Neil Schneiderman. Dept. of Psychology, University of Miami, Coral Gables, Fl. 33214.

Electrical stimulation(10 sec trains, 100 pulses/sec, 0.25 msec pulse duration, M current= 100μA) in medial and lateral parabrachial n. of 14 Urethane-anesthetized rabbits induced bradycardia (M=87 bpm, SD=±34), a small concomitant increase in mean arterial blood pressure (M=10 mmHg, SD=±2), and variable changes in respiration. The bradycardia was mediated by the vagus nerves, since it was abolished after bilateral transection. Bilateral lesions of the dorsal vagal n. abolished the bradycardia elicited by train stimulation of the parabrachial n., indicating that the heart rate decrease was mediated via the dorsal vagal nucleus. The bradycardia was not secondary to a blood pressure increase since the latency of the heart rate response was shorter (<1 sec vs ≈2 sec) than the pressor response. The bradycardia was not secondary to respiratory changes, since the heart rate response did not change following paralysis induced by injection of Decamethonium.

Single-pulse electrical stimulation of the aortic nerve (.1 to 1.0 msec pulse duration, 100-400 μA) activated units in the commissural and dorsomedial portions of the nucleus tractus solitarius (NTS) at a mean latency of 7.5 msec (SD= ±1.5) and throughout the parabrachial n. at a mean latency of 12.1 msec (SD= ±2.9). Stimulation of the parabrachial n. with single pulses activated units in the dorsomedial NTS at a latency of about 4.6 sec; these units were also activated by stimulation of aortic nerve. The connections between parabrachial n. and NTS appear to be monosynaptic rather than antidromic, although injection of horseradish peroxidase (HRP) into the parabrachial n. readily labeled cell bodies in the NTS. Similarly, injection of HRP into the dorsal medulla led to extensive labeling throughout the parabrachial n. Bilateral lesions of parabrachial n. did not attenuate the bradycardia response to train stimulation of the aortic nerve.

It is concluded that the parabrachial n. (a) plays a role in the mediation of bradycardia and (b) receives barosensory information, but (c) is not absolutely essential for the elicitation of the baroreceptor reflex.

275.10 ROLE OF CENTRAL SEROTONIN IN THE PRESSOR RESPONSE TO HYPOTHALAMIC AND MIDBRAIN STIMULATION. P. Gauthier* and T.A. Reader. Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada.

Electrical stimulation of the hypothalamus and the central gray area of the rat anesthetized with chloralose elicits a biphasic increase in arterial blood pressure resulting from the peripheral activation of the sympathetic vasomotor neurons and the adrenal medulla (Gauthier and Reis, unpublished). We sought to determine whether serotonin (5-HT) plays a role in the central mediation of this response. Rats were treated with either intraventricular 5,7-dihydroxytryptamine (5,7-DHT) (200 μg) or intraperitoneal para-chlorophenylalanine (PCPA, 500 mg/kg/ day for 2 days). The cardiovascular responses as well as plasma noradrenaline (NA) and adrenaline (A) changes evoked by stimulation of the anterior hypothalamus and the central gray area of treated rats were compared with those obtained in control animals. The destruction of central 5-HT terminals by administration of 5,7-DHT, two weeks prior to the experiments, did not modify the cardiovascular biphasic response to brain stimulation which also increased plasma NA and A to levels similar to those observed in sham treated animals. In 5,7-DHT-treated animals, serotonin stores were depleted by about 90% in the spinal cord, pons-medulla, midbrain, hypothalamus and the cortex. Endogenous NA and A contents of the brain and of the adrenal medulla were either not modified or increased. The inhibition of 5-HT biosynthesis by administration of PCPA decreased the adrenal component (more than 50%) of the pressor response to brain stimulation. The sympathetic vasomotor component of the response was only mildly affected by the treatment. The concomittant increase in plasma NA levels to stimulation was unchanged in these animals whereas plasma A increased only to about 50% of the levels observed in control rats. Serotonin stores were depleted by about 70% in all investigated areas of the brain. However, in contrast to 5,7-DHT treatment, it was found that PCPA treatment also depleted NA and A stores in selected regions of the brain, such as the hypothalamus and the spinal cord. On the other hand, catecholamine content of the adrenal medulla was either unchanged or increased. The present results first indicate the absence of a role for serotonin in the central mediation of the activation of sympathetic vasomotor neurons and adrenal medulla elicited by hypothalamic or midbrain stimulation. Second, the adrenal component of the response to brain stimulation, and to a smaller extent the vasomotor component, seem to depend upon the integrity of catecholaminergic systems in the hypothalamus and/or the spinal cord.

Supported by the MRC (Canada) and the Canadian Heart Foundation.

275.11 A HIERARCHY OF RESPONSIVITY OF ARTERIAL PRESSURE DURING NATURAL BEHAVIOR IN THE RAT: EFFECTS OF LESIONS OF CENTRAL CATECHOLAMINE NEURONS. J.E. LeDoux, A. Del Bo, G.A. Harshfield, L.W. Tucker, W.T. Talman, and D.J. Reis, Laboratory of Neurobiology, Dept. of Neurol., Cornell Univ. Med. College, New York, NY 10021.

We have sought to characterize the direction and magnitude of changes in arterial pressure (AP) associated with a repertoire of natural behaviors in rat and to determine whether these changes are altered by lesions of the catecholamine containing neurons of the A2 region of the medulla. Male Sprague-Dawley rats were instrumented with an indwelling aortic cannula for computer-assisted recording of AP and heart rate (HR) during behavior. Some animals were instrumented for recording EEG and EMG. Behaviors were categorized by an observer who signaled the onset and termination of behaviors using a keyboard which was read by the computer.

In the normal rat (n=6), a hierarchy of responsivity of AP was observed. Higher average pressures were associated with eating (118±2 mm Hg) and drinking (118±3) than with grooming (110±4) and exploring (108±5) (p<.05), which were in turn associated with higher pressure than rest (95±5)(p<.05). Lability was lower during rest than during other behaviors (p<.05). Standard EEG and EMG recording techniques were used to segregate rest into quiet wakefulness (QW) and the phases of sleep (n=7). Pressures were higher during QW and desynchronized sleep than during synchronized sleep (p<.05). Animals with A2 lesions (n=10) showed lower AP than controls during grooming (99±11), exploring (95±13) and rest (85±11), as well as greater lability of AP during these behaviors. AP during eating and drinking was not different in lesioned and control animals, in spite of occasional elevations up to 80 mm Hg above resting baseline following A2 lesions. We conclude: (a) in the normal rat there is a hierarchy of responsivity of AP during natural behavior; and (b) destruction of the A2 catecholamine neurons, which normally modulate baroreceptor activity (Talman et al., Circ. Res., 1980), disrupts the mechanisms which normally maintain the level and variability of AP appropriate to certain behavioral activities.

275.12 THE ORIGIN, EXTENT AND TERMINAL DISTRIBUTION OF DIRECT AMYGDALA CENTRAL NUCLEUS PROJECTIONS TO THE DORSAL MOTOR NUCLEUS AND THE NUCLEUS OF THE SOLITARY TRACT. James S. Schwaber, Bruce S. Kapp, Gerald A. Higgins* and Peter R. Rapp*, Departments of Anatomy and Neurobiology and of Psychology, Univ. of Vermont, Burlington, Vermont 05405

The central nucleus of the amygdala contributes direct descending input to medullary motor and sensory nuclei involved in autonomic regulation: the dorsal motor nucleus of the vagus (DMV) and the nucleus of the solitary tract (NTS). In the present studies we first characterize the origin and extent of this descending projection system and then examine its pattern of termination in the DMV and NTS.

Multiple injections of HRP (Boehringer, 25-50% in sterile water) were made in 8 rabbits at the border of the DMV and the NTS into the full rostro-caudal extent of the nuclei. Following a 48h survival period tissue was processed using a modification of the TMB procedure of Mesulam (1978). We found the central nucleus of the amygdala to contain a large number of labeled cells throughout its entire rostro-caudal length, but localized within particular regions of the nucleus at given anterior-posterior levels. At the rostral end of the central nucleus, labeled neurons extended dorso-medially beyond the limits of the amygdala into the subtentricular part of the substantia innominata and along the medial border of the internal capsule to the lateral part of the bed nucleus of the stria terminalis. The total field of labeled cells appeared unbroken, forming a continuum.

Stereotaxic injections of ^{3}H-leucine/proline were made in 17 rabbits into the central nucleus and/or bed nucleus of the stria terminalis. As demonstrated by autoradiography a projection from this area descends to dorsomedial, medial, ventrolateral and commissural subnuclei of the NTS, and also to encapsulate and partly innervate the DMV.

HRP labeling of vagus nerve and aortic nerve afferent terminals in the NTS in the rabbit show regions of afferent termination in the dorsomedial, medial, and commissural NTS to be partially coextensive with the regions recipient to the descending projections.

These observations suggest the basal forebrain-to-dorsomedial medulla projection as a possible anatomical substrate for forebrain control of cardiovascular and other autonomic function by direct input to both afferent and efferent nuclei of regulatory reflexes.

275.13 FAILURE TO SUSTAIN DEOXYCORTICOSTERONE-SALT INDUCED HYPERTENSION AFTER PERIVENTRICULAR PREOPTIC (AV3V) ABLATION IN RAT. J. Buggy. Department of Physiology, University of South Carolina, Columbia, South Carolina 29208.

Normal regulation of arterial pressure represents the coordinated interaction of several control systems. While hypertension may result from a variety of dysfunctions in these control systems, it is not unreasonable to expect some degree of central nervous system participation in any chronic elevation of arterial pressure. Studies in goat, rat, and rabbit have identified the preoptic-hypothalamic periventricular region as a receptive or integrative area for cardiovascular and fluid regulatory responses elicited by electrical brain stimulation or peripheral or central chemical stimulation with hyperosmotic fluids, carbachol, and angiotensin. In rat, ablation within this region of the periventricular tissue surrounding the anteroventral portion of the third ventricle (AV3V) results in acute adipsia uncompensated by increased release of vasopressin, and after recovery, persisting deficits in thirst, renal sodium excretion and water conservation, and pressor response to chemical stimulation. AV3V brain lesions affect some but not all models of experimental hypertension; renal hypertension may be prevented or reversed once established whereas spontaneous genetic hypertension in Wistar-Kyoto rats is unaffected in development or maintenance. In this study, the effect of AV3V lesions on maintenance of hypertension already established by ongoing steroid-NaCl treatment was investigated. Systolic arterial pressure was measured twice weekly by tail-cuff sphygmomanometry in conscious, uninephrectomized, adult male rats given 1% NaCl as the sole drinking fluid and injected weekly with deoxycorticosterone pivalate (CIBA, 25 mg/kg, sc). When hypertension was evident after 4 weeks of treatment, rats were randomly selected for AV3V lesioning or a sham lesion procedure. To insure adequate salt intake, sucrose or saccharin sweetener was added to the 1% NaCl as necessary to sustain drinking. Blood pressure measurement and steroid-salt treatment continued for 4 weeks after the lesion when the brains were removed for histological verification of lesion placement. Lesioned rats had a fall in blood pressure and maintained lower blood pressure through the treatment period compared to sham lesioned rats. Thus, rats with AV3V lesions can neither sustain nor as previously reported develop hypertension normally induced by steroid-salt treatment. The consequence(s) of AV3V ablation responsible for the disruption of certain forms of experimental hypertension remain to be determined. Supported by the American Heart Association.

275.14 RABBIT CARDIOVASCULAR RESPONSES PRODUCED BY STIMULATION OF THE AMYGDALA CENTRAL NUCLEUS. B. S. Kapp, M. Gallagher, M. D. Underwood*, and C. L. McNall*, Dept. of Psychol., and D. Whitehorn, Dept. of Physiol. and Biophys., Univ. of Vermont, Burlington, Vermont 05405.

We have demonstrated that lesions or β-adrenergic blockade within the amygdala central nucleus attenuates vagally-mediated conditioned bradycardia in the rabbit (Kapp et al., Physiol. Behav., 1979; Gallagher et al., Pharmac. Biochem. Behav., 1980) and that the central nucleus projects directly to the region of the vagal dorsal motor nucleus and nucleus solitarius in this species (Schwaber et al., Submitted). Since these data suggest a central nucleus contribution to cardiovascular responding, the present investigation was performed to characterize heart rate and arterial blood pressure responses to electrical stimulation within this nucleus.

Twenty-six New Zealand rabbits were anesthetized with α-choralose, and either single or multiple electrodes (monopolar, 0.25-0.50 mm tip exposures) were lowered in 0.25 to 0.50 mm steps through the region of the central nucleus. Pulse duration and frequency (0.2-1.0 msec; 30-100 Hz), train duration (1.0 vs. 5.0 sec) and current intensity (50 μA-1.0 mA) were investigated. Stimulation at sites within the central nucleus produced bradycardia. Maximum bradycardia (up to 40% decrease) was observed from the anterior, medial region of the central nucleus, an area from which a major portion of the projection to the dorsal medulla originates. This response began within two to three beats of stimulus onset, reached peak magnitude within two seconds of stimulation onset, and was followed by a slight tachycardia following stimulus offset. Threshold currents were as low as 75-100 μA (100 Hz; 0.5 msec pulse duration) at the most active sites. The magnitude of the bradycardia increased with increasing current intensity, pulse frequency, pulse duration and electrode tip exposure. The response was observed to occur following artificial ventilation and immobilization by Flaxedil and was blocked by I.V. atropine methylnitrate. While bradycardia was also elicited from the posterior and lateral regions of the central nucleus, the responses were of markedly less magnitude, and of longer latency to peak magnitude, than those from the anterior, medial region. In all cases bradycardia was followed by depressor responses (up to 20 mm Hg). Pressor responses were never observed.

The results demonstrate that stimulation of the central nucleus produces significant bradycardia and are consistent with our previous data suggesting that the central nucleus contributes to conditioned bradycardia during aversive Pavlovian conditioning. (Supported by USPHS Grants RO1 MH31811 and KO2 MH00118)

275.15 CHARACTERISTICS OF SYMPATHETIC NERVE ACTIVITY AND SYSTEMIC BLOOD PRESSURE DECREASES FOLLOWING ELECTRICAL STIMULATION OF THE ANTERIOR CINGULATE CORTEX IN SHR AND WKY RATS. S. Morrison, D. Whitehorn, E.D. Hendley, M.M. Myers*. Dept.of Physiology and Biophysics, Univ. of Vermont, Burlington, Vermont 05405.

In this report, we describe a potent, cardiovascular inhibitory response that follows electrical stimulation of the deep layers of the anterior cingulate cortex and the cingulum. The characteristics of this response were examined in adult, male Spontaneously Hypertensive (SHR) and Wistar-Kyoto (WKY) rats. Animals were anesthetized with α-chloralose (100 mg/kg), and were paralyzed with curare (1.0 mg/kg) and artificially ventilated. A concentric, bipolar stimulating electrode (0.5 mm O.D.) was stereotaxically located (Pelligrino: A.P.:8.5,M.L.:0.7,D.V.:7.5), and three-second stimulations were delivered using 0.3ms pulses at various frequency and intensity combinations between 10-100Hz and 500-1500μA. Blood pressure was monitored from the femoral artery,while multifiber, sympathetic nerve activity was recorded from a branch of the pre-celiac, splanchnic nerve, using a bipolar, hook elecrode. Nerve activity was amplified, filtered (100-3000Hz),and recorded on magnetic tape. Following computer digitization, the nerve signal was quantified with an amplitude variance method.

Stimulation resulted in a decrease in spontaneous levels of sympathetic nerve activity (onset latency:150-200ms), followed by a decline in blood pressure with a latency to maximum decrease of approximately 15s . Although all stimulus parameters tested were effective in lowering blood pressure, maximum responses were obtained at 40Hz and 750μA. The blood pressure changes were often, but not always accompanied by decreases in heart rate. Neither the sympathetic activity nor the blood pressure declines were blocked by atropine, although the heart rate response was attenuated. Blood pressure declines ranged from 10 to 65 mm Hg, with maximum responses in 9 SHR (-47 ± 5 mm Hg) being significantly greater ($p<.05$) than the maximum responses in 6 WKY (-31 ± 4 mm Hg).

Although we have recorded sympathetic nerve activity responses in a limited number of animals, it is clear that when maximally activated (blood pressure declines greater than 50 mm Hg), stimulation of this brain region can result in a nearly complete (greater than 85%) inhibition of splanchnic nerve activity. It is not known what circumstances normally result in activation of this response; however, it would appear that activity emanating from this higher forebrain area constitutes an important contribution to CNS influences upon the cardiovascular system.

275.16 LOCAL CEREBRAL GLUCOSE UTILIZATION IN SPONTANEOUSLY HYPERTENSIVE RATS. M. Kadekaro, H. Savaki*, L. Davidsen*, and L. Sokoloff. Laboratory of Cerebral Metabolism, NIMH, Bethesda, MD 20205.

Spontaneously hypertensive rats (SHR) have been used as an animal model for studies of essential hypertension in attempts to elucidate pressor mechanisms in clinical hypertension. In the initial stage of hypertension blood pressure rises as a consequence of increased peripheral vascular resistance, which leads later to miscellaneous pathological consequences similar to those found in man. Previous findings indicate that neurogenic factors are important in initiating the mechanisms of spontaneous hypertension. It is known that hypertension in SHR rats is maintained when the brain stem is transected at the level of the midbrain, and a marked fall of blood pressure is observed in both SHR and control rats when the transection is made at the upper portion of the cervical cord. The central mechanisms responsible for the increased sympathetic nervous system activity are still unknown. The [^{14}C]deoxyglucose method was employed in the present studies to identify on the basis of altered energy metabolism regions with possibly different levels of functional activity in the brains of SHR and control WKY rats.

Male SHR and WKY rats (78-87 days old) were studied. Local cerebral glucose utilization was determined as previously described. Blood pressure, hematocrit, body temperature, and blood gases were monitored throughout the experimental period.

Mean arterial blood pressure was found to be significantly higher in SHR rats (143 ± 2 mm Hg, n=7) than in the control WKY rats (112 ± 2 mm Hg, n=7). Of 36 nervous structures examined only the external cuneatus n., vestibular n., and fastigial n. of the SHR rats exhibited increased rates of glucose utilization compared to those of the WKY rats. The external cuneate n. receives an input from the aortic depressor nerve and mediates reflex cardiac slowing during arterial hypertension (Ciriello et al., Am. J. Physiol. 235:R286, 1978). Its higher rate of glucose utilization in the SHR rats may reflect its increased activity as a consequence of hypertension. The vestibular n. and the fastigial n. have been shown to be involved in the regulation of orthostatic reflexes in the cat and monkey. Whether or not, however, they are involved in the mechanism of the hypertension in SHR rats is a matter for further investigation.

276.1 DEVELOPMENT OF KITTEN BSER TO PURE-TONE STIMULATION. E. Javel, E.J. Walsh* and J. McGee*. The Boys Town Institute for Communication Disorders in Children, Omaha, NE 68131, and the Department of Physiology, Creighton University School of Medicine, Omaha, NE 68131.

Auditory Brainstem Evoked Response (BSER) potentials elicited by free field pure tone stimulation were studied from birth through the 90th postnatal day in intact, unanesthetized kittens. Signals of 250 Hz, 2000 Hz, and 16,000 Hz with a 17 msec duration were presented in 10 dB steps in order to define the dynamic range of the individual responses. Vertex recorded potentials referenced to the interorbital / supraturbinate position provided optimal records. Earliest responses were obtained for the 2-kHz signal, followed by the 16-kHz and finally the 250-Hz signals. Initial BSER responses to pure tone stimulation were obtained significantly later than responses to click stimulation. The 2000 Hz response was first noted on postnatal day 8 - 9, with the 16-kHz response and the 250-Hz response following at 10 - 11 and 14 - 15 days respectively. Latent periods to individual BSER peaks decreased exponentially as age increased. Once a response to a pure-tone was established, the latencies and amplitudes of BSER peaks as a function of age followed the same patterns seen using click stimulation.

276.2 DEVELOPMENT OF KITTEN BSER TO CLICK STIMULATION. E.J. Walsh*, J. McGee* and E. Javel (SPON: B. Warr). The Boys Town Institute for Communication Disorders in Children, Omaha, NE 68131, and Department of Physiology, Creighton University School of Medicine, Omaha, NE 68131.

Auditory Brainstem Evoked Response (BSER) potentials elicited by free field click stimulation were studied from birth through the 90th postnatal day in intact, unanesthetized kittens. Intensity series in 10 dB steps were recorded in order to define as much of the dynamic range of the response as possible. Vertex recorded potentials were referenced to an interorbital / supraturbinate position. This configuration was shown to produce optimal responses. Results indicate that auditory function can be clearly discerned at high intensities as early as the 8th postnatal day. At earlier ages, low voltage, slow activity occurred which appeared not to be synchronized to the stimulus. The earliest response was always the appearance of wave I. This was followed by a 3 to 4 day period during which 5 to 7 positive peaks were observed in the first 15 - 20 msec following signal onset. Latencies to individual BSER peaks decreased rapidly between 8 - 28 days postnatal, then decreased at a slower rate until 60 days postnatal at which time adult-like latencies were achieved. Interpeak latencies all decreased uniformly with increasing age, indicating that maturation of BSER latencies is cumulative throughout the brainstem pathway. At the same time that latency decreases, amplitudes of BSER peaks increase. Adult amplitudes were attained at ages somewhat earlier than adult latencies. Wave I displayed a split peak throughout maturation. Other waves in the response displayed variations that were not clearly related to maturation but which appeared to be intensity-dependent. Response variations among littermates as well as across litters will be presented.

276.3 DEVELOPMENT OF AN AUDITORY NERVE TERMINAL: THE ENDBULB OF HELD. D.M. Fekete* and D.K. Ryugo. Dept. Anatomy, Harvard Med. School, Boston, MA 02115 and Eaton-Peabody Laboratory, Mass. Eye and Ear Infirmary, Boston, MA 02114.

We began a study of the primary innervation pattern of the cochlear nucleus in the adult cat by injecting horseradish peroxidase(HRP) into the auditory nerve; anterograde movement of HRP completely stained individual auditory nerve fibers and their terminal endings. We were particularly impressed by the morphology of the large, axosomatic endings in the anteroventral cochlear nucleus(AVCN), yet puzzled because they did not correspond to the illustrations of Golgi-stained endbulbs(Brawer and Morest 1975; Held 1893; Lorente de No 1933,1976; Ramon y Cajal 1909) or to the classic description of "bulbs or irregular clubs which issue numerous short appendages"(p.783,Ramon y Cajal 1909). Our observations on endbulb development reveal that the apparent morphological disparity between Golgi-stained and HRP-filled endbulbs is due primarily to age differences.

Kittens of 2,5,10 and 20 days of age and adult cats were prepared by variants of the Golgi method, and analysis was confined to the anterior division of AVCN(Brawer et.al.1974). The classic description of the Golgi-stained endbulb is accurate only for the youngest cats(2,5, and 10 days). We also wish to point out that for these ages, preliminary electron microscopic observations reveal that the endbulbs are flattened in one dimension and appear more like a spoon than a bulb. During these first 10 days the endings enlarge to cradle as much as half of the surface of the postsynaptic cell body. At 10 days, fissures and fenestrations are evident in about half of the endings; the larger and more fenestrated endings no longer exhibit the hair-like extensions. Finally(20 days and adult), significant resorption and remodelling of the endbulbs are demonstrable: the ending is divided into several thick(2-4 um), gnarled branches that are linked together by a delicate reticulum of very fine strands and vericosities of assorted sizes. Maturation has transformed the neonatal endbulb from a large, continuous ending into a network of smaller but interconnected endings.

The multiplicity of developmental events occurring simultaneously with endbulb maturation limits the usefulness of relating the changes in endbulb morphology to any single event in the ontogenetic sequence of auditory functioning. Nevertheless, we cannot resist speculating that endbulb maturation, which produces a significant increase in membrane surface area of the terminal, enhances synaptic transmission by facilitating ion transport necessary to quickly repolarize the endbulb.

276.4 ORGANIZATION OF THE DORSAL COCHLEAR NUCLEUS IN THE ADULT HAMSTER. L. Schweitzer* & N. Cant (SPON: W.C. Hall). Dept. of Anatomy, Duke University Medical Center, Durham, NC 27710

The hamster is well-suited for studies of the development of the mammalian nervous system because of its short gestation and relative immaturity at birth. Our findings suggest that the dorsal cochlear nucleus (DCN) is immature at birth, developing over a course of about ten days. Although the DCN has been described in other species, the adult hamster DCN has not.

In the adult hamster, four neuronal types were identified in Nissl-stained DCN. Fusiform cells, located in the fusiform cell layer, can be distinguished by their large ovoid cell bodies, large nucleus, granular cytoplasm, and prominent nuclear cap of Nissl substance. The giant cells are also granular and often exhibit a Nissl cap, but these cells can be distinguished from the fusiform cells by their larger size and location within the deep layer. The small cells, found primarily in the molecular and fusiform cell layers, have pale, uniform cytoplasm and are smaller than the fusiform cells. The smallest cells, granule cells, are found in all layers and contain several nucleoli in their darkly-staining nucleus.

The size, shape, and distribution of these cell types enabled their identification in Golgi preparations. The apical dendrites of the fusiform cells, which extend into the molecular layer, are oriented perpendicular to the surface of the DCN and ramify predominantly in the sagittal plane. These dendrites are covered with spines in contrast to the spine-free basal dendrites, which extend into the deep layer. The dendrites of the giant cells also ramify primarily in the sagittal plane. These dendrites usually remain in the deep layer but occasionally extend to the superficial layers where sparse thorny appendages may adorn them. The dendrites of the small cells are oriented parallel to the surface of the DCN and run perpendicular to the apical dendrites of the fusiform cells. In the deep layer these cells assume a more stellate appearance. The granule cells have two or three dendrites which are oriented parallel to the surface of the DCN. In conclusion, while the dendritic morphology and Nissl pattern of some of the cell types in the DCN of the hamster differ from other species, the nucleus is highly organized and has a well-established laminar appearance. We are planning to investigate the developmental sequence leading to this organization.

Supported by NIMH Grant 2-T32-MH15177 and US PHS Grant 1R01NS14655.

276.5 ONTOGENETIC DEVELOPMENT OF SINGLE UNIT RESPONSES IN THE COCHLEAR NUCLEUS OF THE MONGOLIAN GERBIL. Nigel K. Woolf and Allen F. Ryan* Otolaryngol. Research Lab, VA Hospital, San Diego and Univ. Calif. at San Diego Medical School, San Diego, CA 92103.

Single neurons in the cochlear nuclei (CN) of mongolian gerbils (Meriones unguiculatis) were examined by conventional extracellular recording techniques at postnatal ages 10, 12, 14, 16, 18, 30, 60, 90 (young adult) days after birth (DAB), and adult. This range of chronological ages included the onset of neonatal hearing through achievement of mature auditory system characteristics. The onset of hearing was confirmed, in addition to single neuron CN recordings, by measurement of intra-cochlear potentials.

Single neuron recordings in the neonatal gerbil CN revealed clear ontogenetic trends. At 10 DAB none of the neurons recorded from within the CN responded to acoustic stimulation. At 12 DAB only a small percentage of the neurons encountered were responsive. For subjects 14 DAB, or older, the vast majority of neurons isolated were responsive to acoustic stimulation. Based upon data taken from neurons which were responsive, it was evident that with increasing chronological age: first, the characterstic frequency (CF) neural threshold values rapidly and monotonically decreased; second, the absolute frequency range of neural CF values increased; and third, the high frequency limits for CFs increased progressively with age. It should be noted that while neural CF thresholds exceeded 95 dB SPL at 12 DAB, by 16 DAB the CF thresholds of the most sensitive CN neurons closely approximated the adult behavioral thresholds for mid-frequency values. This indicates a very rapid developmental sequence of maturation.

In addition to single neuron response at 12 DAB, cochlear microphonic responses were also first recorded at this time. The N_1 compound action potential, however, was not detected until after 12 DAB. The absence of N_1, concurrent with observed neural responses, suggested the population evoked response was asynchronous. Direct support for this hypothesis came from data on neural responses to tone burst stimuli.

In response to gated tone bursts, all CN neuron responded throughout the stimulus period. When stimulus duration was lengthened from 25ms to 500ms even the 12 DAB neurons showed no evidence of habituation or intermittent responses. However, while the great majority of post-stimulus-time (PST) histograms for mature subjects exhibited well defined onset peaks, the great majority of PSTs for neonates did not. This reflects greater variability in initial spike latency and a less pronounced initial rate of firing for neotal responses than are characteristic of mature subject responses. Both of these features are consistent with the absence at 12 DAB of N_1.

276.6 AGE AND POSITION DEPENDENT EFFECTS OF ACOUSTIC DEPRIVATION IN THE AVIAN N. MAGNOCELLULARIS. John W. Conlee* and T.N. Parks. (SPON: M. Jacobson). Dept. of Anatomy, Univ. of Utah Coll. of Medicine, Salt Lake City, UT 84132.

The effects of a unilateral conductive hearing loss on the development of neuron size in nucleus magnocellularis (NM) was investigated. NM receives large calyceal endbulbs from the cochlear nerve. Silicone plastic earplugs which cause a 40dB broadband conductive hearing loss (Kerr et al, J.Exp.Psychol.,5:97,1979) were placed unilaterally in the external auditory meatus of chick embryos on the 18th day of incubation. Animals undergoing prolonged deprivation had their earplugs replaced every 8-12 days. All animals were housed in communal brooders and were sacrificed at predetermined ages: 7(n=3), 13(n=3), 28(n=3),and 63(n=2)days after the initial earplugging. Serial transverse paraffin sections were stained with thionin; NM neurons meeting a nucleolar criterion were drawn with a camera lucida at 1400X at several caudo-rostral percentile levels through NM. The cross-sectional areas of neurons in NM on the normal and deprived sides were compared at chosen caudo-rostral percentile levels; at least 700 cells per brain were drawn. Within-animal comparisons between the deprived and normal sides of the brain showed that the mean sizes in the two NM were not significantly different at 7 and 13 days of unilateral deprivation, but were significantly different ($p<.001$)at 28 and 63 days of deprivation. Neurons on the deprived side showed smaller cross-sectional areas, with differences ranging from 12% at 28 days to 25% at 63 days of deprivation. Neurons in the middle two caudal-to-rostral quartiles (i.e. 25-75%)of NM were significantly smaller ($p<.01$)than those on the control side at 28 days of deprivation. With 63 days of deprivation, the effect spread rostrally and neurons in the three rostral quartiles of NM were significantly smaller ($p<.01$)on the deprived side. Neurons in the caudal quartile of NM receive a substantial innervation from the lagenar nerve and are not included in this analysis.

These results indicate that a moderate unilateral acoustic deprivation results in an age and position dependent smaller mean cell size in NM on the deprived side relative to the control side. The presence of an effect on NM cell size only in those animals undergoing more prolonged deprivation may demonstrate the maintenance role that acoustic stimulation has on the normal growth of NM. The fact that broadband attenuation initially affects the middle region of NM and then expands rostrally with continuing deprivation suggests that there may be regional differences among NM neurons which cause them to be unequally responsive to identical acoustic deprivation.

276.7 DEOXYGLUCOSE LABELING OF AUDITORY FOREBRAIN AREAS IN ADULT AND NEWLY-HATCHED GUINEA FOWL. H. Scheich, V. Maier* and B. A. Bonke*. Zoological Institute, Technische Hochschule Darmstadt, 6100 Darmstadt, FRG.

Adults and chicks at various stages after hatching were injected with 14-C-deoxyglucose (37 µCi/100g) and were stimulated for 45 min with pure tones, harmonic tones or FM. As previously shown in adult birds two areas in the forebrain exhibit tone-activated stripe patterns of labeling which give evidence of tonotopic organization (Scheich,H.,Bonke,B.A.,Bonke,D.,Langner, G.,Cell Tissue Res., 204:17, 1979). Among these areas field L of the neostriatum receives the primary auditory input from the diencephalon. It is a three layer structure with a functionally simple input layer L_2 in the middle. The tone-activated stripes and thus tonotopic organization cut across all three layers and reach dorsally into a lamina of the overlaying hyperstriatum ventrale. This structure receives input from field L (Bonke,B. A.,Bonke,D.,Scheich,H.,Cell Tissue Res., 200:101, 1979). Harmonic tones produce several stripes of labeling in field L each corresponding approximately to the tonotopic place of the particular harmonic frequency. The stripes are less demarcated however than those obtained with pure tones.

In young chicks L_2 is weakly labeled throughout its extend without acoustic stimulation, probably due to high spontaneous spike activity which is also known from adult birds. Immediately after hatching tone-activated stripes were found which form a cross pattern together with L_2, thus tonotopy is present at this stage. Only in chicks of several days of age and most distinctly in adults labeling of L_2 adjacent to the tone- activated stripe is reduced suggesting that the efficiency of inhibitory mechanisms increases with age. Lateral inhibitory areas in tuning curves are typical for L_2 neurones in adult birds (Bonke,D.,Scheich,H.,Langner,G.,J. Comp. Physiol., 132:243, 1979) Towards the end of the first day strong glucose uptake developes in the most lateral part of L_2 and of the overlaying hyperstriatum where frequencies below 1 kHz are represented. This may indicate that low frequency analysis is not fully developed in newly-hatched birds.

276.8 SOMATIC AND DENDRITIC MORPHOLOGY IN AVIAN N. MAGNOCELLULARIS AND N. LAMINARIS AFTER UNILATERAL OTOCYST ABLATION. T.N. Parks. Dept. of Anatomy, Univ. of Utah College of Medicine, Salt Lake City, UT 84132.

The morphology of neurons in the 2nd-order avian brain stem auditory nucleus magnocellularis (NM) and 3rd-order nucleus laminaris (NL) was studied after unilateral surgical ablation of the right otocyst at 50-60 hrs of incubation in several hundred White Leghorn chick embryos. This procedure completely prevents the development of the inner ear and 8th nerve on the right side. After variable survival times, the animals were sacrificed and staged. Brains with verified otocyst ablation were stained by rapid Golgi (n=4, stages 36,37,41) and Golgi-Kopsch (n=10, stages 40,42,43,44) methods. Camera lucida drawings were made of neurons in NM and NL. In NM cells, the morphological transformations described by Jhaveri & Morest (Neurosci. Abstr.,3: 109, 1977) proceed in a relatively normal fashion without 8th nerve afferents. At stages 36 and 37, NM cells are multipolar, with long somatic processes; by stages 42-44, they are spherical, with somata covered by small spines. Cells with a short somatic process are also seen occasionally at this age. Thus, the highly-characteristic morphology of NM neurons may develop normally in relative autonomy from the cochlear nerve. Alternatively, non-cochlear afferents may, in the case of otocyst ablation, fill an interactive role normally played by cochlear afferents. The latter possibility is now under study.

Drawings of 40 NL neurons from five stage 43 embryos were used to measure the dorsal and the ventral total dendritic length for each cell (cf. Smith & Rubel, JCN 186: 213, 1979). These cells came from both sides of all five brains and about equally from all regions of the nucleus (the most rostral area being underrepresented). A quantitative analysis of dendritic lengths in these cells showed the "manipulated" dendritic fields (right side dorsal and left side ventral dendrites connected to the affected right NM) to have an average length 49% smaller than that of the "unmanipulated" NL dendrites connected to the normal left NM ($p<.001$). This effect in NL may be due to the previously reported trans-synaptic loss of NM neurons after otocyst ablation (Parks, JCN 183: 665, 1979; cf. Benes et al., Br.Res., 122:1, 1977)and/or the complete absence of acoustically-driven neuronal activity along auditory pathways leading from the right ear.

Supported by grants from the P.H.S. (#NS 15132), the March of Dimes Birth Defects Foundation, and the Deafness Research Fdn.

276.9 NERVE-TARGET CELL INTERACTIONS DURING THE DEVELOPMENT OF THE AVIAN INNER EAR. Mark Whitehead and D. Kent Morest. Dept. of Anat. UConn Health Ctr. Farmington, Connecticut 06032.

Synapse formation by cochlear fibers and the differentiation of their hair cell targets of chick embryos have been studied with electron microscopy. Before innervation (3½-4 days) hair cells and supporting cells are not distinquished in the sensory epithelium. Apical microvilli extend into a flocculant matrix in the cochlear duct. While junctional complexes occur apically, large extracellular spaces extend transversely in the basal epithelium. During innervation (6-7 days) fibers encounter resistance as they penetrate the basal lamina. Within the epithelium bundles of sensory fibers enter the large basal spaces where they can spread freely in the transverse dimension. The fibers form attachment plaques anchoring them to the basal epithelial processes. Subsequently these processes and the attached fibers assume more superficial positions in the epithelium. Early in synaptogenesis (8-9 days) hair cells and supporting cells can be distinquished. From a nascent cuticular cone the hair cell cilia extend into a loosely commposed tectorial membrane, apparently derived from the flocculent material of earlier stages. Recepto-neural synaptic junctions have symmetrical or asymmetrical membrane densities and a certain dense material organizing in the cleft. At many of these junctions synaptic bodies, as well as dense-cored and coated vesicles gather in the hair cell, while a few clear vesicles and flocculent material appear in the branching endings. Midway in synaptogenesis (day 13) hair cells contain many synaptic bodies, not always located at recepto-neural junctions. The sensory endings form large growth swellings containing flocculent material, endoplasmic reticulum and vesicles. Late in synaptogenesis (16-17 days) the swellings disappear, while synaptic contacts expand into foot-like processes. Synaptic bodies unassociated with junctions disappear. Efferent endings appear at 16-17 days.

In conclusion, there is a parallel sequence of changes in the structure of the developing sensory nerve endings and their target cells. The observations suggest a role of the basal lamina and epithelial end-feet in excluding the ingrowth of all but specific fibers. Once within the epithelium, the fibers may be free to spread within a system of extracellular channels in the transverse direction. The fibers are anchored to the basal processes of presumptive hair cells. This arrangement may promote the radial growth of the fibers which accompany their target cells as the basal processes withdraw to the superficial epithelium. Further differentiation of the hair cells, including synaptic bodies and membrane desities, is accompanied by a transformation in the morphology of the nerve endings.

276.10 REORGANIZATION OF CENTRAL PROJECTIONS AFTER REGENERATION OF THE AUDITORY NERVE IN ANURANS. H. Zakon and R.R. Capranica Section of Neurobiol. and Behav., Div. of Biol. Sci., Cornell Univer., Ithaca, N.Y. 14853.

The vertebrate central auditory system must be precisely organized in its neural connections. The fact that sharp "V" shaped excitatory tuning curves are maintained from the level of the eighth nerve to at least the midbrain suggests that all of the afferents which innervate a given cell share similar best frequencies (BF). Furthermore, binaural cells usually have identical BFs when stimulated by either ear; thus, neurons with the same BFs from each side of the brain must seek out a common target cell.

In order to determine how such highly specific connections might be achieved in the central auditory system, we have studied the frequency sensitivities of neurons in the superior olive (SO) of the leopard frog (Rana pipiens) during reinnervation of brainstem primary auditory nuclei by the regenerating eighth nerve. The nerve was severed unilaterally and the animals were then maintained in separate tanks at 20°C. Under these conditions the eigth nerve regenerates in 5-6 weeks. Single units were then recorded in the SO at 6 and 12 weeks after nerve transection; the response properties in these experimental animals were compared to those in normal animals.

In normal frogs most of the cells in the SO are driven by the contralateral ear: they all have narrow "V" shaped tuning curves. About one-third of these cells are binaural, with the ipsilateral ear usually inhibitory. The BFs of the tuning curves from both ears are similar (usually less than 1/4 octave apart).

Many of the cells in the SO of 6-week regenerates, which are strongly driven by the contralateral ear again (via the regenerated nerve), exhibit narrow "V" shaped tuning curves. Nevertheless, a number of cells were found which were broadly tuned or had multipeaked tuning curves. Furthermore, while some binaural cells had matched BFs from the two ears, there were many binaural cells which were poorly matched (some had disparities of well over 1/2 octave).

By 12 weeks after nerve transection, almost all cells exhibit simple "V" shaped tuning curves, although a few "W" shaped tuning curves remain. The BFs of the binaural cells are once again as closely matched as in normal animals.

These results suggest that, upon their earliest contact with the central auditory system, regenerating auditory nerve fibers may not necessarily return precisely to their former postsynaptic targets. With time, changes occur which lead to the eventual matching of binaural frequency sensitivity.

277.1 DEVELOPMENT OF COMPLEXITY IN RAT NEUROMUSCULAR JUNCTIONS
C.D. Tweedle and K.S. Stephens*. Department of Anatomy, Michigan State University, East Lansing, MI. 48824.

Using a combined silver-cholinesterase stain, motor endplate morphology was examined in both slow-twitch (soleus and adductor longus) and fast-twitch (rectus femoris and plantaris) muscles of 2,3,4,5,6 and 11 week old male rats (N=37 rats). Categorization of endplates from each muscle at each age into defined morphological classes was carried out. The differences between the distribution of endplates among these classes between muscles and between ages was then analyzed statistically. Polyneuronal innervation of endplates dropped dramatically between 2 and 3 weeks. The number of "branched" endings (2 muscle fibers innervated by a single axon) significantly decreased between 3 and 4 weeks in all the muscle groups and did not change thereafter. At 4 and 5 weeks the predominant appearance of the endplates of all the muscles was similar - being basically a single "bare" axon going into the endplate area (with one axon being associated with one endplate per muscle fiber). Complexity of the endplates then developed with maturation. At 6 weeks of age in the slow twitch muscles only there was first seen a significantly greater percentage of double endplates (one axon giving rise to 2 endplates on a single muscle fiber). This difference increased significantly between 6 and 11 weeks. The number of more complex nerve endings with accessory axonal branches to the endplate from the parent axon increased steadily throughout maturation in all the muscle groups. At 3 weeks these made up less than 5% of the endplates. However, by 11 weeks they were seen in between 25 and 40% of the endplates. This study indicates that 1) there is still synaptic re-arrangement (loss of branched endings) between 3 and 4 weeks in all muscle groups: 2) there develops a significantly greater number of double endplates in slow twitch muscles around 6 weeks; and 3) complexity of endplate structure increases with growth of the animal by adaptations of the terminal axon. Thus, even under normal conditions, young adult rats spontaneously display significant evidence of synaptic remodeling and plasticity. Supported by NSF.

277.3 MORPHOLOGICAL PLASTICITY IN THE VENTRAL LATERAL GENICULATE NUCLEUS OF THE CHICK.
W. J. Crossland. Dept. of Anatomy, Wayne State University School of Medicine, Detroit, MI 48201.

The neuropil lamina of the two-layered ventral lateral geniculate nucleus (GLv) of the chick receives topographic projections from both the retina and optic tectum. Based on findings in the visual pathways of certain mammalian species one could predict that removal of one set of these afferents would lead to an increase in the density of terminal arborizations of the remaining set.

To test this possibility a group of newly-hatched chicks was subjected to partial tectal removal. One day prior to sacrifice six weeks later, the eye contralateral to the tectal operation was injected with ^{3}H-proline. Following reconstruction of the GLv and optic tectum from autoradiographs, an area of sharply increased silver grain density was found in the GLv which was in retinotopic correspondence with the lesioned area in the optic tectum. Thus the zone of heightened grain density was located at the site of the degenerated tectogeniculate projection.

This finding suggests a competitive mechanism of terminal arborization growth similar to that reported in mammals. Whether the increased density results from the proliferation of retinotopically appropriate or inappropriate axons remains to be determined.

277.4 A GOLGI STUDY OF THE POSTNATAL DEVELOPMENT OF PYRAMIDAL NEURONS IN THE RAT VISUAL CORTEX.
Michael Miller* (SPON: Alan Peters). Dept. Anatomy, Boston Univ. Sch. Med., Boston, MA 02118.

In the rat visual cortex pyramidal neurons predominate in layers II/III and V. All of these cells undergo similar changes during development to their adult forms. At birth, they appear to be essentially bipolar with a single aspinous dendrite reaching toward the pial surface, whereas the adult appearance, characterized by a prominent apical dendrite and a basal skirt of dendrites, is achieved by day 21. To determine how these cells develop in layers II/III and V, general morphological characteristics such as numbers of visible spines along the apical dendrite, dimensions of the cell body, and numbers of primary basal dendrites were examined. Pyramidal neurons impregnated by the rapid Golgi method were studied in albino rats of 0, 3, 6, 9, 12, 15, and 21 days of age. For all neurons the overall spine density along the apical dendrite increases exponentially with age from 0.20 and 0.22 spines/μm to 1.02 and 0.91 spines/μm for layer II/III and V neurons, respectively, although there is a pause in this increase between the 9th and 12th days. This pause coincides with the arrival of geniculate input (Lund and Mustari, 1977). Moreover at each age spine density increases exponentially with distance from the soma to attain a peak density at about 125 μm from the cell body. At any age apical dendrites of individual layer V cells may show as much as a 3-fold difference in their spine density at the level of layer II/III as compared to layer IV. The mean for all layer V cells, however, shows no significant difference between the two regions. For both populations of neurons the lengths, widths, and volumes of their cell bodies increase linearly with age. For layer V cells the increase in volume is from 1200 μm^3 at day 3 to 4110 μm^3 on day 21, whereas for neurons in layer II/III the gain does not begin until three days later and increases from 930 μm^3 on day 6 to 2510 μm^3 on day 21. This delay of maturation between the two populations is also reflected in the attainment of the number of primary basal dendrites characteristic of adult neurons. Layer V pyramidal neurons achieve a maximum number of 6.2 primary basal dendrites at day 6, but layer II/III cells do not reach a maximum of 4.9 until day 9. Consequently, this study provides quantitative evidence that layer V pyramidal neurons begin to differentiate at an earlier age than layer II/III cells. Apparently the maturation of the general morphology of pyramidal neurons is affected strongly by their time of arrival in the cortical plate (Berry and Rogers, 1965) and by external factors such as thalamic input. Supported by NIH grants NS-07016 and EY-07054.

277.5 SYNAPTIC PLASTICITY WITHIN THE INTERPEDUNCULAR NUCLEUS AFTER UNILATERAL LESIONS OF THE HABENULA IN NEONATAL RATS. G. S. Hamill* and N. J. Lenn. Carnegie Labs. of Embryol., Univ. Calif., Davis, and Dept. Neurol., Univ. Virginia, Charlottesville, VA 22908.

Medial habenular (MH) lesions in neonatal rats have been shown to cause synaptic rearrangements in the interpeduncular nucleus (IPN) which vary for different synaptic types and with the magnitude of the MH lesion. A unilateral MH lesion produces a reproducible 50% reduction of MH input to IPN, and also allows consideration of bilateral integretion at the synaptic level. After such lesioned pups reach maturity, injection of ^{3}H-leucine and demonstration of axonal transport by autoradiography or scintillation counting of punch biopsies, or destruction of the remaining MH with demonstration of degenerating synapses by electron microscopy allow analysis of the induced plasticity. Controls consist of normal animals, with and without ^{3}H-leucine injection or adult lesions.

The S synapses, the principal MH afferents to IPN, are cholinergic, have identifiable fine structure at all ages, and form 90+% of all IPN synapses. 95% of S synapses terminate in IPN ipsilateral to their MH of origin normally, in spite of the fact that their axons cross through the contralateral half of IPN one or more times. Neonatal unilateral lesions result in a symmetrical bilateral districution of S synapses as shown by all 3 methods.

The crest synapses, a less frequent termination of MH afferents to IPN, consist of 2 endings indistingushable from S synapses which contact a markedly narrowed, 75 nm dendritic crest with parallel and coextensive contact zones. They normally are formed by 1 axon from each MH in 98% of cases. After unilateral neonatal lesions they are formed by 2 axons from the remaining MH in approximately 2/3 of cases as shown by degeneration of both axons simultaneously after the adult lesion. However, some crest synapses are formed by 1 MH afferent axon, and 1 presynaptic process of other origin, including processes which form somatic synapses. Occasional bare hemisynapses are seen apposed to myelin or glia, especially at 1½ days post-lesion. A few crest synapses are also formed in this material by 2 presynaptic processes of non-MH but so far unknown origin, a finding which is commonly induced by bilateral neontal MH lesions, as previously demonstrated.

These diverse manifestations of synaptic plasticity imply a loss of specificity, and therefore probably of functional integretity, as well as alterations of bilateral integretation. The underlying normal synaptogenetic control mechanisms implied are lateralized, as well as localized to both pre- and post-synaptic sites.

277.6 PLASTICITY OF ADULT PURKINJE CELL SPINE SYNAPSES FOLLOWING DECREASED AFFERENTS. D.E. Hillman and S. Chen, Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016

Double transection of a cerebellar folium in the adult rat, by separations of one to 2 mm, produced greater than 50% reduction in parallel fiber synapses on Purkinje cells between the cuts. Qualitative observation of Purkinje cell spines after 5 days showed a marked length increase in synaptic profiles such that the entire head of some spines was almost encapsulated by a synaptic site. The majority of spines were greatly enlarged and had elongated synaptic profiles. Multiple parallel fiber synapses were also occasionally seen on enlarged spines. Very noticeable was the enlargement of parallel fiber boutons which appeared to engulf the spine head with a presynaptic thickening in apposition to the postsynaptic site. A proportional increase in the number of synaptic vesicles was evident in the enlarged boutons. Actual shape and size change was determined by three-dimensional reconstruction from serial sections. Quantitation showed an average increase of 30-40% in synaptic profile length. Estimation of contact area (taking into consideration the cupped shape of the synapse) revealed a greater than 50% increase in size. Thus, there appears to be an inverse relationship between synaptic contact size and spine synaptic number as has been shown by afferent reduction due to malnutrition during development (Soc. Neurosci. 5: 100, 1979). Intrinsic determination of synaptic contact area by Purkinje cells give rise to plasticity in synaptic size and thus the integrity of this circuitry is maintained even though certain afferents have been lost. (Supported by NICHD-10934).

277.7 EFFECT OF PERIPHERAL NERVE SECTION ON VIBRISSAE RELATED SEGMENTATION IN THE CENTRAL NERVOUS SYSTEM OF THE RAT. A. Shinder* and H.P. Killackey (SPON: H. Koopowitz). Dept. of Psychobiology, Univ. of Calif., Irvine 92717.

Previously the effect of individual cauterization of all of the vibrissae which compose the five rows of mystacial vibrissae has been determined. In the ventrobasal complex (VB) following this procedure, the five rows of discrete clusters are replaced by five bands. In other words, there is a loss of boundaries between clusters within a given row while the boundaries between rows are maintained (Belford & Killackey, JCN, 1979). The present experiment was undertaken to compare the effect of nerve section on vibrissae related segmentation with that of total vibrissae cauterization on such segmentation.

For the present experiment, the maxillary branch of the trigeminal nerve of littermate rats was severed at the level of the infraorbital foramen on the day of birth (PND 0) or on one of the two following days (PND 1 and PND 2). Animals were then allowed to survive to PND 5 at which time they were sacrificed, their brains removed and processed for succinic dehydrogenase (SDH) activity.

Following this procedure, the brainstem, thalamus and cortex were examined for dense clusters of SDH activity related to afferent segmentation. In the brainstem there were uniform low levels of activity in the trigeminal nuclei and no segmentation was detectable. We attribute the low level of SDH activity to the fact that the peripheral processes of the primary trigeminal afferents are damaged. The results for thalamus and cortex were different from what we found in the brainstem but similar to each other; hence, we describe our findings only for VB. In this nucleus the level of SDH activity was normal. However, the amount of segmentation within VB varied with the age of peripheral nerve manipulation. Damage on PND 0 resulted in no detectable segmentation within the vibrissae related portion of VB. Damage on PND 1 results in some tendency towards segmentation with between-row boundaries being better defined than within-row boundaries. Damage on PND 2 results in even more segmentation, and both between- and within-row boundaries are detectable, although neither are clearly delineated as they are normally.

The present results indicate that the effect of early nerve section is more severe than that of cauterization of all vibrissae follicles on central vibrissae representation. We interpret these results as suggesting that afferent boundary information is "passed" centrally from the periphery during the early postnatal period and that it is a time dependent process.

277.8 COMPARTMENTALIZATION OF PREFRONTAL PROJECTIONS: COMPARISONS OF CORTICAL COLUMNS AND STRIATAL ISLANDS IN OLD AND NEW WORLD MONKEYS. N.M. Bugbee* and P.S. Goldman-Rakic, Sec. of Neuroanatomy Yale Univ. School of Med., New Haven, CT. 06510.

According to several reports, the ocular dominance columns of striate cortex are organized differently in Old and New World monkeys. In Old World monkeys, these columns are most prominent in layer IV, while in New World species, they are confined to the supragranular layers. This difference raises the question of whether the distribution of fiber terminals in other brain regions also varies between these species. Previous studies of rhesus monkeys have shown that cortico-cortical afferents to prefrontal association, limbic, and motor cortex are distributed in sharply demarcated columns; moreover, efferent projections from neocortex to caudate and putamen also terminate in a complex pattern of spatially segregated patches or compartments.

To examine the possibility of species differences in the terminal distribution of cortico-cortical and cortico-striatal projections, we injected tritiated amino acids into the prefrontal cortex of New World squirrel monkeys (Saimiri sciureus) and Old World rhesus monkeys (Macaca mulatta) and prepared their brains for autoradiography. In the rhesus monkey, fibers labeled by such an injection terminate in distinct bands, which in transverse sections appear as vertically oriented columns 200-500 um wide. These columns extend across all layers of cortex. Such columnar-like patterns are equally apparent in the cortex of the squirrel monkey, where again, they traverse all cortical layers and measure 200-300 um across.

Terminal patterns observed in the caudate nucleus of the squirrel monkey are also very similar to those in the rhesus. Labeled fibers are not uniformly distributed, but are separated by territories in which grains do not exceed background; some of these patches of label surround an elliptically shaped island which is relatively grain-free. In addition to their likeness in shape, these caudate patterns are also remarkably similar in dimension, with the diameter of the grain-free island ranging between 300-400 um in both species.

Thus, differences in the distribution of afferent fiber systems in Old and New World monkeys appear to be specific to the geniculostriate system. Our findings demonstrate a marked species similarity in the terminal patterns of cortico-cortical and cortico-striatal projections. The dimensions of cortical columns and striatal compartments are similar in spite of considerable differences in cortical surface area and neostriatal volume. If there is a species difference in the compartmentalization of prefrontal fiber systems, it may be in the number, rather than the size or laminar organization, of the compartments.

278.1 NEOCORTICAL TRANSPLANTS IN THE CEREBELLUM OF THE RAT: AN AUTORADIOGRAPHIC ANALYSIS OF THEIR HISTOGENESIS. D.T. Ross* and G.D. Das* (SPON: L.J. Pellegrino). Dept. of Biol. Sci., Purdue University, W. Lafayette, IN., 47907.

It is well established that embryonic neural tissues, when transplanted into the brains of neonatal or adult hosts, survive, grow, differentiate and become anatomically integrated with the host brain parenchyma. An integral element of transplant growth is the histogenesis of neurons from transplanted neuroepithelial cells. This study was conducted to analyze histogenesis in neocortical transplants obtained from embryos of different ages.

Donor embryos were obtained from pregnant Wistar-albino rats on day 15, 16, 17, 18, 19, 20 or 21 of gestation. The cerebral hemispheres were dissected from these embryos, and $8mm^3$ of this tissue was transplanted into the cerebellum of 10-day-old host animals. Following this, each animal received a single injection of H^3-thymidine. At least one animal per donor age group was given the radiochemical 6 hours after transplantation and at least one animal per group was given H^3-thymidine on each succeeding day throughout the histogenetic period for the transplanted tissue. Ninety days after transplantation host animals were sacrificed and their brains processed for autoradiography. Cresyl-violet counterstained autoradiograms were analyzed for the presence of heavily labelled large pyramidal cells (perikarya 18-22 μm), small pyramidal cells (14-17 μm), large stellate cells (12-16 μm), and small stellate cells (8-11 μm). Labelled and unlabelled neurons were counted in each transplant to determine the percentage of heavily labelled cells for each of the four types. The onset, peak and termination of neurogenesis were determined for each cell type in transplants obtained from embryos of different ages.

Generally, the pattern of histogenesis in transplanted neocortex was similar to that seen for neocortex in situ. Transplants of 15 day embryonic neocortex exhibited the longest duration of histogenesis, 11 days, while transplants from 21 day old embryos showed the shortest duration of histogenesis, 3 days. The duration of histogenesis for transplants of intermediate ages fell between these two extremes in a graded fashion. Transplants from 15, 16, and 17 day old embryos contained heavily labelled pyramidal and stellate cells whereas transplants from older embryos had only labelled stellate neurons. Transplantation was seen to cause some subtle changes in the time course of neocortical histogenesis, delaying the onset and peak and prolonging the termination of neurogenesis for each of the four cell types studied.

278.2 CULTURED FETAL RETINAE TRANSPLANTED TO SUPERIOR COLLICULUS. L. K. McLoon, S. C. McLoon and R. D. Lund. Dept. of Anatomy, MUSC, Charleston, S. C. 29403.

Recent work has demonstrated that fetal rat retinae transplanted adjacent to the superior colliculus (SC) of newborn host rats develop relatively normal cytology and connect only with those regions of the host brain normally retino-recipient (McLoon and Lund, 1980). We have examined here whether a period of growth in vitro would affect the organization of fetal retinae and their ability to form connections after subsequent transplantation to the host brain. On embryonic day 14 rat neural retinae were dissected from the embryo and cultured in MEM supplemented with 10% calf serum. After 2, 3, 5, 7, 10 or 14 days in culture, some of the retinae were fixed, and the rest were transplanted adjacent to the SC of unilaterally enucleated newborn rats. After one month, half of the host rats were sacrificed, fixed, and their brains examined with Nissl and silver stains. Some of these also received transplant lesions for degeneration studies. The second group of rats received an injection of HRP into the left SC 12 hours before sacrifice in order to identify cells in the transplant projecting into the host SC.

Examination of the retinae fixed at the time of transplantation showed them to retain a neuroepithelial appearance. Only a slight degree of differentiation was evident with no obvious lamination present. In the longer term cultures there was evidence of cell death in the center of the explants. Retinae that had been in culture 2 to 7 days when transplanted appeared one month later as rosettes or folded sheets. They developed relatively normal cytology showing three distinct cell layers separated from one another by plexiform layers. After 10 or 14 days in vitro the resultant transplanted retinae were smaller in size and more disorganized, although some distinct cell differentiation and lamination developed. As suggested by fiber patterns and degeneration studies, transplants from all the in vitro periods projected into the superficial layers of the host SC. The retrograde transport of HRP after injection of the host SC labeled cells in the transplant corresponding in position to the ganglion cell layer. Thus, even after 2 weeks in vitro, fetal retinae retain the ability to differentiate relatively normally and form appropriate connections with the host brain. This technique will allow the opportunity to assay the consequences of in vitro manipulation which may modify the developmental program of the retina. (Supported by NIH EY 03414. LKM is an NSF Fellow #14844.)

278.3 CYTOLOGY AND CONNECTIONS OF RETINAL TRANSPLANTS IN RATS. R. D. Lund and S. C. McLoon. Dept. Anat., Medical Univ. South Carolina, Charleston, S. C. 29403.

Fetal retina, when transplanted adjacent to the superior colliculus of newborn rats, develops organization and connections appropriate for normal retina (McLoon and Lund, Neurosci Soc. Abs 5:631). We have extended these results to include ultrastructural findings. Presumptive retinae were excised from the eye cups of rat embryos on gestational day 14 and transplanted adjacent to the superior colliculus of neonatal rats with unilateral enucleations. After 4-6 weeks survival, the transplants were removed from the host brains and prepared for histological examination. Light and electron microscopic examination of the transplants revealed cell and plexiform layers characteristic of normal retinae. The outer plexiform layer contained numerous invaginating ribbon synapses; however, there was a conspicuous paucity of conventional synapses. Dyad ribbon synapses and conventional synapses were found in the inner plexiform layer suggesting relatively normal associations between bipolar, amacrine and ganglion cells. Myelinated axons originated from the ganglion cells.

After removal of the transplants, the hosts were allowed to survive two days, after which their brains were processed by the Fink-Heimer technique and an adjacent slice of the superior colliculus (SC) was prepared for EM. Projections from the transplants were found only to nuclei in the host brain which are normally retino-recipient. Ultrastructural examination of the SC revealed degenerating terminals confined to the appropriate superficial layers of the SC. The terminals, like typical optic terminals, contained round vesicles and large pale mitochondria, and formed mainly axodendritic and some serial synapses.

To determine the cells of origin of the transplant projection, the SC in a number of host rats was injected with HRP. After an appropriate survival time, sections of the transplants were reacted using DAB. This revealed labeled cells in the ganglion cell layer as well as a few along the border of the inner nuclear layer of the transplant. Several of these cells were sufficiently filled with HRP to give a Golgi-like image. They had dendritic processes extending into the inner plexiform layer with many horizontal branches at several levels.

Since the retinal tissue used in this study was transplanted prior to differentiation of all but a few ganglion cells, these results suggest that fetal retinae have the ability to develop certain morphological characteristics even when transplanted to anomalous positions. Furthermore, the retinal transplant efferents not only enter the host SC, but also form synapses in it. (Supported by NIH EY 03414 and EY 03326)

278.4 ABNORMAL BRAIN DEVELOPMENT FOLLOWING FRONTAL OR TOTAL NEODECORTICATION IN INFANT RATS. Bryan Kolb, Arthur J. Nonneman, Robert Sutherland & Ian Q. Whishaw. Dept of Psychology, University of Lethbridge, Lethbridge, Alberta, Canada, T1K 3M4

In the course of studying the behavior of rats with neocortical lesions as neonates we have noticed a number of abnormalities in brain development. This study examined the effect of bilateral or unilateral frontal or total neodecortications one year after surgery as infants or adults. Measurements were made of brain weight, external cerebral and cerebellar dimensions, neocortical thickness, and thalamic width. Note was also made of degeneration or distortion of subcortical structures.

Normal brains showed a consistent cerebral asymmetry. The right hemisphere was 5% longer and wider and 5-10% heavier than the left. This difference resulted primarily from a 5% advantage in neocortical thickness in the right hemisphere. This unexpected asymmetry had to be considered in the analysis of the operated cases and may be of significance to other investigators doing both behavioral and anatomical studies.

Rats with bilateral neonatal frontal lesions had 10-15% smaller brains than adult operates as measured by brain weight or external dimensions. Lesion size was equivalent, however, as brain weight in rats sacrificed following surgery was 90-95% of normal weight in each group. The chronic difference is accounted for by a 10% reduction in neocortical thickness and a 5% reduction in thalamic width as compared to adult operates. Cerebellar size and hippocampal thickness were equivalent in the two groups. Rats with unilateral neonatal frontal excisions had similar reductions in the hemisphere ipsilateral to the lesion but not in the hemisphere contralateral to the lesion. However, rats with unilateral neonatal neodecortication had a significant increase (10-20%) in neocortical thickness in the intact hemisphere.

Neocortical lesions in infancy thus alter subsequent brain development but the nature of the effect depends upon the size of the removal. These effects appear to be neocortical as neodecortication in infancy does not result in a significantly smaller brain than in adult operates. There are, however, abnormalities following neonatal decortication. In particular, the dentate gyrus may form several extra gyri and Ammon's horn is grossly deformed, the thalamus is distorted and many nuclei are unrecognizable, the caudate-putamen and globus pallidus suffer marked gliosis, nucleus accumbens and the septum are shrunken, and there are variable abnormalities in the midbrain tegmentum.

These data indicate substantial plasticity and variability in brain development following neocortical damage in infancy. The mechanisms that mediate these changes are as yet unknown.

278.5 RESTITUTION OF THE CENTRAL NERVOUS SYSTEM AFTER DESTRUCTIVE INJURY BY PRENATAL IRRADIATION IN RATS. Constance J. D'Amato and Samuel P. Hicks, Department of Pathology, University of Michigan, Ann Arbor, MI 48109.

Destructive effects of 150 or 200 R X-irradiation in fetal life in rats usually leads to malformation, but there is always some degree of restitution of the cell loss. Restitution after 150 R on the 10th (6-14 somite pairs) or 12th (26-36 somite pairs) fetal days is remarkable, the resulting animal often appearing to be normal. In mature rats irradiated with 150 R on the 12th day we have found only subtle abnormalities of corticospinal neurons, and diminution of the size of the spinal cord (D'Amato, Hicks 1980) and we are now studying the morphogenetic steps leading to the restitution. Various stages in the development of these rats from 6 hours after irradiation until maturity were studied in four litters. Successive intervals in fetal life were studied by removing members by "caesarean" section. Six hours after 150 R there was extensive necrosis of the G_1 and G_2 cells in the proliferative cell zone throughout the spinal cord, metencephalon and cerebral vesicle, with somewhat less destruction in the diencephalon and mesencephalon. Twenty four to 48 hours after irradiation the residual cells had proliferated and largely restored the cerebral mantle, diencephalon and metencephalon. Except for minute foci of rosette formation in the dorsal anterior and lateral mesencephalon and ventrally at the site of the future interpeduncular region, restoration of the mesencephalon approached normal. By 72 hours there was virtually no evidence of the earlier damage except for rare remnants of necrotic cells, and the minute rosette foci, which had not grown in size. In the spinal cord, as a rule, remnants of necrotic cells could still be seen at 72 hours. There was usually some central rosette formation in the cervical cord visible from 1 to 4 days after irradiation. Five or 9 days (21st fetal day) after irradiation the spinal cord was slightly smaller than normal in diameter, and the number of neurons in the ventral horns was substantially reduced, that is, the ventral horns were sparsely populated compared with normals. Evidence of the rosettes was a reduced or obliterated central canal and jumbling of neurons in the central gray region. The picture in adult animals corresponded to that seen in these fetal rats, but in some animals, there was no disorder of the central canal region, and the cord could not be distinguished from normal. (USPHS NS 10531)

278.6 THE DIFFERENTIAL NEURONAL RESPONSE TO PYRAMIDOTOMY IN THE DEVELOPING AND ADULT HAMSTER. T.E. Durica. Dept. Anat., Rush Coll. Hlth. Sci., Chicago, IL 60612.

The neuronal response to pyramidotomy was studied in the developing and adult hamster to determine if there was an age dependent response for intrinsic (pyramidal) neurons comparable to the response which has been described for developing extrinsic (facial motor) neurons of the hamster. Unilateral pyramidal tract lesions were made in the medulla, rostral to the pyramidal decussation, in 5, 10, 15 and 20 day old, and adult hamsters. The animals were sacrificed at 5 and 10 days postoperative (dpo) and processed for histological examination.

At 5 dpo, the pyramidal cells of the adult and 20 day old animals displayed a central chromatolysis, while the pyramidal cells of 15 and 10 day old animals had a more localized chromatolysis. In the 5 day old animals some pyramidal cells had a chromatolytic response typified by a rounding of the cell, paling of the Nissl substance, and an eccentrically placed nucleus; many of the remaining pyramidal cells were relatively normal in appearance, however, their Nissl substance was less coarse and paler than that of pyramidal cells of the control side (10 days of age).

At 10 dpo, the pyramidal cells of the adult and 20 day old animals continued to show a central chromatolytic response. In the 15 and 10 day old animals many of the cells still had the localized response, while some cells displayed a central chromatolytic response. In the 5 day old animals (at 10 dpo) some pyramidal cells had a response similar to that seen at 5 dpo, however, many of the cells appeared smaller and had less Nissl substance when compared to cells of the control side (15 days of age). It should be noted that these particular pyramidal cells of the operated side had an appearance similar to pyramidal cells of the normal 10 day old animal.

These findings have shown that at 10 dpo the chromatolytic response of pyramidal cells differs cytologically from that reported for facial motoneurons. Notably, the facial motor neurons of the 5 day old hamster do not survive axotomy, while the pyramidal cells not only survive but are apparently continuing to differentiate, though at a delayed rate. It has been reported by Kalil and Reh (Science, 225:2258, 1979) that these young neurons are able to regenerate their axons following pyramidotomy and establish connections in the spinal cord which may account for their particular histological appearance in this study.

278.7 THE EFFECTS OF PRENATAL X-IRRADIATION ON THE DEVELOPMENT OF THE CORPUS CALLOSUM AND THE SUPRAGRANULAR LAYERS OF THE NEOCORTEX. Karl F. Jensen. Lab. Developmental Neurobiology, Dept. Biological Sciences, Purdue Univ., West Lafayette, IN 47907

Neurons of layers II and III of the rat parietal cortex are produced primarily during embryonic days 18 thru 21 (Berry and Rogers '65, Raedler and Raedler '78). A single dose (200 R) of 250 KV x-rays applied at various times during this embryonic period prevents the development and reduces the depth of the supragranular layers with no appreciable reduction in the depth of the infragranular layers. The reduction in the depth of layers II and III decreases with embryonic age according to developmental gradients within the neocortex. On a given embryonic day the extent of the reduction of the supragranular layers decreases in a lateral (rhinal fissure) to medial gradient and an anterior (frontal) to posterior (occipital) gradient. The graduated interference with the late forming neurons of the supragranular layers is associated with the absence of or reduction in the corpus callosum. The pattern of reduction in the corpus callosum closely correlates with the developmental gradients observed in layers II and III. It is concluded that the cells of the supragranular layers are the major source of fibers of the corpus callosum.

278.8 EFFECTS OF MULTIPLE EXPOSURES TO INTENSE ACOUSTIC STIMULATION ON AUDIOGENIC SEIZURE (AGS) SUSCEPTIBILITY (S) AND INTENSITY (I) IN RATS. I. A DEVELOPMENTAL STUDY IN PROGENY FROM A GENETICALLY SUSCEPTIBLE COLONY. P.C. Jobe, R.D. Brown, J.W. Dailey, T.B. Ray*, T.W. Woods*, M.E. Mims* and S. Bairnsfather. VA Med. Center and Depts. of Pharmacol. and Psychiat., LSU Sch. Med., Shreveport, LA. 71130.

Sprague-Dawley derived progeny of the AGS S colony at the VA Med. Center in Shreveport, LA were utilized as experimental subjects. The sound stimulus which consisted of mixed tones was generated by two bells ringing simultaneously. The sound level obtained (115 dB) is sufficient to produce seizures in adult AGS S rats. Four groups of pups from AGS S parents were used. Beginning on day 13 after birth, 3 of these groups were exposed to the sound stimulus on the following schedules: group 1-once daily; group 2-once every 3 days; group 3-once every 6 days. The fourth group was exposed only at 22 days of age. Seizure I was assessed by determining an audiogenic response score (ARS) for each animal (0-9 on an ascending I scale, Jobe et al., JPET 184: 1-10, 1973). Seizure S was determined by recording the fraction (F/S) of rats which displayed an AGS (i.e., where ARS ≥ 1). As shown in the table, pups exposed to the sound stimulus at more frequent intervals became susceptible to AGS more rapidly and exhibited more severe seizures than those exposed at less frequent intervals. Also, the ARS for rats stimulated on a daily schedule reached a peak at day 22 and fell rather dramatically thereafter. Other data not reported in the table, show that in rats which are 40 days of age upon first exposure to the stimulus, the ARS does not significantly decrease as a result of multiple acoustic exposure. These results indicate that neuronal development in very young rats is altered by acoustic stimulation, by seizure activity or by acoustic stimulation plus seizure activity. Either these same neuronal alterations do not occur in more mature rats or they are masked by compensatory changes.

278.9 EFFECTS OF MULTIPLE EXPOSURES TO INTENSE ACOUSTIC STIMULATION ON AUDIOGENIC SEIZURE (AGS) SUSCEPTIBILITY (S) AND INTENSITY (I) IN RATS. II. A DEVELOPMENTAL STUDY IN STRAINS OF NONSUSCEPTIBLE RATS. R.D. Brown, P.C. Jobe, S. Bairnsfather, M.E. Mims* and T.W. Woods*. VA Med. Center and Depts. of Pharmacol. and Psychiat., LSU Sch. Med., Shreveport, LA. 71130.

Two types of rats were used for these investigations: (1) animals obtained directly from Sprague-Dawley, Inc.; and (2) animals obtained from the VA colony of rats which are selectively bred for non-susceptibility to AGS. (Adult rats obtained from Sprague-Dawley, Inc. are also nonsusceptible to AGS.) Type 1 (T-1) and type 2 (T-2) rats were subdivided into 4 groups (G), exposed to the sound stimulus and assessed for seizure I as described in the abstract of Jobe et al. in this volume. Pooled data from both types of animals are presented in the table. At 31 days of age, stimulation on the every 3 day schedule produced a level of S which was greater than that occurring in rats stimulated on the daily or on the every 6 day schedule. The rates of appearance of S in G-1 and G-2 were equivalent until after 28 days of age, at which point S continued to increase in G-2, whereas it showed a tendency to deteriorate in G-1. Responses of T-1 rats were similar to the pooled data reported in the table. However, T-1 responses differed from those of T-2 in two ways: (1) increases in S in T-2, G-1 did not appear to deteriorate after day 28 as they did in this G in T-1 rats; and (2) responses from G-3 were less dramatic in T-2 than in T-1 rats. In all G's in both types of animals, 44 of the 46 rats which became S exhibited an ARS = 1. These observations indicate that in very young rats multiple exposures to intense acoustic stimulation cause the appearance of S but do not alter seizure I. This is in sharp contrast to the results obtained in progeny from AGS susceptible parents where multiple exposures to the acoustic stimulus caused marked increases in seizure I (see the abstract of Jobe et al. in this volume).

278.10 MORPHOLOGIC DEVELOPMENT IN THE BRAINSTEM RETICULAR CORE IN REHABILITATED, PRENATALLY UNDERNOURISHED RATS. R. P. Hammer and E. van Marthens*. Dept. Anat. and Mental Retardation Research Center, UCLA School of Medicine, Los Angeles, CA 90024.

Prenatal exposure of the rat fetus to undernutrition induced in the mother prior to and during the entire gestation period results in a delayed course of development of brainstem reticular cells of the neonatal rat (Hammer, 1980, Inter. Congr. of Anat. Abstr., in press). However, as these animals are rehabilitated on a normal maternal diet to 20 days, their brainstem neuronal milieu tends toward its normal configuration. Developmental status is assessed by comparing gradually decreasing numbers of protospiny appendages and dendritic varicosities upon dendrites in proximal and terminal regions of the reticular arbor. Quantitative measures of greatest dendritic extent, number of dendrities, branchedness, and somal size reflect the state of the neuropil into which these cells extend.

Comparison of these quantified parameters in control and experimental conditions demonstrates the effects of nutritional rehabilitation. A significant increase of proximal dendritic varicosities (nodules) is noted in the experimental group. This denotes that the course of development may be slightly delayed but has rehabilitated since the severely affected neonatal stage. The neuropil appears much more dense at this age since dendritic extent is now signficantly reduced in the experimental group. While numbers of primary dendrites remain the same in both groups, there is a suggestion of increased branchedness in the experimental group.

The obvious differences of dendritic morphology in the experimental group reflect variations in the neuropil as well as reactions of the rehabilitated cell to its surround. The slight reduction in dendritic extent may indicate resistance to dendritic growth by increased glial proliferation in the experimental brainstem while an increase in branchedness illustrates a compensatory effort to sustain dendritic elaboration by the neuron.

278.11 CEREBELLAR HISTOGENESIS DURING GRAFT VERSUS HOST DISEASE. E.N. Crom*, G.W. Miller*, and W.S.T. Griffin (SPON: R.S.A. Tindall), The Univ. Texas Hlth. Sci. Ctr., Dallas, Texas 75235.

A variety of stresses have been shown to alter cerebellar histogenesis. Graft versus host disease (GVHD), caused by grafting mature lymphocytes into an immature host, induces easily assessable alterations in cerebellar histogenesis without comprimising structural integrity. We have previously reported alterations in both cerebellar DNA synthesis and total accumulation of DNA during the progression of this neonatally-induced immunological disease, and this study was an investigation of events which could lead to these findings. Utilizing short pulses of 3H-thymidine to label DNA for assessing the rate of DNA synthesis, autoradiography, to determine the mitotic index, histological analysis of the ratios of cells in mitosis per germinal cell and the stage of mitosis of each mitotic figure, we showed that upon comparison of diseased animals with littermate controls the rate of DNA synthesis was slowed in diseased animals and there were fewer cells with silver grains above them in spite of the fact that there were equal numbers of germinal cells in the external granular layer and an equal number of mitotic figures in diseased and control animals. However, an analysis of the stage of mitosis of each mitotic figure revealed that significantly more mitotic figures in cerebella from animals with GVHD were in metaphase and the subsequent stages of mitosis. Preliminary electronmicroscopic studies of mitotic figures have failed to reveal significant alterations in spindle formation or the chromasomes. These findings suggest that the lesser accumulation of DNA overtime in cerebella from animals with GVHD is not due to a decrease in available DNA precursor nor is it due to a decrease in the number of germinal cells in the external granular layer, but rather it is due to an inability of mitotically active cells to proceed from metaphase anaphase and telophase into G_0 or G_1. We believe that the cerebellar effects due to GVHD can be generalized and will provide a model system for the study of histogenesis in other areas of the CNS as well as in a variety of other organs, both lymphoid and nonlymphoid.

278.12 SELECTIVE DEPLETION OF SPINAL NOREPINEPHRINE IN THE NEONATAL RAT BY SYSTEMIC AND INTRASPINAL 6-HYDROXYDOPAMINE: EFFECTS ON THE POST-DECAPITATION REFLEX. R. M. INGS* and B. A. PAPPAS, Department of Psychology, Carleton University, Ottawa, Ontario, Canada. K1S 5B6

Neonatal 6-hydroxydopamine (NS-6-OHDA, sc., days 1 & 2) did not alter the levels of dopamine (DA) or serotonin in the thoracic spinal cords of Wistar rats aged 5,10,15,20,30, or 60 days. Norepiniphrine (NE) levels were reduced at ages >15 days when a precipitous decline from the control levels was observed. In NS-6-OHDA groups the latency of the post-decapitation reflex (PDR, normally around 1-3 sec.) was infinite at 5 and 60 days but was only attenuated at 15 through 30 days. The number of bilateral clonic kicks in these groups, although markedly attenuated, followed the inverted u-shaped profile of vehicle groups including a plateau from 15 to 20 days of age. A possible α-NE mediation of the temporary return of the PDR at 15 through 30 days in 6-OHDA treated rats was rejected since chlorpromazine, phenoxybenzamine or yohimbine administered to 17 day old rats did not further attenuate the PDR. A serotonin mediation of the PDR at this age was contraindicated by the absence of any effect of p-chlorophenylalanine.

Injection of 6-OHDA (10 ug) directly into the spinal cords (IS-6-OHDA) on the first two days of life selectively decreased NE at 35 days to 7,14, and 13 % of control levels in cervical, thoracic, and lumbar spinal cord segments respectively. The cortex plus hippocampus and cerebellum showed no alteration while brainstem levels were increased to 163% of control. This may be due to localized sprouting of NE terminals from the locus coeruleous when the spinal projections from this nucleus are destroyed. Serotonin levels were elevated in all areas but significant only in the thoracic cord segment. The PDR was completely eliminated by IS-6-OHDA at this age.

Pretreatment with desmethylimipramine eliminated the NE reduction, and protected against the loss of the PDR, but surprisingly did not result in DA depletions in any area. Increased brainstem DA levels however, suggested a stimulated local DA arborization process in some ways analogous to that observed after IS-6-OHDA alone.

278.13 BEHAVIORAL DEFICIT INDUCED IN ADULT RATS FOLLOWING PRENATAL ADMINISTRATION OF ANTIBODIES TO GANGLIOSIDE. Rapport, M.M. and Karpiak, S.E., (SPON: H. Barden). Div. of Neuroscience, N. Y. State Psychiatric Institute and the Depts. of Psychiatry and Biochemistry, College of Physicians and Surgeons, Columbia University, New York, N. Y. 10032.

In previous experiments (1,2) rats receiving an injection at 5 days of age of antiserum to brain ganglioside (into the cisterna magna) showed at maturity impaired performance on a complex learning task (DRL), as well as chemical and morphological alterations in the somatosensory cerebral cortex. The contents of ganglioside sialic acid, galactocerebroside and RNA were decreased (with no loss in DNA), and changes in the number and configuration of oblique dendritic spines were seen. The animals otherwise developed normally and demonstrated typical patterns of behavior. No changes were observed in rats injected either with antiserum which had been absorbed with pure G_{M1} ganglioside (to remove specific antibodies) or saline. In order to determine if an earlier insult would induce similar or more pronounced behavioral alterations, pregnant rats (Day 19 of gestation) were injected intravenously either with antiserum to brain ganglioside or with control antiserum (absorbed with pure G_{M1}ganglioside) or saline. All rat litters developed normally. At 70 days of age, rats were tested on the same DRL paradigm as had been used in the earlier experiments with animals injected on postnatal day 5. The test design was based on progressively more difficult DRL learning schedules: 5,7,10 and 15 sec. delay sequences over a 40 day period. Rats injected prenatally with antiserum to ganglioside showed a significant learning deficit of the DRL behavior only at the DRL-15 sec. level ($p<.025$). Since rats injected at Day 5 had shown deficits at both the DRL-10 ($p<.05$) and DRL-15 sec. ($p<.01$) levels, the postnatal 5th day appears to be a more critical developmental period than the 19th embryonic day for immunologic insult with antibodies to G_{M1} ganglioside. This result is consistent with the hypothesis that interference with dendritic arborization is the mechanism by which antiganglioside antibodies inhibit development.

278.14 ENRICHED PROTEIN INTAKE DURING EARLY BRAIN GROWTH OF ARTIFICIALLY REARED RATS. Jaime Diaz, Colleen Stamper*, Elizabeth Moore*, Jack Schacher*, and Frances Petracca*. Dept. of Psychology, University of Washington, Seattle, WA 98115.

Low protein intake during development may produce deficits in brain growth, even though the available protein will be shunted preferentially to the developing brain.

The artificial rearing procedure first introduced by Messer, et al. (J. Nutr., 98, 1969) permits the direct examination of dietary variables upon brain development. The milk formula used by Messer, et al. contains 5.5 grams% protein, whereas rat milk contains approximately 9 grams% protein (Dymza, et al., J. Nutr., 84, 1964). The purpose of the present study was to examine the effects of two formulas - the "Messer" formula and a formula containing 8.5 grams% protein - on animals artificially reared.

Four day old female Long-Evans hooded rat pups were matched by weight and assigned to one of two groups: 1) animals artificially reared with a formula containing 5.5 grams% protein (the diet used by Messer) or 2) animals artificially reared with a formula containing 8.5 grams% protein (the Messer formula with 3 grams% of casein hydrolysate added). All the animals were infused with the same amount of formula at the same rate. The animals were weighed each day, reflex tested, and the occurrence of developmental milestones was noted. On day 18, all the animals were tested in an open field and then sacrificed. Their brains were removed, dissected and weighed as were their livers, kidneys, and spleens.

The results indicate that by day 18 there was a significant difference in body weight between the two groups. Animals receiving the protein enriched diet were 11% larger ($p<.05$). This difference was also reflected in peripheral organ weights. For all brain parameters there were no differences between the groups. The ontogeny of reflexes and the occurrence of developmental milestones followed the same pattern. Significant differences were found in open field behavior between the two groups.

The daily weights of the animals fed formula with less protein matched those of their normally reared siblings. Although the body weights of animals fed the higher protein formula were greater than those of animals fed the lower protein formula, the brain weights of the animals in the higher protein group matched those of the animals in the lower protein group. Nevertheless, the significant differences in the behavior of the two groups in the open field suggest that the added protein in the formula did exert an influence on brain development which may be too subtle to detect by gross tissue weights.

278.15 THE EFFECTS OF NERVE GROWTH FACTOR (NGF) AND OF ANTI NGF-ANTIBODIES ON THE DEVELOPMENT OF SUBSTANCE P-CONTAINING SENSORY NEURONS. U. Otten, M. Goedert*, N. Mayer* and F. Lembeck*. Department of Pharmacology, Biocentre of the University, Basel, Switzerland and Department of Experimental and Clinical Pharmacology, University of Graz, Austria.

The investigation of the physiological importance of NGF for the development of sensory neurons has been limited so far by the absence of specific biochemical marker substances for these neurons. The recent demonstration that the undecapeptide substance P is present in sensory neurons suggests that it might be such a marker. Substance P is synthesized in dorsal root ganglia and transported to the terminals of C-fibres located in the dorsal horn of the spinal cord and in the skin. In the present study the effects of NGF and of purified anti NGF-antibodies on the content of substance P in rat dorsal root ganglia and in their respective target organs, spinal cord and skin were examined. The effects on tyrosine hydroxylase activity in sympathetic superior cervical ganglia were included as a control for the effectiveness of both NGF and its antibody.

Repeated injections of NGF led to an increase in substance P in rat spinal ganglia (Th 10-12) from 131±20 to 220±14 pg substance P/ganglion. The administration of anti NGF-antibodies caused a gradual decrease in substance P up to 17 days after injection. This reduction was paralleled by a decrease in substance P content of both the spinal cord and the skin. Neither NGF, nor its antibody had any significant effect on the protein content of dorsal root ganglia.

The total tyrosine hydroxylase activity in superior cervical ganglia showed a 3-fold increase after repeated administration of NGF, whereas the injection of anti NGF-antibodies produced an almost complete disappearance of tyrosine hydroxylase activity, thus indicating optimal effects of NGF and of its antibody on sympathetic ganglia.

Our results indicate that postnatal sensory neurons are responsive to NGF and that they require NGF or a cross-reacting NGF-like molecule for their normal development as evidenced by the decrease in substance P content after the administration of anti NGF-antibodies to newborn animals.

278.16 NEURONAL DEATH IN NORMAL AND NGF-TREATED SPINAL GANGLIA. V. Hamburger, J. Brunso-Bechtold and J. Yip. Dept. of Biology, Washington University, St. Louis, MO 63130.

We have established well-defined periods of neuronal death for the two populations of neurons in thoracic dorsal root ganglion 18 of the chick embryo, by counting clearly degenerating neurons in every other section. In the population of large, early differentiating ventro-lateral neurons (VL), the period extends from stages 25 to 33 (4½ - 7½ days), with a peak at stage 27. Degeneration in the small, late-differentiating dorso-medial neurons (DM) extends from stage 34 to stage 36 (8-10 days), with a peak at stages 34 and 35.

To test the effect of Nerve Growth Factor (NGF) on survival of neurons, we made daily injections of 6 µg of NGF into the yolk sac, from stage 21 (3½ days) to the day preceding sacrifice. Degeneration in the VL neuron population was reduced by at least 50%; degeneration in the DM neurons was prevented, except for a small amount of cell death toward the end of the degeneration period.

Preliminary data for brachial ganglion 15 indicates similar periods of degeneration for VL and DM populations, except that the degree of neuronal loss of LV cells is considerably lower than in ganglion 18. NGF injections, following the same protocol as above, had the same effects.

These results show that NGF has a trophic maintenance effect on neurons of embryonic spinal ganglia in vivo. This is the first demonstration that VL cells respond to NGF.

Supported by NIH 08RINSO 57210 and grant from Muscular Dystrophy.

278.17 ANTI-ISCHEMIC EFFECTS OF PENTOBARBITAL IN CATS-CEREBROPROTECTION AFTER 6 AND 72 HOUR ADMINISTRATIONS. J. P. Hansen* and W. J. Giardina. Department of Pharmacology, Abbott Laboratories, North Chicago, IL 60064.

The protective effects of pentobarbital against cerebral ischemia in animals have been widely reported. (Michenfelder, et al., Archives of Neurology, 33:345, 1976; Moseley, et al., Neurology, 25:870, 1975). For the purpose of studying peak time of pentobarbital's cerebroprotective action, regional cerebral ischemia was produced in cats. Cats were anesthetized with ketamine HCl (15 mg/kg/i.m.) and pentobarbital (5 mg/kg/i.v.). The left middle cerebral artery (LMCA) was occluded by electrocoagulation using a transorbital approach. In the first experiment, 3 sham operated cats and 4 cats with LMCA occlusion were sacrificed 72 hours after surgery. In the second experiment, pentobarbital (90 mg/kg) [3 cats] or saline (36 ml) [3 cats] was administered parenterally in divided injections over 72 hours. Administration began 30 min. after occlusion, and cats were sacrificed at 72 hours. In the third experiment, pentobarbital (20 mg/kg) [3 cats] or saline (8 ml) [3 cats] was administered parenterally in divided injections over 6 hours. Administration began 30 min. after occlusion of the LMCA, and cats were sacrificed at 48 hours. Neurological examinations were made at 1, 3, 24 and 48 hours after LMCA occlusion. Five min. before sacrifice, anesthetized cats were injected i.v. with sodium fluorescein (10% solution). Cats were then perfused with normal saline and buffered formalin. Brains were sectioned in situ at sterotaxic coordinates AP +19, +14, +9, +4 and -1. The anterior surface of each section was photographed under ultraviolet light. The area of induced fluorescence for each section was measured with a planimeter. Planimetry was also used to measure the increase in the size of the affected hemisphere caused by edema. Light microscopy was used to examine the anterior surface of each tissue section for ischemia-induced damage. Following LMCA occlusion, cats developed hemiplegia. They showed marked curvature of the torso, and when able to walk, circled to the left. Cats receiving pentobarbital for 6 or 72 hours showed less ischemia-induced injury to brain tissue than corresponding saline treated controls. Ischemia-induced injury to brain tissue in the 6 and 72 hour treatment groups was similar. These data suggest that the cerebroprotective effects of pentobarbital against ischemia-induced cellular insult occurred within the first few hours after its administration. Prolonged administration of large doses of pentobarbital may not be required to achieve a cerebroprotective action.

278.18 NEW GERBIL STROKE MODEL. Charles J. Hannan, Jr. Clinical Investigation Service, Eisenhower Army Medical Center, Fort Gordon, GA 30905.

Variability in occurrence and extent of cerebral infarction with the unilateral carotid occlusion version of the gerbil stroke model is a serious limitation of the method. It was hypothesized that unilateral infarction could be more consistently obtained by limiting the reactive hyperemia through the contralateral carotid artery. It was observed in gerbils, which had both carotids exposed, that unilateral occlusion invariably resulted in distension of the patent carotid artery. Presumably, the animals with sufficient anterior communicating artery capacity would avoid infarction and those with limited interhemispheric blood flow capacity would develop infarction and probably die within 3 days. In an attempt to control for this variability a modified Ligaclip® (Ethicon brand small tantalum ligating clip, LC-100) was used to restrict, but not prevent, blood flow in the patent right common carotid artery of gerbils that had their left common carotid artery completely occluded. To prevent complete closure of the ligating clip, an approximately 1 mm long segment of a 30 gauge needle was epoxied to the inner surface. Nineteen male retired breeder Mongolian gerbils (70-102 grams) were prepared as described above while under ketamine anesthesia (100 mg/kg,ip). The totally occluded left carotid artery was clamped with a standard small ligating clip and the artery cauterized distal to the occlusion.

Mortality data was compiled for five days after which survivors were perfusion-fixed with buffered formalin. Horizontal sections of brain were histologically examined. All modified ligation clips were removed and measured under a microscope. Results are summarized below:

		Modified Clip Width (mm)		Gerbil Weight (gms)	
Day 5	n	Mean ± SD	Range	Mean ± SD	Range
Died	9	.20±.03	.15-.22	80.9±8.9	70-89
Survived	10	.24±.03	.20-.28	85.4±10.7	72-102

One-way analysis of variance reveals a significant difference ($p<.01$) between the clip widths of animals which died and those which survived. There was no significant difference in weight between these groups before the occlusion was induced. The mortality (47%)was higher in these animals than in other retired breeders given only a unilateral occlusion (unreported data) and points to the usefulness of this model, however greater uniformity in the width of the flow-restricting clip must be attained.

279.1 TRANSFER OF MICROPEROXIDASE ACROSS CEREBRAL ARTERIOLES IN THE MOUSE UNDER NORMAL CONDITIONS. E. Westergaard. Anatomy Department C, University of Copenhagen, Copenhagen, Denmark.

From previous light microscopical and fluorescens microscopical studies it has been concluded that there is a blood-brain barrier (BBB) to intravenously injected Evans blue, trypan blue and Na-fluorescein. However, the possibility exists that small amounts, not visible because of the methods' limitations, in fact crossed the BBB. The mentioned dyestuffs bind to albumin in the blood. Later horseradish peroxidase (HRP) was used as tracer, and it was demonstrated by electron microscopical investigations, that a few, short segments of arterioles transferred HRP across the endothelium. HRP (MW: 40,000) does not bind to albumin, and it is likely that the mechanism underlying the passage is vesicular transfer. Other tracers have been used, e.g. microperoxidase (MP, MW: 1,900). It has been observed that MP, like HRP, is transported across the endothelium in short arteriolar segments (15-30 μ in diameter). No sign of interendothelial movement was obtained. The tight junctions might have functioned as a barrier to this small molecule. Some of the injected MP bind to albumin, but part of the MP circulated freely in the blood stream. It is also concluded for MP, that the tracer might have been transferred by vesicles across the endothelium in a few segments of small arterioles of the brain. However, it was not possible to determine whether or not the amount of MP, that crossed the endothelium was bound to albumin. There was no sign of intercellular movement.

279.2 MEASUREMENT OF BRAIN GLUCOSE UTILIZATION WITH THE CAROTID INJECTION TECHNIQUE. W.M. Pardridge, P.D. Crane*, L.D. Braun*, and W.H. Oldendorf*. UCLA School of Medicine, Los Angeles, Ca. 90024

The carotid injection technique, used previously to study the kinetics of blood-brain barrier glucose transport, may be modified to quantitate the rate of cerebral glucose utilization in individual rats. An approximately 200 uL bolus of Ringer's solution containing 2-^{14}C-glucose and ^{3}H-methylglucose (M) was rapidly injected via a common carotid artery in barbiturate-anesthetized rats. At various times up to 4 min after injection, circulation was terminated by microwave irradiation. Based on a 2-compartment model, the following relationships were derived,

$$\ln G_F/M = \ln G_F^o/M^o - k_3 t \quad (1)$$

$$G_T/M = \left(\frac{k_2}{k_2 + k_3}\right) e^{-k_3 t} + \left(\frac{k_3}{k_2 + k_3}\right) e^{k_2 t} \quad (2)$$

where k_2 = the rate constant of glucose or methylgluocse efflux from brain to blood, k_3 = the rate constant of glucose phosphorylation, t = the time after carotid injection, G_F/M = the ratio of ^{14}C/^{3}H dpm in the post-column neutral fraction divided by the ^{14}C/^{3}H dpm ratio in the injection solution (the superscript refers to zero time) and G_T/M = the ratio of ^{14}C/^{3}H dpm in brain without chromatographic separation divided by the same ratio in the injection solution. The use of model (2) is based on the assumption that no loss of brain ^{14}C-radioactivity occurs due to efflux of labeled metabolites of 2-^{14}C-glucose over short experimental periods. This latter assumption was tested by a third model,

$$G_T/G_F = \left(\frac{k_2}{k_2 + k_3}\right) + \left(\frac{k_3}{k_2 + k_3}\right) e^{(k_2 + k_3)t} \quad (3)$$

where G_T/G_F = the ratio of total homogenate ^{14}C dpm to ^{14}C dpm in the post-column neutral fraction. The G_T/G_F ratios at 0.25-4.0 min after carotid injection were fitted to equation (3); these results indicated k_2 = 0.14 ± 0.08 min^{-1} and k_3 = 0.21 ± 0.02 min^{-1} (mean ± SD). The plot of ln G_F/M vs time (equation 1) was linear (r = 0.99) with a slope, k_3 = 0.21 min^{-1}. The rate of brain glycolysis = (brain glucose concentration) x (k_3) = (2.6 umol/g) x (0.21 min^{-1}) = 0.55 umol/min/g for cortical tissue in the barbiturate-anesthetized rat. Conclusions: a) The identical estimates of k_3 as determined by either equation (1) or (3) supports the validity of the assumption of negligible loss of radioactivity from 2-^{14}C-glucose metabolites. b) Blood-brain barrier transport and brain glucose metabolism may be studied with the carotid injection technique using a ^{3}H-methylglucose internal reference.

279.3 SEX AND DEVELOPMENTAL EFFECTS ON GLUCOSE UPTAKE IN CEREBRAL MICROVESSELS. K. M. A. Welch. Dept. of Neurology, Baylor Coll. of Med., Houston, TX 77030.

Experimental studies of brain glucose uptake in vivo have shown clear developmental and sex differences (Daniel et al., J. Physiol.274:141-148,1978). The experiments reported here have examined the influence of development and sex on glucose uptake into the endothelial component of the blood-brain barrier.

Microvessels were isolated by albumin flotation and glass bead filtration (Goldstein et al., J. Neurochem.28:723-725,1977) from the brains of rats of 3 week (early development) and 9 month (adult) age. In vitro 2-deoxy-D-glucose (2-DG) uptake into the isolates was studied. 2-DG uptake was higher in 9-month old rats than in 3-week old rats. Further, in 3-week old rats, 2-DG uptake was higher in females than in males.

The increasing uptake of glucose with age is consistent with increasing cerebral energy demand as these animals reach their adult prime. Further, it is suggested that the significant difference occurring between the sexes for the 3-week old animals is an indication of the differential rate of maturing for males vs. females, that the blood-brain barrier reflects this differential rate, and that this barrier has not yet reached maturity in the males. There may be a "pivot-point" age for each sex after which the blood-brain barrier is complete.

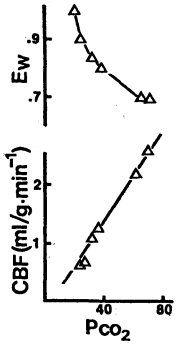
279.4 SIMULTANEOUS MEASUREMENT OF BRAIN PERMEABILITY AND BLOOD FLOW IN THE RAT. G. Irwin* and S. Preskorn (SPON: C. Hughes). Depts. of Psychiatry and Clinical Pharmacology, University of Kansas Medical Center, Kansas City, KS 66103.

Tracer techniques have been used extensively to evaluate cerebral microcirculation. These techniques measure the uptake of a bolus of radionuclide-labeled test substance relative to uptake of a reference tracer during a single transit through brain vasculature. Results are routinely expressed as brain uptake index (BUI) or extraction fraction (E). Interpretation of such results is confounded by dependence of these measures on factors other than capillary permeability. As shown by Renkin (Am. J. Physiol., 1959), uptake during a single vascular transit (E) is related to the permeability coefficient (P), capillary surface area (S), and blood flow (F) as defined by the equation: ln (1-E) = -PS/F. Alteration in E may reflect changes in F as well as changes in PS. For this reason, simultaneous measurement of E and cerebral blood flow (CBF) as accomplished by the ^{15}O method of Raichle and co-workers (Amer. J. Physiol., 1976) is highly desirable. However, need for extensive support equipment (e.g., a linear accelerator) render this method impractical for most investigators. A simple small-animal procedure by which E and CBF might be measured is thus needed.

In the present study, Ew--the cerebral extraction fraction for water--was determined by administering i.v. a tracer solution of ^{3}H-water and ^{14}C-butanol as previously described (Preskorn et al., JPET, 1980). CBF was measured by comparing brain uptake of ^{14}C-butanol with the quantity of ^{14}C-butanol in an arterial blood sample withdrawn at a known, uniform rate. This measure of CBF was validated by comparing results with CBF measured using ^{141}Ce-labeled microspheres. The response of Ew and CBF to altered arterial P CO_2 is shown below. Our measures of Ew and CBF were also shown to be sensitive to amitriptyline, an antidepressant known to effect cerebral microcirculation (Preskorn and Hartman, Biol. Psych., 1979). (Supported by USPHS grants GM 15956 and MH 27201).



279.5 INCREASED LOCAL CEREBRAL GLUCOSE UTILIZATION (LCGU) FOLLOWING OPENING OF THE BLOOD-BRAIN BARRIER BY HYPERTONIC ARABINOSE INFUSION AND BY ACUTE HYPERTENSION. S.I. Rapoport, W.R. Fredericks*, D. Dow-Edwards, E.D. London. Lab. of Neurosciences, National Inst. on Aging, GRC, Baltimore City Hosp., Baltimore, MD 21224.

The blood-brain barrier (BBB) at the continuous cerebrovascular endothelium can be made permeable by infusing a hypertonic solution of arabinose or mannitol into the carotid circulation (Rapoport et al., Am. J. Physiol., in press). Osmotic BBB opening transiently increases brain uptake of ^{14}C-2-deoxy-D-glucose (Spatz et al., Neuropath. Appl. Neurobiol. 2, 53, 1976) and increases local cerebral glucose utilization (LCGU) (Pappius et al., Ann. Neurol., 5, 211, 1979), as measured by the method of Sokoloff et al. (J. Neurochem. 28, 897, 1977). We wanted to know if the increased LCGU following BBB opening is influenced by the stimulation of central α- or β-adrenergic receptors, or if the increase is due to entry of K^+ (from a high plasma concentration to a low brain extracellular concentration) which could stimulate neuronal activity. We also wanted to know if LCGU rises following hypertensive BBB opening.

In conscious rats, the BBB was osmotically opened on the ipsilateral hemisphere by retrograde infusion of 1.8 molal arabinose for 30 sec. into the external carotid artery at a rate of 0.1 ml/sec. 0.35 ml of 2% Evans blue albumin was injected i.v. 5 min before arabinose, and served as an indicator of the degree of BBB opening. Each animal treated in this way was in one of 4 groups: control, propranolol (β-adrenergic blocker, 5 mg/kg i.v. 5 min before and 2.5 mg/kg 25 min after arabinose), phenoxybenzamine (α-adrenergic blocker, 40 mg/kg i.p. 15 min before arabinose), or maintained on a potassium-free diet to reduce plasma K^+ below brain extracellular K^+.

^{14}C-2-deoxy-D-glucose was injected i.v. 15 min after arabinose, and LCGU was estimated by comparing optical densities in autoradiographs of perfused and contralateral cerebral hemispheres. In other rats, the BBB in one cerebral hemisphere was opened by acute hypertension. Isotonic saline was infused into the common carotid artery for 10 sec at a rate of 0.4 ml/sec in a cephalad direction after ligating the external carotid artery (Rapoport, Exp. Neurol., 52, 467, 1976). LCGU was elevated not only in the ipsilateral hemisphere which was stained blue, but also in the contralateral hemisphere. The results indicate that BBB opening, whether by osmotic infusion or by hypertension, is followed by an increased LCGU. The increase is not mediated by α- or β-adrenergic receptors, and is not due to entry of K^+ from plasma to brain. At present, the cause of the increased LCGU is not known.

279.6 IMPAIRED CEREBROSPINAL FLUID ABSORPTION IN THE DEVELOPING RABBIT FOLLOWING EXPOSURE TO LEAD. J. D. Mann and S. L. Cookson*. Dept. Neurology, U. North Carolina, Chapel Hill, N.C. 27514.

Lead intoxication in developing animals is associated with pericapillary hemorrhages, brain edema and increased intracranial pressure. Since bulk absorption of cerebrospinal fluid (CSF) into the venous circulation is a critical part of intracranial pressure regulation, an increase in resistance to absorption would contribute significantly to the development of cerebral edema in association with exposure to lead. Transport of CSF through endothelial cells covering the arachnoid villi is the final process in CSF absorption. In the present study, we have tested the hypothesis that lead, an endothelial cell toxin, interferes with endothelial cell transport of CSF at the arachnoid villi, resulting in impaired CSF absorption.

Intracranial pressure/volume regulation and CSF dynamics were assessed under halothane anesthesia in groups of albino rabbits at 10, 22 and 35 days of age. Lead acetate was administered orally in doses of 3.5, 10.0 and 165.0 mg/day respectively for five consecutive days prior to testing. Controls were give sodium acetate in equimolar (acetate) amounts. Brain lead levels were 0.316 ± 0.024 ug/g (S.D.) for lead intoxicated animals compared to 0.023 ± 0.008 ug/g for controls. Assessment of intracranial fluid dynamics was carried out using a constant flow, manometric infusion technique with continuous monitoring of intracranial pressure (Mann et al., Ann. Neurol. 3:156-165, 1978). Data were analyzed for resistance to CSF absorption, rate of CSF formation, and intracranial compliance.

Changes reflecting maturation of the CSF bulk flow system were noted in the control animals. With development there was a progressive fall in resting intracranial pressure, a rise in CSF formation rate, and a marked improvement in CSF absorption at higher intracranial pressures. Resting intracranial pressure was significantly elevated in lead exposed animals compared to age-matched controls in all three groups ($p<.01$). Brain water content was not increased and CSF formation was unchanged compared to controls. Resistance to CSF absorption was increased in all lead exposed animals at intracranial pressures above 200 mm H_2O, reflecting a disturbance in high pressure, high volume CSF absorption. This finding was particularly noteable in the 10 day old animals where resistance to absorption was increased by more than 40% at pressures of 300 mm H_2O. Our results indicate that lead induced impairment of brain barrier systems includes mechanisms for bulk removal of CSF from the intracranial compartment, independent of the development of brain edema. Results also support the concept of lead as an endothelial cell toxin in the venous portion of the cerebrovascular tree, adversely affecting endothelial cell regulation of CSF absorption.

279.7 GRAFTED BRAIN TISSUE ELICITS BLOOD-BRAIN BARRIER CHARACTERISTICS IN MESENTERIC BLOOD VESSELS. P.A. Stewart and M.J. Wiley*. Dept. of Anatomy, Univ. of Toronto, Toronto, Ont. Canada M5S 1A8

Brain capillaries have structural and functional characteristics that constitute a regulatory interface or "barrier" between the blood and the brain. Because the endothelial cells of the brain capillaries are interconnected by tight junctions, blood-bourne solutes cannot diffuse between them, and so must pass through them to enter the brain. The endothelial cells contain specific transport systems that facilitate the passage of some molecules and degradative enzymes that inhibit or prevent the passage of others. Avian brain capillaries are characterized structurally by tight junctions, and histochemically by alkaline phosphatase and cholinesterase activity. We have found that the density of mitochondria is higher in avian brain capillaries than in capillaries elsewhere in the body, as has been described in other species.

We questioned whether these "barrier" characteristics develop only in brain capillaries or whether capillaries elsewhere in the body could form a barrier if they were made to vascularize grafted brain tissue. A major obstacle in this approach is that when embryonic tissues are transplanted to an ectopic site, their own blood vessels survive and form a part of the new vascular system. This has made the results of previous experiments difficult to interpret. We overcame this problem by transplanting fragments of early embryonic quail brain that had not yet been vascularized into the coelomic cavity of 3-day host chick embryos. The grafts grew and differentiated and were vascularized by the chick mesenteric vessels. The distinctive morphology of the quail nucleus allowed us to demonstrate unequivocally that the capillaries in these grafts are of host origin.

After 2½ weeks of growth the graft capillary endothelial cells were connected by tight junctions and contained a high density of mitochondria and few pinocytotic vesicles. Both alkaline phosphatase and cholinesterase activity could be demonstrated histochemically in the capillaries. A trypan blue solution injected intramuscularly into the host embryo was excluded from the graft tissue. All of these characteristics were absent in the capillaries of the adjacent gut and mesentery.

These results indicate that during normal embryogenesis the development of barrier characteristics in the in-growing capillaries may be elicited by the brain tissue.

279.8 RELATIVE PERMEABILITY OF THE BLOOD-BRAIN AND BLOOD-CSF BARRIERS TO ^{22}Na AND ^{36}Cl. Quentin R. Smith, Conrad E. Johanson, and Dixon M. Woodbury. Dept. Pharmacology, Univ. of Utah College of Medicine, Salt Lake City, Utah 84132.

Though radioactive ion movement across the brain capillaries (blood-brain barrier) has been investigated extensively in the past, few experiments have examined the role of the choroid plexus epithelium (blood-CSF barrier) in ion movement into the CNS. At present, the concept of a high resistance capillary endothelium in parallel with a low resistance choroidal epithelium has evolved. However, the net influx into the CNS would move largely across the blood-brain barrier due to the greater total surface area of the brain capillaries. To test this hypothesis, we conducted the following experiments.

Sprague-Dawley albino rats (90-110 g) were bilaterally nephrectomized under ether anesthesia 4 hr prior to sacrifice. At 1/12, 1/6, 1/4, 1/2, 1, 2, 4, 6, or 8 hr before death, each animal was injected with 0.1 μCi/g of ^{22}Na or ^{36}Cl (0.9% NaCl). Samples from the CNS (cerebral cortex, cerebellum, lateral ventricle choroid plexus (LVCP), fourth ventricle choroid plexus (4VCP), and cisternal CSF) and the periphery (plasma, blood, skeletal muscle, and submaxillary salivary gland) were assayed for radioactivity. Values were expressed as a space (%) = 100 x (dpm/g tissue or CSF)/(dpm/g extracellular fluid H_2O). Uptake curves for the CNS regions were resolved into components by graphical analysis to obtain rate constants and volumes of distribution for the components. Lastly, rate constants were converted to permeability-surface area products (PA), which can be directly related to permeability when the corresponding surface-areas are known.

Cerebral cortex PA values for ^{22}Na and ^{36}Cl agree well with previously published estimates, $PA_{Na} = 0.11$ and $PA_{Cl} = 0.09$ g extracellular fluid/hr/g tissue. For the cerebellum, $PA_{Na} = 0.16$ and $PA_{Cl} = 0.14$, 50% greater than for the cerebral cortex. As predicted by the hypothesis, PA values for the choroid plexuses were up to 3 times larger than those for the brain; LVCP $PA_{Na} = 0.10$ and $PA_{Cl} = 0.31$, 4VCP $PA_{Na} = 0.25$ and $PA_{Cl} = 0.23$. Literature estimates of surface area/g tissue for the capillaries of the cerebral cortex (100-240 cm^2/g) and for the basolateral membranes of the choroid plexus (112-180 cm^2/g) are approximately equal. However, when the mass of the rat brain (1.2 g) is compared to that of the choroid plexuses (0.005 g), the net radioisotope influx into the CNS would be largely associated with movement across the blood-brain barrier. (This work was supported by NIH grants NS 13988, GM 07579, and AM 20935.)

279.9 CHANGES IN THE CONCENTRATION OF BICARBONATE AND HYDROGEN ION IN THE IN VITRO CHOROID PLEXUS EPITHELIUM IN RESPONSE TO ALTERATION IN CEREBROSPINAL FLUID BICARBONATE AND pH. Z. Parandoosh* and C.E. Johanson. Dept. Pharmacology, Univ. of Utah College of Medicine, Salt Lake City, Utah 84132.

There is considerable evidence that the choroid plexus (CP) has an active role in cerebrospinal fluid (CSF) pH regulation. However, the mechanisms of H/HCO_3 transport in the CP are not well understood. To quantify changes in choroid cell [H] and [HCO_3] in response to alterations in the CSF concentration of these ions, we utilized an in vitro CP preparation and the ^{14}C-DMO (dimethyloxazoladinedione) method to indicate cell pH.

Choroid plexuses from the lateral and fourth ventricles in adult Sprague-Dawley rats were pooled for incubation in a synthetic CSF medium. Each of the 28 incubations was carried out for 30 min at 37° C. CSF [HCO_3] was varied over a range of 10 to 52 mM/L by displacing NaCl in the medium with $NaHCO_3$; thus, for each incubation CSF [Na] and osmolarity were constant at 141 mM/L and 290 mOsm/L, respectively. Bath pCO_2 was held as constant as possible between 20 and 30 torr. After each experiment measurements were made of CP H_2O content and ^3H-inulin space (for extracellular fluid volume), and of CSF pH and pCO_2. CP pH was calculated from the steady-state distribution of ^{14}C-DMO between tissue and medium.

There was an inverse relationship between CSF [HCO_3] (range 10 to 52 mM/L) and both the CP H_2O content (range 82 to 78%) and the CP ^3H-inulin space (range 42 to 35%). At CSF HCO_3 concentrations of 10, 18 and 52, respectively, the choroid cell [HCO_3] was 2, 7 and 19 mM/L H_2O; corresponding values for cell pH were 6.51 + .02 (SEM), 6.98 + .04 and 7.42 + .03. Thus, the Δchoroid cell [HCO_3]/Δ CSF [HCO_3] was approximately 0.4, similar to the corresponding value of 0.35 for in vitro renal tubule cells (Struyvenberg et al., 1968). The relationship between internal and external acidity can be described by a straight line, $y = -56 + 4.4x$ ($r = 0.92$), where y and x are [H] in CP and CSF, respectively. Thus, the slope of Δchoroid cell [H]/Δ CSF [H] is approximately an order of magnitude greater than that for renal tubule cells. The substantial increase in choroid cell [H] from 39 to 309 nM/L as the medium (CSF) [H] is increased from 16 to 78 nM/L suggests that there is a sensitive homeostatic transport mechanism in CP for removing H ion from the CSF as this fluid becomes more acidic. (Supported by NINCDS grant #NS 13988.)

279.10 A NEW TECHNIQUE TO EVALUATE REGIONAL BLOOD-BRAIN BARRIER PERMEABILITY TO ZINC. Scott A. Burton* and C.E. Johanson. (SPON: S. Turkanis) Univ. of Utah Col. of Med., Salt Lake City, Utah 84132.

Zinc has been associated with a number of CNS disorders; high zinc serum levels with epilepsy and zinc deficiency with depression, confusion, and dementia. Zinc uptake was measured by a single-injection method. Isotonic NaCl (0.2 ml, pH 7.4) containing $^{65}ZnCl_2$ and ^{14}C-iodoantipyrine was injected (< 0.4 sec) into the inferior vena cava of etherized Sprague-Dawley rats. In contrast to the Oldendorf technique, this method permits uptake studies in infant rats and insures that all areas of the CNS are adequately perfused with the injectate. 30 sec after injection, animals were decapitated and the brains rapidly removed. The brain uptake ratio (BUR) of Zn was defined as:

$$BUR = \frac{DPM\ ^{65}Zn(tissue)/DPM\ ^{14}C\text{-iodoantipyrine(tissue)}}{DPM\ ^{65}Zn(injectate)/DPM\ ^{14}C\text{-iodoantipyrine(injectate)}}$$

Zn BUR was studied in the fourth ventricle choroid plexus (4CP), cerebellum (CER), medulla (MED), cerebral cortex (CC), olfactory bulb (OB), and hippocampus (HIPP) in adult rats (I), in 1-wk old rats (II), in adult rats using pentobarbital instead of ether (III), and in adult rats substituting antipyrine for iodoantipyrine (IV). BUI values (V) were obtained with adult rats using the Oldendorf technique. (VI) is the ratio of the 2-hr uptake (DPM ^{65}Zn/g tissue ÷ DPM ^{65}Zn/g plasma H_2O) after I.V. zinc injection in adult rats to the BUR values of group I. Means + SEM for N = 4 are given below:

	I	II	III	IV	V	VI
4CP	0.60(.04)	0.34(.08)	0.81(.08)	0.62(.04)	0.58(.07)	4.7
CER	0.14(.01)	0.14(.03)	0.14(.02)	0.17(.01)	0.09(.02)	2.4
MED	0.11(.01)	0.11(.03)	0.08(.01)	0.12(.01)	0.14(.01)	3.2
CC	0.12(.01)	0.09(.02)	0.12(.02)	0.13(.01)	0.05(.001)	2.9
OB	0.22(.01)	0.11(.02)	0.23(.01)	0.21(.02)	0.06(.005)	1.6
HIPP	0.08(.01)	0.09(.02)	0.08(.01)	0.11(.01)	0.04(.004)	3.0

In adult controls (I), Zn BUR was similar in all regions except in the 4CP and OB where it was 2-4X greater; a similar relationship among BUR values was found in infant animals (II). Except for 4CP, BUR values in pentobarbital-anesthetized animals were comparable to those in etherized rats. There was no considerable difference between BUR values obtained using either antipyrine or iodoantipyrine as the internal standard. A comparison of group V with group III reveals that BUI values were disproportionally higher than BUR values in the 4CP, CER, and MED; these differences occur since solutes injected into the carotid artery do not adequately perfuse these areas. The similarity among the ratio values in group VI shows that there is a constant correlation between Zn BUR and 2-hr Zn spaces in all CNS regions. (Supported by NIH grants NS 13988 and GM 07579.

279.11 QUANTITATION OF VASOGENIC CEREBRAL EDEMA BY NUCLEAR MAGNETIC RESONANCE ANALYSIS. Andrew M. Rudin*, J. S. Schneider, M. J. Glucksman* and David M. Kramer*. (SPON: N. Peress). Depts of Chemistry and Psychology, SUNY at Stony Brook, N. Y.

There exist measurable differences in proton nuclear magnetic resonance spin lattice relaxation times (T_1) of various tissues and between normal and diseased states of the same tissue. The T_1 differences appear, in general, to be related to differences in water content. NMR zeugmatographic imaging, a non-invasive technique, may be used to measure all these differences and generate two or three dimensional images which may be useful for detecting various disease states. Since vasogenic cerebral edema results in localized increases in tissue water content, we have chosen to assess the potential of water proton NMR analysis to identify regions of cerebral edema.

Vasogenic edema was produced cryogenically in 8 cats. After a suitable incubation period, brains were rapidly excised and sectioned. The water proton spin lattice relaxation times (T_1) were measured using a 180°-τ-90° pulse sequence at 4 megahertz.

T_1's are significantly higher for edematous tissue and these increases are correlated with water content increases in the tissue, as shown in Table 1.

Table 1

	Mean T_1 (Msec.)	Mean % H_2O
Control	381.7 ± 56.4	74.9
Edema	492.0 ± 36.3	78.8

The findings presented here indicate that the NMR relaxation time, T_1, is sufficiently sensitive to detect small changes in water content in cerebral tissue. The ability to accurately detect regional cerebral edema is of obvious clinical importance. These findings are of particular interest in light of recent developments in proton NMR zeugmatographic techniques which have been used to obtain true three-dimensional images of human subjects. Examples of three-dimensional zeugmatographic images will be presented.

279.12 SERUM OSMOLARITY AND GLUTAMATE-INDUCED BRAIN DAMAGE. M.T. Price, J.W. Olney, O.H. Lowry,* & S. Buchsbaum* Departments of Psychiatry & Pharmacology, Wash. Univ. Med. Sch., St. Louis, MO 63110.

Glutamate (Glu) and aspartate (Asp) are excitatory neurotoxins which selectively destroy neurons in circumventricular organ (CVO) regions of brain following systemic administration, presumably because CVO lack blood brain barriers (BBB). Since both Glu and Asp are common food additives, their neurotoxicity invites controversy; e.g., R.J. Wurtman argues that CVO do have BBB that protect CVO unless intake doses of Glu or Asp are high enough to create "hyperosmolar opening" of BBB. He reasons that Glu and Asp are safe because an 80 mosmolar increase in serum osmolarity is required to "open" BBB and neither man nor animal would ever voluntarily ingest enough Glu or Asp to induce such an extreme osmolar disturbance in blood. Here we report our recent evidence relevant to this argument.

Administering Glu or Asp or both (2 g/kg) to immature mice and measuring Glu or Asp concentrations in microdissected samples of CVO and non-CVO brain tissue at intervals from 15-180 min after treatment, reveals striking increases (3-8 X control values) of either amino acid in CVO and no increase in non-CVO regions (the expected result if CVO lack BBB).

When infant rats are given a CVO-damaging dose of Glu sc (0.5 g/kg) and serum osmolarity is measured at 15 min intervals by freezing point osmometry, no significant increase is detected at any post-treatment interval up to 1 hr; thus, acute toxic degeneration of CVO neurons occurs in the Glu-treated infant rat in the absence of any change in serum osmolarity.

When mannitol or sucrose are administered in high dosage (3 g/kg) to immature mice in combination with a CVO-damaging-dose of Glu (0.5 g/kg), the severity of CVO lesions is not increased compared to control mice receiving only 0.5 g/kg Glu. Hyperosmolarity does not augment Glu neurotoxicity.

When weanling mice are deprived of fluids overnight, then offered aqueous solutions of Glu or Glu + Asp (10% Glu, 5% Glu, or Glu 2.5% + Asp 2.5%), they *voluntarily* ingest enough Glu or Glu + Asp to sustain conspicuous CVO damage.

It is also known that the more potent excitotoxins (e.g., N-methyl aspartate)induce CVO brain damage at doses as low as 10 mg/kg sc and Inouye has shown autoradiographically that tracer amounts of C^{14} labelled Glu pass readily from blood into CVO but not into other regions of brain. The evidence suggests, contrary to Wurtman's thesis, that CVO lack BBB and serum osmolarity lacks relevance to the determination of Glu or Asp safety. Supported by USPHS grants NS-09156, NS-08862, DA-00259, RSA MH-38894 (JWO) and American Cancer Society BC-Q4.

279.13 EFFECT OF pH ON BLOOD-BRAIN BARRIER TRANSPORT OF AMINO ACIDS. Lester A. Wade, Helen M. Brady* and Darnell M. Barbay*. Dept. Physiology, Tulane Univ. Sch. Med., New Orleans, La. 70112.

Previous studies using Ehrlich ascites cells have shown that the rate of amino acid uptake by the leucine (L) neutral amino acid transport system is dependent upon extracellular pH. Garcia-Sancho (1977) also reported that the portion of glutamic acid transported by the L neutral amino acid transport is dependent upon the pH of the incubating solution. In the present experiments, we determined the effect of pH on amino acid transport at the blood-brain barrier using the intracarotid single pass bolus injection techniques in the rat. A mixture of a radioactively-labeled amino acid and ^{3}H-H_2O over a pH range was injected into the carotid artery, the rat was decapitated at 5 seconds, and the brain dissected into 5 regions before counting. The injectant also included one of the following buffers (10mM): Bicine, Hepes, Pipes, Mes and ε-aminocaproate. We measured the uptake of the synthetic amino acid (^{14}C)2-aminonorbornane-2-carboxylic acid (BCH) (0.25mM) over a pH range of 4.5 to 8.0. BCH is specific for the L neutral amino acid transport system. The greatest rate of BCH uptake was at a pH 7.0 (BUI = 19.1), with a lower uptake at pH 7.5 and 6.5 *(BUI of 15.4 and 16.3 respectively). There were no further* changes in BCH uptake at a more extreme pH. When non-radioactive glutamic acid (10mM) was added to the injectant as a potential inhibitor of BCH uptake, blood-brain barrier transport of BCH was unaffected at pH 7.5, 6.5 and 5.5. At an injected pH of 4.5, glutamic acid decreased BCH uptake from 16.0 ± 0.07 to 11.2 ± 0.4. These results indicate a pH optimum of 7.0 for the L neutral amino acid transport system at the blood-brain barrier. Unexpectedly, the rate of BCH uptake at a strongly acidic pH was similar to that observed at pH 7.5. Glutamic acid interacted with the blood-brain barrier L neutral amino acid transport system only when the pH was below 5.5.

279.14 6-HYDROXYDOPAMINE ABLATION OF AMITRIPTYLINE-INDUCED ALTERATIONS IN BLOOD:BRAIN BARRIER. S. Preskorn, B. Hartman, C. Hughes, H. Clark* and G. Irwin*. Depts. of Psychiatry, Kansas U., Kansas City, KS 66103 and Washington U., St. Louis, MO 63110.

The central adrenergic system (CAS) has been postulated to have central vasoregulatory functions. Supporting this hypothesis, all tricyclic antidepressants--which act as indirect adrenergic agonists by blocking norepinephrine re-uptake--increase the diffusibility of water across blood:brain barrier, E_w Preskorn and Hartman, Biol. Psychiat., 1979). Their potency is directly related to their affinity for α-adrenergic receptors (Preskorn et al., JPET, 1980).

To further investigate this hypothesis, the effect of CAS ablation on the drug-induced alteration in E_w was tested. Following stereotaxic cannula placement, 6-hydroxydopamine (6-OHDA, 125µg/10µl) was administered intraventricularly in artificial cerebrospinal fluid (CSF) over a 10 minute period. Controls received only the drug-free CSF. For both groups, E_w was measured in half of the animals 6 weeks later without *further treatment. The other half received amitriptyline* (AMI, 62.5µmols/kg intraperitoneally) 15 minutes prior to the measurement of E_w. This dose and time was based on the studies cited above. The results are shown in the table below.

Total Forebrain E_w
(Mean ± Standard Error)

Groups	Sham	6-OHDA	Sham +AMI	6-OHDA+AMI
E_w	0.71±.07	0.75±.08	0.88±.07*	0.74±0.10

*$p < 0.001$

6-OHDA treatment did not by itself alter E_w but did abolish the AMI-induced increase in E_w. The sham treatment, however, did not influence the AMI effect. CAS ablation was confirmed by immunohistochemistry and direct electrochemical quantification of biogenic amines using the contralateral forebrain for each animal. Histology revealed no ventricular or primary lesions.

These studies support the hypothesis that antidepressants alter BBB through their effects on the CAS and also the concept that one function of this system is central vasoregulation. Results from ongoing studies of adrenergic and serotoninergic blockers will also be discussed.

280.1 COMPARATIVE THREE-DIMENSIONAL MORPHOLOGY OF THE MAMMALIAN SUPRACHIASMATIC NUCLEI. R. Lydic, H.E. Albers*, B. Tepper*, M.C. Moore-Ede. Dept. Physiol., Harvard Med. School, Boston, MA 02115.

Total lesions of the suprachiasmatic nuclei (SCN) disrupt circadian (≃24 hr) oscillations normally displayed by many mammalian physiological variables. Partial lesions involving SCN, *pars preopticus suprachiasmaticus* (POSC), or retrochiasmatic area (RCA), however, suggest that anterior (A) and posterior (P) SCN may not be functionally identical (Fuller, C.A. *et al., Physiologist 22:* 41, 1979; Arendash, G.W. and Gallo, R.V., *Neuroendocrin. 28:* 349, 1979; Rusak, B., *J. Comp. Physiol. 118:* 145, 1977). We report structural differences along SCN AP axis by morphological analyses conducted at the gross nuclear level. Using brains from hamster, rat, cat, squirrel monkey (*Saimiri sciureus*) and rhesus monkey (*Macaca mulatta*), we have combined histological techniques with computer graphics to describe the three-dimensional (3-D) morphology of SCN. In each species SCN appear to have their own unique 3-D structure and geometrical relationship to third ventricle (III) and optic chiasm (CHO). In primates A- poles expand along the medio-lateral (ML) axis, but the P- poles extend dorsally, rotated 90° from the ML plane. SCN of rhesus are smaller (AP length ≃0.8mm, ML width of A- pole ≃0.7mm) and more diffusely organized than squirrel monkey (AP length ≃1.0mm, ML width of A-pole ≃0.8mm). In cat SCN are triangular in shape throughout their ≃1.0mm AP expanse. The A- pole has ≃0.6 to 0.8mm ML width which tapers to ≃0.4mm posteriorly. POSC in cat extends for ≃1.0mm along the AP axis. In hamster (AP ≃0.5mm, ML ≃0.2mm) and rat (AP ≃1.0mm, ML ≃0.5) SCN are easily visualized. Rodent SCN are cylindrically shaped along the AP plane and middle portions are deeply embedded in CHO, more so in rat than hamster. In hamster SCN P-poles are ventral rather than lateral to III and appear to merge at midline. SCN characteristics at the cytoarchitectonic and connectional level have not been systematically integrated with 3-D analyses at the nuclear level. The pattern of afferent or efferent fiber systems involving SCN, RCA or POSC may correlate with AP differences in SCN morphology. Retrograde transport studies suggest that the retinohypothalamic tract (RHT) of squirrel monkey innervates the caudal SCN. Destruction of RHT/SCN input may account for some of the specific effects associated with partial SCN lesions in squirrel monkeys.

280.2 Effects of SCN Lesions and Feed/Starve Entrainment Conditions on Activity and Retention Performance Rhythms. F. A. Holloway, D. C. Bird*, J. Devenport*, & W. N. Tapp. Dept. Psychiat. & Behav. Sci., Univ. Okla. Health Sci. Ctr., Oklahoma City, OK 73190.

We previously reported (Holloway & Wansley, Behav Biol. 9:1 1973) that retention performance fluctuated periodically as a function of time since training and suggested that these oscillations may represent some state-dependent phenomenon based on internal biorhythms. Indeed, later research (Wansley & Holloway, Neurosci. Abst., 1:810, 1975) indicated that lesions of the suprachiasmatic nucleus (SCN) altered both circadian activity rhythms and retention oscillations. Recently (Tapp, Bird & Holloway, Neurosci. Abst., 4:181, 1978) we showed that the disruption in circadian rhythms after SCN lesions could be reversed in part by the imposition of a 24-hr Feed/Starve (FS) schedule. We now report that a 24-hr FS condition may result in the re-establishment of retention performance fluctuations in rats with SCN lesions.

In Experiment 1, independent groups of male albino rats (n=6) were defined by surgical condition (unoperated, sham-operated, bilateral SCN lesion) and by active avoidance retention test intervals (6, 12, 18, 24, 30, 36 hr). All animals were maintained under 12:12 LD conditions with ad lib food and water. Prior to avoidance training each animal's activity was monitored continuously for several days. Both unoperated and sham groups displayed clear circadian activity rhythms and major fluctuations in avoidance retention performance, (poor at test intervals of 6, 18 or 30 hrs and relatively good at 24 hr). The SCN animals as a rule displayed a marked attenuation of circadian activity and drinking rhythms. The SCN groups displayed no sign of fluctuations in retention performance across testing intervals. Experiment 2 utilized a similar protocol except that for half the animals food was available for only 2 hr each day beginning 1 hr after lights-off (12:12 LD). Active avoidance training was given 10-14 days after imposition of the FS-schedule. Subgroups of controls and SCN rats were given retention tests 6, 24, or 30 hrs post training. A separate set of control and SCN animals received identical treatment except no FS-schedule was imposed. Retention performance of the non-FS groups replicated their counterparts in Experiment 1. The control-FS group displayed poor retention at both 6 and 30 hr while the SCN-FS group showed poor retention only at the 6 hr interval.

These results suggest that the multiple fluctuations in retention performance may depend on the presence of some undetermined constellation of biorhythmic phenomena but not perhaps on the integrity of SCN. The 24 hr FS plus the 12:12 LD schedule appeared to have produced some change in circadian rhythmicity sufficient for the retention fluctuation to reemerge in the SCN animals.

280.3 LIMITS OF ENTRAINMENT TO RESTRICTED FEEDING SCHEDULES IN RATS WITH SUPRACHIASMATIC LESIONS. Friedrich K. Stephan, Dept. of Psychology, Florida State University, Tallahassee, FL. 32306.

Although rats with lesions of the suprachiasmatic nuclei lose their circadian rhythms in activity and drinking when food and water are ad lib., we have shown that these animals can anticipate periodic access to food when food is made available at 23 or 24 hr intervals, but not at 18 hr intervals (Stephan, Swann, & Sisk, 1979, Behavioral and Neural Biology 25, 346-363 and 25, 545-554). Thus, anticipatory activity may be analagous to entrainment of a circadian rhythm. The present experiment was designed to define the limits of entrainment of anticipatory wheel running in rats with suprachiasmatic lesions. One group of 8 rats was sequentially exposed to 24, 21, 20, and 23 hr, and the other group to 24, 27, 29, 31, and 33 hr feeding schedules. In the former group, all 8 rats entrained to the 24 hr schedule within 2-5 days. Only 4 rats entrained to 21 hr cycle and none to the 20 hr cycle. In the latter group, all 8 rats entrained to the 24, 27, 29, and 31 hr schedules. Entrainment to the 23 and 33 hr schedules is still under investigation. These results indicate that the lower limit of entrainment is near 21 hrs while the upper limit is in excess of 31 hrs. The asymmetry of these entrainment limits may provide an important clue to the functional properties of the mechanisms which mediate entrainment to periodic food availability.

280.4 SUPRACHIASMATIC NUCLEI LESIONS AND SENSORY REACTIVITY. Z. M. Wenzel*** and W. A. Bengelloun. Dept. Psychology, State University of New York, Binghamton, NY 13901 and Dept. Biologie, Université Mohammed V, Rabat, Morocco.

The profound arrhythmia produced by lesions of the suprachiasmatic nucleus of the hypothalamus suggests that this structure is involved in the generation and/or integration of circadian rhythmicity. It is not known,however, whether the generation of the rhythm itself is abolished, or the integration of internal and external periodic events. This study investigated whether SCN lesions alter the responsiveness to general environmental stimuli, a number of which might serve as synchronizing agents.

Adult, albino, male rats were individually housed under a light-dark cycle and were subjected to either SCN or sham lesions. Ten days following surgery, animals were tested for light reactivity in an open field, one week later reactivity to quinine and sucrose solutions, and three weeks later reactivity to noise in a shuttlebox. All testing was completed during the light phase of the cycle. Histological verification revealed complete SCN lesions.

In general, SCN-lesioned rats were more, rather than less, sensitive to environmental stimulus change. SCN animals were more reactive to a noise stimulus than controls and inhibition of fluid intake in response to quinine was enhanced ($F=5.46$, $df=1/38$, $p<.025$). Although activity levels were similar to controls in the presence of the flashing white light stimulus, decreased baseline activity under red light again suggests increased responsiveness in SCN rats ($F=8.59$, $df=2/76$, $p<.001$).

These results indicate that rats with SCN lesions are not lacking external stimulation or synchronizers, but, in fact, are more reactive than intact animals. These data suggest that the SCN may have an inhibitory influence on response to external stimuli, and perhaps on synchronizer input to the circadian system.

280.5 DIURNAL VARIATION IN THE RESPONSIVENESS OF HIPPOCAMPAL PYRAMIDAL NEURONS TO SEROTONIN: MICROIONTOPHORETIC EVIDENCE. S. Brunel* and C. de Montigny (SPON: Laurent Descarries). Centre de recherche en sciences neurologiques, Université de Montréal, Montréal, Québec, Canada H3C 3T8.

Chronic treatments with tricyclic antidepressant drugs or electro-convulsive shocks have been shown to induce a selective increase of the effect of iontophoretically-applied serotonin (5-HT) on rat hippocampal pyramidal neurons (de Montigny and Aghajanian, 1978; Gallager and Bunney, 1979; de Montigny, 1980). The time course of this sensitization to 5-HT is consistent with that of the therapeutic response to these treatments. Most of the patients suffering from a major affective disorder exhibit diurnal variation of mood during their depressive phase, usually with worsening in the morning and alleviation in the evening. In the present study, the responsiveness of hippocampal pyramidal neurons to iontophoretically-applied 5-HT, norepinephrine (NE) and γ-aminobutyric acid (GABA) was examined at two periods of the day.

Male Sprague-Dawley rats (200-275 gm) were used. Morning experiments were carried out between 8:00 and 12:00 hrs and evening experiments between 20:00 and 24:00 hrs. Unitary recordings of pyramidal cells were obtained from the CA_1 and CA_3 regions of the hippocampus under urethane (1.25 g/kg, i.p.) or chloral hydrate (400 mg/kg, i.p.) anesthesia. The following solutions were used for iontophoresis: 5-HT creatinine sulfate (0.002 M in 0.2 M NaCl, pH: 3.9) (Regis); GABA (0.05 M in 0.05 M) NaCl, pH: 4) (Calbiochem); NE bitartrate (0.1 M, pH: 4) (Regis); acetylcholine (Ach) chloride (0.02 M in 0.2 M NaCl, pH: 4) (Calbiochem). Ach was used to activate silent or slowly discharging units. The responsiveness of hippocampal neurons was estimated from the charge $I \cdot T_{50}$ required to obtain a 50% decrease from the baseline firing rate {charge $I \cdot T_{50}$ = current (nA) x time(s)}. To control the micropipette efficacy variable, the same micropipette was used for two consecutive experiments.

In a first series of experiments carried out under urethane anesthesia, the responsiveness of pyramidal cells to 5-HT was about 4 times greater in rats tested in the evening than those tested in the morning. The effect of NE was not markedly changed. In a second series of experiments in chloral hydrate-anesthetized rats, the sensitivity to 5-HT was enhanced 6 folds in the evening whereas that to GABA tended to be decreased.

These data suggest that the postsynaptic 5-HT receptors of rat hippocampal neurons undergo marked diurnal variations in their responsiveness. Such changes in 5-HT receptor sensitivity, should they occur in the human brain, could be related to the diurnal variation of mood occuring during the depressive phase of major affective disorders. (Supported by M.R.C. grant).

280.6 **SEROTONIN MIMICS THE ACTION OF OPTIC EFFERENTS IN RESETTING THE PHASE OF THE CIRCADIAN OSCILLATOR IN THE APLYSIA EYE.** **J. Nadakavukaren* and M. E. Lickey (SPON: D. P. Kimble). Depts. of Biology and Psychology, Univ. of Ore., Eugene, OR 97403.**

The two eyes of Aplysia are independent circadian oscillators. They are connected to the brain via optic nerves. As demonstrated by Prichard, neural signals from the brain can initiate phase resetting of the eye rhythm via efferent activity in the optic nerve. The present experiments were undertaken to see if chemical synaptic transmission is involved in neural resetting and if so what putative transmitters might duplicate the action of the optic efferents. Using Prichard's paradigm, Aplysia were entrained to LD 12:12 for at least 3 LD cycles. Following the last dawn, animals were exposed to continuous light (LL) for 12 to 24 hours. At the end of LL the eyes, together with the brain, were removed from the animal and placed in a culture dish. Compound action potentials (CAPs) were recorded from the optic nerves with suction electrodes in constant darkness (DD). Just before the onset of DD one of the eyes was detached from the brain by severing the optic nerve. The frequency (number of spikes/half hour) of CAPs plotted against time is a rhythmic function. The data were analyzed by comparing the phase of the rhythm of an attached eye to that of a detached eye. High Mg^{++} low Ca^{++} solutions, when bath applied separately either to the eye or the brain, blocked phase-resetting by the optic efferents. Serotonin bath applied to the detached eye mimicked the important characteristics of neural resetting. As described by Prichard, these characteristics include: (1) The phase of the 5-HT treated (or attached) eye is different than its untreated (or detached) paired control and the magnitude of the difference is a precise function of the duration of LL pretreatment. (2) There is a restricted "critical period" during which 5-HT (and efferent activity) can reset the ocular phase. The critical period recurs during the second cycle in vitro. The fact that bath application of 5-HT can mimic the action of optic efferent activity indicates that the information specifying the magnitude of phase resetting is stored in the eye, not the brain. Activity in the optic efferents appears to be an "enabling" signal rather than an "informative" signal. 5-HT is effective in a dose range of 10^{-6}M to 10^{-4}M. At 2 X 10^{-3}M 5-HT blocks neural resetting when applied to either the eye or the brain. This is perhaps a case of receptor desensitization at saturating doses of 5-HT. Other putative neurotransmitters and transmitter analogs were tried and found to be inactive in phase resetting. Corrent, McAdoo and Eskin, using a different paradigm, also found that only 5-HT among various putative transmitters can reset the eye rhythm. 5-HT may be a phase resetting transmitter in the Aplysia circadian system. **(NSF 77-28251)**

280.7 **A cAMP ANALOG WITH A PHOSPHODIESTERASE INHIBITOR RESETS THE PHASE OF THE CIRCADIAN OSCILLATOR IN THE APLYSIA EYE.** **W. P. Jordan, S. O. Hiaasen*, and M. E. Lickey. Dept. of Psychology, Univ. of Ore., Eugene, OR 97403.**

Each eye of Aplysia contains at least one circadian oscillator which can be entrained to environmental light cycles. In vitro, a circadian rhythm of compound action potentials (CAPs) may be recorded from the optic nerve of either a detached eye or an eye that remains attached to the cerebral ganglion. Prichard has shown that, following LD 12:12 entrainment, extension of the final light time to 15-27 hr in vivo causes eyes that remain attached to the cerebral ganglion to be reset in vitro due to efferent activity in the optic nerve. The resetting occurs during a critical period in the early subjective day. Using Prichard's paradigm, Nadakavukaren and Lickey, in a companion abstract, report that bath applied serotonin (5-HT) will reset a detached eye in vitro in a manner that mimics the action of the optic efferents.

The present in vitro experiments demonstrate that bathing a detached eye with a medium containing a cAMP analog (dibutyryl-cAMP, 10^{-3}M) and a phosphodiesterase inhibitor (3-isobutyl-1-methyl-xanthine (IBMX), 10^{-3}M) also phase shifts the ocular oscillator. A 5.5 hr application during the critical period for an attached or a 5-HT treated detached eye caused large (9-11 hr) phase shifts in the CAP rhythm. Separate application of either drug at 10^{-3}M failed to phase shift the CAP rhythm. However, addition of 5-HT at 10^{-7}M to a 10^{-3}M IBMX medium produced large phase shifts. Nadakavukaren and Lickey found the threshold for 5-HT application alone to be about 10^{-6}M. The synergism between 5-HT and IBMX, as well as that between db-cAMP and IBMX, suggests that cAMP acts as a second messenger for 5-HT within the eye. cAMP has been implicated in the action of 5-HT at several other sites in Aplysia.

Two-hour pulses of db-cAMP at 10^{-3}M with IBMX at 10^{-3}M during the critical period produced large phase shifts in detached eyes similar to those produced by the 5.5 h drug pulses. The 2 hour pulses have been applied at various phases of the circadian cycle. The phase shift due to the drugs varies with the phase of treatment. Further experiments are under way to see if there is a critical period for cAMP analogs and phosphodiesterase inhibitors actions as there is for 5-HT and neural activity. **(Supported by NIH 1 F32 NS06425 and NSF 77-28251)**

280.8 EFFECTS OF CONSTANT DARKNESS AND RE-EXPOSURE TO CONSTANT LIGHT ON THE CIRCADIAN RHYTHM OF LOCOMOTOR ACTIVITY AFTER "SPLITTING" HAS OCCURRED. D. Earnest* and F. Turek (SPON: A. Eskin). Dept. of Biol. Sci., Northwestern University, Evanston, IL 60201.

Exposure of golden hamsters to constant light (LL) often results in the splitting of the circadian rhythm of activity into two distinct components which become stably coupled to each other at about 180^{o} out of phase. Since splitting has never been observed to develop in hamsters maintained in constant darkness (DD), we sought to determine what effect transfer to DD would have on hamsters whose activity rhythms had already split into two components during exposure to LL. In addition, we investigated what effect re-exposure to LL would have on these animals.

Adult male hamsters whose activity rhythm had split into two distinct components during exposure to LL were transferred into DD on 13 different occasions. In all cases, splitting was abolished within 1-3 days of exposure to DD and a normal free-running rhythm with a bimodal distribution of activity was observed. After 15-30 days in DD, the hamsters were transferred back into LL at various circadian times. The effect of the transfer from DD into LL appeared to depend on the phase relationship between the transition into LL and the activity rhythm. In 4 of 6 hamsters transferred into LL 4-5 hours after the onset of activity, splitting of the activity rhythm into two distinct components was evident within 2-4 days. In the other two animals, a very erratic pattern of activity was observed initially which eventually led to the split condition. In contrast, transfer of 7 hamsters into LL at other circadian times simply resulted in the activity rhythm continuing to free-run in a normal fashion.

These studies suggest that transfer of split hamsters from LL to DD results in the rapid re-establishment of the normal phase relationship between the two circadian oscillators which underlie the two components of activity during splitting. This coupling, however, appears to be very labile as demonstrated by the rapid desynchronization of the components of the activity rhythm upon transfer back into LL. The rapid induction of splitting when hamsters are transferred into LL 4-5 hours after the onset of activity may be related to the phase response curve of this species. This region of the phase response curve represents a transition point. If hamsters maintained in DD are exposed to a brief light pulse 4-5 hours after the onset of activity, the rhythm may be phase delayed or phase advanced. Perhaps the rapid onset of splitting observed in hamsters transferred from DD into LL at this circadian time is due to one oscillator being phase advanced while the other is phase delayed by the abrupt onset of light. (Supported by USPHS Grants HD-12622, HD-09885, and HD-00249.)

281.1 DIFFERENTIAL DISTRIBUTION OF THE Ca BUFFERING IN APLYSIA NEURONS. D. Tillotson and A.L.F. Gorman. Boston University School of Medicine, Boston, MA 02118.

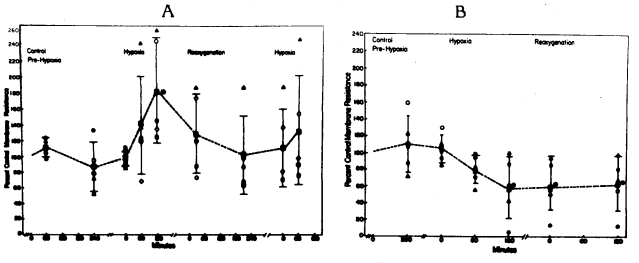
The intracellular concentration of Ca^{2+} ions in nerve cells is known to be in the submicromolar range. Mechanisms for maintaining this resting level and handling increases in Ca^{2+} during membrane activity continues to be the subject of study. Experiments reported here were performed to investigate the distribution of the Ca^{2+} buffering machinery in the interior of nerve somas. Selected neurons in the abdominal ganglion of Aplysia were voltage-clamped and injected, to a known concentration, with the Ca^{2+} sensitive dye arsenazo III. The differential light absorbance change associated with a standard iontophoretic Ca^{2+} injection (20 nA, 5 sec) was used as a monitor of Ca^{2+} buffering in a region near the tip of the Ca^{2+} microelectrode. Absorbance measurements were made at various points in the soma as the Ca^{2+} electrode was advanced into or withdrawn from the cell. It was reasoned that changes in the measured peak absorbance corresponded to changes in buffering such that the largest signals would be obtained in regions of lowest buffering. We found the smallest absorbance signals in a cytoplasmic layer near the plasma membrane and largest signals near the center of the cell. To control for the possibility that this result was a consequence of the measurement procedure rather than the buffer distribution, a large iontophoretic injection of the Ca^{2+} chelator EGTA (100 nA, 5 min) was made. A substantial concentration of internal EGTA should render the whole of the interior of a cell equivalent with respect to Ca buffering. After EGTA injection the previous standard injection (20 nA, 5 sec) produced no measurable absorbance change. The localization experiment was repeated using a 10X greater Ca^{2+} injection intensity (200 nA, 5 sec) and the predicted uniform distribution was obtained. Our results suggest that the Ca^{2+} buffering machinery is differentially distributed in the molluscan nerve soma being greatest in a cytoplasmic layer near the plasma membrane. This study supported by NIH grant NS11429.

281.2 THE SELECTIVITY OF THE Ca^{2+} ACTIVATED K^+ CHANNEL FOR MONOVALENT CATIONS. J.C. Woolum and A.L.F. Gorman. Boston University School of Medicine, Boston, MA 02118.

The calcium activated potassium current is of considerable importance for the function of mammalian as well as of invertebrate neurons. We studied the Ca^{2+} activated K^+ current of the molluscan neuron soma membrane to investigate whether the selectivity of this channel for various monovalent cations is similar to that for the delayed rectifying K^+ channels or to that for the leakage channels (or neither). The relative permeabilities of the Ca^{2+} activated K^+ channel for a number of monovalent cations were measured using the reversal potential method described by B. Hille (J. Gen. Phy. 1973, 61, 669). Cells in the abdominal ganglion of Aplysia were voltage clamped (two electrode voltage clamp) and a third electrode was used to inject Ca^{2+} ions by iontophoresis into the soma. We find that the Ca^{2+} activated K^+ channel is quite selective. The relative order for the selectivity of the channel is $P_K > P_{Rb} > P_{NH4} > P_{Cs} > P_{Na}$, P_{Li}, P_{TMA} (the Na^+, Li^+ and tetramethylammonium permeabilities are too small to measure with our technique) and is similar to that found for the delayed rectifier K^+ channel of myelinated axon. For the molluscan neuron Ca^{2+} activated K^+ channel the permeability ratio $P_{Cs}/P_K = 0.04$ whereas for the delayed rectifier K^+ channel of myelinated axon $P_{Cs}/P_K < 0.077$. Our results suggest that the mechanisms responsible for channel selectivity (channel size, etc) are similar for the Ca^{2+} activated K^+ and the delayed rectifier K^+ channels, but differ from those for the leakage channels. This study supported by NIH grant NS11429.

281.3 DETERMINATIONS OF MEMBRANE RESISTANCE, I-V RELATIONSHIPS, AND INTRACELLULAR K^+ ACTIVITY IN HYPOXIC AND NORMAL APLYSIA CALIFORNICA NEURONS. P.E. Coyer. Laboratory of Neurophysiology and Cerebrovascular Research, Dept. of Neurology, Univ. of Alabama in Birmingham, The Medical Center, Birmingham, Alabama 35294.

Recently I have found two responses of Aplysia californica neurons to hypoxia (see figures below). While one group (A) of neurons in the abdominal ganglion was observed to be resistant to hypoxia, another group (B) was found to be non-resistant during exposure to hypoxic bath conditions lasting 2 hours. A period of reoxygenation lasting up to 4 hours followed hypoxia during which recovery of the neurons' membrane potentials and resistances were observed. During hypoxia the resistant neurons (N=7) had membrane resistances that increased significantly above ($P < 0.05$); paired t-test) control measurements. Non-resistant neurons (N=5) depolarized, and their membrane resistances decreased significantly below ($P < 0.05$) control measurements following 2 hours' exposure to hypoxia. For the non-resistant neurons, these changes were irreversible, and the electrophysiological and/or anatomical bases accounting for these differences existing between resistant and non-resistant neurons is being investigated. I-V curves were constructed with an X-Y plotter before, during, and after hypoxic bath conditions monitored with PO_2 microelectrodes. Hypoxia was achieved by nitrogen bubbling and is defined as a PO_2 of less than 20 torr in the suffusate. The non-resistant, characterized by linear I-V curves, showed a decrease in membrane resistance in the depolarizing direction. The resistant group showed rotation (i.e. a change of slope measured as a line tangent to the 0 current point) of non-linear I-V curves. These changes were reversible. Intracellular K^+ activity was determined in both groups (Coyer, Neurosci. Abs. 5, 1979), and I-V curves were constructed during pump inhibition (low K^+_o in the bathing solution). The effects of pump inhibition achieved in this manner were reversible for both resistant and non-resistant neurons. However, the effects of hypoxia as described above were not. Supported in part by NINCDS Grants NS 07123 and NS 08802.



281.4 PRELIMINARY EVIDENCE OF ABNORMAL ELECTRICAL MEMBRANE PROPERTIES FOR DOWN'S DRG NEURONS IN CELL CULTURE. B.S. Scott, T.L. Petit, L.E. Becker*, B.A.V. Edwards*. Surrey Place Centre, Toronto, Canada M5S 2C2.

Cell cultures were prepared from normal and Down's syndrome dorsal root ganglia (DRG). Both pre- and post-natal specimens were utilized; seven normal and four Down's. Cultures were maintained in medium with normal (4mM) and elevated (20mM) potassium (K) since the latter was found to enhance neuron survival. After various periods of incubation, cultures were transferred to normal K medium and their electrical membrane properties (EMP) determined.

A qualitative comparison of the EMP of the normal and Down's DRG neurons revealed no differences. Therefore we carried out a quantitative investigation of various EMP including resting membrane potential (Vm), specific membrane resistance (Rm), and capacitance (Cm), membrane time constant (τ), rheobasic current (I_{RH}), rheobasic voltage depolarization (ΔV), action potential duration (Δt), overshoot (OS), after hyperpolarization (AHP) and absolute refractory period (ARP).

As indicated in the Table, Down's neurons had significantly reduced OS, AHP and ΔV compared to normal neurons for both K media. Also Down's neurons had reduced Rm in 4K, but increased Rm in 20K suggesting K had a differential effect on Rm of normal and Down's neurons. Statistically significant correlations were found between certain EMP and various factors including developmental stage, culture duration, type of action potential (i.e. monophasic or biphasic falling phase) and cell size. However, the abnormal Down's EMP mentioned above were also indicated when these factors were taken into consideration by using samples matched for developmental stage, type of action potential, etc. These preliminary results suggest that Down's neurons may have subtle abnormalities in their EMP which may be the neurobiological basis of the mental retardation observed in this syndrome.

281.5 SPECIFIC MEMBRANE CAPACITANCE AND RESISTANCE OF MOUSE DORSAL ROOT GANGLION NEURONS. Donald H. Perkel, Thomas H. Brown, Jane C. Norris*, and John H. Peacock. Departments of Biological Sciences (DHP), Neurobiology (JCN), and Neurology (JHP), Stanford University, Stanford, CA 94305, and Division of Neurosciences (THB), City of Hope Research Institute, Duarte, CA 91010.

Because of their simple morphology, sensory ganglion neurons lend themselves well to studies of the specific membrane properties of a vertebrate neuron. Previous estimates of the specific electrical constants in these neurons failed to take into account the electrotonic structure of the cells; that is, the actual distribution of current flow through the membrane of the soma as well as that of the process. Failure to take the electrotonic structure into account can cause large errors in the estimates of specific membrane capacitance (C_m) and resistance (R_m). The present study examined the electrotonic structure and specific membrane properties of mouse dorsal root ganglion neurons in mature dispersed cell cultures.

Electrophysiological recordings were made from cultures bathed in defined salt solutions. The soma of each cell was penetrated with two independent microelectrodes, using one for passing current and the other for recording membrane potential. Voltage transients were induced within the ohmic range of the membrane by imposing a hyperpolarizing current step. The slope of the resultant charging curve was measured and analyzed to estimate cable-theory parameters of the neuron: the electrotonic length (L) of the process and the ratio (ρ) of input conductance of the process to that of the soma. Three different analytical methods were used to estimate the cable parameters. The results of the three methods were in substantial agreement. Their adequacy was further investigated by using the parameter values in computer simulations which furnished theoretical charging functions which were then compared with the corresponding experimentally derived curves. In every case, the two sets of curves were within experimental error.

In 14 cells, the mean (±SE) values of ρ and L were , respectively, 1.3±0.3 and 1.1±0.1. The values of C_m and R_m were determined from the electrotonic structure combined with soma area measurements. The mean (±SE) values of R_m and C_m were, respectively, 6900±1000 Ωcm^2 and 0.90±0.1 $\mu F/cm^2$. This value of C_m agrees with that of other carefully studied biological membranes. Discrepancies with some earlier studies of sensory ganglion neurons can be attributed to the effects of electrotonic structure. This implies that C_m is nearly constant in a wide variety of cells. [This research was supported by NIH grants NS-09744 (DHP) and NS-12151 (JHP).]

281.6 EFFECTS OF LOCAL ANESTHETIC QX-314 ON MEMBRANE PROPERTIES OF HIPPOCAMPAL NEURONS. B.W. Connors and D.A. Prince. Dept. of Neurology, Stanford University Medical School, Stanford, CA 94305.

Local anesthetics are known to block peripheral nerve conduction by suppressing voltage-sensitive sodium and potassium conductances. We have used the quaternary lidocaine derivative QX-314 to characterize local anesthetic actions on a mammalian CNS neuron. This agent is permanently charged and exerts its effects most potently when applied to the inside of the membrane. Studies were performed on CA1 cells of the transverse hippocampal slice maintained in vitro. Intracellular electrodes were filled with 4 M K acetate or QX-314 (0.1-0.3 M) + 4 M K acetate.

Immediately following impalement with a QX-314-containing electrode, fast, TTX-sensitive action potentials could be evoked synaptically or by direct current injection. Over several minutes, the amplitudes of these Na^+ spikes gradually decreased and thresholds increased. During the period of partial action potential suppression, spike amplitudes rapidly attenuated during repetitive stimulation at 5-50 Hz. Complete block occurred within 5-10 min following impalement, at which time it was usually possible to restore spike generating capacity by delivering a hyperpolarizing pulse before stimulation.

Often, as fast Na^+ spikes became depressed, long duration (10-20 msec), regenerative depolarizing events could be evoked at low thresholds. These potentials were insensitive to focal application of TTX (10^{-5} M), but were abolished by the application of Mn^{++} (10 mM) and were presumably mediated by Ca^{++}. It may be that the anesthetic depression of voltage-sensitive K^+ conductance allowed the generation of Ca^{++} spikes at thresholds lower than normal. When Ba^{++} (0.25-1.0 mM) was added to the bathing medium, broad, TTX-resistant spikes or depolarizing plateaus occurred spontaneously or could be triggered by brief current pulses. Ba^{++}-induced events persisted even after an hour of recording with a QX-314-containing electrode.

Intracellular QX-314 abolished depolarizing anomalous rectification, which is mediated in part by inward Na^+ current and known to be depressed by TTX. During prolonged recordings there were no systematic changes in resting membrane potential or excitatory and inhibitory synaptic potentials. Some delayed rectification always remained.

These results are consistent with the hypothesis that internal QX-314 inhibits voltage-dependent sodium conductances in CNS neurons without altering calcium or synaptic conductances. This agent is a useful pharmacological tool for assessing CNS membrane properties.

281.7 VOLTAGE CONTROL OF SPONTANEOUS BURSTING IN HIPPOCAMPAL CA3 NEURONS J. J. Hablitz and D. Johnston, Sect. of Neurophysiol., Dept. of Neurol., Baylor Col. of Med., Houston, TX 77030.

At rest, in the absence of externally applied currents, CA3 pyramidal neurons usually burst spontaneously at a low rate. These bursts consist of clusters of APs triggered by an underlying depolarization. Displacement of the resting membrane potential by applied DC currents markedly affect both the rate and configuration of of the spontaneous bursts (SB). Hyperpolarization by 5-10mV increases both the duration and period between SBs; another 5-10mV of hyperpolarization leads to suppression of bursting. Depolarization initially evokes an increase in the frequency and decrease in duration of SBs while further depolarization results in a shift to repetitive firing. Local application of 5mM Ba^{2+} produces an increase in the frequency and duration of SBs and leads to development of plateau bursts 30-50mV in amplitude and 500-800mS in duration. Subsequent application of 10mM Co^{2+} suppressed SBs. This evidence suggests that SBs result from voltage dependent intrinsic membrane events. They do not appear to be synaptically mediated since no underlying depolarization was uncovered during hyperpolarization and SBs persisted when all evoked synaptic activity was abolished by high Mg^{2+}, low Ca^{2+} perfusion.

SBs were recorded also in neurons where all regenerative Na^+ activity was blocked by perfusion with TTX. Bursting in the TTX was readily apparent following either Ba^{2+} application or caesium (Cs^+) injection. SBs consisted of one or more regenerative events, presumably Ca^{2+} spikes, triggered by a slow membrane depolarization. This slow oscillation could result in a plateau depolarization lasting many seconds; these plateaus could end spontaneously or be terminated by hyperpolarizing currents. Small applied currents caused the membrane potential to move rapidly between resting and plateau levels; maintained hyperpolarizing currents prevented the further occurrence of SBs.

Under voltage clamp conditions we have previously described a persistent inward current in CA3 neurons. Under unclamped conditions, after Cs^+ injection, the persistent inward current exerts almost complete control over the membrane potential; small applied currents moving the membrane potential rapidly into and out of the region of negative slope resistance (approx. -50 to -10 mV) seen under clamp. This inward current in CA3 neurons resembles the slowly inactivating inward current responsible for endogenous bursting in invertebrate and spinal neurons suggesting that the burst tendancies of CA3 neurons may arise from similar mechanisms. (Supported by NIH Grants NS-15772 and NS-11535.)

281.8 In the presence of tetraethylammonium, a late delayed depolarization follows the action potential of rat sympathetic neurons grown in cell culture. Trisha Suppes* (Spon: P.H. O'Lague). Dept. Anatomy, UCLA, Los Angeles, CA 90024.

Intracellular microelectrodes were used to study the electrophysiological properties of sympathetic neurons dissociated from the superior cervical ganglia of newborn rats and grown in cell culture. Neurons tested (n=52) had resting potentials of -55 to -70 mV and action potential amplitudes of 70 to 100 mV recorded during continuous perfusion of the cultures (see O'Lague et al., DEV BIOL 67:384, 1978, for methods and perfusion media). When cultures were exposed to a modified perfusion media containing tetraethylammonium ions (60 mM, TEA+) the action potential duration increased (range 150 to 520 mS, measured at half peak amplitude) and the resting potential depolarized (range 5 to 12 mV, n=8). In TEA+ perfusion media the action potential was followed, after a delay of 1-2 seconds, by a substantial depolarization. This late delayed depolarization (LDD) had peak amplitudes, range from 4 to 26 mV, and its duration ranged from 18 to 70 seconds (n=12). The values obtained for the amplitude and duration of the LDD were constant and reproducible in a given cell, and the LDD was present regardless of the age of the culture studied (20 to 90 days). The LDD was accompanied by a conductance increase (10 to 76%, n=5). In preliminary experiments to test the ionic dependence of the LDD, no effect on the LDD was seen with extracellular Na+ completely replaced by tetramethylammonium (n=3) or with the addition of tetrodotoxin (a blocker of voltage-sensitive Na+ channels, 3 micromolar, n=10) to the TEA+ perfusion media. In contrast, the LDD was reversibly abolished by conventional Ca++ channel blockers Mn++ (2.8 mM, n=5) or Cd++ (0.75 mM, n=5), or by reducing extracellular Ca++ (to less than 0.2 mM) in the TEA+ perfusion media. Further details of the ionic basis and properties of the LDD will be presented.

281.9 QUINUCLIDINYL BENZILATE (QNB) INTERACTION WITH IONIC CHANNELS OF THE NERVE TERMINAL AND NICOTINIC RECEPTOR. G. G. Schofield*, E. X. Albuquerque and J. E. Warnick. Dept. of Pharmacol. & Exptl. Therap., Univ. of Maryland, Sch. of Medicine, Baltimore, MD 21201.

The effects of the muscarinic antagonist QNB were studied on frog sciatic-sartorius preparations using conventional microelectrode techniques. These studies revealed sensitive sites at both pre- and postjunctional regions of the nicotinic synapse. QNB produced a concentration dependent decrease in miniature endplate potential (MEPP) amplitude such that at 10 and 100 μM, MEPP amplitude was 77% and 24% of control, respectively, while MEPP frequency and resting membrane potential were unaffected. In curarized sartorius muscles, QNB (60 μM) produced a stimulation dependent increase in the latency of both the nerve terminal action potential and the endplate potential (EPP). However, conduction velocity in the isolated sciatic nerve of the frog was unaffected by this concentration of the agent. In Mg^{2+}-treated preparations QNB produced a concentration dependent decrease in the quantal content of EPPs. QNB (60 μM) also decreased the rate of rise and increased the half decay time of directly elicited action potentials in sartorius muscles and reduced the probability of secondary (repetitive) action potentials without affecting the process of delayed rectification. Repetitive stimulation in these muscles enhanced the effect of QNB on the rate of rise and half decay time of action potentials. Under voltage clamp conditions QNB produced concentration dependent decreases in the peak amplitude and time course of endplate currents (EPCs). Concentrations of QNB greater than 30 μM produced non-linearity in the current-voltage relationship and a reduction of the voltage sensitivity of the rate of decay of the EPCs. Similar effects were noted on miniature EPCs. Noise analysis of EPC fluctuations in response to microiontophoretically applied acetylcholine in the presence of QNB revealed no effect on the single channel conductance but a shortening of the channel lifetime. At lower temperatures (10 °C) when acetylcholine modulated channels remain open for longer periods of time, QNB produced a greater decrease in the ionic channel lifetime although no change in the channel conductance was observed when QNB was compared to control. Thus in addition to its marked effect on the muscarinic receptors it significantly blocks sodium conductance and the ionic channel of the acetylcholine receptor. The locus of the latter effect is primarily the open conformation of the channel. The effect of QNB on the electrical properties of nerve and muscle may explain some of the hallucinatory properties of the agent. (Supported in part by USPHS Grant NS-12063.)

281.10 ELUCIDATION OF THE SITE OF ACTION OF OPIATE ANTAGONISTS WITH THE IONIC CHANNEL OF THE NICOTINIC ACETYLCHOLINE RECEPTOR. L. de Oliveira* and E. X. Albuquerque. (SPON: L. Guth). Dept. of Pharmacol. & Exp. Therap., Univ. of MD School of Medicine, Baltimore, MD 21201.

The interaction of naltrexone and levallorphan with the ionic channels at synapses of the frog sartorius muscle has been investigated with conventional techniques for measurement of endplate or miniature endplate currents (EPC and MEPC) and acetylcholine noise analysis. Naltrexone, a pure opiate antagonist shortens the time constant of decay (τ) of both EPC and MEPC. A semi-logarithmic plot of τ vs. membrane potential reveals a curvilinear relationship prominent at negative to positive potentials whose onset of inflection seen at negative potentials is a function of the drug concentration. At 60 and 300 μM, naltrexone accelerated the single exponential decay of the EPC, at –150 mV, from 3.3 to 0.8 msec and from 3.3 to 0.3 msec, respectively. This pattern shows a nonlinear function when the inverse of τ was plotted against the drug concentration at the hyperpolarized region. At drug concentrations of 300 μM, EPC peak amplitude was decreased to values less than 10% of the corresponding control condition. The onset of the nonlinearity in the current/voltage relationship was also dependent on the drug concentration. The ability of naltrexone to interact with the open conformation of the ionic channel was further evidenced by an increase in drug efficacy at a lower temperature (i.e., 10 °C rather than 22 °C). Acetylcholine noise analysis experiments show that channel lifetime and single channel conductance parameters also decreased in a voltage dependent manner and as a function of drug concentration. At a membrane potential of –75 mV and drug concentration of 40 μM, the values for channel lifetime and single channel conductance were 0.6 msec and 16 pS, respectively vs. 1.2 msec and 26 pS for control conditions. Further investigations on naltrexone suggest that the action of this agent is on the closed and open conformations of the channel. Levallorphan, a mixed antagonist of morphine also reveals a similar depressant action on both the peak amplitude and τ of the EPCs although some striking differences were noticed. Levallorphan has a stronger depressant effect on EPC amplitude than naltrexone. Indeed, levallorphan (100 μM) markedly depressed the peak amplitude of the EPC such that at –150 mV, the peak amplitude of the EPC was reduced to about 10% of control values and such an effect was highly voltage dependent. The ability of these agents to react with ionic channels of the acetylcholine receptor at concentrations similar to those used for opiate antagonism suggests that in addition to reacting with the opiate receptor, these agents display similar potencies at other types of receptor-ionic channel complexes. (Supported in part by USPHS grant NS-12063.)

281.11 REACTION OF HISTRIONICOTOXIN AND ITS ANALOGS WITH THE IONIC CHANNEL DURING AGONIST ACTIVATION OF THE ACETYLCHOLINE RECEPTOR AT THE NEUROMUSCULAR JUNCTION. M. A. Maleque*, C. E. Spivak*, M. Adler*, L. Masukawa*, J. E. Warnick, J. W. Daly*[1] & E. X. Albuquerque. Dept. of Pharmacol. & Exp. Ther., Univ. of MD Sch. of Medicine and LBC[1], NIH, Bethesda, MD 20205.

Natural and semisynthetic analogs of the saturated alkaloid histrionicotoxin (HTX; 2pR, 6S, 7pS, 8aS)-7-(cis-1-buten-3-ynyl)-8-hydroxy-2-(cis-2-penten-4-ynyl)-1-azaspiro [5.5] undecane) are: H_4–iso, H_8– and H_{12}–HTX. Both HTX and H_{12}HTX have been examined for their ability to block K conductance and to interact with the ionic channel of the ACh receptor. These studies did not include either a dose-response relationship or any of the analogs of HTX. The present study used voltage clamp techniques to analyze the endplate currents (EPCs) in frog sartorius muscles. Both HTX and H_{12}HTX depressed the peak amplitude of the EPC at all membrane potentials in a concentration dependent manner. However, the time constant of decay (τ) of the EPC exhibited saturation of the response. For example, at –90 mV, with 10, 20, 30 and 40 μM HTX, the peak EPC amplitude was reduced by 56, 86, 90 and 92% while the corresponding reduction in τ was 38, 47, 47 and 49%. With 10, 20, 30 and 40 μM H_{12}HTX, the peak EPC amplitude was reduced by 61, 72, 84 and 89%, while the corresponding reduction in τ was 36, 40, 43 and 44%, respectively. The depression of peak EPC amplitude is concentration dependent up to at least 40 μM of the toxins while τ exhibits saturation at 10–20 μM. At 4 μM H_4–iso-HTX and 25 μM H_8–HTX, peak EPC amplitude was reduced by 76 and 65% and τ was shortened by 31 and 34%, respectively, values similar to those seen with HTX and H_{12}HTX. H_4isoHTX appears to be the most potent compound. Under control conditions, the amplitude of the EPC increased initially during tetanic stimulation (25 Hz for 1 sec) and then returned to control level at the end of the train. Within 10 sec the tetanic train could be repeated 2-3 times without any difference. In the presence of HTX (35 μM) or H_{12}HTX (30 μM), there was a slight potentiation of the first 2-3 EPCs and then a rapid rundown of the EPC amplitude. At the end of the train the EPC amplitude was depressed by 57%. With 10 sec rest intervals (or less) between tetanic stimulation, subsequent trains of EPCs could be elicited in which the initial EPC in the second and third trains were 65 and 57% of the initial EPC in the first train, respectively. Although the peak amplitude of the EPC decreased significantly during the trains of stimuli, τ was unaltered during the entire tetanus (first, second or third trains). At 35 μM HTX, the mean value of τ of the first, fifth and last EPC during any tetanus was 65, 67 and 69% of control, respectively. With H_{12}HTX (30 μM) the first, fifth and last EPCs were 60, 67 and 70% of control, respectively. Thus, the complete block of peak amplitude without further shortening of τ during activation produced by the agonist in presence of HTX or H_{12}HTX suggest that the agent reacts with the channel in resting or closed conformation, open and at least one intermediate nonconducting stage. (Supported by USPHS grant NS-12063.)

281.12 INTERNAL AND EXTERNAL SITES OF ACTION OF QUATERNARY COMPOUNDS AT THE NICOTINIC ACETYLCHOLINE RECEPTOR-CHANNEL COMPLEX. L. G. Aguayo* and E. X. Albuquerque. (SPON: R. A. Sjodin) Dept. of Pharmacol. & Exp. Therap., Univ. of MD Sch. of Med., Baltimore, MD 21201.

The effects of several quaternary molecules were studied on the endplate region of the frog sartorius muscle using bath application or intracellular injection. Tetraethylammonium (TEA), atropine methyl bromide, phencyclidine methiodide (PCP MeI) and piperocaine MeI were injected into the sarcoplasm just beneath the postjunctional membrane from microelectrodes filled with 2 M, 2 M, 0.01 M and 0.001 M solutions, respectively. Taking advantage of the ability of these quaternary agents to block K conductance, the agents were released inside the cell and the prolongation of the muscle action potential was monitored. While external application of TEA (50-1000 μM) decreased the peak amplitude of the endplate current (EPC) and its time constant of decay (τ) with a simultaneous shortening of channel lifetime, this agent and atropine methyl bromide were ineffective when injected internally. However, PCP MeI (3–30 μM) had a potent action on EPCs and miniature EPCs (MEPC) when applied to either the inside or outside of the membrane. PCP MeI caused nonlinearity of the peak amplitude and a shortened channel lifetime while it sensed only 7% of the membrane potential at its binding site. Internal injection of the agent caused significant depression of the EPC and MEPC peak amplitude, the effect being more evident initially on the peak amplitude than on τ. However, as the internal concentration of the agent increased inside the cell, the effect on τ became more evident at less negative membrane potentials, somewhat different to that observed when it was applied externally. The peak amplitude of the EPC recorded at –90 mV was reduced to 43 and 46% of control with external application of PCP MeI (10 μM) and with internal application, respectively. PCP MeI had no effect on the reversal potential of the EPC which implies that the selectivity of endplate channels for Na and K ions remained unchanged. The power spectra of MEPCs were then measured in voltage-clamped fibers before and after application of drug. The half power frequencies at –60 mV were 88 Hz (τ = 1.8 msec) and 118 Hz (τ = 1.35 msec) in control and in the presence of internally applied PCP MeI, respectively. At –90 mV the corresponding values were 79 Hz (τ=2.0 msec) and 72 Hz (τ = 2.2 msec). Preliminary experiments with piperocaine MeI have shown similar effects when applied to both sides of the membrane. The ability of PCP MeI and piperocaine MeI to block the ionic channel of the acetylcholine receptor at both the outside and inside of the membrane in contrast to TEA and atropine methyl bromide, shows that active sites for binding drug may explain some of the mechanism related to voltage and time dependent effects of agents and a possible assymetry of the ionic channel. (A portion of these initial studies with PCP MeI were presented earlier as part of a New York Academy of Sciences Symposium on "Carriers and Membranes", February, 4-7, 1980.) (Supported in part by USPHS grant NS-12063.)

281.13 SWELLING OF NERVE FIBERS DURING ACTION POTENTIAL. K. Iwasa* and I. Tasaki. Lab. of Neurobiology, National Institute of Mental Health, Bethesda, MD 20205 and Marine Biological Lab., Woods Hole, MA 02543.

Concurrent with production of an action potential, a small rapid swelling of nerve fibers was observed in a variety of invertebrate nerves. The material used includes claw nerves of the crab, walking leg and claw nerves of the lobster, claw nerves of the crayfish, and squid giant axons. A piezo-ceramic bender (Gulton Industries, Inc.), pressing the surface of a nerve via a bristle with a small disc attached to the tip, was employed to demonstrate a pressure increase of about 1 dyne/cm^2 in squid giant axons and 5 dyne/cm^2 in crab nerves. A fiber optic device, Fotonic sensor (Mechanical Technology, Inc.), was used for recording a displacement of the nerve surface, and showed outward displacement of 0.5-0.7 nm in squid giant axons and 5-20 nm in crab nerves. The swelling, measured in terms of both pressure increase and surface displacement, was shown to start simultaneously with the action potential at the site of mechanical recording. In squid giant axons the rapid swelling phase is followed by a slower contraction phase. A small decrease in the length was also observed in both squid axons and crab nerves (I. Tasaki and K. Iwasa, Biochem. Biophys. Res. Commun., in press). In frog sciatic nerves no mechanical responses could be demonstrated.

Application of long pulses of electric currents was shown to generate mechanical changes in the nerve fiber. At the site of cathodal polarization, there was a smooth rise in the swelling pressure. This smooth rise was interrupted by a large abrupt rise associated with generation of a propagated action potential. At the site of anodal polarization, a large mechanical change representing a contraction of the fiber diameter was observed.

The sum of the volume of the surrounding seawater and that of nerve fibers was found to remain roughly unaltered when the fibers were excited. From this suggestive evidence it seems probable that the observed swelling is produced by invasion of water into the fibers. These observations opens up the possibility of offering new interpretations of various optical and biochemical changes that are known to occur when the nerve fibers are excited electrically.

281.14 MEMBRANE CURRENTS OF SINGLE, FRESHLY ISOLATED SMOOTH MUSCLE CELLS STUDIED WITH VOLTAGE CLAMP. Joshua J. Singer and John V. Walsh, Jr. Dept. of Physiology, Univ. of Massachusetts Medical School, Worcester, MA 01605

Single, smooth muscle cells, enzymatically dissociated from the stomach muscularis of the toad, Bufo marinus, were used to study membrane currents with the voltage clamp technique. By using single cells, we avoided the difficulties associated with syncytial tissue preparations,i.e., narrow intercellular spaces which constitute a substantial series resistance preventing uniformity of membrane potential and allow local ionic accumulation or depletion; intercellular coupling via resistances of unknown quantity and characteristics; and neural elements which may indirectly alter the membrane permeabilities of the muscle. The isolated cells were impaled with two micropipettes (30-60 MΩ), each of which was connected to a high input impedance amplifier with current injection capability. One pipette was used exclusively for recording membrane potential; the second pipette was used for current injection, but over a low range of currents where it was "in balance" the second pipette could also be used to monitor membrane potential. Thus at low current levels the membrane potential could be recorded at two separate points in the cell. Each electrode was shielded over most of its length. Since in previous studies of ours it was shown that Ca^{++} but not Na^+ was a carrier of the inward current of the action potential and that the rate of repolarization of the action potential was decreased by TEA, studies were carried out at elevated $[Ca^{++}]_o$ and in the presence of TEA (45 mM). In current clamp mode, action potentials elicited on anode break and recorded simultaneously in both electrodes were superimposable (within 2%) indicating that the cell was essentially isopotential during the action potential. In voltage-clamp mode, a positive command step gave rise to a net inward current followed by a net outward current. The net outward current reached a peak value after several hundred milliseconds and then declined over a period of seconds. The initial inward current displayed a region of negative slope resistance. In "two pulse experiments" the net inward current was reduced by more than 50% during the second pulse, requiring more than a second for full recovery.

281.15 CONDUCTION BLOCK IN PERIPHERAL NERVES: A STRUCTURE-ACTIVITY STUDY OF A SERIES OF TRIAZINONE COMPOUNDS. G.A. Condouris, D.M. Havelin*, W.L. Studt* and G.H. Douglas*, Dept. Pharmacol., N.J. Med. Sch., CMDNJ, Newark, N.J. 07103 and W. H. Rorer, Inc., Fort Washington, Pa. 19034.

A series of triazinone compounds was examined on isolated myelinated fibers of the desheathed frog sciatic-peroneal trunks to compare conduction block potency with oil/water partition coefficient and the degree of ionization. Conduction block potency was established for both a simple block of low stimulation frequency (0.5 Hz) and for a block of trains with high frequency impulses (200 Hz). Because of the low water solubility of some compounds, all were first dissolved in a small quantity of dimethylsulfoxide (DMSO). Although DMSO had no effect on nerve excitability, recovery of conduction block was always accomplished with drug-free Ringer solution containing the same concentration of DMSO as in the drug solutions. One member, WHR 1489, was selected as the reference compound for comparisons. Chemically, it is 1-(2'6'-diethylphenyl)-4-methylamino-1,2-dihydro-1,3,5-triazin-2-one-hydrochloride. WHR-1489 proved to have weak simple blocking activity, but substantial ability to block conduction at high frequencies, i.e., it causes high frequency failure (HFF). Simple local anesthetic activity is thus dissociable from HFF activity. Other members of this series had varying proportion of these two pharmacologic actions. They differed chemically by having either diethyl or dimethyl substitutions on the 2,6 positions of the phenyl ring; and also by having one of the following substitutions on the 4-amino position of the triazin: hydrogen, methyl, ethyl, propyl, or butyl.

All compounds have pKa values less than 3, therefore are uncharged at physiologic pH. Oil/water partition coefficients (P) ranged from 1.5 to more than 10,000. Only compounds with P between 10 and 65 had HFF activity without any simple blocking activity. Compounds with P >100 showed both kinds of blocking activity. Three members of the dimethyl series were inactive as blocking agents. Simple anesthetic potency was generally greater for the diethyl series, with the higher N-alkyl derivates showing significant activity; HFF potency resided mainly in the diethyl series.

The results show that uncharged amines can have nerve depressant activity and that HFF activity can reside with a molecule that has low simple local anesthetic potency.

282.1 KAINIC ACID NEUROTOXICITY IN THE RAT LATERAL GENICULATE NUCLEUS. W.R. Woodward and B.M. Coull*. Depts. of Neurol. and Biochem., Univ. of Oregon Health Sci. Ctr., Portland, OR 97201

Local injections of kainic acid (KA) into the nervous system produce destruction of neuronal perikarya while sparing axons and terminals of neurons projecting into the injection site. As a prelude to neurotransmitter studies we have examined the effects of KA injections into the dorsal lateral geniculate nucleus (dLGN) on geniculocortical and corticogeniculate neurons in Sprague Dawley rats.

Projections of dLGN neurons to visual cortex were visualized by autoradiography of radiolabelled, axonally transported phospholipids. Twenty-four hours following ^{3}H-choline injections (30 nl, 100 µCi) into dLGN, silver grains were found over a band of fibers in the outer third of the callosal radiation, immediately subadjacent to cortex, extending from dLGN to layer IV in area 17.

We made slow (5 minute) injections of KA (30 nl of 20 mM KA in buffered saline, pH 7.1) into one dLGN and buffered saline into the contralateral, control dLGN followed by survival times of 10 days. Extensive neuronal degeneration in dLGN, optic radiation, and layer IV of area 17 on the KA injected side was confirmed by a modified Fink-Heimer stain. The distribution of neuronal degeneration products coincided with the choline labelled dLGN fibers described above. On the contralateral, control side, no degeneration was observed.

The functional effects of KA injections into dLGN were assessed by comparing physiological recordings and orthograde axonal transport between injected and control sides. Ten days after a KA injection, microelectrodes containing ^{3}H-proline and ^{3}H-fucose (30 nl, 50 µCi each in saline) were used to record single unit activity from cells in area 17 and then to inject the labelled substances (Woodward & Lindström, Brain Res. 137:37, 1977). In contrast to the many units with definable receptive fields found in cortex on the control side, only spontaneous units with no definable receptive fields were found in cortex on the KA injected side. Following 24 hour survivals, no differences in labelling between control and lesioned sides were found in autoradiographs of labelled material transported from visual cortex to dLGN and superior colliculus.

In conclusion, the neuronal degeneration and alteration in physiological activity in the visual cortex confirm that KA injected into dLGN destroys geniculocortical neurons, and orthograde axonal transport of labelled proteins in corticogeniculate neurons suggests that these neurons are functionally spared.

This work has been supported by the Oregon Medical Research Foundation and by NEI grant 02456.

282.2 SYNAPTIC TERMINALS IN DORSAL LATERAL GENICULATE N. FROM NEURONS OF THE THALAMIC RETICULAR N.: AN ELECTRON MICROSCOPE AUTORADIOGRAPHIC STUDY. V.M. Montero and G.L. Scott*. Dept. Neurophysiology, Univ. Wisconsin, Madison, WI 53706.

Although the projection of TRN on dLGN and on other dorsal thalamic nuclei has been described (Cajal, '11; Jones, JCN 162: 285, '75), its synaptic terminals in these nuclei are still unknown. Also, there is no knowledge about the origin of terminals with flat vesicles in dLGN; however, they are known to survive retinal or cortical lesions. To address these questions, the visual segment of TRN of gray rats was injected with H3 proline to study its projection and synaptic terminals in dLGN, using light and electron microscopy autoradiography (LMAR, EMAR). A short survival time of 6-8 hr was used to avoid transneuronal transport of the label. The LMAR material showed that connections of TRN on dLGN are distributed along projection lines, indicating a retinotopic arrangement comparable to that of striate cortex to TRN projection (Montero et al., Brain Res. 138:407, '77). For the EMAR material, ultrathin sections of dLGN were covered with a layer of Ilford L4 emulsion, exposed for 8-12 wks and developed with D19. The identification of labeled TRN terminals in dLGN was done by quantitative analysis (Ogren and Hendrickson, JCN 188:179, '79) and by examination of labeled profiles in serial sections. Both types of analyses showed that TNR labeled terminals in dLGN are characterized by tightly packed flat synaptic vesicles and dark mitochondria. These F terminals are presynaptic, with symmetrical synapses, to perikarya, and to proximal, intermediate and distal dendrites, frequently adjacent to RL (retinal) or RS (cortical) terminals synapsing the same dendrite. They do not take part in intraglomeruli serial synapses, as P profiles (with pleomorphic vesicles) do, and they are not postsynaptic to other terminals (RL, RS, F or P). These properties are similar to those described for F terminals in rat's dLGN by Lieberman and Webster (J. Neurocytol. 3:677, '74), with the exception of F to P synapses described by these authors. Since there is electrophysiological evidence of inhibitory influences of TRN on dLGN relay cells (Sumimoto et al., Exp. Neur. 51:110, '76; Yigling and Skinner, EEG Clin. Neur. 41:476, '76), these results provide yet another example of association of terminals with flat vesicles and inhibitory synapses (Uchizono, Nature 207:642, '65; Gottlieb and Cowan, Z. Zellf. 129:413, '72). TRN terminals are strategically positioned to block excitatory inputs from retina or visual cortex on dLGN relay cells. These results suggest, in addition, that TRN terminals in other thalamic relay nuclei may also correspond to F terminals that are present in these nuclei.

Supported by NIH grants EY 02877 and HD 03352.

282.3 THE NATURE OF THE SUPERIOR COLLICULUS INPUT TO THE LATERAL GENICULATE NUCLEUS. S. Molotchnikoff and P. Lachapelle*. Dept Sciences biologiques, Université de Montréal, Qué. Canada.

We have reported previously that the Superior Colliculus (CS) projects to the dorsal Lateral Geniculate Nucleus (CGL) (Exp. Brain Res. in press). The aim of the present investigation is to study the neurophysiological relationships between the CS and the CGL. This goal was achieved by simultaneously recording single unit activity evoked from both structures in anesthetized and paralysed rabbits. The experimental protocol consisted of three successive steps. In the initial step (first control: (C1) a moving spot was swept across the geniculate cell's receptive field. In the second step (test: T) the same stimulus was used but this time its presentation was triggered by the collicular cell's spontaneous activity; in this way the stimulus presentation was made to be time locked with the CS endogenous neural activity. In the third step, a second control (C2) was repeated. In all three steps the frequency of stimulus presentation was gated to be approximately the same. This sequence was adopted to test over 142 pairs of cells. The geniculate evoked responses thus obtained in each step were compared.

Analysis of the results showed that the CS exerts two separate effects on CGL units. First in 37 pairs (26%) conditioning the stimulus presentation to collicular firing produced a significant enhancement ($P < .005$) of geniculate discharges. Second, in 24 pairs (17%) the CS decreased geniculate evoked responses ($P < .005$). In 82 pairs (57%) no significant effects were observed. Increment effect was more pronounced if the distance (D) between the R.F. was short ($0^{o} < D < 40^{o}$) or if the collicular and geniculate R.F. were far apart ($120^{o} < D < 180^{o}$). On the other hand, the decrement effect was attenuated with the distance separating the two R.F. Furthermore, collicular cells which enhanced the geniculate responses were recorded in the superficial layer of the CS (upper part of SGS), whereas collicular cells leading to the opposite effect were mostly encountered close to the stratum opticum layer.

These results clearly point toward a collicular contribution to the processing of the visual information conveyed by the retino-geniculo-cortical pathway, thus bringing new insights on less known collicular functions.

282.4 EVIDENCE FOR DIRECT LATERAL GENICULATE PROJECTIONS TO HIPPOCAMPAL FORMATION IN MAN. T. L. Babb, C. L. Wilson, E. Halgren and P. H. Crandall. Brain Research Institute, UCLA, Los Angeles, CA 90024.

Although it has long been known that the geniculostriate fibers pass over and lateral to the temporal horn in man (Meyer's loop), only recently has it been suggested that geniculate axons may actually terminate in the temporal lobe. MacLean and co-workers have demonstrated in the squirrel monkey that neurons in the posterior hippocampal gyrus give tonic on-responses to sustained light and that terminal degeneration may be followed into that gyrus following lesion of the lateral geniculate. Using fine wire microelectrode recordings in epileptic patients (Babb and Crandall, Electroenceph. clin. Neurophysiol. 1976, 40: 225-243) the following evidence has been found to support the notion of a direct geniculate projection to hippocampal formation in man: 1) Neurons give unimodal on or off responses to light (Babb et al., Neurosci. Abstr. 1976, 380). 2) The latencies are as short as 27 msec but may be longer than 100 msec, (Wilson et al., Neurosci. Abstr. 1979). 3) The neurons may respond as a geniculate X-cell by sustained firing to sustained illumination. 4) The rate of firing may be directly related to the light intensity. 5) The neurons may exhibit the Chang-effect. 6) Some neurons have discrete receptive fields similar to those plotted in animal striate cortex.

One of three neurons in one patient having receptive fields was recorded from the right posterior hippocampal gyrus and had the following characteristics: 1) The field was monocular and in the left upper quadrant, 30 degrees from the vertical meridian. 2) The size of the field was 1 degree in the shape of a circle with an on-response to a dim light in the mesopic range while dark adapted (approx. 0.3 ft-l ambient illumination). 3) In the photopic range of background illumination the location of the receptive field was the same but the size and shape decreased to a vertical ellipse 30 mins. by 15 mins. (i.e., a black bar covering that field caused cessation of firing that was sustained).

These results demonstrate that there are lateral geniculate axons that project into the hippocampal formation of man, representing a source of visual information to the limbic system significantly different than the cortico-cortical projections from peri-striate.

282.5 TECTAL AND PRETECTAL PROJECTIONS TO THE LATERAL THALAMUS OF THE RAT. Scott M. Thompson* and Richard T. Robertson (SPON: Earle A. Davis). Department of Anatomy, College of Medicine, University of California, Irvine, CA 92717.

Brainstem projections to the lateral thalamic complex were studied with retrograde transport of horseradish peroxidase (HRP). Small unilateral iontophoretic injections of HRP were made into the lateral dorsal (LD) and lateral posterior (LP) nuclei of the rat thalamus. Frozen sections were cut in the horizontal or transverse plane and the tissue was processed by conventional histochemical techniques using benzidine dihydrochloride as the chromagen.

Injections of HRP confined to LD resulted in retrogradely labelled cells in the pretectum, superior colliculus, ventral lateral geniculate nucleus, zona incerta, and thalamic reticular nucleus. Labelled pretectal cells were most prominant in the ipsilateral nucleus of the optic tract (NTO), olivary nucleus (NOL), posterior pretectal nucleus (NPP), and the anterior pretectal nucleus (NPA). A few labelled cells were seen bilaterally in the medial pretectal region. A few labelled cells were observed at the rostral tip of the superior colliculus in laminae III and IV. Retrosplenial and presubicular cortices were also labelled by anterograde and retrograde transport of HRP from LD injections.

Injections of HRP confined to LP resulted in retrogradely labelled cells in the pretectum, tectum, and the ventral lateral geniculate nucleus. Only a few labelled cells were observed in the pretectal nuclei and these were found ipsilaterally in NTO, NOL, NPP, and the dorsal part of NPA. Labelled cells were observed throughout the rostral-caudal extent of the superior colliculus in laminae II and III. Peristriate cortical areas were also labelled by anterograde and retrograde transport of HRP from LP injections.

Although the distributions of pretectal cells projecting to LD and LP are similar, the number of cells projecting to LD is much greater. Conversely, many more cells in the superior colliculus appear to project to LP than to LD. Further, these cells that project to LP are found over a much greater portion of the superior colliculus. Thus, it appears that parallel neural systems relay visual information to lateral thalamus and then to cerebral cortex. One system involves the pretectum, lateral dorsal nucleus, and limbic cortex; the other system involves the superior colliculus, lateral posterior nucleus and peristriate cortex.

282.6 FUNCTIONAL PROPERTIES OF CELLS IN THE DORSAL VENTRICULAR RIDGE OF TURTLE (PSEUDEMYS). K.R. Dünser, J.E. Fulbrook, A.M. Granda and J.H. Maxwell. Institute for Neuroscience, University of Delaware, Newark, DE 19711.

The major afferent visual pathway in turtle leads from retina to the contralateral optic tectum, thence via thalamic nuclei (mainly nucleus rotundus) into the dorsal ventricular ridge (DVR). The DVR is characterized anatomically by two types of cells according to Balaban, C.D. (J. Morph., 158: 291, 1978): large spiny neurons with overlapping dendritic fields of more than 300 μm; and aspiny neurons with few primary dendrites.

Extracellular unit recordings were taken from steel and tungsten microelectrodes at various depths in the DVR. Recording sites were identified by electrolytic lesions according to the Prussian-blue staining technique. Receptive fields (RF) were analyzed for size and driving characteristics.

Multicomponent responses were isolated from units apparently corresponding to the large spiny neurons of Balaban. The majority of cells responded to a host of spatial, temporal and chromatic stimuli over most of the monocular visual field. Cells responded well to slight movements anywhere within a RF larger than 140° in diameter but exhibited heightened responsiveness to stimuli falling in the region of visual space corresponding to the linear area centralis. Units habituated quickly to repetitive moving and stationary stimuli. All cells responded to broad chromatic spectra in both light and dark adaptation.

The large RF at later stages of the afferent visual pathway corresponds to similar findings in pigeon, where very large visual fields subtending angles of 150° have been reported in ectostriatum as well as nucleus rotundus (Revzin, A.M. and Karten, H.J., Brain Res., 3: 264, 1966/1967).

Supported by Grant 01540, from the National Eye Institute.

282.7 EFFECTS OF NUCLEUS ROTUNDUS LESIONS ON VISUAL INTENSITY DIFFERENCE THRESHOLDS IN TURTLES. A.S. Powers and R. Frank*. Department of Psychology, Bryn Mawr College, Bryn Mawr, PA 19010.

Preoperative intensity difference thresholds were assessed in seven eastern painted turtles (Chrysemys picta picta). The method used was to train the animals to discriminate between a very bright and a very dim stimulus. The stimuli were presented on two keys in a standard turtle chamber by a Kodak Carousel projector. The animals were required to make a simultaneous discrimination. After reaching criterion on the training pair (.1 vs. 2.0 log units of optical density) the turtles were trained on a procedure in which 28 trials were given per day, eight with the training discrimination and four with each of five more difficult discriminations. The animals were always reinforced (with beef baby food) for responding to the brighter stimulus (.1 log units of optical density). Since relatively little data could be collected per day, each threshold determination used data from four consecutive days. To determine the threshold, performance on each of the problems was plotted, and the threshold was taken as the point where the turtle responded correctly 75% of the time (50% being chance). Preoperative criterion was reached when the threshold did not vary more than .04 log units of optical density in two consecutive four-day blocks.

Following achievement of preoperative criterion, each animal was given bilateral electrolytic lesions aimed at nucleus rotundus thalami. After a week's recovery the threshold was measured again. Postoperatively, performance on the training stimuli continued to be above 90% correct, but thresholds were elevated in those animals with damage to nucleus rotundus. Two turtles with severe damage to nucleus rotundus (greater than 70% bilateral destruction) had elevations of .20 and .40 log units of optical density respectively and showed no recovery in three to five months of postoperative retraining. Two turtles with slight damage to nucleus rotundus (less than 40% bilateral damage) showed respectively threshold elevations of .15 and .12 log units optical density and recovered to preoperative levels after about two months of postoperative training. Three control animals, two with lesions of the thalamus dorsal to nucleus rotundus and one with a unilateral telencephalic lesion, showed little or no elevation of threshold.

These data suggest that damage to nucleus rotundus in turtles produces a deficit specific to vision. The subjects with lesions of nucleus rotundus showed no apparent impairment in their ability to press response keys, to eat, and to do easy discriminations. Their impairment was limited to the difficult intensity problems.

282.8 VISUOMOTOR CORRELATES OF THE ANURAN ACCESSORY OPTIC SYSTEM. K. Fite, N. Montgomery*, C. Wojcicki* & L. Bengston*. Psychol. Dept., UMass, Amherst, Mass. 01003.

The major component of the accessory optic system in anurans is the nucleus of the basal optic root(nBOR) which receives direct, bilateral input from a variety of retinal ganglion cells via the basal optic root(BOR) (Montgomery, Fite & Bengston, Neurosci. Abstr., 1979). Our recent studies indicate that nBOR also receives input from several cell groups in anterior thalamus which are post-synaptic to the optic neuropils. Both ganglionic and elongate neurons within nBOR project directly to the rostral portion of n. Profundus, which is located below the optic pretectal nucleus and also receives input from the optic tectum. (Based on connectivity and topographical position, n. Profundus appears to be the homologue of n. lentiformis mesencephali) Neurons in the peri-nBOR region, oculomotor complex and anterior-ventral cell groups also receive input from nBOR. The latter give rise to projections to the vestibular nuclei.

Previous studies have suggested that the accessory optic system mediates at least some aspects of visuomotor function, in particular, OKN in frog (Lazar, 1973). However, our recent results indicate that transection of BOR does not consistently eliminate horizontal OKN in Rana pipiens, although changes in the OKN frequency-velocity function may occur. Either direct damage to nBOR or elimination of both BOR and thalamic inputs to nBOR appear to result in a complete loss of OKN. Since large lesions of the pretectal region also are reported to reduce or eliminate OKN (Lazar, 1973; Ingle, pers. comm,), we hypothesize that n. Profundus may be a crucial element in the neural circuitry underlying OKN in anurans.

Monocular enucleation does not eliminate bidirectional OKN, although temporal-to-nasal stimulation is more effective than nasal-to-temporal for the remaining eye. Ipsilateral visual input to nBOR may sustain OKN for the nasal-to-temporal direction in monocular frogs. Preliminary analysis of prey-catching behaviors in BOR-transected frogs revealed an increase in the average latencies of orientations and strikes at live prey throughout the visual field. The accessory optic system of anurans may thus be involved in a variety of visually guided behaviors.

282.9 METABOLIC MAPPING OF AVIAN BRAIN AREAS RESPONSIVE TO RETINAL SLIP. Olivia McKenna and Josh Wallman. Dept. of Biology, City College of the City University of New York, New York, N.Y. 10031

Stabilizing eye movements require detection of retinal slip, i.e. movement of the visual world across the retina. The retinal signal is thought to be transmitted along anatomically distinct visual pathways to sites in the accessory optic system (AOS) and the pretectum (PT). In the AOS, electrophysiological studies have demonstrated that in the mammalian brain cells of the medial terminal nucleus and in the avian brain, cells in two subdivisions of the nucleus of the basal optic root (nBOR), the nBOR proper and the nBORd, are responsive to slow whole-field vertical movement. In the PT, the cells of the nucleus of the optic tract (NOT) in mammals respond to slow whole-field horizontal movement; structures in the avian brain with similar function have not been reported. To identify these areas and to confirm the earlier studies of the nBOR, we undertook a metabolic mapping study in chicks using the 2-deoxyglucose (2DG) method of Sokoloff.

Chicks with heads restrained were placed in a striped drum rotating at 2-4°/sec. After a 10 min pretrial, animals were injected with ^{14}C-2DG (0.16 μCi/g) and returned to the experimental apparatus for 45 min. Alternate brain sections were stained or placed against x-ray film to produce autoradiograms. Since visual pathways of chicks are crossed, differential stimulation of the two eyes provides differential stimulation of the two sides of the brain. In chicks tested with one eye stimulated by vertical moving stripes and the other eye either covered or viewing stationary stripes, the nBOR proper and nBORd contralateral to the stimulated eye became heavily labeled compared to the ipsilateral eye. This confirms the electrophysiological evidence that nBOR proper and nBORd process vertical retinal slip signals. Chicks tested with both eyes viewing horizontal moving stripes developed strongly asymmetric labeling; the lentiform nucleus of the mesencephalon (LM) and the lateral subdivision of the nBOR (nBORl) contralateral to the eye viewing temporal to nasal movement became densely labeled while the LM and nBORl contralateral to the eye viewing nasal to temporal movement showed little or no discernible label. The demonstration that the LM is responsive to horizontal stimulation supplements previous embryological evidence that LM is homologous with NOT. The similar labeling of the nBORl suggests that, although anatomically related to the nBOR, it is functionally related to the LM. The finding that only the side of the brain presented with temporal to nasal movement is heavily labeled argues that, as in the rabbit, the stronger optokinetic nystagmus shown to this direction of stimulation in the bird reflects differences in the sensitivity of the afferent pathways. (Supported by NIH grant EY-2937.)

282.10 NEURONAL MORPHOLOGY IN THE CHICKEN ECTOMAMILLARY NUCLEUS: A GOLGI STUDY. J. D. Peduzzi* and W. J. Crossland (SPON: H. Goshgarian). Dept. of Anatomy, Wayne State Univ., Detroit, MI 48201.

The cellular morphology of the ectomamillary nucleus (EMN) or nucleus of the basal optic root was investigated using the Golgi method. Ten-day old White Leghorn chicks were perfused with 3% glutaraldehyde and 3% paraformaldehyde, processed by Valverde's modification of the rapid Golgi technique, embedded in soft Epon and sectioned at 120 μm. Four types of neurons were found: 1) Multipolar neurons with large cell bodies (> 250 μm^2) which had rapidly tapering, frequently branched dendrites sometimes possessing moderate numbers of spines on the larger dendritic trunks. 2) Neurons with medium to large cell bodies (> 150 μm^2) which had dendrites issuing at opposite poles of the soma. The dendrites had varying numbers of spinous appendages on the larger trunks and resembled the large multipolar neurons. 3) Neurons with medium-sized cell bodies (150-250 μm^2) which had two dendrites leaving the soma at opposite poles or (infrequently) at right angles. These dendrites were long, lacked spines, tapered gradually and made relatively few branches. 4) Neurons with small round cell bodies (50-150 μm^2) which also had dendrites leaving the soma at opposite poles and which lacked spines. These dendrites tapered rapidly and branched more frequently than those in category (3). In general, most of the large and medium sized neurons had large dendritic arborizations extending across one-half to two-thirds of the mediolateral extent of the EMN. Nearly all categories of neurons exhibited relatively small diameter processes with conspicuous dilations along their length.

Although we are unaware of any ultrastructural studies on the chick EMN, as yet, it will be of great interest to determine the relationship of the retinal afferent synaptic terminals to these four cell types and especially to the spine bearing dendrite and varicose processes.

(Supported by PHS grant EY-01796 to W. J. C.)

282.11 ELECTROPHYSIOLOGICAL MAPPING OF THE EXTRAGENICULATE VISUAL THALAMUS IN THE CAT: RETINOTOPIC ORGANIZATION. Denis Raczkowski and Alan C. Rosenquist. Dept. Anat., Sch. of Med., Univ. Pensylvania, Phila., Pa. 19104.

In order to determine the retinotopic organization of the extrageniculate visual thalmus, we have been using single and multiple unit recording techniques to map the lateral posterior-pulvinar (LP-P) complex in lightly anesthetized (N_2O/O_2), paralyzed cats. Thirty minutes prior to recording, each animal was administered chlorolose (40 mg/kg) in a single intravenous injection. Electrode tracks were reconstructed anatomically. These findings were derived from experiments in eight cats. We have evidence for at least three separate representations of all or nearly all of the contralateral visual hemifield in the LP-P complex, which roughly corresponded to the parcellation scheme of this complex based on cortical efferent projections (Updyke, J. Comp. Neur.,173: 81-122, 1977). The representation of central vision was located along the lateral border of P and, again, on either side of the common border formed by LPl and LPi. The visual periphery was representated on either side of the common border formed by P and LPl, and also, along the medial edge of LPi. The mapping data indicted that there was litle or no expansion of central vision in any of these representations. The representation of the horizontal meridian (HM) can be visualized as a broad band oriented orthogonal to the three slab-like zones. Upper visual fields were located dorsal to the HM and lower visual fields were found ventral to the HM. With the exception of both the rostral and caudal portions of the LP-P complex, where the retinotopic organization was more complex, nearly every coronal level throughout the LP-P complex contained a representation of both the upper and lower visual fields. Thus, when viewed in three dimensions, the LP-P complex appears to contain a 'point to line' representation of the visual field, with any point in the visual field represented as a rostro-caudal linear array of points in the extrageniculate thalamus. Supported by EY-05342 and EY-02654.

282.12 LATERAL GENICULATE, LIMBIC AND MIDBRAIN AFFERENTS TO THE SUPRACHIASMATIC NUCLEUS AND PREOPTIC AREA. S. Anschel and M. Shivers*. Lab. of Neurophysiology, Yerkes Regional Primate Research Center, Emory University, Atlanta, GA 30322.

We previously reported a major convergence of afferents to the medial hypothalamus from the preoptic, lateral septal, and midbrain areas (Anschel, S., Alexander, M., and Perachio, A. A., Neurosci. Abst. 4: 215, 1978, and in preparation). Neurons receiving these diverse inputs were also found to project to extra-hypothalamic areas. Such reciprocal connections are indicative of neurons that might subserve integrative roles in regulating physiological, endocrine and behavioral functions attributed to the medial hypothalamus. In the present study we concentrated on the medial preoptic area (MPO), preoptic area (POA), and suprachiasmatic nucleus (SCN). The type and origin of input that produced short latency responses in single neurons were determined. The efferent projection sites were identified by testing for antidromic activation of the neuron.

A transpharyngeal approach through the surgically exposed optic chiasm was used in urethane anesthetized male rats. Bipolar stimulating electrodes were previously implanted in limbic and midbrain sites. A lateral geniculate bipolar stimulating electrode was positioned at a height where a maximal visual flash evoked potential was recorded at the time of recording. An additional bipolar stimulating electrode was positioned on the surface of the median eminence.

Approximately 300 neurons were tested. Histological verification is complete on 71 neurons (MPO=35, POA=30, SCN=11) responsive to single pulse (0.1 msec, 0.2-2.0 mA) electrical stimulation. The major source of input to this region was from the septal area (both medial and lateral septum). Efferents from the septum were found to converge with inputs from the lateral geniculate nucleus, reticular formation, periventricular grey, region of the mammillary body, amygdala, and recurrent collateral axons of tuberoinfundibular neurons. Additional convergence on an SCN neuron was from the lateral geniculate nucleus and periventricular grey.

Based on tests for antidromic activation of these neurons, it was determined that MPO, POA, and SCN neurons reciprocally innervate limbic areas and midbrain. Reciprocal connections were also found between MPO and lateral geniculate. These findings illustrate the neural substructure whereby secondary sensory information may be processed to regulate the physiological and behavioral functions attributed to this area.

(Supported by NIH Grant #RR 00165)

282.13 AREA 17 AND ITS PROJECTIONS TO THE SUPERIOR COLLICULUS AND LATERAL GENICULATE NUCLEUS IN THE GOLDEN HAMSTERS. K.-F. SO* and L.S. Jen* (SPON: J.C. Hwang). Dept. of Anatomy, University of Hong Kong, Hong Kong.

Area 17 was delineated in the hamsters based on the distribution pattern of projections from the contralateral cortex and from the ipsilateral dorsal nucleus of the lateral geniculate body (LGd). The callosal projections were studied in the brains of 4 hamsters with corpus callosum transection 3 days before sacrifice(Fink-Heimer stain). The geniculocortical projections were obtained in 2 hamsters using the transneuronal method. A mixture of 50 µCi of ^{3}H-Proline and 50 µCi of ^{3}H-Fucose was injected into one eye of each animal. One animal was sacrificed 10 days and the other 20 days later and the brains were processed with the autoradiographic method. It is shown by the degeneration method that area 17 is completely surrounded by callosal projections arising from the contralateral cortex and the result also shows that the caudal part of area 17 continues and passes underneath the caudal pole of the cortex forming a cap-like structure. The distribution pattern of projections from LGd agrees with that of the callosal indicating that LGd projects exclusively to area 17 in the hamsters.

The corticotectal and corticogeniculate projections were studied by placing small iontophoretic injections of tritiated amino acids into various parts of area 17 in 4 hamsters. The animals were perfused one day later and the brains were processed with the autoradiographic method. Corticotectal projections resulted from such an injection were found as a discrete patch of grains located mainly in the lower half of the superficial gray (SG) of superior colliculus although sparse grains could also be detected in the upper half of SG. The distribution pattern of cortical fibers in LGd was in the form of a column running in a rostromedial to caudolateral direction. The cortical projections to the ventral nucleus of the lateral geniculate body (LGv) seems to be more restricted and appears as a small patch of grains. For each of these cortical projections to SC, LGd and LGv, a retinotopic organization was demonstrated.

282.14 A COMPUTER-BASED PLOTTING AND ANALYSIS SYSTEM FOR BOTH LIGHT AND ELECTRON MICROSCOPES. R. Ranney Mize and John V. Harrell*. Department of Anatomy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163

Analyzing the spatial distribution of organelles within biological structures is often essential to understanding their function. We have designed a computer-assisted microscope plotting system which maps the location of organelles within tissues prepared for either light or electron microscopy and analyzes their distribution. The system consists of three components: 1) Optical incremental shaft encoders; these encoders are attached to the stage drives of the microscopes and translate stage drive rotation to electrical impulses. The effective encoder resolution is 0.39 µm for the electron microscope and 14.7 µm for the light microscope. 2) A microprocessor-based conversion/control unit; this device converts the shaft encoder impulses to 16-bit parallel binary code for computer input and provides an LED x-y coordinate readout of stage position. 3) A Hewlett-Packard 9845S 62K byte graphics minicomputer; this computer is used for input-output control during data acquisition as well as for storage, analysis, and graphic representation of data. The software which operates the plotting system is written in enhanced BASIC and includes routines for set-up, tracing, plotting, and analysis. In set-up mode, the operator initializes the system and inputs identifying information about the experiment. In tracing mode, an outline of the biological structure is obtained. To accomplish this the operator moves the stage drives so that the contours of the structure pass under a cross-hair in the microscope eyepiece. This movement produces a digital trace of the structure which is stored by the computer. In plotting mode, the positions of different types of profile within the structure are recorded automatically by pressing a single special function key on the computer keypad. Thirty special function keys are available to encode separate types of profile. In analysis mode, the computer compares trace and plot data and calculates profile depth and medial-lateral distance of each plotted profile from the appropriate contours of the structure. The analysis routine also sorts profile types, calculates profile densities, and graphically represents the plots. Hewlett-Packard utility software statistically analyzes and graphs this data. The system is currently being used to map the spatial distribution of synapses in the visual system with the electron microscope and to plot the position of cytochemically labeled neurons using the light microscope. The system should prove useful in other areas of neurobiological research as well. (Supported by NIH Grant EY-02973 and New Faculty Research Grant H-00025.)

283.1 VIP INCREASES QUANTAL CONTENT AT THE NEUROMUSCULAR JUNCTION. Michael R. Gold and A. R. Martin. Dept. Physiol., Univ. of Colorado Med. School, Denver CO 80262.

Vasoactive Intestinal Polypeptide (VIP) is one of a number of peptidergic hormones that recently have been localized to the nervous system. Previous anatomical and physiological studies suggest a close association between VIP and cholinergic systems (e.g., Phillis et al., Can. J. Physiol. Pharmacol. 56: 337, 1978; Lundberg et al., PNAS 77: 1651, 1980). To assess if there might be direct interactions between these two systems, the effects of VIP on neuromuscular transmission were studied. All experiments were done on neuromuscular junctions in the sartorius muscle of the frog, using conventional electrophysiological and analytical techniques.

In Mg^{++}-blocked preparations (1.5 mM Mg^{++}, 0.3 mM Ca^{++}) bath application of VIP produced a dose-dependent (10^{-8}-10^{-7} M) increase in quantal content of the end-plate potential (e.p.p.) while having no significant effect on quantal size (i.e.miniature e.p.p. amplitude) or resting membrane potential. At a concentration of 10^{-7} M, quantal content was increased by 16 ± 3% (mean ± SEM, n=10). In preparations blocked with curare (2.6 µM) a similar increase (16 ± 5%, n=6) was observed in e.p.p. amplitude, suggesting that the effect of VIP was independent of the level of transmitter release.

In 5 cells the effects of ionophoretic application of VIP onto Mg^{++}-blocked end-plates were studied. Long ionophoretic current pulses (1.8 sec) of 130-220nA, from electrodes containing 0.3 mM VIP, 0.1 M NaCl, 1 mM MES (pH 5.5), produced no change in membrane potential or input resistance in the muscle fibers. However, during such pulses, the quantal content of e.p.p. produced by nerve stimulation was again increased (by 28 ± 5%), while quantal size was unaffected.

These results indicate that VIP modulates neuromuscular transmission by a presynaptic mechanism which increases quantal content. (Supported by NIH grants NS06283 and NS09660)

283.2 TRANSMITTER-LIKE EFFECTS OF ANGIOTENSIN II ON CULTURED SPINAL NEURONS. P. Legendre*, G. Simonnet*, B. Dupouy* and J.D.Vincent. Unité de Neurobiologie des Comportements, U.176,INSERM, rue C. Saint-Saëns,33077 BORDEAUX-CEDEX (France).

Evidence exists that angiotensin II (AII) may play a role in neuronal function (Phillips I. et al., Fed. Proc., 38 : 0008, 1979). The high density of AII immunoreactive nerve terminals found in the substantia gelatinosa and the lateral column suggests, moreover, that AII may act at the spinal cord level (Fuxe, K., et al., Neurosci. Lett., 2 : 229, 1976). The present investigation has studied the effects of AII on the membrane properties of cultured spinal neurons.

Neurons were dissociated from spinal cords of 13 day-old fetal mice and grown in tissue culture according to methods previously described (Barker, J.L. and Ransom, B.R., J. Physiol., 280 : 331, 1978). Intracellular recordings were made on the modified stage of an inverted phase microscope at 30°C using micropipettes filled with 3M KCl.Ten mM Mg^{2+} was added to the bathing medium to block ongoing synaptic activity and thus allow clearer examination of the membrane events. AII (Bachem.) was applied by pressure from an extracellular pipette containing 100 µM (dissolved in the bathing medium) placed close to the cell surface. GABA (Sigma) was iontophoresed from a 0.5 M solution brought to pH 3.5.

Application of AII caused an hyperpolarisation associated with a decrease in membrane conductance in 46 of 109 cells tested. The response was rapid in onset and in offset and no desensitization was observed with sustained application or closely repeated pulses of the peptide. The inversion potential of the hyperpolarizing response to AII (-20 mV) was identical to that of the depolarizing response to GABA recorded from the same cell when using KCl pipette.This suggests that the conductance inactivated by AII is the same conductance activated by GABA i.e. conductance to Cl^-. Furthermore,AII depressed and suppressed in a dose-dependent reversible manner the response to GABA when applied simultaneously. We conclude that AII may have an excitatory role at the level of spinal cord neurons.

283.3 EFFECTS OF MORPHINE AND MET-ENKEPHALIN ON THE NEURONAL RESPONSE TO SUBSTANCE P IN THE MESENCEPHALIC RETICULAR FORMATION OF THE RAT. (D.D. Spring* and H.J. Haigler, Dept. of Pharmacology, Emory Univ., Atlanta, GA 30322)

The mesencephalic reticular formation (MRF) is an area where a nociceptive stimulus (Haigler, Life Sci. 19, 841, 1976) and substance P (SP), a putative nociceptive neurotransmitter (Walker, et al., Experientia 32, 214, 1976) can produce an increase in neuronal firing. In the MRF, morphine (MS) and met-enkephalin (ME), administered microiontophoretically, blocked the excitation produced by a nociceptive stimulus (Hosford and Haigler, J. Pharmacol. Exp. Ther., in press, 1980). SP was administered microiontophoretically in the MRF to determine 1) if there was any correlation between SP and the neuronal response to a nociceptive stimulus (i.e., foot pinch); and 2) if iontophoretically administered MS or ME would block the neuronal response to SP.

Male Sprague-Dawley rats (220-350 gms) were anesthetized with chloral hydrate (400 mg/kg). A five-barrel micropipette was lowered into the brain through a hole drilled in the skull. The micropipette contained ME (10 mM), MS (50 mM) and SP (1 mM) in three side barrels; a fourth side barrel, filled with 4 M NaCl, was used as a current balance barrel; the central barrel, filled with 2 M NaCl and fast green, was used to record single unit activity. Most neurons tested with the nociceptive stimulus responded with a significant ($p < 0.05$:1-way ANOVA) increase in firing. SP, administered microiontophoretically, significantly increased ($p < 0.05$) the neuronal firing in 9 cells; significantly decreased the neuronal firing in 10 cells; and had no effect on neuronal firing in 23 cells. In 5 neurons, both SP and the nociceptive stimulus produced a significant increase in firing. In 1 cell, both SP and the nociceptive stimulus produced a significant decrease in firing. However, in some cases, SP and the nociceptive stimulus did not produce the same effect on neuronal firing. For instance, SP produced a significant decrease in firing in 4 cells in which the nociceptive stimulus produced a significant increase in firing. When tested in conjunction with SP, iontophoretic MS blocked the effects of SP on neuronal firing in 2 of 4 cells; iontophoretic ME, on the other hand, blocked the effects of SP in only 1 of 4 cells.

Because SP did not consistently mimic the response to the nociceptive stimulus (foot pinch) used in this study, SP may not be the neurotransmitter that mediates the type of pain associated with foot pinch. SP may mediate the increase in firing evoked by other types of nociceptive stimuli (e.g., radiant heat). However, SP may also mediate other behavioral effects (i.e., catatonia); MS and ME may also alter these behavioral effects of SP. (Supported in part by NIDA grant 1-R01-DA-01344-04.)

283.4 SOMATOSTATIN INHIBITS SUBSTANCE P-EXCITABLE DORSAL HORN NEURONS OF THE LUMBAR SPINAL CORD. M.F.Piercey and F.J.Einspahr*, The Upjohn Company, CNS Research, Kalamazoo, MI 49001.

According to Hökfelt et al. (Neurosci. 1:131-136, 1976), somatostatin (SRIF) and substance P (SP) exist in separate but comingling populations of small diameter sensory axons synapsing in the spinal cord dorsal horn. We have used multibarreled microelectrodes to iontophoretically eject these peptides onto lumbar dorsal horn neurons of unanesthetized decerebrate low (L_1) spinal cats. Center barrels of the microelectrode assemblies were used for recording nerve impulses extracellularly, while the outer barrels were filled with SRIF (1 mM in 165 mM NaCl), SP (1 mM in 165 mM NaCl), glutamate (500 mM, pH 8), 2M NaCl (for current controls and balancing) and pontamine sky blue (ejected at the end of the experiment to insure dorsal horn locations for recorded cells). As Randic' and Miletic' reported for the sacral cord (Brain Res. 152:196, 1978), we found that SRIF (100-200 nA) sometimes inhibited lumbar dorsal horn neurons. These inhibitions were typically weak (complete cessation of firing rarely occurred) and prolonged, the effects sometimes outlasting the ejection period by several minutes. Some of the cells inhibited by SRIF were excited by SP. Although SP-evoked responses usually had a slow onset, more rapid responses could sometimes be elicited with higher ejection currents. This suggests that slow onsets were due to the unusually poor ejection of SP from microelectrodes (shown in separate in vitro experiments). SP-excitable dorsal horn neurons were also excited by noxious (>45°C), but not by non-noxious cutaneous heat, supporting the hypothesis that SP may be the neurotransmitter for nociceptor afferents. Although it is not yet clear how the inhibitory responses to SRIF relate to sensory transmission, the fact that single dorsal horn neurons possess receptors for both SRIF and SP raises the possibility for complex processing of sensory information in the dorsal horn should the appropriate afferents converge on these cells.

283.5 RECEPTOR-MEDIATED RELEASE OF PLASMA MEMBRANE-ASSOCIATED CALCIUM AND STIMULATION OF CALCIUM UPTAKE VIA VOLTAGE-SENSITIVE CALCIUM CHANNELS BY THYROTROPIN-RELEASING HORMONE IN CULTURED PITUITARY CELLS. K.-N. Tan* and A. H. Tashjian, Jr.* (SPON: P. B. Dews) Dept. of Pharmacol., Harvard Med. Sch. and Lab. of Toxicol., Harvard Sch. Pub. Health, Boston, MA 02115.

GH_4C_1 cells are a clonal strain of rat pituitary cells which synthesize and secrete prolactin (PRL). They have specific functional receptors for the hypothalamic tripeptide thyrotropin-releasing hormone (TRH) which stimulates the acute release of PRL. GH-cells have recently been found to be electrically excitable, and TRH has been reported to enhance the generation of Ca-dependent action potentials (Ozawa, S., PNAS USA, 76:6017, 1979). By kinetic analysis of $^{45}Ca^{2+}$ uptake and treatment of the cells with trypsin-EDTA, we can distinguish calcium bound to the extracellular surface of plasma membrane from the intracellular pool. We report here that TRH has two distinctive effects on calcium fluxes in the cells. First, at 37°C, TRH (10^{-7} M) caused an acute release of calcium from cells into medium in a dose-dependent manner (ED_{50} = 0.8 nM; $t_{½}$ = 15 sec.). Calcium released was mobilized from a cellular compartment which was removed by treatment of intact cells for 10 min. at 24°C with trypsin(0.5%)-EDTA(0.02%) or viokase(0.1%), suggesting that the calcium was released from the outer surface of the cells. The second effect of TRH was to stimulate uptake of calcium into intracellular compartment. ED_{50} for stimulation was ~ 0.2 nM in good agreement with ED_{50} for stimulation of PRL release, 0.3 nM. TRH-enhanced calcium uptake was blocked by 200 ug/ml verapamil or 4 mM Co^{2+} suggesting the involvement of voltage-sensitive Ca-channels. The same concentrations of verapamil and Co^{2+} also inhibited TRH-stimulated PRL release. Calcium uptake, therefore, appears necessary for TRH-induced PRL release. On the other hand, TRH-mediated release of membrane calcium was not blocked by verapamil; calcium release alone was, therefore, insufficient to cause enhanced PRL release. Relative potencies of TRH and four TRH analogs for stimulation of calcium uptake and rapid release of membrane calcium correlated well with their potencies for stimulation of PRL release and affinities for the TRH receptor. TRH did not affect calcium fluxes in pituitary cells lacking TRH receptors. We conclude that two types of calcium movements in GH_4C_1 cells are regulated by the TRH receptor and that an increased uptake of calcium into the intracellular compartment via voltage-sensitive Ca-channels is required for TRH-enhanced PRL release.

283.6 NEUROTENSIN BLOCKS BEHAVIORS INDUCED BY INDIRECT, BUT NOT DIRECT DOPAMINE AGONISTS: EVIDENCE FOR MEDIATION AT A MESOLIMBIC DOPAMINE TERMINATION SITE, THE NUCLEUS ACCUMBENS. C. B. Nemeroff, D. Luttinger, A. J. Osbahr, III*, A. J. Prange, Jr.* Biol. Sci. Res. Ctr., Dept. Psychiatry, and the Neurobiology Program, University of North Carolina School of Medicine, Chapel Hill, NC 27514.

Neurotensin (NT), a neuropeptide, has been reported to produce a variety of effects after CNS administration in rodents including muscle relaxation, hypothermia, analgesia and potentiation of pentobarbital and ethanol-induced sedation (Brain Res. 128:485, 1977; PNAS 76:5368, 1979). Many of these properties of NT are shared by antipsychotic drugs. The purpose of the present study was two-fold: (1) we have previously shown that intracisternally (IC) administered NT blocks the increase in locomotor activity seen after d-amphetamine administration in mice. The effect of NT on the locomotor hyperactivity induced by another indirect-acting dopamine (DA) agonist, cocaine (20 mg/kg subcutaneously [SC]) and by two direct acting DA agonists: apomorphine (5 mg/kg, SC) and lergotrile (10 mg/kg, SC) were evaluated utilizing circular photocell cages. Such studies aid in discerning the locus of action (presynaptic vs postsynaptic) for the apparent "antidopaminergic" effects of NT. NT (1 µg IC) blocked the increase in locomotor activity induced by d-amphetamine and cocaine ($p < 0.05$) but did not alter apomorphine or lergotrile-induced hyperactivity. (2) The direct bilateral injection of NT or haloperidol into the nucleus accumbens (a termination site of the mesolimbic DA system) of rats significantly blocks the behavioral effects (↑ locomotor activity and rearing) of a low dose of d-amphetamine (2 mg/kg, IP) (Biol. Psychiat. 15:283, 1980). These results were extended by evaluating the effect of direct bilateral injection of NT or haloperidol into the caudate nucleus (a termination site of the nigrostriatal DA system) on stereotypies induced by a higher dose of d-amphetamine (5 mg/kg, IP). The incidence of certain behaviors was assessed by a trained observer ignorant of the treatment regimen (Brain Res. 132:507, 1977). NT injections (3 or 5 µg) into the caudate nucleus did not block d-amphetamine-induced stereotypy, whereas haloperidol (5 µg) did. Conclusions: (1) NT blocks the effects of indirect, but not direct DA agonists. (2) NT blocks d-amphetamine-induced behaviors thought to be mediated by the mesolimbic DA system but not those mediated by the nigrostriatal DA system. These findings, taken together with the current view of the importance of the mesolimbic DA system in the pathogenesis of schizophrenia, indicate that NT, which is found in high concentration in mesolimbic regions, may modulate dopaminergic function in regions thought to be involved in the pathogenesis of schizophrenia.

283.7 INHIBITION OF CONDITIONED AVOIDANCE RESPONDING AND REWARDING ELECTRICAL SELF-STIMULATION OF THE BRAIN BY CENTRALLY ADMINISTERED NEUROTENSIN. D. Luttinger, R. Wiggins*, R. A. King, C. B. Nemeroff, A. J. Prange, Jr.* Biological Sciences Research Center, Depts. of Psychiatry & Psychology, and the Neurobiology Program, University of North Carolina, Chapel Hill, North Carolina 27514.

Neurotensin (NT), an endogenous tridecapeptide, produces several effects after CNS administration which are similar to effects produced by neuroleptics. These similarities include hypothermia, muscle relaxation, and antagonism of amphetamine-stimulated locomotor behavior. To extend the investigation of similarities of the effects of NT and neuroleptics, the actions of NT were assessed in adult male albino rats in two behavioral paradigms commonly used as screens for neuroleptic activity.

The effect of intracerebroventricular (ICV) NT on discrete trial avoidance responding in rats implanted with a lateral ventricular cannula was qualitatively similar to the effect of neuroleptics. Every thirty seconds an avoidance trial was initiated with the onset of a tone and light conditioned stimulus; if the rat did not move to the other side of the box within ten seconds, it was presented with the unconditioned stimulus--a 0.7 mA footshock for a maximum of five seconds. After a stable baseline criterion of greater than 90% avoidance responding was obtained, the rats were injected with NT (0.3-30 µg/10 µl) or 0.9% saline (10 µl), 30 min before behavioral testing. NT (⩾ 1 µg) decreased avoidance responses by approximately 30%; escape responses were unaffected. ICV administration of ß-endorphin and bombesin, two peptides previously shown to produce similar effects to NT, did so in this paradigm as well. Several neuropeptides did not affect avoidance responding after ICV administration: TRH, LHRH, MIF-I, bradykinin, and substance P.

In the self-stimulation paradigm, a unipolar electrode was placed in the A_{10} region and a cannula was implanted in the ipsilateral nucleus accumbens. Every lever press produced brain stimulation and the current (45 to 85 µA) was adjusted for each animal so that stable rates of responding were obtained (6000 to 9000 responses/hour). Injections of NT (1-5 µg/2 µl 0.9% saline vehicle), like neuroleptics, produced a dose-dependent decrement in the rate of self-stimulation. The 5 µg dose resulted in a 30-50% decrement; the 2 µg dose 20-40%; 1 µg exerted no effect. The onset of the decreased rate of self-stimulation after NT was observed approximately 15 min post injection and remained depressed for at least 45 min.

Conclusion: In both paradigms, the effects of NT were similar to neuroleptics. The data, together with previous findings, suggest that neurotensin may exert neuroleptic-like effects.

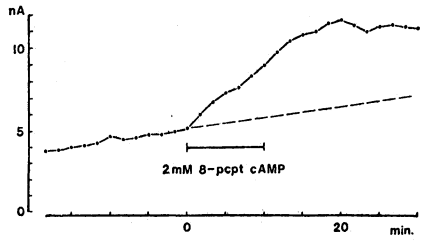
This work was supported by NIMH MH-32316, NH-22536, MH-33127 and NICHHD HD-03110.

283.8 HYPOTHERMIA AND INHIBITION OF FEVER INDUCED BY CENTRAL ADMINISTRATION OF ACTH AND α-MSH. J.R. Glyn* and J.M. Lipton. Depts. of Physiology and Neurology, University of Texas Health Science Center at Dallas, Dallas, Texas 75235.

Preliminary testing of the effects on body temperature of several peptides yielded two, ACTH(1-24) and α-MSH, which lowered body temperature (Lipton, J.M. & Glyn, J.R., Peptides, 1:15, 1980). In the present experiments, this response was dependent on the ambient temperature (T_a) in that both ACTH and α-MSH (1.25-5µg ICV) caused dose-related decreases in body temperature at T_a = 23°C, greater hypothermia at T_a = 10°C, but no temperature change at T_a = 30°C. Leukocytic pyrogen-induced fever and PGE_2-induced hyperthermia were also reduced by α-MSH and ACTH (5µg ICV). The reduction in temperature was associated with peripheral vasodilitation. The small peptide α-MSH is contained within ACTH (residues 1-13), and the shared sequence could be responsible for the effects on temperature. ACTH has been used clinically to reduce fever (Kass, E.H. & Finland, M., New Engl. J. Med., 243:693, 1950) and is released during endotoxin fever in man (Conn, J.W., et al., Recent Progress in Hormone Research, 10:471, 1954). ACTH and α-MSH are found in hypothalamic areas involved in temperature regulation (Kreiger, D.T., Liotta, A. & Brownstein, M.J., Brain Res. 128:575, 1977; O'Donohue, T.L., et al., Neuroendocrinology 27:281, 1979); therefore, these peptides may have a role in central thermoregulation in afebrile and febrile states. (Supported by National Institutes of Neurological and Communications Disorders and Stroke Grant NS 10046.)

284.1 Ca-ACTIVATED K CURRENT IS ENHANCED IN MOLLUSCAN NEURONS BY AGENTS THAT ELEVATE INTRACELLULAR CYCLIC AMP CONCENTRATION. D. Ewald & R. Eckert. Dept. of Biology, UCLA, Los Angeles, CA 90024.

Calcium ions were iontophoretically injected into somata of neurons of the Aplysia abdominal ganglion voltage-clamped at -30 to -40 mV in 1/10 K ASW. Ca pulses 1 to 2 sec long elicited outward current transients of 2 to 10 nA lasting 2 to 4 sec (measured at half peak amplitude) which reversed at the K equilibrium potential. Such current transients were produced with constant Ca injections delivered at 100-sec intervals for up to 3 hr. Agents known to increase intracellular cyclic AMP concentrations were superfused onto the ganglion in concentrations of up to 2 mM for periods of 10 min. Derivatives of cyclic AMP which resist hydrolysis by phosphodiesterase caused a significant increase in the amplitude of the K current. The magnitude of this increase was 30-50% (n=3) in response to 8-benzylthio cAMP and 40-120% (n=3) in response to 8-p-chlorophenylthio cAMP (Fig.). Simultaneous exposure to dibutyryl cAMP and either methylxanthine or imidazoladinone phosphodiesterase inhibitors caused an increase in amplitude of 30-40% (n=3) which was readily reversed at the end of exposure. The adenylate cyclase activator cholera toxin increased the K current amplitude 20-60% (n=4). Enhancement of the Ca-activated K current by these agents might come about by 1) an increased rise in intracellular levels of ionized Ca^{++} during Ca injections, due to reduced Ca-buffering capacity of the cytoplasm, or 2) an increase in the sensitivity of the K channel to Ca^{++}. (Supported by NIH grant NS08364.)



284.2 SEROTONIN STIMULATES PHOSPHORYLATION OF A 137,000 DALTON MEMBRANE PROTEIN IN THE ABDOMINAL GANGLION OF APLYSIA. C. Gregory Paris,* Eric R. Kandel, and James H. Schwartz. Div. of Neurobiol. & Behavior, Depts. of Physiol., Psychiat., and Neurol., Columbia Univ., P&S, New York, N. Y. 10032.

There is considerable evidence that a serotonin-stimulated adenylate cyclase initiates the synaptic events underlying sensitization of the gill withdrawal reflex in Aplysia. We therefore searched for proteins that might be phosphorylated, focusing on membrane components because they are likely to mediate the changes in Ca^{++} current implicated in the presynaptic facilitation of the reflex.

We have obtained reproducible SDS gel electrophoretic profiles of phosphorylated membrane proteins from excised abdominal ganglia incubated for 0.5 to 3 hours in $^{32}P_i$. We have identified a single protein (molecular weight 137 kD) whose extent of phosphorylation was increased dramatically in ganglia incubated in the presence of 10^{-4} M serotonin. This concentration was previously found to increase the content of cAMP in the ganglion maximally. The effects of serotonin were mimicked by dibutyryl-cAMP (10^{-4} M). Demonstration of ^{32}P-phosphorylation depended on the inclusion of a phosphodiesterase inhibitor: Ro-20 and IBMX, both at 10^{-4} M, were equally effective and much better than theophylline at 10^{-3} M.

From the physiological point of view, the phosphorylation was unexpectedly slow. The 137 kD protein was not visibly labeled after the ganglion had been exposed to serotonin for 0.5 hours; at one hour the protein was incompletely labeled; by two hours maximal labeling had occurred, and persisted for at least an additional hour. A partial explanation for these kinetics may be that exogenous $^{32}P_i$ only slowly becomes available to a critical pool of ATP in the ganglion. In support of this explanation, we found that $^{32}P_i$ was incorporated into ATP at a constant rate for as long as 24 hours.

We have found that the phosphoprotein is a membrane component. Membranes were prepared from the incubated ganglia, after removal of the bag cell clusters, and were exhaustively washed in a buffer of low ionic strength. In addition, the phosphorylated protein was not found in the cytoplasmic fraction of stimulated or unstimulated ganglia.

To localize the regions where phosphorylation takes place we isolated cell bodies and neuropil by dissection. Relatively small amounts of the protein were phosphorylated in cell bodies and neuropil from unstimulated ganglia. Exposure to serotonin greatly increased phosphorylation of the protein in both regions of the ganglion. A glial cell origin for this protein has not yet been ruled out. Experiments are now in progress to determine in single neurons where the protein is phosphorylated.

284.3 RELATIONSHIPS BETWEEN CYCLIC NUCLEOTIDES AND ELECTROPHYSIOLOGIC ACTIVITY IN HIPPOCAMPAL SLICES. J.A. Ferrendelli, A.C. Blank*, D.A. Kinscherf* and E.W. Lothman. Div. of Clin. Neuropharm. and Depts. of Neurol. and Pharm., Washington Univ. Med. Sch., St. Louis, MO. 63110.

Previous studies have indicated that cyclic AMP and cyclic GMP may be involved in pathophysiologic mechanisms of epilepsy. To better define the relationships between seizures and cyclic nucleotides we have examined the effects of [K+] on electrical activity and endogenous levels of cyclic AMP and cyclic GMP in incubated slices of hippocampus. In addition, the actions of exogenous cyclic nucleotide derivatives were assessed.

Tissue slices, 350 - 400 mμ thick, were prepared from freshly killed guinea pigs using conventional methods and incubated in an oxygenated physiologic buffer, pH 7.4, containing 127 mM NaCl, 2 mM KCl, 1.5 mM $MgSO_4$, 1.5 mM $CaCl_2$, 25 mM $NaHCO_3$, 1.1 mM KH_2PO_4 and 10 mM glucose. Tissues were analyzed for cyclic nucleotide content by radioimmunoassay as described previously. Standard techniques for recording from CA_3 and stimulation of mossy fibers were used.

In control media the tissue slices exhibited random single unit discharges, and stimulation of mossy fibers produced complex evoked potentials of 10 - 20 msec duration in CA_3. Control levels of cyclic GMP and cyclic AMP were 0.92 ± 0.03 and 14.6 ± 0.7 pmoles/mg prot, respectively. Increasing the [K+] in the incubation media had a marked effect on both electrical activity and cyclic nucleotide levels. Cyclic GMP levels were increased 50 - 100%, in a dose-dependent manner by [K+] between 6 and 15 mM, and cyclic AMP levels were depressed 50%. At 6 - 9 mM K^+, evoked potentials were more complex and of longer duration, and spontaneous activity markedly increased. In most slices, 6 - 9 mM K^+ produced epileptiform activity. Higher [K+] progressively depressed activity, and with 15 mM K^+ there was electrical silence. At normal [K+] (3.1 mM), isobutylmethylxanthine (100 μM) elevated cyclic GMP levels, depressed cyclic AMP, and produced increased spontaneous and epileptiform activity in the slices. Addition of 8-Br-cyclic GMP (0.03 - 0.1 μm) also augmented evoked potentials, increased spontaneous activity, and, in some slices, produced epileptiform activity. In contrast, 8-Br-cyclic AMP (0.1 - 10 μm) always reduced activity.

The results of this study suggest electrophysiologic activity in hippocampal slices is positively correlated with cyclic GMP concentration and negatively correlated with cyclic AMP concentration. In addition, the results support the hypothesis that cyclic GMP is involved in seizure genesis and/or maintenance and cyclic AMP may have a role in seizure suppression.

Supported, in part, by USPHS Grant NS 14834.

284.4 GUANOSINE 3';5'-MONOPHOSPHATE (cGMP) ACCUMULATION BY AND RELEASE FROM RAT SUPERIOR CERVICAL GANGLIA. R. L. Volle, B. A. Patterson* and L. F. Quenzer. Dept. of Pharmacol., Univ. of Connecticut, Farmington, CT 06032.

Ganglia treated with theophylline (1 to 10mM) accumulate cGMP when bathed in solutions containing elevated [K^+] (30 to 60mM) or sodium azide (NaN_3; 10^{-5} to 10^{-3}M). Intact and denervated ganglia contained 0.67 pmol cGMP·mg^{-1} protein. When $[K^+]_o$ was increased to 60mM in intact ganglia, cGMP content was raised to 30.8 pmol·mg^{-1} protein. K^+ had no effect on the cGMP content of denervated ganglia or on intact ganglia bathed in solutions lacking Ca^{++}. With intact ganglia, NaN_3 (10^{-4}M) increased cGMP content to 5.7 pmol·mg^{-1} protein. The response to NaN_3 was reduced by 40% in denervated ganglia and unaffected by low $[Ca^{++}]_o$. The loss of response to K^+ following preganglionic nerve section, paralleled the loss of ganglionic choline acetyltransferase activity and was complete within 24 hrs. The decreased response to NaN_3 was complete 48 hrs after nerve section. Cholinergic drugs (atropine, hexamethonium and eserine) had no effect on the cGMP response to K^+. Release of cGMP into the medium followed cGMP accumulation by the ganglia. K^+-induced release occurred only from intact ganglia and required Ca^{++}. The amount of cGMP in the medium was increased by 60mM K^+ from 0.02 pmol·ml^{-1}·ganglion to 0.20 pmol·ml^{-1}·ganglion after 10 min incubation. cGMP release produced by NaN_3 (10^{-3}M) was increased from 0.012 to 0.032 pmol·ml^{-1}·ganglion. When Ca^{++} was omitted from the medium, NaN_3 increased cGMP to 0.30 pmol·ml^{-1}·ganglion. These results suggest that cGMP accumulation occurs in pre- and postganglionic neurons, that depolarization per se cannot account for the responses to K^+ and that acetylcholine is not involved in the accumulation of cGMP caused by K^+. (Supported by NS 07540-13).

284.5 ELECTRICAL STIMULATION OF THE SUPERIOR CERVICAL GANGLIA INCREASES THE CONCENTRATION OF CYCLIC AMP OF RAT PINEAL GLAND. W.E. Heydorn, B. Weiss and A. Frazer. Depts. of Psychiat. and Pharmacol., Univ. of Penna., Dept. of Pharmacol., Med. Col. of Penna., and Vet. Adm. Hospital, Phila., Penna. 19104.

There is as yet no clear demonstration that electrical stimulation of discrete sympathetic nerves increases the concentration of cyclic AMP in a well-defined sympathetically innervated end organ. Recent results showing that desmethylimipramine (DMI) potentiates the effects of exogenously administered norepinephrine (NE) in elevating cyclic AMP levels in rat pineal gland suggested the means by which one might demonstrate a rise of cyclic AMP induced by electrically stimulating its sympathetic input. Rats were kept in constant light for 6 days prior to sacrifice. Animals were decapitated, both superior cervical ganglia (SCG) were rapidly isolated, attached to platinum bipolar electrodes and stimulated with square wave pulses. After stimulation, pineal glands were removed and frozen on dry ice within 20 sec. Cyclic AMP was measured by radioimmunoassay. In the absence of DMI, stimulation of the SCG produced small and inconsistant increases in cyclic AMP in pineal gland. However, in rats pretreated with DMI (40μmoles/kg, i.p., 1 hr before decapitation) electrical stimulation of the SCG produced a reproducible, marked (greater than 5-fold) and highly significant ($p<0.001$) elevation of cyclic AMP. In the DMI-treated animals, maximal elevations of cyclic AMP were found following 1 min of stimulation using 10V, 1 msec duration and a stimulus frequency of 10 Hz. Administration of reserpine, which depletes NE in sympathetic nerve terminals, blocked the rise of cyclic AMP caused by electrical stimulation of DMI-treated rats. Bretylium, which inhibits the release of NE caused by nerve stimulation, also reduced the elevation of cyclic AMP induced by SCG stimulation. Pretreating rats with the beta-adrenergic blocking agent, propranolol, prevented completely the increase of cyclic AMP caused by electrical stimulation whereas pretreating rats with the alpha-adrenergic antagonist, phentolamine, did not. These results demonstrate for the first time a pronounced elevation in cyclic AMP in a sympathetically innervated organ induced by electrically stimulating discrete sympathetic fibers innervating this organ. They indicate further that the increases in cyclic AMP are due to NE, released from presynaptic nerve terminals, stimulating β-adrenergic receptors located on the postsynaptic cell membrane. 284.6 EFFECT OF TREATMENT WITH CYCLIC AMP (cAMP) AND PARACHLOROPHENYLALANINE (pCPA) ON THE EEG AND BEHAVIORAL ACTIONS OF MORPHINE IN THE RAT. K. Sharifi Hossaini and M.S. Shahid Salles. Departments of Pharmacology and Physiology, Medical School, Shiraz University, Shiraz, Iran

Rats were prepared with permanent electrodes for recording EEG and EMG. Morphine injections of 10 mg/kg given s.c. were followed by the appearance of high voltage EEG slow bursts associated with stuporus behavior. This phase was suppressed by the appearance of behavioral arousal shown by EMG and behavior of the rat and afterwards behavioral sleep became apparent on the EEG. Administration of a 10 mg/kg dose of morphine to rats pretreated with pCPA (100 mg/kg/day for 3 days) was followed by an almost immediate EEG and behavioral arousal with only a few intervening episodes of behavioral stupor associated with slow bursts. Combined treatment with pCPA and cAMP (50 mg/kg, i.p., 24 hrs before morphine) does not affect the antagonistic effect of cAMP on morphine analgesia (Shahid Salles et al., Sleep Research 1 : 1979). The result of tailflick-tests in another series of animals pretreated with pCPA (100 mg/kg, i.p./day, for 3 days) or both pCPA and cAMP (50 mg/kg, i.p., 24 hrs before morphine) were in agreement with those obtained from our EEG recording. This may suggest that there is no interaction between cAMP and brain serotonin in the mediation of morphine's analgesic effect.

285.1 THE SPINAL CORD DORSAL HORN IN AN ANIMAL THAT LACKS UNMYELINATED AXONS IN THE DORSAL ROOT. Stewart C. Birse and Richard E. Coggeshall. Depts. of Anatomy and of Physiology and Biophysics and the Marine Biomedical Institute. The University of Texas Medical Branch, Galveston, Texas 77550.

The nervous system of the stingray, Dasyatis sabina, is remarkable because there are no unmyelinated axons (C fibers) in the dorsal roots and peripheral nerves. This presumably implies that the spinal cord does not receive a primary afferent C fiber input. In view of recent studies suggesting that a major input to the substantia gelatinosa in mammals consists of C fibers from the dorsal roots, the stingray offers an interesting opportunity for a comparative analysis of spinal cord organization.

The dorsal horn of the stingray is relatively large. Overlying the dorsal horn is a prominent layer of myelinated and unmyelinated axons which are in the same position as the primary afferent axons in the dorsal white columns of mammals. Under this fiber layer is an area that closely resembles the mammalian substantia gelatinosa. In the ray, this area is large, proportionately much larger than in the mammal or in a teleost, the goldfish. Myelinated fibers are almost completely absent and small, closely packed neurons form the major cellular component of the layer. Synaptic glomeruli, which consist of a central, relatively electron dense axonal terminal surrounded by numerous small dendrites, are common. These appear identical to the glomeruli which are regarded as the most characteristic features of mammalian substantia gelatinosa. Thus, in an animal that has a spinal cord that seems to lack a primary afferent C fiber input, the substantia gelatinosa is indistinguishable cytologically and proportionately larger from the substantia gelatinosa in mammals.

Subjacent to the gelatinosa is a region of gray matter which resembles the mammalian nucleus proprius. This area contains many myelinated axons. Dorsal root section leads to a wedge-shaped area of degenerating axons located in the lateral funiculus, substantia gelatinosa, and nucleus proprius in the segment of root entry. Rostral and caudal to the lesion, degeneration is prominent only in the nucleus proprius. Degeneration products can be traced for only one or two spinal cord segments and are never found in the dorsal fiber system.

These latter results suggest that primary afferents 1) synapse within one or two segments of their entry into the ray spinal cord, and 2) do not branch to form a dorsal column system as in the mammalian CNS. Therefore ascending sensory information is probably carried by second order myelinated neurons in the stingray. This work was supported by grants NS 06309, NS 10161, NS 11255, and NS 07377.

285.2 SEGMENTAL PATTERN OF THE EVENTS ASSOCIATED WITH THE EARLY DEVELOPMENT OF MARGINAL ZONES IN *XENOPUS* SPINAL CORD. Golda A. Kevetter and Raymond J. Lasek, Cept. of Anatomy, Case Western Reserve Univ., Cleveland, OH 44106

We have been studying the morphological transformations that result in longitudinal columns of axon pathways throughout the rhombencephalon and spinal cord of *Xenopus*. Previously we observed that the marginal zone developed in an orderly progression in both the rostrocaudal and dorsoventral axes (Anat. Rec., 1980, 196: 96). Early axons were located in fascicles on the ventrolateral border of the developing brainstem. The development of the marginal zone originated from foci located adjacent to differentiating cells throughout the rostral medulla. The pattern of marginal zone development reflected the addition of axons within fascicles and also the addition of fascicles of axons.

In order to analyze the early events which preceeded the longitudinal organization of the marginal zone, we examined 1 µm serial sections through the rhombencephalon and spinal cord of embryos stages 22-28 which had been embedded in epon. We investigated this rostrocaudal series for the segmental organization which preceeded the longitudinal formation of the marginal zone.

Axons were present before a distinct marginal zone could be identified. Longitudinally-directed axons were present at stage 22, shortly after the formation of the neural tube. The earliest axons passed lateral to differentiating cells and traveled along the periphery of the neural tube. The first longitudinally-directed axons appeared in the mid-medullary levels on the lateral aspects of the brainstem. Electron microscopy through the medulla at stage 22 verified that a small number (1-6) of axons were grouped in fascicles along the peripheral border. These axons were surrounded by ependymal processes.

In contrast, no longitudinal axon pathways were observed in the caudal rhombencephalon and rostral spinal cord at stage 22. However, rostral to the exit of the dorsal or ventral root, a small fascicle appeared which contained several broad cytoplasmic processes cut in cross section. Each bundle of processes could be followed caudally for short distances to the exit of the nerve root. Fascicles could not be identified immediately caudal to the exit of the ventral or dorsal root. This suggested that these processes exited with their associated nerve root. This segmental pattern of processes grouped into fascicles and involved with exiting nerve roots was repeated throughout the rhombencephalon and spinal cord.

Our results suggest that development of the segmental organization seen in *Xenopus* preceeds development of the longitudinal pattern. The segmental development is likely to be associated with the longitudinal pattern of marginal zone development.

285.3 MORPHOLOGICAL DEVELOPMENT OF SENSORY AXONS AND MOTORNEURONS IN THE BRACHIAL SPINAL CORD OF BULLFROG TADPOLES (RANA CATESBIANA) Sonal Jhaveri and Eric Frank. (SPON. P, Baccaglini) Dept. of Neurobiology, Harvard Med. Sch., Boston, MA. 02115.

The ingrowth of dorsal root (DR) axons and the development of motor neuron dendrites was studied for the 2nd. nerve, which innervates the foreleg, in tadpoles (stage 4 and older) and in adult frogs. By stage 13, sensory axons form a ventral neuropil region into which motorneuron dendrites enter, scantily at first, but densely by stage 17, when an adult-like pattern of distribution is observed.

A pellet of horseradish peroxidase was applied to the central stump of the 2nd. nerve, cut peripheral to the DR ganglion. After 15-24 hours, the animal was fixed and the spinal cord reacted with diaminobenzidine for the visualization of the transported enzyme. Diffuse filling of motorneurons and DR axons was observed.

In the adult frog, thick sensory axons course longitudinally in the dorsal cord. Finer axons enter the grey matter of the cord, forming two distinct neuropil regions: dorsomedially and ventrolaterally. Motorneuron dendrites are oriented ventromedially, dorsolaterally and dorsomedially. The dorsomedial dendrites enter the ventral neuropil, where they overlap extensively with the sensory axons.

In stage 4 tadpoles, longitudinally coursing DR axons are evident, but ventrally coursing fibers are scant, thin and are tipped by growth cones. The number of these thinner fibers increases throughout development until, by stage 10, the two neuropil regions are clearly distinguished.

Motorneuron dendrites develop concomitantly with the differentiating sensory axons which will contribute to their input. In stage 4 tadpoles, motorneurons bear dendrites oriented ventromedially and dorsolaterally. However, the dorsomedial dendritic field is scant; few motorneuron dendrites are observed close to the ingrowing sensory axons. Although all three dendritic fields increase in complexity throughout development, the most striking is the growth of the dorsomedially directed dendrites. Thus, as the differentiation of the ventral neuropil region of the sensory axons occurs, more and more motorneuron dendrites enter into it and lie in juxtaposition to the incoming axons.

285.4 DEVELOPMENT OF THE MONOSYNAPTIC REFLEX IN THE FROG'S SPINAL CORD M. Westerfield* and E. Frank. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Development of stretch reflexes of the triceps muscles in the forelimb of bullfrogs was studied by electrical recordings from motoneurons in isolated spinal cords. In adults, there is a high degree of synaptic specificity: a) sensory afferents from triceps muscles have monosynaptic connections only with triceps motoneurons; b) polysynaptic and inhibitory responses from triceps sensory axons are seldom observed either in triceps or other brachial motoneurons. In contrast, during development triceps sensory afferents evoke polysynaptic responses in brachial motoneurons before most monosynaptic connections have appeared. When triceps afferents do form monosynaptic inputs onto motoneurons, these synapses are made specifically onto triceps motoneurons.

At stage 14, when touching the skin evokes reflex movements, triceps sensory afferents generate synaptic potentials in motoneurons within the triceps motor nucleus. These potentials are probably polysynaptic because they occur at latencies greater than 20 ms, show large latency fluctuations and fatigue at frequencies of 1 Hz. Recordings from the cut ventral root show a similar long latency signal indicating that the intracellular recordings did not miss a population of motoneurons with monosynaptic inputs from triceps afferents. This pattern persists until stage 17 when such potentials can still be recorded in most brachial motoneurons. At this time, however, short latency potentials are produced in some brachial motoneurons by stimulation of the ulnaris nerve, which innervates muscle and skin distal to the triceps muscles. This suggests that some sensory fibers innervating more distal parts of the arm form monosynaptic reflexes before triceps sensory axons, unlike the normal proximal-distal gradient of development. Near the end of stage 17, many motoneurons can first be identified by antidromic activation, and short latency, 5-10 ms, synaptic potentials are evoked by triceps sensory afferents in triceps motoneurons. In addition, these afferents still produce excitatory and inhibitory polysynaptic potentials in many motoneurons. By stage 19, one stage before the arms emerge through the body wall, synaptic input from triceps afferents has the same latency, 3-4 ms, and specificity seen in adults, and the polysynaptic potentials are reduced.

These results indicate that a monosynaptic reflex arc develops only after polysynaptic connections are formed. The monosynaptic pathway is highly specific from the time it first appears.

285.5 DEVELOPMENT OF THE ANURAN SPINAL CORD: ASCENDING AND DESCENDING SYSTEMS. Cynthia J. Forehand and Paul B. Farel. Neurobiol. Prog. and Dept. Physiol., Sch. Med., Univ. N. Carolina, Chapel Hill, NC 27514.

Anurans present a unique opportunity to study the ontogeny of neuronal connections subserving tetrapod locomotion and somatic sensibility. Transition from the aquatic, limbless tadpole to juvenile frog (R. catesbeiana) occurs over a protracted period of time during which the animal is accessible for experimental observation. Using horseradish peroxidase (HRP), we have found that developmental changes in sources of descending fibers consist primarily of increases in size and number of retrogradely labeled supraspinal neurons. In contrast, differences in the sources, as well as the extent, of ascending projections were found in comparisons of tadpole and mature frog.

In both limb bud tadpole and adult frog, HRP injections into the lumbar enlargement retrogradely labeled neurons bilaterally in the paraventricular area of the hypothalamus, midbrain tegmentum, ventral vestibular nucleus, and reticular formation. In early tadpole stages the tegmental projection arises only from cells in the caudal midbrain. By Stage XIII, however, lumbar projections of rostral tegmental neurons are identified. In all stages the bilateral vestibulospinal projection is asymmetrical, arising from neurons in the caudal half of the contralateral ventral vestibular nucleus and the entire extent of the ipsilateral ventral nucleus.

More striking developmental differences are seen in ascending systems. Lumbar spinovestibular cells, while numerous in the frog, are rarely observed before tadpole Stage XV. Similarly, projections to vestibular nuclei by lumbar primary afferent fibers are present in frog but not in tadpoles as late as Stage XVII. Thalamic HRP injections in the adult label neurons dorsal and lateral to the solitary tract in the region of the bulbospinal junction, presumably representing a dorsal column nucleus. In contrast, although primary afferent fibers project to this area as early as Stage V, these presumptive dorsal column nuclei cells do not project to the thalamus before Stage XVII.

Developmental differences between ascending and descending fiber systems provide an intriguing comparison with the situation following spinal transection. Juvenile frogs whose spinal cords were transected as larvae have neurons from all normal supraspinal regions projecting to lumbar spinal cord (Forehand and Farel, Neurosci. Abstr.,5:677, 1979). However, ascending fiber systems originating below the level of the transection have not been demonstrated. The difference in regenerative properties of ascending and descending fiber systems may lie in their different degrees of maturity at the time of transection.

285.6 REFLEX DEVELOPMENT IN ANURAN LARVAE: ELECTROPHYSIOLOGICAL AND ANATOMICAL CORRELATES. Paul B. Farel. Dept. Physiol, Univ. N. Carolina Sch. Med., Chapel Hill, NC 27514

Motoneurons of the lumbar lateral motor column (LMC), which innervate the hindlimb, proliferate and differentiate during the larval (tadpole) period in anurans. In R. catesbeiana, the larvae are large enough to permit the use of conventional electrophysiological and anatomical techniques to monitor the developmental course of these motoneurons. In the present study, electrophysiological responses of dorsal and ventral roots were compared in tadpoles as early as St. IV (Taylor and Kollros) to those found in juvenile frogs. These data were correlated with anatomical results obtained by applying HRP to dorsal or ventral roots.

The lumbar enlargement of tadpoles, unlike that of frogs, contains large ventromedially situated motoneurons innervating axial musculature (primary motoneurons). These primary motoneurons, which mediate swimming, send their axons out the ventral root in a fascicle separate from those of LMC motoneurons. These fascicles were dissected apart in order to record simultaneously activity in the axons of primary and LMC motoneurons. All electrophysiological experiments were performed using an in vitro spinal cord preparation.

The only qualitative electrophysiological difference found between St. IV tadpoles and juvenile frogs was the appearance at St. VII/VIII of primary afferent depolarization elicited by antidromic activation of LMC motoneurons (VR-DRP). Prior to St. VII/VIII, primary afferent fibers scarcely impinge on spinal cord gray matter, although direct projections to more rostral spinal cord can be seen. Coincident with the appearance of fine bundles of sensory fibers invading the gray matter, the VR-DRP elicited by stimulation of LMC motoneuron axons could be demonstrated.

The DRP evoked by antidromic activation of primary motoneurons or by stimulation of descending fibers was present at all stages examined. Dorsal root-ventral root reflexes and reflexes evoked by stimulation of descending fibers, although of long latency (20-30 msec.), were present at the earliest stages examined in LMC motoneurons.

Reflexes involving primary motoneurons showed no marked tendency toward change during the larval period.

285.7 CHANGES IN CUTANEOUS INPUT TO DORSAL HORN NEURONS FOLLOWING SPINAL CORD HEMISECTION IN CATS. G. L. Brenowitz and L. M. Pubols. Dept. Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

The responses of L7 dorsal horn neurons to electrical stimulation of the sural nerves and to tactile stimulation of the skin were studied in methoxyflurane anesthetized normal and acutely (6h-5d survival) or chronically (3-6 mo. survival) hemisected cats (right T_{13} hemisection sparing the dorsal columns). The somatotopic organization and sizes of light touch (1 gm von Frey hair) receptive fields were similar in normal and acutely hemisected groups. In chronic cats receptive fields in the lateral part of the dorsal horn ipsilateral to the lesion (proximal hindlimb fields) showed a significant ($p = 0.031$ in a binomial test) increase in size, when compared to fields on the contralateral side, and when compared to fields in normal and acute animals. Split fields with two separate components on the body surface were found infrequently in normal cats but were common in acute and chronic cats.

Recording sites yielding short latency ($\leq$ 5msec) reliable responses to electrical stimulation of the sural nerve were more numerous in caudal L7 than in rostral L7. In normal and acute cats, responsive sites were symmetrically distributed on both sides of the cord. In chronic cats, there were more responsive loci ipsilateral to the hemisection than contralateral to it (asymmetrical distribution). These physiological changes are correlated with recovery of function and collateral sprouting of primary afferents known to follow spinal cord hemisections in cats (Murray and Goldberger, J. Comp. Neurol. 158, 1974).

Supported by NS13768 and NS07061.

286.1 INCREASED TYROSINE HYDROXYLASE ACTIVITY IN THE RAT SUPERIOR CERVICAL GANGLION FOLLOWING PREGANGLIONIC NERVE STIMULATION IN VITRO. N.Y. Ip and R.E. Zigmond. Department of Pharmacology, Harvard Medical School, Boston, MA 02115

Previous experiments have demonstrated that direct electrical stimulation of the preganglionic cervical sympathetic trunk produces an increase in tyrosine hydroxylase (TH) activity in the rat superior cervical ganglion in vivo (Zigmond and Chalazonitis, Brain Res., 164: 137, 1979). We now report that a similar elevation of TH activity occurs following preganglionic nerve stimulation in vitro.

Superior cervical ganglia from male Long-Evans rats were desheathed, superfused with oxygenated Kreb's solution and stimulated via the preganglionic trunk for periods of 30-90 min at 37°C. The effectiveness of stimulation was monitored by recording the elicited compound action potentials from the postganglionic internal carotid nerve. The contralateral ganglia from the same animals served as unstimulated controls. At the end of the stimulation period, "stimulated" and "contralateral control" ganglia were cultured for 48 h in BGJ_b medium supplemented with 10% newborn calf serum. TH activity was then assayed in these ganglia as well as in non-cultured ganglia taken from control animals ("in vivo control"). TH activity per mg protein was elevated in stimulated compared to contralateral control ganglia by 18, 31 and 47% following 30, 60 and 90 min of stimulation at 5 Hz. Stimulation at 10 Hz for 30, 60 and 90 min produced a 34, 50 and 49% increase in TH activity respectively. These increases in TH activity were not accompanied by changes in total ganglion protein. TH activity of cultured "contralateral control" ganglia was similar to that of "in vivo control" ganglia. The magnitude of the increase in TH activity was not affected by substituting 10% bovine serum albumin for newborn calf serum in the culture medium.

A study of the time course of the increase in TH activity in organ culture following 30 min of stimulation at 10 Hz showed that no change in TH activity occurred during the first 12 h in culture. After 24 h, TH activity was elevated by 32% and this increased activity was maintained for at least 48 h. Addition of the nicotinic antagonist, hexamethonium, at a concentration (1 mM) which completely blocked the compound action potentials normally recorded during preganglionic nerve stimulation, prevented the increase in TH activity in the stimulated ganglia.

These data demonstrated that preganglionic nerve stimulation in vitro produces a delayed increase in TH activity in the superior cervical ganglion comparable to that observed in vivo. This in vitro system should prove useful for further studies on the mechanism of the regulation of TH by preganglionic nerve activity.

(Supported by NIH grant 12651.)

286.2 IN VITRO TRANSLATION OF TYROSINE HYDROXYLASE AND PHENYLETHANOLAMINE N-METHYLTRANSFERASE BY mRNA FROM BOVINE ADRENAL MEDULLA AND RAT PHEOCHROMOCYTOMA (PC12) CELLS. E. Baetge, T. Joh, B. Kaplan, E. Ross, D. Park, and D. Reis, Laboratory of Neurobiology, Dept. of Neurology, Cornell Univ. Med. College, New York, NY, 10021.

Tyrosine hydroxylase (TH) and phenylethanolamine N-methyltransferase (PNMT) from bovine and rat adrenal glands differ with respect to electrophoretic mobility, stability, pH optima and immunocrossreactivity. We sought to determine whether these differences in molecular forms are due to genetic variation or posttranslational modification of enzymes by: (1) synthesizing these enzymes in vitro using poly (A) mRNA from bovine adrenal medulla and PC12 cells, a tumor line of rat adrenal origin; (2) investigating the immunocrossreactivity of the translated enzymes from rat with those of bovine origin so as to compare their basic protein structures. We also sought to determine the relative proportion of TH and PNMT in bovine adrenal medulla translated in vitro. Antibodies used were anti-rat or bovine adrenal TH (THAb), either raised in rabbits or from hybridoma cell culture (Ross et al., Fed. Proc., 1980), and anti-PNMT (PNMTAb) raised against the rat or bovine enzyme.

From 10^6 dpm of total protein translated from bovine mRNA, 8,500 and 8,700 dpm for TH were identified by SDS-PAGE after precipitating by rat THAb and bovine THAb, respectively, indicating full crossreactivity of these Abs. From the same amount of protein translated by PC12 mRNA, 4,000 and 3,800 dpm were precipitated by rat THAb and bovine THAb, suggesting that the basic protein structure of TH translated by mRNA from both species is similar.

Rat PNMTAb precipitated PNMT translated from mRNA of bovine adrenal medulla even though the Ab inhibits the enzyme activity of only rat PNMT. From 10^6 dpm of total protein translated from bovine mRNA, 21,000 and 22,000 dpm were precipitated by rat PNMTAb and bovine PNMTAb, respectively, indicating that PNMT from both species has a similar basic protein structure.

Comparing the proportions of bovine mRNA translated, approximately 0.9% and 2.2% of total proteins were TH and PNMT, respectively. Thus the amount of PNMT translation is three-fold greater than TH. Furthermore, only 0.4% of total protein translated by PC12 mRNA was TH in contrast to 0.8% for bovine mRNA.

We conclude that: (1) the basic protein structure of TH and PNMT from rat is similar to those of bovine origin, (2) the differences in the biochemical properties of the enzymes in different species may be due to a post translational modification of enzymes, and (3) in bovine adrenal medulla, the amount of PNMT translated was three-fold greater than that of TH.

(Supported by NIH grants, HL 18974 and MH 24285)

286.3 IDENTIFICATION, USING MONOCLONAL ANTIBODY, OF TYROSINE HYDROXYLASE TRANSLATED IN VITRO BY POLY(A)mRNA. E. Ross, T. Joh, E. Baetge, B. Kaplan, M. Brodsky* and D. Reis. Laboratory of Neurobiology, Dept. of Neurology, Cornell Univ. Med. Coll., New York, N.Y. 10021.

Monoclonal antibodies (Ab) to rat striatal TH were produced by fusion of mouse lymphocytes, sensitized to TH, with murine plasmacytoma (NS1) cells. Eight percent of hybridomas secreted TH antibody, as detected by an enzyme linked immunosorbant assay (ELISA). Four stable lines (CMTH 29, 31, 78, and 95) were established by limiting dilution cloning. Antibodies were highly specific, as demonstrated both on ELISA, using TH antigen purified to homogeneity, and on immunoelectrophoresis, producing a single immunoprecipitin arc against a crude striatal TH preparation. High titres of CMTH Ab were obtained from ascities fluid of a mouse injected i.p. with a single hybridoma clone. Alone, these Abs failed to inhibit or fully precipitate TH activity from solution. However, with addition of rabbit anti-mouse IgG (RAM), CMTH-TH complexes were precipitated and virtually 100% of TH activity was removed from solution. All 4 CMTH Abs were used for immunohistochemically localizing catecholamine neurons of rat brain by the peroxidase-antiperoxidase method. The monospecificity of these Abs afforded unusually clear definition of cell bodies, axons and fine terminals with virtually no background staining.

Monospecific antibody (CMTH 31) was used to isolate the TH gene product, translated in vitro by poly(A)mRNA. Polysomes were prepared from bovine adrenal medulla or PC12 cells and poly(A)mRNA was isolated by affinity chromatography on oligo(dT)-cellulose. Translation was carried out using a rabbit reticulocyte system in the presence of [^{35}S]methionine. Radiolabeled proteins from the translation were incubated with CMTH Ab at 10°C overnight. CMTH-TH complexes were then precipitated with RAM. The precipitate was subjected to SDS-PAGE and a fluorograph of the gel was obtained. In both instances, a single protein band of MW=62,000 dlt was present, indicating that the CMTH 31 Ab is directed against an antigenic site common to both rat and bovine adrenal TH.

Monospecific antibodies to rat striatal TH have been produced which are useful for both immunotitration and immunocytochemistry. The CMTH 31 Ab unequivocally identified TH of subunit MW=62,000 dlt, translated in vitro by poly(A)mRNA from both PC12 cells and bovine adrenal medulla. The antigenic site recognized by this monospecific antibody is common to both rat and bovine TH.

286.4 SEPARATION OF TYROSINE HYDROXYLASE FORMS BY ISOELECTRIC FOCUSING, K. A. Markey, S. Kondo*, V. Burroughs*, L. Shenkman* and M. Goldstein. New York Univ. Med. Cntr. Dept. of Psychiatry, Neurochemistry Lab., New York, N. Y. 10016

We have recently purified and characterized tyrosine hydroxylase (TH) from a cultured rat pheochromocytoma (PC-12) cells, (Mol. Pharmacol. 17, 79-85 (1980). As a continuation of this study, we have examined the isoelectric focusing patterns of purified TH as well as those of crude enzyme from rat striatum and adrenal glands. Isoelectric focusing was performed with an LKB Multiphor on polyacrylamide or agarose gels over a pH range of 3.5-10. Purified TH exhibited an isoelectric point (pI) of 5.3. After phosphorylation by purified catalytic subunit of c-AMP dependent protein kinase, purified TH showed two isoelectric points -- one at 5.3 and the other at 6.9. The major portion of enzyme activity was found at pI 6.9. ^{32}P incorporated into TH from ATP-γ^{32}P also focused at pI 6.9.

The isoelectric focusing was performed on TH obtained from rat adrenal glands and striatum. Crude striatal TH revealed two isoelectric points of 5.3 and 6.9. Preincubation of the striatal enzyme with alkaline phosphatase diminished the TH activity focused at pI 6.9. Rat adrenal TH obtained following decapitation of non-anesthetized animals showed a major peak of enzyme activity at pI 6.9 and a minor peak at pI 5.3. However, TH from anesthetized rats showed a single peak of activity at pI 5.3. These results suggest that TH can be separated into two forms upon isoelectric focusing. The form with a pI at 6.9 appears to be the predominant form after phosphorylation.

286.5 AN ACTIVE SITE MODEL OF PHENYLETHANOLAMINE N-METHYLTRANSFERASE (PNMT). CONFORMATIONAL AND STEREOCHEMICAL REQUIREMENTS FOR THE BINDING OF AROMATIC AND NONAROMATIC SUBSTRATES AND INHIBITORS. G. L. Grunewald, M. F. Rafferty*, R. T. Borchardt and Polina Krass*. Department of Medicinal Chemistry, University of Kansas, Lawrence, KS 66045.

PNMT catalyzes the methylation of norepinephrine to epinephrine utilizing S-adenosyl-L-methionine as the methyl donor. We have previously reported [Mol. Pharmacol., 11, 694 (1975)] that substitution of the aromatic ring of the substrate phenylethanolamine (PEA) with a fully saturated ring (most notably cyclooctyl) resulted in improved affinity for the active site and provided a potent alternate substrate inhibitor for PNMT. The high inhibitory activity reported for amphetamine and related compounds [J. Med. Chem., 14, 322 (1971)] prompted us to synthesize and evaluate some saturated ring analogs of amphetamine of the type $RCH_2CH(CH_3)NH_2$ where R is cyclohexyl, 3-cyclohexenyl and cyclooctyl. On the basis of reports which indicated a 3-fold stereochemical preference of the enzyme for both the amphetamines (S>R configuration) and substrate (R>S) [Biochem. Pharmacol., 14, 1896 (1965)], the above compounds were resolved. As in the PEA analogs, it was found that replacement of the aromatic portion of amphetamine with a fully saturated ring greatly improved activity (R=phenyl, K_i=760 μM, R=cyclooctyl, K_i=86 μM). The saturated amphetamine analogs exhibited a 10-fold difference in activity of the enantiomers (but now R>S). In contrast, virtually no stereochemical preference was seen in the fully saturated PEA analogs. We also examined a number of conformationally restricted amphetamine analogs as probes of the optimal conformation of amphetamine at the binding site. A distinct preference was observed (10-fold) for the extended (trans) as opposed to the folded (gauche) conformation. Details of the biochemical evaluation and an interpretation with respect to a model of the active site of PNMT will be presented.

286.6 MESOCORTICAL DOPAMINE NEURONS: ROLE FOR AUTORECEPTORS IN SYNTHESIS REGULATION? M. J. Bannon, R. L. Michaud* and R. H. Roth. Departments of Pharmacology and Psychiatry, Yale University School of Medicine, New Haven, CT 06510

The regulation of dopamine (DA) synthesis in rat mesocortical DA neurons was studied and compared to DA synthesis in nigrostriatal DA neurons. The increase in striatal DA content seen 35 minutes after γ-butyrolactone (GBL) treatment was prevented by activation of nerve terminal DA autoreceptors by apomorphine. In contrast, the increase in prefrontal cortical DA seen 35 or 60 minutes after GBL was unaffected by the DA agonists apomorphine and bromocriptine. Using the 30 minute accumulation of dopa after the administration of the dopa decarboxylase inhibitor Ro4-4602 (800 mg/kg) as an index of in vivo tyrosine hydroxylation, it was demonstrated that the increase in striatal DA following GBL was most likely due to an acceleration of DA synthesis. In contrast, GBL did not increase cortical dopa accumulation. GBL pretreatment did, however, completely prevent the rapid decline of DA seen following α-methyltyrosine treatment (250 mg/kg, 55 minutes), indicating that DA turnover had been inhibited in the mesocortical neurons, as has been previously demonstrated with other DA neurons. The monoamine oxidase inhibitor pargyline (75 mg/kg, 180 minutes before sacrifice) raised both striatal and cortical DA levels, leading to greatly attenuated dopa accumulation in both regions. Finally, the DA antagonist haloperidol (1 mg/kg, 45 minutes prior to sacrifice) greatly accelerated striatal dopa accumulation, but affected only a modest increase in cortical dopa accumulation which was completely prevented by the GBL-induced inhibition of impulse flow. These results suggest that synthesis in the prefrontal cortical terminals of mesocortical DA neurons is subject to end product inhibition and is only moderately altered by changes in impulse flow. The synthesis of DA in these terminals does not seem to be modulated by terminal DA autoreceptors. (Supported in part by USPHS Grants MH-14092, NS-10174, MH-25642 and the State of Connecticut).

287.1 TWO FORMS OF AMNESIA IDENTIFIED THROUGH AN ANALYSIS OF FORGETTING
Larry R. Squire. Veterans Administration Medical Center, San Diego, California, and Dept. Psychiat., Univ. Calif. San Diego, La Jolla, CA 92093.

The nature of forgetting has been of special interest in studies of memory pathology because of what it can reveal about the nature of the defect and about the structure of normal memory. The present study was designed to compare forgetting rates in two groups of amnesic patients, using a procedure (Huppert and Piercy, 1977) developed to minimize the problem of comparing forgetting rates between groups that already differ in level of acquisition. Amnesic and control patients saw 120 colored pictures and then were tested for retention at 10 min, 2 hr, and 32 hrs. after learning. By exposing pictures eight times longer to the amnesic patients than to controls, we were able to equate amnesic and control performance at 10 min. after learning. We then asked whether forgetting from 10 min. to 32 hrs. after learning was normal or abnormal.

Two types of amnesic patients were tested: patients receiving a prescribed course of bilateral ECT (N=9) and patients with alcoholic Korsakoff disease (N=7). ECT patients saw each of 120 pictures twice for 4 sec. each. These patients served as their own controls and were tested again four months after treatment when they had recovered from anterograde amnesia. In the control condition, patients saw each picture once for one second each. The Korsakoff patients saw each picture twice for 4 seconds each. Their controls were age and IQ-matched alcoholics, who saw each picture once for one second each.

Korsakoff patients exhibited a normal forgetting rate. ECT patients performed at the same level as Korsakoff patients at 10 min. after learning but exhibited abnormally rapid forgetting. The results indicate 1) amnesia is not a unitary disorder. The amnesia associated with ECT is different from the amnesia associated with Korsakoff's disease; 2) forgetting rate can be affected by memory pathology; thus forgetting rates are not inextricably coupled to or determined by strength of acquisition.

Based on evidence from the medial temporal patient H.M., on indirect evidence that ECT amnesia is related to temporal lobe dysfunction, and on the diencephalic distribution of lesions in the Korsakoff syndrome, it is suggested that bitemporal and diencephalic amnesia are distinct syndromes of memory dysfunction, that the "stage" of memory function disrupted is different in each syndrome, and that the medial temporal and diencephalic regions normally contribute in different ways to the formation of memory.

287.2 PRESERVED LEARNING OF RULES AND PROCEDURES IN AMNESIA
Neal J. Cohen and Larry R. Squire. Depts. of Neurosciences and Psychiatry, Univ. Calif. San Diego, La Jolla, CA 92093 and VA Medical Center, San Diego, CA 92161

The memory deficit in the amnesic syndrome is global, affecting both verbal and non-verbal material irrespective of modality. Yet there have been numerous reports that amnesic patients can learn and remember perceptual-motor skills such as rotary pursuit and mirror tracing across several days of testing, frequently at a rate comparable to that of control subjects. These findings have suggested that perceptual-motor skills are afforded a special neurologic status. In order to determine whether what is preserved in amnesia is limited to motor skills, or whether motor skills are part of a broader class of preserved learning ability, the present study examined learning and retention of a pattern-analyzing skill selected to minimize motor involvement.

Patients with alcoholic Korsakoff syndrome, patients receiving bilateral ECT, and the patient N.A., who has chronic amnesia for verbal material, were trained to read word triads presented by mirror reflection in a tachistoscope on each of three consecutive days and also on a fourth day approximately 13 weeks later. The amnesic patients were able to acquire the mirror-reading skill at a rate equivalent to that of matched control subjects and were able to retain it for more than three months, despite amnesia for the words that had been read and despite negligible recollection of having previously performed the task. These findings are consistent with the recent finding that amnesic patients can learn the application of new numerical rules despite amnesia for the specific features of the training situation.

It is suggested that the class of preserved learning skills is considerably broader than previously believed. Perceptual-motor skills and the present pattern-analyzing skill may belong to a class of rule-governed or procedural-based operations whose information-processing and memory characteristics differ from those operations that depend upon specific, declarative, data-based material. This distinction, which is reminiscent of the classical distinction between "knowing how" and "knowing that", has been discussed in the cognitive science and artificial intelligence literatures. The experimental findings described here provide evidence that such a distinction is honored by the nervous system.

287.3 EFFECT OF SUPERIOR PARIETAL LOBE LESIONS ON LATERALIZED REACHING IN HUMAN.
K. J. Kaufman* (SPON: G. L. Gerstein), Unité 111, INSERM, Paris, France; School of Medicine and Department of Physiology, University of Pennsylvania, Philadelphia, Pa.19104.

Tests were designed to differentiate homonymous half field abilities and side of motor activity. Three patients had sustained left parietal lesions of which two were verified surgically for localization at the cortical lip of the superior parietal lobule. The third was localized by EEG, neurologic exam and echo encephalography to this area. A fourth case had right surgical lesion near the parieto-occipital junction superior to occipital horn; while a fifth case had a tomography verified right superior parietal lesion. Matched controls also performed all tests. At the time of testing, all patients had grossly intact and stable neurologic exam, including full visual fields and lack of deficit in motility or somasthesis.

Patients (1-5) in experiment 1a were asked to reach ballistically for targets in the visual field, on a horizontal, opaque surface, from underneath that surface. Two right lesion cases were moderately to severely impaired reaching with contralateral (CL) limb into CL field. Left sided cases were moderately to severely impaired reaching with CL limb into either right or left fields. In experiment 1b (cases 1-4) a clear surface was substituted to allow visual guidance of the limb. All left lesion cases were severely impaired reaching with right hand into left field, and moderately impaired for the opposite condition. Case 4 was severely impaired as in 1a. Experiment 2a involved reaching for a point of light on vertical surface in dark. Left lesion cases were impaired as in experiment 1a. In 2b, room was illuminated to allow limb guidance, and there was moderate to severe impairment in CL fields in four cases (1-4) tested.

Other tests were visual localization in a perimeter, finger manipulation in reaching, and forearm supination/pronation, to evaluate the combined contribution to misreaching. Cases 3 and 4 erred in all CL fields; cases 1 and 2 were normal. These data suggest a deficit related to abnormalities of both CL limb and CL field not reducible to elementary disturbance of motility, vision, or somasthesis. Also, deficits for coding movements of the CL limb into the ipsilateral (IL) half field exist in left lesions, suggesting that remaining right parietal cortex is unable to compensate for visuomotor command during IL motor acts, or that the lesioned left lobe had significant sensory control over IL field stimuli. Finally, visual feedback of limbs (1b and 2b) during CL field reaching caused increase in deficits in 3 out of 4 cases and revealed an additional component-a disordered percept of CL fields-but only extant during limb guidance.

287.4 COMPLEMENTARY PROGNOSTIC VALUE OF EEG AND I.Q. DATA WITH RESPECT TO SURGICAL OUTCOME IN TEMPORAL LOBE EPILEPSY.
J.P. Lieb, R. Rausch*, J. Engel, and P.H. Crandall*. Reed Neurological Res. Ctr., UCLA Sch. of Med., Los Angeles, CA 90024.

Previous retrospective studies of a group of 52 medically refractory temporal lobe epileptics in whom pre-lobectomy surface and depth ictal and interictal EEG recordings were collected, and for whom long term post-lobectomy seizure relief ratings were available, demonstrated that certain ictal and interictal EEG characteristics are indicative of: 1) poor seizure relief; 2) an absence of pathology in the resected lobe, 3) lower pre-surgical I.Q. scores, and 4) a drop in I.Q. scores following lobectomy. Negative interictal EEG signs included long duration spikes, bilaterally synchronous spikes, and diffuse bilateral slowing in background activity. Negative ictal EEG signs included bilaterally synchronous seizure onsets, variability in seizure onset locus, and unilateral surface onsets. These studies also showed a correlation between reduced pre-surgical I.Q. scores and poor post-surgical seizure relief. In the present study patients were analyzed according to: a) whether or not they displayed any negative ictal or interictal EEG signs, b) whether or not they were above or below the group mean in full scale I.Q., and c) whether or not they demonstrated good or poor post-surgical seizure relief. The results demonstrated that patients who displayed both negative EEG signs and lower I.Q. scores were more likely to display poor post-surgical seizure relief (85.7%) than patients displaying either lower I.Q. scores (57.1%) or negative EEG signs (62.5%). These results indicate that EEG and I.Q. data provide non-redundant information for predicting seizure relief following surgery for temporal lobe epilepsy and that decisions regarding surgery should incorporate both EEG and psychological measures.

287.5 INITIAL AND FOLLOWUP NEUROPSYCHOLOGICAL STUDIES OF CHILDREN WITH POSTERIOR FOSSA TUMORS.A.L. Campbell, Jr., Aaron Smith and Marion Walker* Dept. of Psych., Howard U., WA.,D.C.20059 Neuropsych. Lab., U.ofM., Ann Arbor, MI,48209, Dept. of Neurosurgery, Primary Children's Hosp., Salt Lake City, UT. 54117

Accumulating findings indicate that the most common site of intracranial tumors in childhood is the posterior cranial fossa. The majority of these infratentorial tumors, usually medulloblastomas or astrocytomas, invade the cerebellum and fourth ventricle. While the literature abundantly details surgical procedures radiation and chemical treatment regimens and neuropathological findings, few studies have reported changes of higher cortical functions associated with the presence of posterior fossa tumors and/or their surgical resection.

This report summarizes the salient findings in repeated (15 month interval) postoperative neuropsychological examinations of 7 children with posterior fossa tumors and one child tested before and after excision of a recurring infratentorial tumor. In addition to the differential sensitivity of the various measures of higher (cognitive) and lower (sensory and motor) level functions indicated in initial postoperative tests, the varying frequencies and magnitudes of gains in 15 month follow-up studies also indicated differential rates of recovery and/or development in the test-retest interval. The practical and theoretical implications of these findings will be discussed.

288.1 ^{3}H-LISURIDE BINDING TO SEROTONERGIC AND ADRENERGIC RECEPTORS. G. Battaglia and M. Titeler. (SPON: P. Muller). Department of Pharmacology, University of Toronto, Toronto, Ontario, Canada.

Fujita et al. (1) showed that ^{3}H-lisuride labeled D_2-dopamine receptors in rat brain. In order to determine if ^{3}H-lisuride labels other receptors, the binding of ^{3}H-lisuride to bovine frontal cortex crude membrane homogenates was studied using the assay procedure of Titeler et al. (2). Competition experiments revealed that 35-40% of the ^{3}H-lisuride binding was inhibited by excess serotonin and that 35-40% of ^{3}H-lisuride binding was inhibited by excess clonidine. Excess clonidine and serotonin produced an additive effect inhibiting 70-80% of ^{3}H-lisuride binding. Blockade of the serotonergic or adrenergic components was accomplished using 200 nM serotonin or 200 nM clonidine respectively. Results obtained from competition experiments performed in the presence of each blocking drug indicates that ^{3}H-lisuride labels α_2 adrenergic and serotonin receptors in the frontal cortex (Table). Further results obtained using ^{3}H-lisuride to label receptors in other brain areas and species will be discussed.

	IC_{50} values (nM)	
^{3}H-Lisuride binding in the presence of →	200 nM Serotonin	200 nM Clonidine
Lisuride	0.7	0.5
Phentolamine	1.4	1,800
Clonidine	5.6	1,800
d-LSD	200	11
Prazosin	1,400	9,000
Serotonin	5,000	7.0
Bufotenin	14,000	50

288.2 ^{3}H-YOHIMBINE BINDING TO α_2-ADRENERGIC RECEPTORS IN RAT BRAIN AND HUMAN PLATELET MEMBRANES. D.C. U'Prichard, M. Daiguji* and D.J. Kahn. Dept. of Pharmacol., Northwestern Univ. Sch. Med., Chicago IL 60611, and Dept. of Psychiatry, Chicago Univ. Pritzger Sch. Med., Chicago, IL 60637.

α_2-Adrenergic receptors have been labeled in brain and periphery with ^{3}H-catecholamine (CA) and ^{3}H-imidazoline (IM) ligands. At these sites agonists have high (nM) affinity and it is not clear whether these ligands label the entire population of α_2-receptors, or merely a fraction in a high-affinity state for agonists. This question is important in the interpretation of recent reports concerning changes in CA and IM α_2-sites, and is best resolved by examination of binding of a selective α_2-antagonist ligand. While the antagonist ^{3}H-dihydroergocryptine (DHEC) does not show appropriate selectivity especially in brain, yohimbine is α_2-selective in central and peripheral pharmacological and binding studies. ^{3}H-Yohimbine (YOH, 80-90 Ci/mmole) interactions at platelet and brain α_2-receptors were examined. In human platelet membranes, NE-displaceable ^{3}H-YOH binding was 85-90% of total binding, linear with increasing protein and maximum at pH 7.0. Association and dissociation kinetics were rapid and linear at 25°C, and ^{3}H-YOH labeled a single order of sites with a K_D of 1.2-1.5 nM, compared to k_{-1}/k_1 of 0.45 nM. Platelet ^{3}H-YOH binding exhibited α_2-receptor characteristics, with yohimbine 700 times more potent than prazosin. Antagonist affinities for inhibition of ^{3}H-YOH binding were similar to affinities for inhibition of CA suppression of adenylate cyclase activity. Agonists were quite potent inhibitors of ^{3}H-YOH binding, with K_I values of 50, 230, 70 and 26,000 nM for (-)-EPI, (-)-NE, clonidine and (-)-isoproterenol respectively. Agonist interactions showed apparent negative cooperativity (n_H 0.6-0.8). Agonist K_I and n_H values were not influenced by 1.0 mM Mg^{2+}, which however decreased ^{3}H-YOH binding 20%. 5.0 mM Mg^{2+} decreased agonist K_I values 2-fold. 10 µM GTP increased K_I values for (-)-EPI and (-)-NE 2-3 fold and increased n_H values to 1.0-1.1. ^{3}H-YOH labeled brain α_2-receptors with lower affinity and, unlike platelets, exhibited non-linear saturation kinetics. However agonist K_I and n_H values were similar at brain and platelet ^{3}H-YOH sites. ^{3}H-YOH is thus a useful α_2-receptor antagonist probe which appears to label the entire population of low- and high-affinity α_2-receptors in brain and platelets.

288.3 AGONIST AND PARTIAL AGONIST RADIOLIGAND INTERACTIONS AT NEURAL AND NON-NEURAL α_2-RECEPTORS. J.C. Mitrius, D.J. Kahn, and D.C. U'Prichard. Dept. Pharmacol., Northwestern Univ. Sch. of Med., Chicago, Il. 60611.

α_2-receptors located at central and peripheral NE synapses have been characterized using both catecholamines (CA) and imidazolines (IM) as radioligands. Clonidine may act as a partial agonist while CAs are full agonists in inhibiting release of NE. However, in the CNS, CA and IM ligands label the same α_2-site in terms of high (nM) affinities for agonist competitors. To examine agonist vs. partial agonist interactions at α_2-receptors, we have compared the binding characteristics of (-)-^{3}H-epinephrine (EPI,40-50 Ci/mmol) and ^{3}H-p-aminoclonidine (PAC,40-60 Ci/mmol) in both neural (rat and bovine cortex) and non-neural (human platelets) tissue. ^{3}H-PAC and ^{3}H-EPI assays were performed as in brain, except that in platelet experiments, 2mM pyrocatechol was used. Platelet membranes were prepared with final resuspension in Tris 8.4-1.0 mM $MgCl_2$. Saturation of ^{3}H-PAC binding in cortex and platelets was single-order, while ^{3}H-EPI saturation was non-linear. Distinct components of ^{3}H-EPI binding in platelets had K_D values of about 2 nM and 20 nM. The total number of platelet α_2-receptor sites labeled by ^{3}H-EPI exceeded the number of ^{3}H-PAC sites. As in brain platelet ^{3}H-PAC and ^{3}H-EPI binding was stereospecific and consistent with the pharmacology of an α_2-receptor. Hill plots of both agonist and antagonist competitors against ^{3}H-PAC and ^{3}H-EPI gave n_H values of 1.0. No ^{3}H-Prazocin specific binding to α_1-receptors was observed in platelet membranes. However, ^{3}H-WB-4101, previously assumed to be an α_1-specific ligand, bound saturably and with high affinity to platelet membranes (K_D = 1.5 nM). Kinetic analysis of ^{3}H-PAC and ^{3}H-EPI binding to platelet membranes revealed rapid association and biphasic dissociation at 25° C. Unlike brain ^{3}H-PAC and ^{3}H-EPI binding in platelets was Mg^{2+}-dependent. In the absence of Mg^{2+}, the K_D of ^{3}H-PAC at platelet sites was 8.0 nM. With the addition of 1.0 or 5.0 mM $MgCl_2$, the K_D was reduced to 2.0 nM. In addition, Mg^{2+} was necessary for potent and complete guanine nucleotide inhibition of ^{3}H-PAC and ^{3}H-EPI specific binding. For both ligands, the nucleotide order of potency was similar to that found at brain α_2-receptors with GTP=GDP=Gpp(NH)p>ITP>GMP>CTP=ATP. However, GTP was a more potent inhibitor of ^{3}H-PAC (ED_{50}=0.2 µM) than of ^{3}H-EPI (ED_{50}=1.5 µM) binding. With 1.0 or 10 µM GTP present, previously non-cooperative interactions of agonist competitors and of ^{3}H-PAC itself at ^{3}H-PAC sites assumed marked cooperativity. The data suggest that interactions of agonist and partial agonist radioligands at the high-affinity conformation of brain and platelet α_2-receptors can be distinguished primarily by increased occupancy using a full agonist ligand. Thus efficacy may be related to extent of high-affinity binding.

288.4 CHARACTERIZATION OF α_2-RECEPTOR SITES IN NEUROBLASTOMA X GLIOMA CELLS. D.J. Kahn, J.C. Mitrius, and D.C. U'Prichard, Dept. of Pharmacol., Northwestern Univ. Sch. Med., Chicago, Il. 60611

Recently, Sabol and Nirenberg (J.Biol.Chem., 254:1913, 1979) demonstrated the presence of α-adrenergic receptors which are inversely coupled to adenylate cyclase (AC) on the hybrid neural cell line NG108-15(108CC15). The NG108-15 cell was used as a model for examining neural α-adrenergic receptor ligand interactions and the coupled biochemical response of AC inhibition. Binding isotherms of the agonist (-)-^{3}H-epinephrine (EPI) in NG108-15 membranes were non-linear as previously seen with brain ^{3}H-clonidine (CLO) binding. ^{3}H-EPI saturation constants were the same in NG108-15 and brain membranes. ^{3}H-p-aminoclonidine (PAC) shows a 3-5 fold lower affinity at a single site in NG108-15 membranes, compared to its one-site interaction in brain. ^{3}H-PAC labels fewer sites than ^{3}H-EPI (25-30,000 vs. 40,000 sites/cell, respectively). α-Receptor density on NG108-15 cells is thus comparable to that of opiate receptors. Pharmacological properties of NG108-15 ^{3}H-PAC and ^{3}H-EPI binding were similar to brain sites, with (-)-norepinephrine (NE, K_I 1.6 nM) and (-)-EPI (1.9 nM) affinities somewhat higher in the cells, while imidazoline and antagonist affinity constants were virtually identical. Binding studies confirmed the speculation that NG108-15 cells possess a pure α_2-receptor population: 40-fold stereoselectivity between (-)- and (+)-NE; NE and EPI were 25-fold more potent than isoproterenol in inhibiting ^{3}H-PAC binding; yohimbine was 10-fold more potent than WB-4101; and there was no detectable specific binding of the α_1 antagonists ^{3}H-prazocin or ^{3}H-WB-4101. Antagonist affinities were identical for inhibition of ^{3}H-PAC binding and AC inhibition. However, catecholamines (CA) were 2-3 orders of magnitude more potent in inhibiting ^{3}H-PAC binding than AC (K_D/K_I << 1). Thus both ligands label the receptor responsible for AC inhibition, but either coupling is inefficient, or ^{3}H-PAC and ^{3}H-EPI both label a high affinity state GTP selectively lowered NG108-15 ^{3}H-PAC binding with an ED_{50}=2µM. ATP was substantially less potent. As in the brain, high affinity NG108-15 ^{3}H-PAC binding and its regulation by GTP did not require Mg^{2+}. ^{3}H-EPI and ^{3}H-PAC thus appear to label analogous α_2-sites in NG108-15 cells and brain. GTP regulation and Mg^{2+} independency of binding in the two tissues are identical supporting the hypothesis that brain α_2-receptors are inversely coupled to AC as may also be the case with opiate receptors in both tissues. GTP/M^{2+} interactions are different for neural and platelet α_2-receptors, and NG108-15 cells provide an excellent model for examining α_2-coupling in neural tissue. Studies are in progress to correlate binding of various ^{3}H-ligands with AC and other membrane responses in naive cells and cells chronically treated with CA.

288.5 β-ADRENERGIC RECEPTORS: FUNCTIONAL HETEROGENEITY INDUCED IN A HOMOGENEOUS POPULATION BY AGONIST, GTP, AND Mg^{2+}. William C. Broaddus,* Georges Vauquelin,* and Michael E. Maguire, Dept. Pharmacology, Sch. Medicine, Case Western Reserve Univ., Cleveland, OH 44106.

Pharmacological and biophysical studies have indicated previously that wild type mouse S49 cells contain a single class of β-adrenergic receptors (βARs) which are coupled to adenylate cyclase (AC). However, this homogeneous population is functionally heterogeneous. N-Ethylmaleimide (NEM) in the presence of agonist inactivates 65% of total βARs, while NEM alone or with antagonists has no effect on βAR density or affinity. The percentage of βARs inactivated is time- and NEM concentration-dependent, but always attains a maximum of 65%. We have found that only the βARs susceptible to agonist/NEM are coupled to AC, or show GTP and Mg^{2+} effects on agonist-specific receptor affinity. GTP plus Mg^{2+} but not Mg^{2+} alone protect against NEM inactivation. This functional heterogeneity is a common property of βARs since similar data is obtained in turkey and frog erythrocytes and human adipose tissue. Studies in mutant S49 cells and in sealed membrane vesicles of wild type S49 cells demonstrate the following. a) Agonist/NEM inactivation requires βAR interaction with the GTP/Mg^{2+} coupling protein (G/M) since cells containing βARs and cyclase catalytic unit but not G/M do not show agonist/NEM effects. b) Similar data show that GTP and Mg^{2+} act on βARs indirectly by interaction with G/M. c) The physical site of GTP and Mg^{2+} action is on the cytoplasmic face of the plasma membrane since in sealed membrane vesicles external GTP and Mg^{2+} do not alter agonist affinity for βARs nor protect against agonist/NEM inactivation unless the pore-forming agent alamethicin is added. d) βARs of the S49 cell are genetically homogeneous since the β_d mutant of S49 which has an 85% decrease in βAR density still exhibits homogeneous binding sites for βARs but heterogeneous functionality. Thus, βARs are, for structural or stoichiometric reasons, functionally heterogeneous even though molecularly homogeneous. It emphasizes the fact that receptor binding done in the absence of functional correlations, does not necessarily measure a physiologically relevant population of receptors.

288.6 PROPERTIES AND REGULATION OF β-ADRENERGIC RECEPTORS ON L6 MYOBLASTS. R.N. Pittman* and P.B. Molinoff (SPON: C.O. Rutledge). Dept. of Pharmacology, Univ. Colo. Health Sci. Ctr., Denver, CO 80262.

A binding assay has been developed for β-adrenergic receptors on L6 myoblast cells growing in monolayer cultures. Binding assays were performed on attached cells, cells in suspension following exposure to EDTA or trypsin and on membranes prepared from myoblasts. The binding of ^{125}I-IHYP was saturable, reversible, and stereoselective. The number of receptors per cell was a function of both plating density and time in culture. Receptors are of the β_2 subtype and there are approximately 14,000 receptors per cell at confluency. The density of receptors was reduced by 15-20% following disruption with a Polytron tissue homogenizer. The number of receptors per cell was the same on attached cells as on cells in suspension. However, when cells in suspension were allowed to attach, the apparent number of receptors per cell was greatly reduced within the first hour following plating. Receptors subsequently reappeared over the next 2-6 hours. No reduction in the density of β-adrenergic receptors occurred if attachment of cells was blocked by either mechanical shaking or by maintaining the cells in culture dishes treated with bovine serum albumin.

Insel and Stoolman (Mol. Pharmacol.,14:549,1978) and Terasaki and Brooker (J. Biol. Chem., 253:5418,1978) have reported that the affinities of agonists measured by inhibition of ^{125}I-IHYP or ^{3}H-DHA binding to β receptors on S49 and C6 cells are lower than are those determined with membranes prepared from the same cultures. The Kd values of antagonists were the same for intact cells and membranes. The Kd values for radioligand displacement by agonists in whole cells was approximately 2-3 orders of magnitude lower than the Kact for cyclic AMP accumulation. These phenomena are also observed in studies with L6 cells. The Kd for l-isoproterenol in L6 membranes was approximately 0.1-0.2 μM in the absence of GTP and 0.6 μM in the presence of GTP. The Kd for isoproterenol in L6 cells in suspension was 0.8-1.0 μM and for cells in monolayer culture about 50 uM. The Kact for isoproterenol stimulated cyclic AMP accumulation in monolayer cells was about 0.02 uM. Although the affinities of agonists were very low in studies with intact cells, antagonists had high affinities for the binding site. Viable L6 cells in suspension resemble membrane preparations with respect to agonist affinity; however, once cells reattach receptors again show low agonist affinity for displacement of radioligand. (Supported by USPHS NS 13289).

288.7 CHARACTERIZATION OF AGONIST BINDING TO β-ADRENERGIC RECEPTORS IN RAT LUNG MEMBRANES. Kim A. Heidenreich*, Gregory A. Weiland* and Perry B. Molinoff. Univ. Colo. Health Sci. Ctr., Dept. of Pharmacology, 4200 E. Ninth Ave., Denver, CO 80262.

Recent evidence suggests that the molecular interactions of agonists with β-adrenergic receptors differ from those of antagonists. There are differences in the thermodynamics of binding to the receptor and in the regulation of ligand binding to the receptor by ions and guanine nucleotides. Most of this evidence has come from indirect studies of agonist binding, that is, by observing agonist inhibition of radiolabelled antagonist binding to the receptor. We have examined agonist binding directly in rat lung membranes using radiolabelled hydroxybenzylisoproterenol (^{3}H-HBI). The K_D for dl-^{3}H-HBI derived from inhibition curves of ^{125}I-IHYP binding was 4.2 ± 1.0 nM (n=3) in the absence of guanine nucleotides and 57 ± 3.0 nM (n=3) in the presence of 100 μM Gpp(NH)p. Concominant with the decrease in affinity observed in the presence of 100 μM Gpp(NH)p was an increase in the Hill coefficient from 0.55 ± 0.017 to 0.88 ± 0.03. Specific binding of ^{3}H-HBI was stereoselective with l-propranolol and l-isoproterenol being 90-100 times more potent than their stereoenantiomers. Catecholamines inhibited ^{3}H-HBI binding with a potency order characteristic of a β_2-adrenergic receptor. Binding of ^{3}H-HBI (3 nM) to rat lung membranes reached equilibrium rapidly at 20° C with a t 1/2 of approximately 5 min. In the presence of 100 μM Gpp(NH)p, steady state binding was reduced by approximately 70%, and association was more rapid with a t 1/2 of <30 sec. Dissociation of ^{3}H-HBI from the receptor was very slow in the absence of guanine nucleotides (t 1/2 ~ 3 hr). As expected, in the presence of guanine nucleotides, dissociation was rapid and complete. For example, in the presence of a maximally effective concentration of Gpp(NH)p (100 μM) dissociation was biphasic with 80% of the binding dissociating in less than 30 sec and the remainder dissociating with a t 1/2 of about 5 min. Scatchard analysis of ^{3}H-HBI binding to rat lung membranes was carried out. In the absence of guanine nucleotides, Scatchard plots were curvilinear suggesting apparent high and low affinity components of binding. The total number of ^{3}H-HBI binding sites (581 ± 51 fmoles/mg protein, n=6) was similar to that measured with ^{125}I-IHYP (544 ± 91 fmoles/mg protein, n=6). In the presence of increasing concentrations of Gpp(NH)p, the affinity of ^{3}H-HBI was decreased and Scatchard plots became linear. Sodium chloride mimicked the effect of guanine nucleotides in lowering the affinity of the receptor for ^{3}H-HBI. Magnesium chloride had the opposite effect of promoting high affinity binding. These results are consistent with a two-step model for agonist binding to the β-adrenergic receptor. In this model, the initial step of agonist binding is the formation of a low affinity hormone-receptor complex which is followed by the formation of a high affinity ternary complex consisting of hormone, receptor and a guanine nucleotide binding site. The formation of the ternary complex appears to be regulated by the concentration of monovalent and divalent cations and by guanine nucleotides. Supported by the USPHS (NS 13289).

289.1 EVIDENCE THAT LYSOSOMES ARE INVOLVED IN THE INHIBITORY ACTION OF DOPAMINE ON PROLACTIN RELEASE. D.D. Nansel*, G.A. Gudelsky, and J.C. Porter. Depts. of Ob-Gyn and Physiology, Cecil H. and Ida Green Ctr. for Reprod. Biol. Sci., Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

It is now well established that dopamine can act directly on the anterior pituitary gland to inhibit the release of prolactin. However, the intracellular mechanism(s) which mediate the inhibitory action of dopamine on prolactin secretion have not been ascertained. Since there is morphological evidence that lysosomes may have a role in the function of prolactin cells (Farquhar, M.G., In Adv Exp Med Biol, vol 80, 1977), the present study was undertaken in order to examine whether lysosomes are involved in the inhibitory action of dopamine on prolactin release. Incubation of anterior pituitary glands in the presence of dopamine resulted in an increase in the activity of the lysosomal enzyme, β-glucuronidase, in the tissue. This dopamine-induced stimulation of tissue β-glucuronidase activity was detectable after only 15 min of exposure of the gland to dopamine, and was dose-related between 10^{-9} and 10^{-5} M dopamine. Moreover, the dose-response relationship for the stimulatory effect of dopamine on anterior lobe β-glucuronidase activity was identical to the dose-response relationship for the inhibitory effect of dopamine on the release of prolactin from pituitary tissue into the medium. Preincubation of anterior pituitary tissue in the presence of the dopamine antagonist, cis-flupenthixol, an agent known to bind competitively to dopamine receptors, markedly attenuated both the stimulatory effect of dopamine on β-glucuronidase activity and the inhibitory effect of dopamine on prolactin release, suggestive of the view that the actions of dopamine on lysosomal enzyme activity and on prolactin release operate through a common cellular mechanism involving a dopamine receptor. In addition, preincubation of anterior pituitary tissue in the presence of either chloroquine or NH_4Cl, two agents that are known to interfere with lysosomal function, also markedly attenuated both the stimulatory effect of dopamine on β-glucuronidase activity as well as the inhibitory effect of dopamine on prolactin release. In view of these findings, we suggest that not only are the effects of dopamine on lysosomal enzyme activity in the anterior pituitary gland and on prolactin release closely related, but that the dopamine-induced stimulation of lysosomal enzyme activity is, in fact, an essential component of the mechanism by which dopamine inhibits the release of prolactin.

289.2 EFFECT OF ESTROGEN ON THE DOPAMINERGIC CONTROL OF PROLACTIN SECRETION. G.A. Gudelsky, D.D. Nansel*, and J.C. Porter. Depts. of Ob-Gyn and Physiology, Cecil H. and Ida Green Ctr. for Reprod. Biol. Sci., Univ. of Texas Southwestern Med. Sch., Dallas, TX 75235.

There is now considerable evidence in support of the hypothesis that dopamine released from tuberoinfundibular neurons into hypophysial portal blood inhibits the secretion of prolactin by a direct action on prolactin cells in the anterior pituitary gland. Estrogen, on the other hand, is known to stimulate the secretion of prolactin. In the present investigation, we have addressed the issue of whether this effect of estrogen is the result of an interference in the dopaminergic control of prolactin secretion. Treatment of ovariectomized female rats with estradiol benzoate (25 μg/kg, sc) daily for 5 days resulted in a marked elevation of the serum concentration of prolactin. However, the estrogen-induced increase in the serum prolactin concentration was apparently not the result of a suppressed release of dopamine, since dopamine concentrations in hypophysial portal plasma were, in fact, significantly higher in estrogen-treated rats than in vehicle-treated animals. On the other hand, when the sensitivity of the anterior pituitary gland to the inhibitory effect of dopamine on prolactin release was examined in vitro, it was found that dopamine was much less effective in inhibiting the release of prolactin from anterior lobes of estrogen-treated rats than from glands of vehicle-treated controls. We have shown previously that the prolactin cell has the capacity to internalize dopamine and incorporate it into prolactin secretory granules. When anterior lobes of estrogen- and oil-treated ovariectomized rats were incubated in the presence of dopamine (10^{-5} M) and then subjected to continuous sucrose density gradient fractionation procedures, it was found that the amount of dopamine that had become associated with prolactin secretory granules was reduced approximately 60% in anterior pituitary glands of estrogen-treated rats when compared to that in glands of vehicle-treated controls. In conclusion, it is unlikely that the effect of estrogen to elevate serum prolactin concentrations is due to a suppressed release of dopamine from tuberoinfundibular neurons into hypophysial portal blood but is due, rather, to a reduced sensitivity of the prolactin cell to the inhibitory action of dopamine. It is interesting to speculate that the ability of estrogen to antagonize the inhibitory effect of dopamine on prolactin secretion may be mediated through an estrogen-induced impairment in the capacity of the prolactin cell to internalize dopamine and incorporate it into secretory granules.

289.3 ACTH AND RELATED PEPTIDES IN HYPOPHYSES FROM NORMAL DOGS AND THOSE WITH CUSHING'S DISEASE. M. Peterson*, A. Liotta†, G. Colurso†, N. Halmi†, and D. Krieger† Divisions of Endocrinology, The Animal Medical Center, New York, New York, 10021*, and the Mount Sinai Medical Center, New York, New York, 10029†.

Among 11 hypophyses of dogs with Cushing's disease, 7 had pars distalis (PD) adenomas and 2 adenomas of the pars intermedia (PI). No discernable tumor was evident in the 2 others. Four of the PD tumors and both PI adenomas stained immunocytochemically for ACTH. The PI tumors also contained variable numbers of cells reactive for α-MSH. The occurrence of PI tumors secreting bioactive ACTH in dogs is of interest, since in the rat PI, ACTH (1-39), which is the biologically active form, is not released as such but is further processed to α-MSH and a C-terminal fragment, CLIP. The normal dog pituitary was therefore compared to that of the rat with immunocytochemical methods. Antibodies employed were against synthetic ACTH (1-39), β-lipotropin (β-LPH), synthetic human and porcine β-endorphin (β-END) and α-MSH. In both species, the corticotrophs of the PD stained with anti-ACTH and anti-β-LPH, but weakly or not at all with anti-β-END or anti-α-MSH. The PI of the rat contained a single cell type that reacted with all 4 antibodies. The predominant PI cell of the dog (called the A cell) stained well with anti-α-MSH, more weakly with anti-ACTH and anti-β-LPH, and not at all with anti-β-END. Scattered throughout the canine PI, and sometimes in clusters, were, however, cells that resembled PD corticotrophs in every respect (B cells): they stained strongly for ACTH and β-LPH and not for α-MSH. An ACTH bioassay using dispersed adrenocortical cells showed that the PI of dogs (unlike that of rats) contained high concentrations of ACTH, similar to those in the PD. (PD: 219 ± 29 ng/mg; total content 21.2 ± 3.2 μg. PI: 364 ± 180 ng/mg; total content 3.2 ± 1.5 μg.) This could be attributed to the presence of B cells in the canine PI. PI adenomas causing Cushing's disease in dogs could originate from the B cells or from A cells which have (at least in part) lost their ability to cleave ACTH to α-MSH and CLIP. The inability to detect immunoreactive β-endorphin in the dog PI may be secondary to a different structural form in this species.

289.4 GAP JUNCTION MORPHOMETRY IN THE RAT NEUROHYPOPHYSIS WITH DEHYDRATION. D. Friedenbach, C. Tweedle and G. Hatton. Depts. of Anatomy, Psychology and Zoology and the Neuroscience Program, Michigan State University, East Lansing, Michigan 48824.

Several parameters of gap junctions have been quantified during functional changes in the neurohypophysis of the rat. Three groups of adult male rats: control, 24h dehydrated (DEH) and 24h dehydrated + 24h rehydrated (REH), were vascularly perfused with buffered aldehydes either with or without $CaCl_2$. The neurohypophysis were routinely cryoprotected and freeze-fractured. Morphological parameters were quantified for all intracellular junctions where the contributing intercellular processes were identified. In addition a random sample of gap junctions was quantified for each treatment group with or without $CaCl_2$. Results were analyzed by ANOVA. Gap junctions for which the contributing elements were identified were all between pituicyte processes (n=19). Therefore, the random sampling of gap junctions in each treatment group was combined with the categorized junctions (n=79). Junction size (μm^2) is decreased 25% from controls in the DEH and REH groups. The presence of $CaCl_2$ increased junction area 60-65% within each treatment group but had no differential effect between control and treatment groups. The average area of tissue (replica) examined to find one gap junction was used as an index of gap junction frequency. Again, there were no significant differences between DEH and REH groups (46 and 40μm^2/junction). Each treatment group, however, had lower values than controls (64μm^2/junction). Therefore each treatment group had more gap junctions per unit area of tissue. $CaCl_2$ had no effect within each control or treatment group. When these data were expressed as μm^2 junction/μm^2 replica, there were no differences between control and either treatment group. $CaCl_2$ however increased the amount of junction per area within each group by an average of 84%.

In summary, following dehydration there are more and smaller junctions. This is also true following rehydration. It, therefore, is apparent that these pituicyte processes have not reestablished the same functional level as before despite a morphological reversion (Tweedle and Hatton, Soc. Neurosci. Abs., 1979). The addition of $CaCl_2$ to the fixative solution produced fewer and larger junctions but had no overall effect upon the changes in junctions with treatment except in magnitude. Work is currently under way on other types of intracellular junctions and junctions between other types of cellular processes.

289.5 SPECIFIC IN VITRO UPTAKE OF ^{3}H-5HT IN THE PITUITARY OF THE RAT. M. A. Johns*, E. C. Azmitia, E. A. Zimmerman+ and D. T. Krieger. Depts. of Anat. and Endocrinol., Mount Sinai Med. Ctr., NY 10029 and Dept. of Neurol.+, Columbia Coll. of P & S, NY 10032.

There are conflicting reports over the presence and the nature of 5-HT and its metabolites in the anterior pituitary(AP). CNS serotonergic neurons, via their projections to the hypothalamus, have been implicated in the regulation of release of several pituitary hormones. To investigate the possibility of a direct 5-HT effect on pituitary cells two types of experiments were done:

(1) Determination of uptake of ^{3}H-5HT(10^{-8}-10^{-6}M) into AP of adult male and female rats in the presence and absence of excess (10^{-5}M) unlabelled 5-HT, NE, desipramine, fluoxetine(FLUOX) or metergoline (MET). Tissue was incubated (37°) with ^{3}H-5HT in Ringer's soln. with pargyline(10^{-4}M), dextrose(10^{-2}M) and ascorbic acid(10^{-3}M) for 10 min. The observed total uptake [218 ± 21 pmoles/gm at(5 x 10^{-8}M) ^{3}H-5HT] was reduced 62% by excess 5-HT and 50% by FLUOX(a 5-HT uptake inhibitor) whereas no effect was seen with MET(a putative specific 5-HT receptor blocker). Uptake was not affected significantly by NE or desipramine(a NE uptake inhibitor). These findings suggest the presence of a saturable, specific, non-receptor mediated uptake mechanism.

(2) Radioautography alone or combined with immunocytochemistry was performed to delineate the localization of ^{3}H-5HT uptake. Tissue was incubated with ^{3}H-5HT(10 min) fixed in Bouin's (½h), paraffin-embedded, sectioned (5µ) and processed sequentially for radioautography and immunocytochemistry. Deparaffinized sections were reacted by immunoperoxidase technique using primary antisera to hLH β, hTSH β, ACTH, ß-endorphin, hß-LPH, hGH, oPRL. Reaction products were formed with diaminobenzidine, and the sections were air-dried and processed for radioautography.

Radioautography showed three types of silver grain labeling patterns: 1) Dense aggregates of silver grains near blood vessels and between cells; 2) a random distribution of silver grains throughout the tissue; 3) a concentration of silver grains over certain pituitary cells. The type 1 pattern is similar to that seen when CNS serotonergic fibers are labeled by ^{3}H-5HT uptake, raising the possibility of 5-HT nerve terminals in the AP. Type 2 uptake was not blocked by excess 5-HT and probably reflects non-specific binding. The type 3 pattern was most common and the combined radioautography-immunocytochemistry procedure indicates that these are LH cells. These results suggest that 5-HT may have a role in gonadotropin regulation at the pituitary level.

289.6 EFFECTS OF GABA ON THE ELECTRICAL PROPERTIES OF A CLONAL PITUITARY CELL LINE. J.M. Israel* and, B. Dufy*, (Spon : J.D. Vincent). U.176,INSERM,rue C.Saint-Saëns,33077 BORDEAUX (France).

The recent discovery that some anterior pituitary cells are excitable and are able to generate Ca^{2+}-dependent action potentials has led to the hypothesis that such an electrical activity may play a role in the stimulus-secretion coupling. In this study, we report the effects of GABA on the electrical properties of a Prolactin (PRL) secreting pituitary cells line (GH_3/B6). We have chosen to use GABA because its effects on post synaptic membrane properties have been extensively studied and it is also a potent inhibitor of PRL secretion. Stable intracellular recordings were obtained from 450 cells ; 160 cells were excitable (resting potential 46 ± 2 mV ; input resistance 425 ± 60 MΩ) ; 190 cells were spontaneously active. GABA directly applied to the cell membrane (10^{-4} M, 2 nl, 0.5 sec) provoked a biphasic change in the electrical properties of 108 cells recorded with 3M KCl micropipettes. The immediate effect consisted of an hyperpolarisation with an increase of input resistance and a reversal potential of 39 ± 2 mV. Spontaneous action potentials were suppressed by this hyperpolarisation. The effect lasted for 20 to 120 sec and was reversible. It was followed by a large and progressive decrease in the resistance with a slight depolarisation (2 - 5 mV). Simultaneously, the amplitude of the action potentials was dramatically reduced.The late effect was less consistent when using a 2M K-citrate electrode and it was never observed with a 0.6 M K_2SO_4 pipette. It may be concluded that this late effect of GABA is dependent on the intracellular fluid composition of the cell which can be altered according to the type of recording pipette used. Both immediate and secondary effects were blocked by application of picrotoxine (10^{-6} M) but were not affected by haloperidol which blocked the inhibitory effect of DA (Dufy, B. et al., Nature,282 :855, 1979). These observations show that the inhibitory effects of GABA and DA involve different receptor sites. The fact that GABA, which directly inhibits PRL secretion by pituitary cells, has also an inhibitory effect on action potentials is consistent with the concept of stimulus-secretion coupling. The mechanisms by which GABA acts on electrical properties of the endocrine cell membrane appear different from the conventional effects of GABA on post-synaptic ionic conductance in neurons.

290.1 ADMINISTRATION OF PROPYLTHIOURACIL TO RATS FROM EARLY PREGNANCY THROUGH LACTATION: EFFECTS ON THE SUCKLING BEHAVIOR OF THE OFFSPRING. Y. Narayanan * and C.H. Narayanan (SPON: A. Jayaraman Rao). Dept. Anat., LSU Sch. Med., New Orleans, LA. 70119.

Female albino rats (Holtzman) were given propylthiouracil (PTU) in order to induce hypothyroidism. All treatments were begun from seven days of pregnancy and continued until 20 days after birth. Various methods of feeding and their effectiveness were tested. In one group, standard rat chow was coated with a suspension of PTU in sodium alignate to make up a 3% PTU diet. Other groups were fed with powdered rat chow containing 0.3% or 0.5% or 1% PTU. Mouth opening, hand and mouth coordinated activity of the fetuses, and the suckling behavior of the pups were studied. Control animals received standard rat chow and drinking water ad libitum.

In all cases, the experimental rats delivered after a delay ranging from about 24 hours to two days when compared with control animals raised under otherwise similar conditions. Fetuses and pups of all the experimental groups were without exception smaller in size. At birth, pups of control animals weighed on an average 8.10g, while pups of the experimental groups weighed 6.5g. At 13 days after birth, control pups weighed 30.30g, while experimental pups weighed 9.7g. Eyes in the experimental pups did not open until 18 days after birth. Mouth opening and hand-mouth synchronous activity in fetuses of the experimental series were drastically reduced in frequency and in some cases altogether absent. The pups of some experimental cases were unable to attach and suckle the nipples of their mother, while in others, suckling behavior was severely retarded. The neurological deficits produced by thyroid deficiency during development and their impact on the sequential development of non-neuronal elements such as the squamosomandibular joint are currently being examined.

290.2 OPIOID CONTROL OF PLAY AND SOCIAL DOMINANCE. J.E. Jalowiec*, J. Panksepp, F. DeEskinazi, P. Bishop*. Dept. of Psychology, Bowling Green State Univ., Bowling Green, OH 43403.

Our previous work has indicated that brain opioids control social emotions. In the following studies we evaluated the effects of opiate agonists and antagonists on play behavior--a possible source process for development of social comptetence. Play was studied in 20-50 day old Long-Evans rats by measuring the frequency and duration of pinning behavior in pairs of socially isolated animals permitted 5 min periods of social interaction. Measures of dominance and submissive postures permitted continuous evaluation of the dominance status of animals. Naloxone (1-5 mg/kg s.c.) reduced pinning by 33-66%. Morphine at 1 mg/kg increased pinning by 80% while 5 mg/kg reduced pinning by 32%. If brain opioid activity mediates social affect, opiates may facilitate neural activity underlying "social strength" while opioid blockade may hinder processes which can increase the social status of animals. When one rat of each test pair was administered morphine and the other, naloxone (0.5 - 1.0 mg/kg), morphine animals invariably became dominant while naloxone treated ones became submissive. Stable dominance required several days to develop, but after 6 test sessions, morphine animals pinned naloxone animals twice as often as naloxone animals pinned morphine treated ones. Similar results were obtained when morphine or naloxone treated animals were pitted against saline treated ones. Drug reversal did not invariably reverse dominance, suggesting that social learning factors could counteract drug effects. Also, in animals permitted to establish their dominance relationships prior to drug treatment, naloxone tended to reduce and morphine to increase dominance, but the drugs did not consistently reverse established hierarchies. These results affirm the participation of opioid systems in organizing social behaviors. High opioid activity facilitates the development of social dominance while reduced opioid activity leads to more submissive behavior patterns in juvenile play.

290.3 THE ONTOGENESIS OF CARDIAC AND BEHAVIORAL HYPERREACTIVITY IN SPONTANEOUSLY HYPERTENSIVE RATS. D. C. TUCKER and A. K. JOHNSON. Dept. of Psychology, Univ. of Iowa, Iowa City, Iowa 52242.

Substantial experimental evidence exists demonstrating that adult spontaneously hypertensive rats (SH) evidence both cardiovascular and behavioral hyperresponsivness to environmental stimuli (e.g. Mc Carty, R., Chiueh, C. & Kopin, I., Beh. Bio., 22:405, 1978). However, little is known of the course of early developmental events which are associated with this increased responsiveness. The ontogeny of autonomic control over heart rate (HR) in normotensive rats has also been well described (e.g. Adolph, E., Am. J. Physiol., 212:1095, 1965; Hofer, M. & Reiser, M., Psychosom. Med., 31:372, 1969). The rationale of our research program is to study the motor behavior and HR of SH rats and of normotensive rats from the Wistar Kyoto strain (WKY) prior to weaning in the hope of identifying critical periods or events that may influence the development of hypertension.

During a preliminary investigation, HR was sampled daily from implanted silver wire electrodes beginning at two days of age; divergence of HR between these litters of nondisturbed SH and WKY pups tested in their home cage was first seen at 16 days of age.

In the present study, 10 litters of SH and 10 litters of WKY 16 day old pups were studied under a sequence of four conditions. For each pup the testing session included 1-2 min. of baseline HR recorded in the home cage with minimal disturbance of the litter. The pup was then placed in a small open field apparatus which was maintained at nest temperature. After 2 min. a loud auditory stimulus was presented and the HR and behavior monitored for 30 sec. The pup was subsequently returned to the home cage and recording was continued for an additional 2 min. Throughout the recording period, behavior was coded as either still or active.

Sixteen day old SHR pups were observed to have higher HR than WKY of the same age both when still {$F(1,16)=7.9$, $p<.01$} and when active {$F(1.16)=94$, $p<.001$}. The magnitude of the HR differences between strains did not change with the testing situation. An estimation of activity level in the open field situation was made by counting the number of 5.5x8cm. grids the pup crossed during the test period. Although animals showed substantial locomotor activity, SH and WKY pups did not differ in the number of grids crossed.

The results of the present experiment define the period during which a marked change in cardiovascular function occurs in the SH. It is important to note that the hyperkinetic cardiovascular response is apparently distinct from increased locomotor activity. Future studies determining the controlling mechanisms associated with this increase of HR may suggest means through which interventions could be made during this potential critical period.

290.4 ENHANCED LABELING OF ECF PROTEINS IN MOUSE BRAIN AFTER TRAINING. V. E. Shashoua and M. E. Moore*. Mailman Research Center, McLean Hospital, Harvard Med. Sch., Belmont, MA 02178.

In previous studies, we found that the labeling of three brain proteins is increased after goldfish acquired a new pattern of swimming behavior. Two of these proteins (β and γ Ependymins) were found to be rapidly labeled and secreted into the brain extracellular fluid (ECF). Antisera to the ependymins injected into the fourth ventricle of goldfish brain at critical periods after training [Shashoua and Moore (1978) Brain Res. 148:441-449] inhibited long-term retention of the behavior. Using these techniques as a model system, we now find that specific protein changes can also occur in mammalian brain after training. Thirsty mice (Balb c) were trained to find water in one arm of a T-maze according to the method of Naranjo and Greene [Expt. Neurol. (1980) in press]. At 1½ hours after completion of the training, each animal was injected with valine ^{3}H and labeled for one hour. An untrained control mouse (litter mate) received valine ^{14}C. After the labeling, the animals were anesthetized in ether, perfused with saline through the heart, and the brains from each pair (one experimental and one control) were pooled and extracted with 0.32 M sucrose to give the ECF fraction [Shashoua (1979) Brain Res. 166:349-358]. The extracted brains were then homogenized and separated by ultracentrifugation into the nuclear, synaptosomal, and cytoplasmic subcellular fractions. Each fraction, including the ECF fraction, containing ^{3}H labeled proteins from the trained mouse and ^{14}C labeled proteins from a control animal, was analyzed by SDS-polyacrylamide gel electrophoresis. Only the ECF fraction showed increased valine incorporation at two bands migrating at 32,000 and 27,000 daltons, respectively. The average increase for the two bands was 250% and 80%, respectively. Several types of control behavioral experiments showed no detectable protein changes by these double-labeling procedures. Thus pretrained mice which performed the task without acquisition of new information, thirsty animals and highly stressed mice showed no protein changes. The results suggest that it is essential to acquire new information before obtaining the concomitant increase in the labeling of the specific ECF proteins. These findings extend our previous studies in goldfish brain to mammalian brain and again focus on the brain extracellular fluid as an important channel of communication in the process of "fixing" information in the CNS.

290.5 RABBIT VISUAL CORTEX AND THE EFFECTS OF DIFFERENT FLASH FREQUENCIES DURING STROBOSCOPIC REARING. H. E. Pearson, N. Berman, and E. H. Murphy. Anatomy Department, The Medical College of Pennsylvania, Philadelphia, PA 19129

The rabbit visual cortex appears resistant to most forms of visual deprivation, but we have shown that deprivation of the experience of visual motion during early postnatal life does result in alteration of the response characteristics of visual cortical cells (Pearson, Berman and Murphy, 1980). Such deprivation was achieved by raising the rabbits from birth in a stroboscopically illuminated environment, with a flash frequency of 4 per second (4 Hz rabbits). We have now extended the study to include a group of rabbits raised with a flash frequency of 8 per second (8 Hz rabbits).

Single unit recordings were made from primary visual cortex when the rabbits were at least 8 weeks of age. Responsive units were classified according to their receptive field properties and were compared with data obtained from normal rabbits. The greatest effect of the stroboscopic rearing, at both frequencies employed, was the reduction in the proportion of orientation selective cells which also show direction selectivity. In normal rabbits, 87% of orientation selective cells are also direction selective. This proportion was reduced to 45% in the 4 Hz rabbits and 37% in the 8 Hz rabbits. A significant decrease in the proportion of orientation selective cells was found with the 4 Hz rabbits but not with the 8 Hz rabbits. Orientation selective cells comprise 74% of responsive units in normal rabbits and 81% in 8 Hz rabbits, whereas in 4 Hz rabbits this was decreased to 59%. Therefore, the result of deprivation of visual motion during development is dependent on the flash frequency used. The lower frequency affects both orientation and direction selectivity, whereas the higher frequency affects only direction selectivity. Similar findings on the effects of different flash frequencies during stroboscopic rearing have been reported for the visual cortex of the cat (Cynader, Berman and Hein, 1973; Olson and Pettigrew, 1974; Cynader and Chernenko, 1976).

This work was supported by NIH grants EY 02488 and EY 2088.

290.6 BEHAVIORAL ESTIMATES OF VISUAL ACUITY IN CATS WITH EXPERIMENTAL AMBLYOPIA. G. D. Mower*, J.L. Burchfiel, K.S. Rockland, F.H. Duffy. Lab. of Developmental Neurophysiology, Children's Hosp. Med. Ctr. and Harvard Med. Sch., Boston, Mass. 02115.

Visual acuity of the normal and treated eyes of amblyopic cats was assessed in a discrimination task between square wave gratings (85% contrast) and a blank of matched mean luminance ($22 cd/m^2$). Three preparations were studied: monocular deprivation (N=2), surgical esotropia (N=2), and cats reared with a rotatable prism over one eye (N=2). Further studies are in progress.

The acuity of the normal eye was comparable in all preparations and was in the range we find for normal cats (3.5 - 5.0 cycles/degree). All preparations showed an acuity deficit with the treated eye and the magnitude of the deficit varied between preparations. Expressed as the ratio of normal eye acuity/treated eye acuity, the deficits were: monocular deprivation: 3.3, rotating prism: 2.8, esotropia: 2.3.

Comparisons were made between these acuity estimates and the physiological correlates of amblyopia measured in these and other animals with identical rearing histories. In all preparations, the deficits in spatial resolution of LGN X-cells driven by the treated eye were comparable, and indicated a reduction by a factor of 2 compared to the normal eye. Physiological deficits in visual cortex varied among the preparations. In terms of the percentage of cells responsive to the treated eye (both monocular and binocular cells), the results were: monocular deprivation: 30%, rotating prism: 40%, esotropia: 68%.

Thus, the magnitude of the deficits in LGN did not correlate with the magnitude of the behavioral deficit, and when cortical deficits were present, the behavioral deficit was greater than the LGN deficit would predict. Cortical deficits appear to add to LGN deficits in determining the behavioral acuity of cats with different forms of amblyopia.

290.7 FOUR HOURS OF ENRICHED EXPERIENCE ARE SUFFICIENT TO INCREASE CORTICAL WEIGHT OF RATS. P.A. Ferchmin and V.A. Eterović. Dept. of Biochem. Univ. Central del Caribe Sch. of Med. Cayey, P.R. 00633.

We have shown previously that a 4-day-exposure to environmental complexity (EC) is enough to increase brain weight of rats compared to littermates kept in impoverished conditions (IC) (Ferchmin, P.A., Eterović, V.A. and Caputto, R. Brain Research 20 (1970) 49-57). The purpose of the present study was to determine the minimum exposure time required to elicit detectable differences in cortical weight between EC and IC rats. Four groups of rats were exposed to EC for 4 days, either for 24 hours, 7 hours, 1 hour or 0 hours a day; they spent the remaining hours in IC (24hEC, 7hEC, 1hEC and IC groups). There were 20 animals in each condition. After sacrifice their brains were dissected into several regions and weighed. In accordance with previous results for this and other strains, occipital cortex was the brain region most affected by the environment: 1hEC > IC by 13.0%, $p<0.01$, 7hEC > IC by 10.7%, $p<0.05$ and 24hEC > IC by 7.6%, non significant. In the ratio of visual cortex over non-cortical brain, 1hEC > IC by 14.4%, $p<0.01$, 7hEC > IC by 11.9%, $p<0.01$ and 24hEC > IC by 9.3%, $p<0.05$. Although there is a trend of higher increases with shorter exposure times (1hEC > 7hEC > 24hEC), the three EC groups did not differ significantly. At variance with longer exposure times, total cortex was not significantly changed. It is possible that the occipital cortex is the initial focus of environmentally-stimulated trophic response, which then spread to other cortical regions.

This study demonstrates that a relatively gross anatomical change in occipital cortex can be induced by 4 hours of enriched experience. This period of time is comparable to the time necessary for the rat to master some common learning tasks. Therefore, the anatomical changes observed in EC vs IC rats could be related to brain adaptation for storage of the increased amount of information conveyed by the complex environment.

290.8 PLASTICITY, EXPERIENCE AND RESOURCE ALLOCATION IN MOTOR CORTEX AND HYPOTHALAMUS. D. N. Spinelli, Frances E. Jensen* and Gonzalo Viana Di Prisco*, Department of Computer and Information Science and Psychology, University of Massachusetts, Amherst, MA 01003.

Training normally reared kittens to avoid an "unsafe" visual stimulus by flexing one forearm has major effects on visual and somatic cortex adult organization. Here we show that two important interfaces to the world, motor cortex and the hypothalamus, are similarly affected. Punctate stimulation of the motor cortex reveals a four-fold increase in the area allocated to the control of movement of the trained forearm relative to the untrained one. Some of the motor responses with increased representation resembled elementary movements involved in correct responses during training. Cellular responses in the hypothalamus showed a shift toward cells with selectivity for the trained forearm; some of these cells showed the additional characteristic of selective responsivity to the visual stimuli used in training. It appears that the partitioning of the motor cortex and the repertoire of responses available to it are substantially influenced by early experience. The access that sensory stimuli have to the hypothalamus is also modified, possibly changing the way in which the adult will later cope with demanding tasks. The results dramatically demonstrate that simple early experience exerts widespread effect on structures which will later prove critical in setting the limits of individual potential.

291.1 ACTIVITY PATTERNS OF CROSS-REINNERVATED FLEXOR DIGITORUM LONGUS AND SOLEUS MUSCLES IN THE CAT DURING UNRESTRAINED MOVEMENT. M.J.O'Donovan*, M.J.Pinter*, R.P.Dum and R.E.Burke. (Spon. W.B. Marks) Lab. of Neural Control, NINCDS. NIH, Bethesda, MD 20205

As part of a study of "fast-slow" nerve cross union on the motor units of the largely fast twitch flexor digitorum longus (FDL) and pure slow twitch soleus (SOL; see Neurosci. Abstr. 5:765; 5:766, 1979), we examined EMG and mechanical activity in cross-reinnervated FDL and SOL muscles in 4 adult female cats. In 2 cats, FDL motoneurons innervated SOL muscle units (FDL→SOL); in 2 others, SOL motoneurons innervated FDL muscle units in one leg (SOL→FDL) while FDL was intentionally self-reinnervated (FDL→FDL) in the contralateral leg. Chronically implanted devices were used to measure FDL and SOL EMGs, forces and lengths (see Neurosci. Abstr. 5:380, 1979) 18 to 24 months after nerve cross-union (bipolar EMG electrodes were also implanted in several other muscles). After full recovery from aseptic surgery, data was recorded during treadmill locomotion, postural adjustments, and various reflexes (paw shaking, scratching and electrical stimulation of the sural nerve via implanted electrodes). At terminal experiments, force and length gauges were calibrated and sources of abnormal innervation determined. In 3/4 FDL→SOL muscles, innervation derived solely from FDL motor axons (pure cross-reinnervation). These muscles exhibited very low levels of EMG and force output during standing, and in locomotion displayed only short bursts of activity in the late stance and early flexion phases of stepping (typical of the normal FDL but very different from normal SOL, which has high activity levels in standing and throughout the stance phase of stepping). In the 4th FDL→SOL muscle, SOL axons had reinnervated parts of the SOL muscle (dual innervation) and its activity pattern was a mixture of the normal SOL and FDL patterns. In the reverse version of cross-innervation, the pure SOL→FDL muscle in 1 cat exhibited a high level of EMG activity during standing and throughout stance during locomotion; its peak force production (~600 g) was several times larger than the contralateral self-innervated (FDL→FDL) muscle. In the last cat, both SOL and FDL axons dually reinnervated the FDL muscle and it displayed activity throughout stance plus extra bursts at end stance and during swing (the latter similar to the contralateral FDL→FDL muscle). In all cases, activity during shake, scratch and sural-evoked reflexes were in exactly the patterns normally expected from the innervating motoneurons. Thus, the motor activities of cross-reinnervated muscles remain those characteristic of the normal innervating α motoneurons, resulting in alterations in muscle unit duty cycle that must be taken into account in the interpretation of such experiments.

291.2 THE EFFECTS OF AXOTOMY ON LOCAL RATES OF PROTEIN SYNTHESIS IN THE RAT SUPERIOR CERVICAL GANGLION. C.B. Smith*, P. Yarowsky, A.M. Crane* (SPON: L. Sokoloff). NIMH, Bethesda, MD 20205.

In a previous study (Agranoff et al., Trans. Am. Soc. Neurochem. 11:95, 1980) we observed that unilateral section of the hypoglossal nerve results in an increased rate of protein synthesis in the ipsilateral nucleus. In order to examine the influence of the afferent input on the response of the perikarya to injury of their axons, the rat superior cervical ganglion (SCG) was used as a model system because of the relative ease of manipulation of its input as well as its output. Four different experimental conditions were studied: 1). Axotomy, in which the external carotid nerve (ECN) was severed unilaterally at the level of the superior thyroid artery, 2). Deafferentation, in which the cervical sympathetic trunk (CST) was severed unilaterally about 1 cm from the caudal pole of the ganglion; 3). Axotomy/Deafferentation, in which both nerves were severed unilaterally; and, 4). Sham-operated controls.

Rats (290-355 g) were surgically prepared under halothane anesthesia. Three days later, the procedure for the determination of local rates of protein synthesis was carried out (Smith et al., Trans. Soc. Neurochem. 11:95, 1980). A pulse of the tracer, L-[1-^{14}C]leucine (100μCi/kg), was injected intravenously, and arterial plasma concentrations of labeled and unlabeled leucine were monitored during the entire 30 min of the experimental period. The SCG were then excised, frozen, and sectioned, and local tissue concentrations of ^{14}C were determined by quantitative autoradiography. Regional rates of leucine incorporation into protein were calculated on the basis of these measured variables.

It has been demonstrated (Bowers & Zigmond J. Comp. Neurol. 288:227, 1979) that the perikarya of the ECN reside only in the caudal region of the ganglion and that there are some perikarya in the caudal pole that send their axons down the CST. Axotomy alone resulted in an increased rate of protein synthesis in the caudal region compared to that of the control side. Deafferentation alone also caused an increase in this area, but it is uncertain whether this reflects an effect on the perikarya of the axons of the CST or ECN. In ganglia which were both axotomized and deafferented, however, the rate of protein synthesis in the caudal region was reduced to a level below that of the sham-operated animals.

In our previous study of the response of the hypoglossal nucleus to axotomy we also found an increased rate of glucose utilization in the axotomized nucleus as compared to the control. Similarly, in the present study we have determined by means of the deoxyglucose method that the local rates of glucose utilization are increased over control values in the caudal region of the SCG following either axotomy or deafferentation.

291.3 CHANGES IN GLUCOSE METABOLISM DURING HYPOGLOSSAL NEURON REGENERATION. Philip Singer and Sharon Mehler*. Research Service, Veterans Administration Medical Center and University of Kansas Medical Center, Kansas City, Missouri 64128 and Kansas City, Kansas 66103.

We have previously reported a marked increase in ^{14}C-2-deoxyglucose uptake (Singer and Mehler, Neurosci. Abstr. 5:683, 1979 and Exp. Neurol. in press) in the rat in hypoglossal nucleus beginning 24 hours after transection of the hypoglossal nerve. This suggests increased glucose use during motorneuron regeneration. Others have found a similar increase using the quantitative ^{14}C-2-dexyglucose method (Agranoff, Smith and Sokoloff, Trans. Am. Soc. Neurochem. 11:95, 1980). In order to better determine the pathways of this increased utilization we studied citric acid cycle, glycolytic, and pentose phosphate shunt enzymes with histochemical stains.

The left hypoglossal nerve of 150 gm male Sprague-Dawley rats was sectioned under nembutal 50 mg/kg IP and the animal allowed to recover. The animals were reanesthetized at 24, 48, 72 hrs and 7, 14, and 30 days and the brainstem removed and immediately frozen in Freon cooled to -70°C. 10 μ sections were made at -18°C and stained for succinic dehydrogenase (SDH), lactic dehydrogenase, (LDH), diphosphopyridine nucleotide (DPNH), triphosphopyridine nucleotide (TPNH) and glucose-6-phosphate dehydrogenase (G-6-PD). The operated and control nuclei were compared. Intracellular SDH and LDH decreased on the side of axotomy beginning at 24 hrs through 72 hrs but increased above control after this. However, staining of the neuropil for SDH and LDH on the side of axotomy decreased beginning at 72 hrs and remained decreased at 7, 14, and 30 days. Intracellular DPNH, TPNH and G-6-PD staining on the side of axotomy increased beginning at 48 to 72 hrs. It appears that the citric acid cycle, glycolysis and pentose phosphate pathways all ultimately participate in the increased glucose use after axotomy. However, because of the early decrease in intracellular staining of SDH and LDH, the early increase in glucose use is probably due to pentose phosphate enzymes and perhaps glycoprotein synthesis. Previous studies have shown both increases and decreases in citric acid cycle activity after axotomy. This probably reflects the bimodal early vs. late activity of this pathway when compared using different animal models and times after axotomy. The decreased SDH and LDH staining in the neuropil may reflect decreased action potential activity in dendrites after axotomy as opposed to synthetic activity in the cell body.

291.4 AN ULTRASTRUCTURAL STUDY OF RETROGRADE CHANGES IN HYPOGLOSSAL NEURONS OF CATS. J. L. Cova*, D. J. Allen and H. Aldskogius*. Departments of Anatomy, Medical College of Ohio, Toledo, OH 43699 and Karolinska Institutet, Stockholm, Sweden.

Adult cats under ketamine anesthesia were subjected to crush of the left hypoglossal nerve at the level of the posterior belly of the digastric muscle. Animals were sacrificed by intra-aortic perfusion with 4% neutral buffered paraformaldehyde followed by 2.5% neutral buffered glutaraldehyde at 1, 5, 10, 35 and 60 days after surgery. Two intact animals served as controls. Blocks of medulla containing the rostral 2 mm of the hypoglossal nucleus were embedded in epon-araldite. Thin sections were "stained" with lead citrate and uranyl acetate.

Preliminary results from animals killed at 5 and 10 days indicate that ultrastructural changes vary with the length of the postoperative survival period. At 5 days after axon crush, the nerve cell bodies of injuried neurons contained increased numbers of elongated, electron-dense mitochondria with reduced cross-sectional area. Occasionally these mitochondria assumed a lobulated configuration. Morphological changes in the RER were variable and ranged from partial to complete disaggregation. In certain instances, the disaggregated RER was confined to "islands" separated by neurofilaments and large numbers of mitochondria. Vesiculation and vacuolation of Golgi membranes were frequently observed. In many instances autophagic membranous foci of Golgi membranes were also present.

At 10 days after crush, the granular endoplasmic reticulum was markedly depleted, and when present consisted of broad, irregularly arranged cisterns containing an amorphous electron-opaque material. Rossette ribosomes were randomly distributed throughout the cytoplasm and within the abnormal cisternal arrays. The number of single ribonucleoprotein granules in the cytoplasm of reacting neurons appeared greater than those of intact neurons. The Golgi complexes appeared to be hypertrophic and exhibited a pattern of vesiculation and vacuolation similar to that observed 5 days after axon injury. These complexes frequently assumed a peripheral position in the cytoplasm. Large amounts of smudged electron-opaque material resembling lipofuscin was randomly dispersed throughout the cytoplasm at 5 and 10 days after surgery.

These results, when compared to published descriptions of morphological changes associated with axon reaction in neurons of different species and nerve cell populations, further emphasize the variability of the ultrastructural features of the retrograde response.

This investigation was supported by General Research Support Grant 2-1-4-94209, National Institutes of Health.

291.5 TASTE BUDS ON CAT CIRCUMVALLATE PAPILLAE REINNERVATED BY THE CAROTID SINUS NERVE. B. Dinger*, L.J. Stensaas, S.J. Fidone. Dept. Physiol., Sch. Med., Univ. Utah, Salt Lake City, UT 84112.

Mammalian taste buds disappear from the gustatory epithelium several days following deafferentation. Buds will reappear in their usual places subsequent to reinnervation of gustatory papillae by nerves known to contain gustatory fibers. Cross-reinnervation experiments by earlier investigators have failed to detect fibers with a gustatory potential in motor or general sensory nerves even though other work has shown that gustatory papillae transplanted to the anterior chamber of the eye form taste buds under the influence of either intrinsic trigeminal fibers or following innervation by similarly transplanted lumbar dorsal root ganglia. We have re-examined this question by testing the gustatory potential of arterial chemosensory and barosensory neurons in cross-reinnervation type experiments.

In cats, 2-19 months following cross-anastomoses of the carotid sinus nerve to the distal stump of the lingual branch of the IXth n. taste buds are present in their usual locations on the circumvallate papillae. These buds are normal in size and appearance when compared to tissue from reanastomosed control cats. The buds contain both light and dark cells organized into nuclear and apical regions with a taste pore and a taste pit. Light microscope autoradiography of this tissue several days following labeling of the petrosal ganglion shows that these buds are innervated by petrosal ganglion neurons. Whole nerve recordings made proximal to the anastomoses indicate that these receptors respond to the same gustatory stimuli as do normally innervated vallate buds.

We have investigated the possibility that the original gustatory fibers of the lingual n. have reinnervated the papillae in cross-anastomosed cats via several possible routes. The available neuroanatomical, histological and physiological data indicates that these taste buds are not innervated by such fibers.

We are currently testing the hypothesis that the fibers possessing a gustatory potential in these experiments normally serve an arterial chemosensory function in the carotid body. Supported by USPHS research grants NS 12636 and NS 07938.

291.6 NERVE REGENERATION THROUGH SEMIPERMEABLE TUBES. Betty Geren Uzman and Gloria M. Villegas*. V.A. Med. Center and U. Tenn. Health Sci. Ctr., Memphis, TN 38104 and Instituto Venezolano de Investigaciones Cientificas, Caracas, Venezuela.

Mouse sciatic nerves known to regenerate through impermeable polyethylene tubes are more abundantly reconstructed across a 3 mm gap when regenerated through semipermeable acrylic copolymer tubes+. In the latter, regeneration is accomplished by the formation first, through the entire length of the tube, of a vascularized connective tissue cord, along the center of which course the earliest regenerating axons growing parallel to the length of the tube and enveloped in Schwann cells. At the periphery of the vascularized cord fibroblasts are arranged in circumferentially concentric layers between which, with time, fascicles of Schwann cell-enveloped axons accrue, increasing the diameter of the nerve fiber. Nerve outgrowth, radial enlargement and fiber maturation proceed proximodistally along the vascularized cord and from its center to the periphery. Central fibers reach the distal stump first and myelinate first. The regenerated nerve is gradually remodeled with the refasciculated appearance first obscured centrally, but retained for a longer time peripherally. Evaluation of the role of the vascularized cord, that very early spans the entire gap, in guiding and modeling the regenerated nerve-Schwann cell units will be reported separately from, and in combination with, that of the acrylic copolymer tube, after removal of one or the other, or both, at varying times after the initial nerve transection. Use of multiple tubes divides the regenerated segments across the gap. "Control"regeneration outside a tube results in a refasciculated structure composed of perineurial enveloped fascicles of 15 to 20 axons each, but the fascicles are not usually enclosed by a covering epineurium.

+ Amicon X-50 tubes.

291.7 FORMATION OF NEUROMA IN-CONTINUITY BY SENSORY FIBERS THAT FAIL TO REGENERATE AFTER SCIATIC NERVE CUT AND SUTURE. Z. Seltzer and M. Devor. Neurobiology Unit, Life Sciences Institute, Hebrew University of Jerusalem, Jerusalem, Israel.

Clinical studies have reported that sutured nerves are frequently a source of pain. To study possible causes, 2 normal adult rats served as controls and 5 adult rats were subjected to a transection of the sciatic nerve and to immediate end-to-end sutures of the epineural sheaths. Care was taken not to trap nerve fibers in the sutures. Four to five hundred and fifty days later, in acute electrophysiological experiments we recorded from single myelinated fibers in minute strands teased from L_{4-6} dorsal roots. We utilized collisions of action potentials evoked by electrical stimulation distal and proximal to the suture line, and in comparable sites in the normal rats. In the normal rats, all action potentials evoked by the distal stimulus collided with those evoked by the proximal stimulus. However, in each of the rats with sutured sciatic nerve we found that in sampled sciatic nerve fibers, a substantial number of fibers could not be evoked distal to the suture line (36.9% ± 21.6, mean and S.D.). Most conduction velocities of fibers that failed to cross the suture line were in the Aδ range. In contrast, the distribution of velocities of parent fibers that did cross, resembled fibers sampled from intact nerve. Moreover, the overall distribution of velocities of parent fibers sampled proximal to the suture line, regardless of whether they crossed the suture line or not, showed less Aαβ fibers than that of intact nerve. Therefore, we conclude that not all the fibers that failed to cross the suture line were Aδ fibers. Rather, a portion of these were Aαβ fibers, whose conduction velocity had been slowed down by the retrograde shrinkage process.

Since the distribution of the fibers that failed to cross the suture line is very similar to that of fibers in a nerve end neuroma and since in both lesion types rats exhibit very similar self-mutilation, which was suggested as the rats' attempt to alleviate its pain (Wall et al., Pain 7:109-113, 1979), we suggest, that fibers trapped proximal to a suture line compose a neuroma in-continuity, and may be one of the peripheral sources of pain in humans with sutured nerves.

292.1 DECREASED β RECEPTOR BINDING IN RAT BRAIN AFTER DAILY ADMINISTRATION OF PIPEROXANE. A. Swann* and S.J. Grant, Department of Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06510.

Certain psychiatric disorders, such as depression, may represent a failure of the brain to adapt to stress. Clinically effective antidepressant treatment may act by bringing about the required adaptation. A delayed decrease in β adrenergic receptor binding has been suggested as such an adaptation. One model for this effect is intermittent stimulation of the locus coeruleus (LC). In order to determine the relevance of this model, we examined the effect of intermittent LC stimulation with low doses of piperoxane on β-adrenergic receptor binding in the rat. Rats (11 in each group) received 1.0 mg/kg (I.P.) piperoxane or an equal volume of saline once daily for three weeks. This increased neuronal activity in the LC for about 30-60 min per day by blocking inhibitory α-2 adrenergic autoreceptors on LC neurons. Rats were killed 24-48 hours after the last injection. ^{3}H-hydroalprenolol (DHA) binding was measured in homogenate of cerebral cortex. Piperoxane reduced DHA binding from 6.26±0.96 (S.D.) to 4.75±0.89 pmol/g, ($p<.005$). These results showed that intermittent pharmacological stimulation of the LC produced persistent changes in β adrenergic receptor binding.

Supported in part by USPHS grants MH 07740, MH 14276.

292.2 DIFFERENTIAL REGULATION OF MUSCARINIC CHOLINERGIC RECEPTORS FOLLOWING CHRONIC CHOLINESTERASE INHIBITION. M.H. Smit*, F.J.Ehlert*, W.R.Roeske* and H.I. Yamamura. (SPON: W.D.Barber). Dept. of Pharmacology, Univ. of AZ HSC, Tucson, AZ 85724.

Rats injected with paraoxon, an irreversible cholinesterase inhibitor, display symptoms of excessive muscarinic activity which diminish with chronic administration. The role of receptor regulation in the acquisition of tolerance was investigated using specific muscarinic receptor affinity labels. The antagonist, [^{3}H] quinuclidinyl benzilate ([^{3}H]QNB), binds to a single population of sites having uniform affinity. The muscarinic agonist, [^{3}H]cis methyl dioxolane ([^{3}H]CD), binds to a heterogeneous population of sites. Three distinct affinities have been identified: superhigh (SH), high (H), and low (L). The pattern of receptor down regulation may help elucidate its mechanism and the physiological significance of these distinct populations of agonist binding sites. Male Sprague-Dawley rats (150-250g) were injected s.c. with 0.23 mg/kg twice daily for up to 2 weeks. Binding experiments were performed on washed membrane preparations using [^{3}H]-QNB and [^{3}H] CD. Following 2 weeks of paraoxon treatment, muscarinic receptors in the cerebral cortex were investigated. The following results were obtained by weighted nonlinear regression analysis.

	CONTROL	PARAOXON	%DECREASE
$[^3H]QNB$ B_{max} (fm/mg prot)	1360	766	44%
$[^3H]CD$			
B_{max} (SH) (fm/mg prot)	101.2	115.5	0%
B_{max} (H) (fm/mg prot)	531	337	38%
B_{max} (L) (fm/mg prot)	728	314	57%

It can be seen that there is a marked decrease in the total number of receptors identified by antagonist binding. Also there is a differential regulation of the various agonist binding sites. It is interesting to note that the order of regulation appears to be L>H>SH, with the SH not undergoing down regulation. This may offer some insight regarding the physiological significance of these sites. Following 2 day paraoxon treatment, there was no significant decrease in the number of antagonist binding sites. Agonist binding, however, measured at a concentration of 10nM [^{3}H]CD showed a significant decrease in binding. This may reflect an early desensitization process. The following models provide a conceptual explanation.

$$\text{(A) } H+R \underset{}{\overset{K_1}{\rightleftharpoons}} HR \qquad \text{(B) } H+R \overset{K_2}{\rightleftharpoons} HR \overset{K_3}{\rightleftharpoons} HR^*$$

A change in the process of receptor isomerization (K_3) will show up as a change in affinity of agonist binding (B), but not in antagonist binding (A). These data suggests that the process of receptor isomerization is changed.

292.3 CHRONIC ANTIDEPRESSANT TREATMENT ENHANCES α-ADRENERGIC RESPONSES IN BRAIN: A MICROIONTOPHORETIC STUDY. D. B. Menkes and G. K. Aghajanian. Departments of Pharmacology and Psychiatry, Yale School of Medicine, New Haven, CT 06510

Chronic treatment of animals with tricyclic antidepressants (TCAs) has been increasingly used to investigate biochemical and physiological changes in brain which may be related to the delayed therapeutic action of these drugs. Thus a number of biochemical studies have pointed to the production of β-adrenergic subsensitivity as a possible common mechanism of various antidepressant treatments. The present study was designed to determine the effect of chronic TCA treatment on adrenergic responsiveness in two brain areas, the dorsal lateral geniculate and the facial motor nucleus, which are characterized by postsynaptic (α_1) adrenoceptors. Adult male albino rats were pretreated once daily for 2-3 weeks with injections of various TCAs (imipramine, desipramine, chlorimipramine, amitriptyline [5 or 10 mg/kg] or iprindole [2.5 or 5 mg/kg]) or control drugs (saline, fluoxetine or chlorpromazine [10 mg/kg]). Single cell recordings were conducted 24 hours after the last injection in anesthetized (chloral hydrate, 400 mg/kg, i.p.) or unanesthetized (cerveau isole) preparations. In one study, carried out in the facial motor nucleus, single motoneurons were identified and sensitivity to iontophoretic norepinephrine (NE) and serotonin (5-HT) was determined as previously described (McCall and Aghajanian, Neurosci. 4:1501, 1979). Chronic TCA treatment was found to reduce (by at least 50%) the minimal iontophoretic dose of NE required to facilitate the activation of facial motoneurons. This change was not observed in animals receiving the control drugs. Enhanced responsiveness to 5-HT was also observed in chronic TCA animals, consistent with previous reports of heightened sensitivity to 5-HT in several forebrain areas (deMontigny and Aghajanian, Science 202:1303, 1978). Neurons in the lateral geniculate nucleus receive a prominent NE input and possess physiologically characterized α_1-adrenoceptors (Rogawski and Aghajanian, Brain Res. 182: 345, 1980). Accordingly, further experiments were designed to test whether chronic TCA treatment would enhance α-responsiveness in this forebrain system. As in the facial nucleus, 2-3 week treatment with a variety of TCAs produced at least a 2-fold reduction in the iontophoretic dose of NE needed to activate geniculate neurons. By contrast, treatment with saline or chlorpromazine failed to increase responses to NE. These results indicate that chronic TCA treatment can enhance single cell responses mediated by α_1-adrenoceptors in brain. It remains to be determined to what extent this effect contributes to the clinical response to antidepressant therapy.

Supported by USPHS Grants MH-17871, MH-14459, Medical Scientist Training Program GM-07205 and the State of Connecticut.

292.4 SEROTONIN RECEPTOR SUBTYPES AFTER CHRONIC TREATMENT WITH TRICYCLIC ANTIDEPRESSANT DRUGS. M. Ann Blackshear*, Larry R. Steranka and Elaine Sanders-Bush. Dept. Pharmacol., Vanderbilt Sch. of Med., Nashville, TN 37232

Saturation curves and Scatchard analyses of ^{3}H-LSD binding in cortex/hippocampus reveal only a single binding site with K_D and B_{max} value of 7.2 nM and 54.3 pmoles/gm tissue, respectively. However, in agreement with findings of Peroutka and Snyder (Mol. Pharmacol. 16, 687-699, 1979) displacement curves with spiroperidol and serotonin are clearly bisigmoidal suggesting two LSD binding sites. The site with high affinity for 5HT (K_D = 21 nM) is referred to as 5HT1; the other with low affinity for 5HT (K_D = 2000 nM) and high affinity for spiroperidol (K_D = 4 nM) is referred to as the 5HT2 site. Our studies suggest that these are distinct, non-interconvertible sites. Assay conditions have been adapted to measure these sites independently using 20 nM spiroperidol or 200 nM 5HT to saturate the 5HT2 and 5HT1 sites, respectively. Regional studies show that the hippocampus have a preponderance of 5HT1 sites (65-70%) whereas frontal cortex has nearly equal proportions of the two sites.

In agreement with other investigators, we have found no changes in the K_D or B_{max} for the 5HT1 site in the hippocampus or cortex after chronic treatment (2 or 3 weeks) with desmethylimipramine or chlorimipramine. However, in the frontal cortex of rats treated daily for 21 days with 10 mg/kg (i.p.) of chlorimipramine and assayed 48 hours after the last dose, a significant decrease in K_D value for the 5HT2 site is observed [5.75 ± 0.71 versus 3.85 ± 0.45 nM ($p = .05$), respectively, for control and drug-treated animals] with no change in B_{max} (24.2 ± 2.1 and 19.3 ± 2.0 for control and chlorimipramine treated animals). Moreover, small but insignificant decreases [K_D = 4.1 ± 0.76; B_{max} = 19.0 ± 2.1 ($p = .15$)] were observed in the frontal cortices of rats treated daily with 10 mg/kg of desmethylimipramine for 21 days and assayed 48 hours after the last dose. We therefore propose that changes in the 5HT2 site may relate to the reported postsynaptic 5HT receptor supersensitivity which develops on chronic administration of tricyclic antidepressants. (Supported by USPHS Grants MH-15452 and MH-26463 and the State of Tennessee).

292.5 EFFECT OF CHRONIC TRICYCLIC ANTIDEPRESSANT TREATMENT ON SEROTONERGIC AND HISTAMINERGIC RECEPTORS. S.W. Tang, P. Seeman and S. Kwan*. Psychopharmacology Unit, Clarke Institute of Psychiatry, 250 College Street, Toronto, Canada M5T 1R8.

Since certain tricyclic antidepressants block serotonin receptors and are also potent antihistamines, we tested the effect of long-term tricyclic antidepressant treatment on serotonin receptors in rat cerebral cortex (using ^{3}H-spiperone), on striatum dopamine receptors (using ^{3}H-spiperone), and on midbrain histamine receptors (using ^{3}H-mepyramine and ^{3}H-cimetidine). There are no previous reports on the effects of long-term antidepressant medication on histamine receptors, and previous findings on antidepressant-induced changes in serotonin receptors (using ^{3}H-serotonin) have differed. Rats received either amitriptyline (AMT) (10 mg/kg/day, i.p.), desmethylimipramine (DMI) (10 mg/kg/day, i.p.) or saline (1ml i.p./day) for 21 days.

Both AMT-and DMI-treated groups showed decreased specific ^{3}H-spiperone binding in the cerebral cortex. Scatchard analysis revealed that the decrease in binding was due to a reduction in maximal binding sites (B_{max}) and not to change in affinity. The absence of changes in specific ^{3}H-spiperone binding in the caudate nuclei, apart from showing that dopamine receptors do not change after chronic tricyclic treatment, also suggests that changes seen in the cerebral cortex were due to changes in serotonin receptors. ^{3}H-spiperone has been previously shown to label serotonin receptors in the rat frontal cortex.

^{3}H-cimetidine and ^{3}H-mepyramine have been shown to label histamine H_2-receptors and histamine H_1-receptors respectively. There were no changes observed in either specific ^{3}H-mepyramine or ^{3}H-cimetidine binding in the mid-brain, which suggests that histamine receptors in rats do not change under chronic exposure to tricyclic antidepressants (Supported by the Ontario Mental Health Foundation.)

292.6 DRUG-INDUCED CHANGES IN RAT PINEAL GLAND N-ACETYLTRANSFERASE ACTIVITY. Anthony Altar*, Robert L. Terry*, Gary L. Brammer*, and Loy D. Lytle. University of California, Department of Psychology, Laboratory of Psychopharmacology, Santa Barbara, California 93106.

Previous research indicates that the activity of the pineal gland enzyme, N-acetyltransferase (NAT) is regulated by the release of norepinephrine from afferent sympathetic nerves that innervate this organ. Increased release of norepinephrine from these sympathetic nerve terminals onto pineal gland *B*-adrenergic receptors during the onset of darkness or following stress or other manipulations produces increases in NAT activity via a cyclic AMP-dependent mechanism [J. Axelrod, Science 184: 1341 (1974)]. The present experiments were conducted to determine if several sympathomimetic amines including d-amphetamine sulfate and the monoamine oxidase inhibitor, pargyline HCl, increase pineal NAT activity in light-stimulated male and female rats.

Adult male or female Sprague-Dawley rats (approximately 250 g) were offered *ad libitum* access to food (Purina Rat Chow) and water during a 12:12 hr light-dark cycle (lights on at 0700 hr). At 1800 hr food was removed and animals were injected intraperitoneally with the 0.9% saline vehicle (1.0 mg/kg) or with 8.0 mg/kg of d-amphetamine sulfate, 8.0 mg/kg of l-isoproterenol HCl, or 40 mg/kg of pargyline HCl and were killed following 3 hr of continuous lighting. Additional amphetamine-treated male animals were killed 2 or 4 hr post-injection.

Each of the drugs tested produced significant elevations of NAT. The maximal amphetamine response occurred 3 hr following the injection. By 3 hr, preliminary results indicate that the amphetamine-induced increases in pineal NAT activity were elevated approximately 300% more in female animals compared to the males. Preliminary results also indicate that other drugs, such as pargyline, might produce larger increases in pineal NAT activity in females compared to males, thus ruling out a possible idiosyncratic effect of amphetamine. In previous research we have shown that amphetamine produces age- and sex-dependent changes in a variety of behavioral (locomotor activity and food consumption) and physiological (temperature regulation) responses in rodents [E. Meyer and L.D. Lytle, *Proc. Western Pharmacol. Soc. 21*:313 (1978)]. This drug produces larger changes for longer durations of time in the responses of adult female animals compared to males apparently as a result of slower rates of amphetamine metabolism and excretion by female animals compared to males. Although presently unproven, these findings indicate that a variety of psychoactive drugs may produce greater behavioral, physiological and neurochemical effects in females compared to males as a result of the relative inability of female animals to metabolize and excrete drugs.

293.1 SHR RATS: ADRENERGIC HYPERRESPONSIVITY TO FOOTSHOCK STRESS BUT NOT TO COLD EXPOSURE. R. McCarty and C. C. Chiueh. Dept. of Psychology, Univ. of Virginia, Charlottesville, VA 22901 and Lab. of Neurosciences, NIA, Baltimore, MD 21224.

Recent studies from our laboratory suggest that the sympathetic-adrenal medullary system of spontaneously hypertensive (SHR) rats is hyperresponsive to several forms of stressful stimulation when compared to Wistar-Kyoto (WKY) normotensive controls (Behav. Biol. 23: 180, 1978; Physiol. Behav. 21: 951, 1978; Am. J. Physiol. 234: H690, 1978). The excessive release of catecholamines into the circulation in response to even mildly altering stimuli may contribute to the development and/or maintenance of high blood pressure in this animal model of essential hypertension. In the present study, we were interested in comparing the sympathetic-adrenal responses of SHR and WKY rats to two different challenges: cold exposure or inescapable footshock.

Chronic tail artery catheters were inserted into rats of each strain (4-10 months old) while under pentobarbital anesthesia. Two days after surgery, basal blood samples were obtained from rats while resting and undisturbed in their home cages. SHR and WKY rats were then exposed to one of two treatments: placement in a cold room (4°C) for 4 hr. or 5 min. of intermittent footshock (2.5 mA, 0.4 sec duration, every 5 sec). Blood samples were collected during both treatments and plasma levels of norepinephrine (NE) and epinephrine (EPI) were measured by a radioenzymatic assay.

No significant differences were obtained in basal plasma levels of NE or EPI for SHR and WKY rats. Exposure to cold for 20 and 240 min. resulted in significant increments in plasma levels of NE and EPI which were similar in SHR and WKY rats. In contrast, exposure to intermittent footshock resulted in significantly greater increments in plasma levels of NE and EPI in SHR rats than in WKY controls. Fifteen minutes after the termination of footshock, plasma levels of both catecholamines remained significantly above baseline in SHR rats but returned to baseline in WKY rats. Our results indicate that SHR rats are hyperadrenergic in their responses to some but not all forms of stressful stimulation.

293.2 LASTING EFFECTS OF REPETITIVE UNPREDICTABLY SCHEDULED RESTRAINT STRESS UPON VARIOUS STRESS MARKERS IN THE RAT. C. M. Quirce*, M. Odio* and R. P. Maickel, Lab. of Neurosci., Sch. of Pharmacy, Univ. of Costa Rica, San Jose, Costa Rica and Dept. of Pharmacol. and Toxicol., Sch. of Pharmacy and Pharmacal Sci., Purdue Univ., W. Lafayette, IN 47907.

Adult male rats were subjected to 25 four hr. sessions of physical restraint, carried out between 1300 and 1700 hrs. on randomly varied days over a total time span of 6 weeks. A previous report (Quirce and Odio, Soc. Neurosci. Abstr. 5: 456, 1979) indicated that such unpredictable chronic restraint caused elevations of plasma levels of corticosterone, free fatty acids, and glucose that were maintained for at least 48 hrs. after the last restraint session. In contrast, predictably scheduled sessions failed to produce such elevations. Further studies have indicated that the elevations of plasma corticosterone persist for at least 4 days after the last restraint; by the 6th post-stress day, these levels fall below control values. Free fatty acid levels remain elevated for at least 6 days post-stress, while plasma glucose levels decrease from elevated levels on day 2 post-stress to values below corresponding controls on 4 and 6 post-stress. These results suggest that repetitive exposure of rats to stressful stimuli on a non-predictable basis (a situation not dissimilar to the normal life situations of humans) produces a long-lasting perturbation of normal auto-regulatory mechanisms. This may provide a useful model for the study of stress-induced pathological states, since the stress-like responses are manifested, not only during the course of the application of stimuli, but persist for a significant period after the organism is no longer exposed to the stressful situations. (Supported in part by a grant from CONICIT of Costa Rica and by the Vicerrectoria de Investigacion of the University of Costa Rica.)

293.3 CENTRAL EFFECTS OF ECDYSTERONE CONTROLLING WANDERING BEHAVIOR IN THE CATERPILLAR, MANDUCA SEXTA. O.S.Dominick* and J.W.Truman (SPON: W.Calvin). Dept. of Zoology, Univ. of Washington, Seattle WA. 98195.

The prepupal wandering behavior of last (5th) instar larvae of the tobacco hornworm , Manduca sexta, is induced by a pulse of the steroid molting hormone, ecdysterone. Infusion of ecdysterone into intact larvae controls both initiation time and duration of the behavior in a dose dependent manner, and requires a latency of 10-20 hours as is typical of steroid hormone action. The ecdysterone induced effects include changes in neural function of a number of different parts of the CNS. In addition, all earlier instars which we have been able to test (2nd, 3rd,4th) can produce the behavior when the appropriate ecdysterone signal is precociously presented to them.

We can investigate ecdysterone induced changes in neural function directly by long term (24 hr) studies of the isolated (entire) CNS of Manduca larvae. Extracellular recordings are obtained from a compound nerve whose role in locomotion is known. Such recordings from the CNS isolated from larvae prior to edysterone release show consistently low levels of spontaneous bursting (8.8 ± 3.8bursts/15 min.), while the spontaneous activity of the CNS from wandering animals is much greater (42.9 ± 13.6 bursts/15 min.). Several independent lines of evidence indicate that these bursts represent locomotor behavior symptomatic of wandering: recordings from chronic preparations of whole larvae demonstrate that bursts from this nerve occur only in conjunction with observable locomotor events, and anteriorly directed phasing between ganglia is preserved.

The active bursting state characteristic of the isolated wandering CNS can be induced in vitro in "quiet" pre-ecdysterone nerve cords by prolonged incubation (15 hrs) in ecdysterone (1 ug/ml). Therefore, we feel that the behavioral action of this steroid is directly on the larval CNS. Several of the motoneurons which participate in the behavior, as well as the synaptic inputs to them have been identified and we are now studying these as possible sites for the alteration of neural function by a steroid hormone.

293.4 APPLICATION OF ANISOMYCIN TO THE LATERAL VENTROMEDIAL NUCLEUS BLOCKS THE ACTIVATION OF SEXUAL BEHAVIOR BY ESTRADIOL AND PROGESTERONE. T.C. Rainbow, P.G. Davis*, M. McGinnis*, and B.S. McEwen. The Rockefeller University, New York NY 10021.

We have found recently that peripheral administration of the protein synthesis inhibitor, anisomycin (Ani), inhibits the induction of sexual behavior in rats by estradiol (E_2) and progesterone (P) (Brain Res. 1980, in press). We report here that local application of Ani aimed to reach the lateral portion of the ventromedial hypothalamic nucleus (LVMN) is sufficient to block the activation of lordosis behavior by systemic gonadal steroids. Ovariectomized rats received Silastic implants of E_2 for 6h. They were tested for sexual behavior 24h after insertion of the Silastic capsules and 4-5h after systemic P injection. Removable 28 gauge cannulae were inserted bilaterally into the ventromedial hypothalamus during either E_2 or P exposure. When empty cannulae were placed in the vicinity of the LVMN, sexual behavior was uniformly high after treatment with E_2 and P (lordosis quotient (LQ) $\sim$80). However, there was a marked reduction in lordosis behavior when crystalline Ani was introduced into the LVMN during exposure to either E_2 or progesterone (LQ$\sim$20).

Rats treated intracranially with Ani showed high levels of sexual behavior when re-exposed to gonadal steroids one week later, indicating that the effects of Ani on behavior was reversible. Biochemical studies determined that 3H leucine incorporation into protein was inhibited in the hypothalamus after intracranial insertion of Ani. No inhibition was seen in the preoptic area, amygdala and pituitary in these animals. Similarly, we observed little spread of Ani outside the ventromedial hypothalamus when the area of inhibition was mapped with S^{35} methionine autoradiography. Our results support the idea that gonadal steroids induce lordosis behavior by acting on target cells in LVMN and suggest that E_2 and P may activate sexual behavior in part by inducing the synthesis of specific proteins in these neurons.

293.5 CHANGES IN BRAIN SEROTONIN AND DOPAMINE RECEPTORS AFTER SLEEP
A. K. Sinha, S. Hamersky*, W. Ciszewski* and M. K. Poddar. Dept. of Physiology & Biophysics, College of Med. & Dent. of New Jersey, Rutgers Medical School, Piscataway, NJ 08854

It has been suggested that serotonergic and dopaminergic neurons may be involved in the sleep-wakefulness process. In the present study in vitro serotonin (5-HT) receptor binding was determined in cerebral cortex, upper brain stem and pons-medulla of adult male hamsters (body wt. 100-120 g) after sleep and wakefulness. The dopamine (DA) receptor binding was studied only in corpus striatum. Animals were decapitated following 50 min of non-rapid eye movement sleep (Macho & Sinha, Life Sci. 26, 291, 1980) or a comparable period of wakefulness. For specific binding of 5-HT receptor the membrane suspension (≃ 1 mg protein) was incubated in buffer (pH = 7.1) containing ^{3}H-5-HT (7 nM) in the presence or absence of unlabeled 5-HT (10 µM) at 37° C for 5 min. For specific binding of DA receptor the membrane suspension (≃ 250 µg protein) was incubated in buffer (pH = 7.1) containing ^{3}H-apomorphine (8 nM) in the presence or absence of unlabeled DA (10 µM) at 37°C for 10 min. Immediately after sleep the specific binding of 5-HT increased (46%) only in cerebral cortex with no significant changes in upper brain stem and pons-medulla. Unlike 5-HT binding, the specific binding of apomorphine decreased (36%) in corpus striatum. Scatchard analysis of 5-HT and DA receptor binding data indicate that after sleep the number of 5-HT binding sites increased (34%) without any significant change in the affinity of the receptor for the ligand. The affinity of the DA receptor to the ^{3}H-apomorphine decreased (123%) after sleep whereas a significant increase (75%) was found in the number of binding sites. [Supported by grants from NIH (NS13118) and AFSC (78-3532A)].

293.6 MIDBRAIN RETICULAR NEURONS DECREASING FIRING RATES DURING EEG DESYNCHRONIZATION AND AROUSAL.
Zeev Elazar, John P. Nelson, Robert W. McCarley and J. Allan Hobson. Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School, Boston, MA 02115.

Since the classic studies of Moruzzi and Magoun, the mesencephalic reticular formation has been considered as the active neuronal substrate of EEG desynchronization and behavioral arousal. Thus it was surprising to Huttenlocher in 1961 to find cells which increased firing rate during synchronized sleep (S) compared to waking (W). Steriade's recent work has emphasized a subpopulation of neurons with the expected positive correlation between firing rate and EEG activation. We now report a confirmation and extension of Huttenlocher's observations emphasizing features not previously described for the interesting class of "S-on" cells.

The discharge pattern of neurons in the mesencephalic reticular formation (FTC) was studied in chronically prepared head-restrained cats free to make limb movements and postural adjustments. Extracellular action potentials from 40 neurons in 24 stereotaxically controlled penetrations of the midbrain were recorded continuously during sleep-waking cycles.

10 "S-on" cells were recorded. They discharged high amplitude spikes at low firing rates during W (median 0.64/sec, range 0.09-4.98/sec). Single sensory stimuli silenced or greatly slowed them for a few seconds. Spontaneous fluctuations between EEG desynchronization and synchronization during drowsy periods were correlated with slowing or speeding of the firing. No correlation was found between frequency of neuronal discharge and individual EEG spindles or delta waves but when sleep was established the firing rates increased gradually as the amplitude of slow waves increased in the EEG. During S firing rates were: median 1.69/sec, range 1.1-5.66/sec.

7 of the "S-on" cells were followed through desynchronized sleep (D). 2 cells showed long trains of very high frequency spikes (200-300/sec) alternating with periods of very slow rates. 2 cells decreased firing rates to the low waking level and other 3 cells had in D firing rates higher than in W. Interestingly, 4 of the 7 cells studied in D showed significant intensification of firing in the last seconds before and at D sleep onset in obvious correlation with the progressive loss of muscle tone.

These results suggest a possible reciprocal interaction between two classes of midbrain neurons in the regulation of EEG and an active role of midbrain neurons in the atonia of REM sleep.

293.7 RESPIRATORY RESPONSES TO ELEVATED CO_2 IN AWAKE AND SLEEPING CATS.
Theodore L. Baker, Kurt Sizer* and W. C. Dement, Sleep Research Center, Stanford University School of Medicine, Stanford, CA 94305

We measured ventilation in six adult cats during hyperoxic hypercapnia in waking, REM sleep and non-REM sleep (NREM) using a rebreathing method. Prelaryngeal airflow was recorded pneumotachographically via an endotracheal cannula inserted into a chronic tracheostomy. Tracheal end-tidal PCO_2 was measured with a Beckman infrared CO_2 analyzer. Data were collected and analyzed on-line with a PDP-11 computer on a breath-by-breath basis. Linear regression anaysis of either tidal volume (V_T) or instantaneous minute volume ($\dot{V}_E$) vs. end-tidal PCO_2 revealed a greater respiratory response to hypercapnia during waking than during sleep. CO_2 responses during NREM and REM were very similar, although the slope of the $\dot{V}_E$ vs.CO_2 line tended to be slightly greater during NREM. During all states, the increase in $\dot{V}_E$ during CO_2 rebreathing was due primarily to increased V_T. Computer plots of raw V_T data vs.time indicated a progressive and predictable breath-to-breath increase during waking and NREM. Breath-to breath variability of respiratory parameters was higher during REM sleep, but the ventilatory response to CO_2 was clearly intact. As during normocapnic REM sleep, increased respiratory variability during REM CO_2 rebreathe tests was associated with bursts of phasic events (eye movements, PGO waves, twitches). Brief respiratory irregularities, usually increased f, were superimposed upon a baseline of continuously increasing V_T. That is, f increased while V_T remained elevated at a level consistent with the ongoing CO_2 stimulus. Mean V_T during phasic REM episodes at higher PCO_2 levels was always greater than V_T at a lower CO_2. Increased f during phasic REM bursts typically resulted in a transient increase in mean $\dot{V}_E$. Progressively higher PCO_2 stimuli during REM CO_2 rebreathing tended to diminish the magnitude of the respiratory disturbances associated with phasic events. Arousal from REM rebreathing tests consistently occurred later and at higher PCO_2 levels, compared to NREM. We conclude that brainstem mechanism controlling V_T are responsive to elevated CO_2 during both stages of sleep. $^TCO_2$ sensitivity is increased even further during waking. We suggest that differences between REM and NREM CO_2 responses in the cat are largely qualitative and are attributable to phasic irregularities inherent to the REM state.

From Session 4: Symposium

MOLECULAR CHARACTERIZATION, RECONSTITUTION AND "TRANSPORT-SPECIFIC FRACTIONATION" OF THE SOLUBILIZED STX BINDING PROTEIN/ION GATE OF MAMMALIAN BRAIN. S.M. Goldin, V. Rhoden,* E.J. Hess*. Dept. of Pharmacology, Harvard Medical School, Boston, Mass. 02115.

The saxitoxin (STX) binding protein has been solubilized by sodium cholate, both from axolemma and from synaptosomal membranes of mammalian brain. Based on agarose gel filtration and on sedimentation properties in H_2O and D_2O sucrose gradients containing lipid and cholate, the solubilized particle has the following properties: Stokes radius, 120 Å; partial specific volume, 0.85 ml/g; mass, 1,020,000 daltons; f/fo, 1.6. No more than 570,000 daltons of this particle is protein. The solubilized STX binding protein was incorporated into homogeneous (∿550Å) unilamellar artificial phosphatidyl choline vesicles by removing the cholate using hollow fiber dialysis (Goldin, S.M. (1977) J. Biol. Chem. 252, 5630-5642).

Based on the expectation that the reconstituted STX binding protein contains functional monovalent cation gating activity ("action potential Na^+ gate") that can be activated by veratridine and inhibited by tetrodotoxin and STX, a strategy was devised for partial purification of the reconstituted Na^+ gate/STX binding protein by "transport-specific fractionation" (c.f. Papazian, D., Rahamimoff, R., and Goldin, S.M. (1979) PNAS 76, 3708-3712). This approach involves reconstitution of the transport system of interest into artificial vesicles before purification so as to insert only one or at most, a few membrane proteins into each artificial vesicle. The transport properties of the protein of interest are then used as a physical tool (e.g., transport-specific changes in vesicle density are created) to separate vesicles containing this transport system from the rest of the crude preparation and thus results in its purification.

When the entire vesicle population was preloaded with 0.4 M Cs^+, addition of veratridine allowed Cs^+ efflux from specifically those vesicles containing the ion gate; the concomitant reduction in intravesicular density permitted the ion gate/STX binding protein to be fractionated on density gradients. These observations demonstrate functional reconstitution and partial (30- to 50-fold) purification of the solubilized STX binding protein/putative action potential Na^+ gate of mammalian brain. Because reconstitution of transport activity is required for the viability of this approach, we know that what is being purified is an ion gating protein, and not just a toxin binding site. (Supported by NIH grant NS 15236, to S.M.G.).

DUAL NEUROENDOCRINE CONTROL OF PITUITARY INTERMEDIATE LOBE FUNCTION IN THE FROG. M. Duff Davis* and Aubrey Gorbman* (SPON: R. Pinter). Dept. of Zoology, NJ-15, University of Washington, Seattle, Washington 98195.

The central lobe of the vertebrate pituitary, the pars intermedia, has recently been the subject of renewed interest since it was discovered that the highest concentration of endorphins is found here. It has been suggested that endorphin-like peptides are contained in a cell type previously believed only to synthesize melanophore stimulating hormone (MSH). Consequently, past and present studies on the CNS control of MSH secretion may also be applicable to the control of endorphin secretion. Although several types of neuronal populations exist in the pars intermedia, as yet, only an inhibitory control of MSH has been established through a catecholaminergic neurotransmitter. We present data here implicating the presence of both an excitatory and inhibitory neuronal input in the pars intermedia.

During the course of this study, six adult Mexican frogs, Rana berlandieri forreri, were used. The head of each was guillotined and the hypothalamo-hypophyseal complex removed to a nutrient bath and gassed with $95\%O_2$-$5\%CO_2$. Recording microelectrodes were positioned into the intermediate lobe to monitor endocrine cell membrane potentials. Platinum wire electrodes were used to stimulate a one millimeter area of median eminence. Biphasic 60 Hz, 100 microamp pulses were passed through these. When a cell exhibited spontaneous action potentials, the current was turned on. In about 75% of the 25 cells studied, a decrease in frequency of spikes was seen while 20% of them showed an increase. In the remaining 5%, no significant change in basal activity was found. Often, cells were observed to give phasic bursts of spikes with varying intervals of silence. The average latency between the onset of electrical stimulation and any change in spike rate was anywhere from 100 milliseconds to 10 seconds. The duration of this latency would indicate that not every cell in the pars intermedia is under synaptic contact with axonal endings. Instead, neurotransmitters may be released directly into intercellular spaces to perfuse the tissue. These observations indicate that the pars intermedia gland and its secretions are influenced by both inhibitory and excitatory hypothalamic control.

INSULIN-LIKE FACTORS MAY SUBSTITUTE FOR SERUM IN THE MAINTENANCE OF CHICK SENSORY NEURONS IN VITRO. E.Y. Snyder* and S.U. Kim* (SPON: D. Pleasure) Lab. of Neuropathology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA 19104.

The inability to culture neurons in the complete absence of complex, poorly defined biological additives (e.g. serum) has proven a major obstacle to a rigorous investigation of the nutritional and growth requirements of the developing nervous system. We have previously reported that insulin, when substituted for serum at supraphysiologic concentrations (50µg/ml), was both necessary[1,2] and sufficient[3,4] for the survival of 9-12 day embryonic chick dorsal root ganglia (DRG) neurons in vitro. (Indeed, in cell systems where a salubrious effect of insulin has been noted, it has usually been at supraphysiologic concentrations[5-8]).The present study was designed to explore the possibility that the actual requirement of sensory neurons may not be for insulin per se but rather for a closely related molecule for which insulin in high concentrations may serve as an analogue. A series of well-recognized growth factors were screened for their ability to support the survival in vitro of dissociated chick DRG neurons in serum-free media. Insulin-like growth factors, some at their biological concentrations (e.g. Insulin-like Growth Factor [IGF] (0.1mU/ml) and Multiplication Stimulating Activity [MSA] (50ng/ml)) were indeed found to be sufficient to promote survival. Non-insulin-like growth factors, even at high concentrations, were found to be inadequate (e.g. Fibroblast Growth Factor [FGF]), Epidermal Growth Factor[EGF], Nerve Growth Factor [NGF]).(A preparation of Somatomedin A+C, like insulin, was effective only at high concentrations (100mU/ml)). Insulin-like factors proved a sufficient substitute for serum in both NGF-free and in more conventional NGF-supplemented dissociated chick DRG culture systems. This data lends support to the notion that the occupation -- and occupation by whatever means -- of receptors sensitive to insulin-like activity (including, of course, by insulin itself) may prove a sine qua non for early neuronal survival in culture.

LYSOSOMAL DISTRIBUTION IN NEURONS FROM THE CEREBRUM AND SPINAL CORD DURING EARLY VITAMIN E DEFICIENCY IN RATS: ELECTRON MICROSCOPIC STUDY. Arun S. Dabholkar. Dept. of Anatomy, Northwestern Univ. School of Med., Chicago, Ill. 60611 and Dept. of Anatomy, Kyoto Univ. School of Med., Kyoto, Japan.

Vitamin E is an antioxidant which is associated with cellular membrane and known to control the membrane stability and permeability.

The present study was designed to demonstrate appreciable change in lysosomal size and number in the early stage of vitamin E deficiency in nerve cells. Young male Wistar rats of 100 to 150 gms. of body weight were used for this experiment. They were fed vitamin E deficient diet (supplied by Eisai Co. Ltd., Tokyo) and control rats were kept on regular chow containing vitamin E. Thus, vitamin E deficient and control rats of 4 to 13 weeks were sacrificed. They were perfused and neurons from the cerebrum and spinal cord were studied electron microscopically to show the increase in lysosomes within 13 weeks of deficiency.

Lipid containing enlarged lysosomes as appeared could be termed as secondary lysosomes, chromolipoids or ceroids. It is known that a dietary antioxidant of vitamin E as alpha tocopherol plays significant role in the oxidative process by preventing oxidation of unsaturated lipids in cells. The enlarged structures are the result of copolymerization of unsaturated fats (lipid peroxidation) and proteins in depleting vitamin E from the cellular membranes.
