5.1 POSTSYNAPTIC LOCALIZATION OF RESERPINE-INDUCED α-ADRENERGIC RECEPTORS IN RAT SUBMAXILLARY GLAND. D.B. Bylund and J.R. Martinez*, Departments of Pharmacology and Child Health, University of Missouri School of Medicine, Columbia, Missouri 65212.

We recently reported that reserpine treatment results in the appearance of α_2-adrenergic receptor binding sites (AR) in the rat submaxillary gland (Nature, 284,in press). In control animals the amount of α_2 receptor binding was too low to be reliably quantitated ($\sim$0.3 pmol/g tissue). However, after one week of daily treatment with reserpine, the density of α_2-AR increased to 6 pmol/g. This system thus seemed ideally suited for the study of the synaptic localization of α_2-AR.

The following treatments were used: reserpine, 7 daily injections (0.5 mg/kg, i.p.); 6-hydroxydopamine (6-OHDA) two injections (34 mg/kg, i.v.) within 24 hours, followed a week later with an additional two injections (68 mg/kg); unilateral ligation of the main excretory duct. Rats were sacrificed two weeks after the first 6-OHDA treatment or the duct ligation, or one week after the start of reserpine treatment.

Treatment with 6-OHDA, which causes destruction of the presynaptic terminal and a severe depression in norepinephrine levels, resulted in only a slight increase in α_2-AR, while reserpine treatment resulted in the expected large increase. The combination of 6-OHDA and reserpine did not produce any further increase. Ligation of the excretory duct causes atrophy of the submaxillary gland, presumably due to a decrease in the size of acinar cells, while the innervation is not effected. The increase in α_2-AR induced by reserpine was markedly lower in the ligated gland as compared to the unligated gland of the same animal.

	Control	6-OHDA	Reserpine	6-OHDA+Res.
B_{max} (pmol/g)	0.4±0.1	1.4±0.2	4.6±0.3	4.7±0.3
	Control	Ligation	Reserpine	Lig.+Res.
B_{max} (pmol/g)	0.5±0.1	0.2±0.1	4.1±0.4	1.5±0.3

Previous attempts to localize the α_2-AR using either chemical or surgical denervation, have been hampered by the possibility that some presynaptic membrane may adhere to the postsynaptic membrane, even after degeneration of the nerve terminal. These 6-OHDA studies overcome this objection, and show a postsynaptic localization for the α_2-AR which are regulated by reserpine. The studies with ligated animals further support this conclusion. In addition, the results suggest that the mechanism whereby reserpine increases α-AR is not soley dependent on the depletion of norepinephrine.

5.2 ALTERATIONS IN PRESYNAPTIC ALPHA-ADRENOCEPTOR ACTIVITY IN GUINEA PIG AND RAT VAS DEFERENS FOLLOWING GANGLIONIC BLOCKADE. Robert D. Sax* and Thomas C. Westfall. Departments of Pharmacology, University of Virginia, Charlottesville, VA 22908 and St. Louis University, St. Louis, MO 63104.

Surgical decentralization of the guinea pig vas deferens results in an increase in the release of ^{3}H-norepinephrine (^{3}H-NE) and dopamine-β-hydroxylase induced by electrical field stimulation (FS) of the isolated, superfused tissue (The Pharmacologist 18:208, 1976). This increase in release was in part due to a decrease in the activity of presynaptic α_2-adrenoceptors. Presently guinea pigs and rats were treated with the ganglionic nicotinic blocker chlorisondamine to induce a chemical decentralization of the postganglionic neurons of the vas deferens. The release of NE induced by FS from isolated, superfused tissues was determined in the presence and absence of α_2 agonists (clonidine and α-methyl-NE) and antagonist (yohimbine). FS-induced twitch contractions and ^{3}H-NE release were used as markers for the release of endogenous NE. After a 45 min preincubation in the presence or absence of l-^{3}H-NE (5×10^{-7}M) tissues from chlorisondamine (8mg/kg, b.i.d., i.p.) or saline treated animals were superfused at 2 ml/min with a Krebs-Henseleit solution with an extracellular Ca^{++} concentration of 1.8 or 1.0 mM. Blockers of $uptake_1$ and $uptake_2$ were present during the labelled-release experiments. Tissues were subsequently field stimulated at various frequencies and for various durations and the release of ^{3}H-NE or the twitch contractions was observed. In the absence of exogenous agents, FS induced a greater development of tension in tissues from chlorisondamine-treated animals than from the corresponding controls. Clonidine was observed to produce a concentration-dependent decrease in the FS-induced contractions and ^{3}H-NE release which was significantly attenuated in tissues from chlorisondamine-treated animals. In tissues from both species, α-methyl-NE was observed to be a weaker presynaptic agonist. Yohimbine was observed to produce a concentration-dependent increase in the FS-induced contractions and ^{3}H-NE release which was likewise attenuated by chlorisondamine pretreatment.

These results are consistent with our previous observations and extend to the rat the concept that a decrease in nerve impulse traffic in postganglionic sympathetic nerves as caused by chronic ganglionic blockade can cause a subsensitivity in the presynaptic α-adrenoceptor system of those nerves. This sensitivity change is modified by altering extracellular Ca^{++} concentration and thus implicates regulation of Ca^{++} metabolism as a controlling mechanism in the activity of the inhibitory α_2-adrenoceptors.

(Supported in part by USPHS-NINCDS 16215 and NIGMS 67055)

5.3 RECIPROCAL ALTERATIONS IN RAT BRAIN β- AND α_2-ADRENERGIC RECEPTOR SITES AFTER CHRONIC INTRAVENTRICULAR INFUSION OF ISOPROTERENOL. C.H. Wang* and D.C. U'Prichard (SPON: E. Silinsky) Dept. of Pharmacol., Northwestern Univ. Sch. Med., Chicago, IL 60611.

Decreases in β-receptor number can be achieved rapidly and reversibly in vitro by incubation of rat cortical slices with isoproterenol (ISO) (U'Prichard and Enna, Eur. J. Pharmacol. 59: 297, 1979), and in vivo following chronic tricyclic and atypical antidepressant treatment, over a much longer time-course with the loss being essentially irreversible in vitro (Wolfe et al., J. Pharmac. exp. Ther. 207: 446, 1978). While this in vivo treatment probably induces true β-receptor desensitization, it has not yet been shown that the antidepressant action is directly due to increased β-receptor activation; the loss of β-sites after in vitro ISO incubation may be mainly due to tight binding of agonist sequestered in membranes. Both treatments however induce an increase in the number of cortical α_2-receptor sites labeled by ^{3}H-clonidine (CLO) or ^{3}H-p-aminoclonidine (PAC), presumed agonist ligands. To resolve these issues, the effect of chronic infusion of a direct β-agonist on cortical adrenergic receptors was ascertained. Intracerebroventricular infusion in rats of 0.1, 1.0 and 10 mM ISO by Alzet minipump achieved dose-related steady-state brain ISO concentrations of approximately 0.1, 1.0 and 10 M after 2 days, which were maintained up to 7 days. ^{3}H-Dihydroalprenolol (DHA) β-receptor binding declined in a time- and ISO-concentration- dependent manner. DHA binding was decreased 0% by 0.1 mM ISO, and 20% by 1.0 or 10 mM ISO, after 2 days infusion, and 10% by 0.1 mM ISO and 26% by 10 mM ISO, after 7 days infusion. After 1 or 2 days infusion of 10 mM ISO, Scatchard analysis showed 30-40% reductions in the B_{max} of DHA (vehicle-infused control, 126 fmol/mg protein), with no change in K_D (0.9-1.1 nM). However 20% increases in the B_{max} of PAC (control, 105 fmol/mg protein) were observed, with a slight but not significant change in K_D (control 1.3 nM, ISO 2.0 nM). ^{3}H-Prazosin α_1-receptor binding was unaffected by ISO infusion. The results suggest that direct agonist-induced β-receptor desensitization in vivo induces reciprocal changes in functionally related cortical α_2-receptors which may reside on the same postsynaptic membranes.

5.4 PHENOXYBENZAMINE DIFFERENTIATES DOPAMINE RECEPTOR SUBTYPES. M. Hamblin* and I. Creese. Department of Neurosciences, University of California, San Diego, 92093

Receptor binding studies with reversible ligands have been instrumental in establishing the existence of multiple dopamine receptor subtypes within the CNS. There still remains, however, considerable difficulty in equating the binding sites variously differentiated on the basis of their agonist/antagonist specificities, linkage to adenylate cyclase, guanine nucleotide sensitivity, and subcellular localization. The availability of a sufficiently selective irreversible dopaminergic ligand not only would offer an additional means of distinguishing multiple receptor subtypes, but, by inactivating certain subtypes of receptors while sparing others, would also allow the pharmacologic characterization of a relatively pure receptor population. We have investigated the effect of in vitro phenoxybenzamine (POB) treatment on dopaminergic ^{3}H-ligand binding to bovine striatal membrane fragments, and now report the utility of this agent as just such an irreversible dopaminergic antagonist.

POB treatment followed by thorough washing of membranes reduced subsequent binding of all dopaminergic ^{3}H-ligands investigated. Saturation studies showed this to be due to a decrease in receptor number without change in affinity. This effect was highly selective for certain receptor subtypes. Binding of ^{3}H-spiroperidol displayed high sensitivity and that of ^{3}H-dopamine low sensitivity, with respective IC_{50}'s of 1 and 100um POB (10 min, 37°C exposure). ^{3}H-Apomorphine binding showed intermediate sensitivity, and the dose response curve could be resolved into approximately equal high and low sensitivity components, paralleling the sensitivity of ^{3}H-spiroperidol and ^{3}H-dopamine binding sites respectively. That the parallel sensitivity of ^{3}H-spiroperidol sites and high sensitivity ^{3}H-apomorphine sites reflected alkylation of identical receptors was confirmed by spiroperidol displacement studies of bound ^{3}H-apomorphine. These showed that the half-maximal POB mediated decrease in ^{3}H-apomorphine sites resulted from complete loss of the ^{3}H-apomorphine sites with high spiroperidol affinity without effect on the sites with low affinity for spiroperidol. POB/receptor interaction is binding site-directed, as was shown by the ability of cold dopaminergic ligands to protect against POB mediated attack.

The number of high affinity binding sites for ^{3}H-spiroperidol, ^{3}H-apomorphine, and ^{3}H-dopamine are approximately equal in striatum. These studies therefore suggest that there are four striatal dopamine binding sites with respective high affinities for spiroperidol only, spiroperidol and apomorphine, apomorphine and dopamine, and dopamine only. 5.5 Butyrophenone Interactions with Distinct Monoaminergic Receptors in Human Prefrontal Cortex: Evidence for the Involvement of α_1-Adrenergic But Not $5HT_2$ or Dopaminergic Sites. A.C. Andorn*, J.C. Mitrius, and D.C. U'Prichard, (SPON: V. Rowland). Dept. Psychiat., Case Western Reserve Univ., Cleve., Oh. 44106, Dept. Pharmacol., Northwestern Univ. Schl. of Med., Chicago, Ill., 60611.

^{3}H-Spiroperidol binds specifically to an apparently heterogeneous set of sites in human prefrontal cortex. Competition of ^{3}H-spiroperidol binding in this region shows dopamine to be relatively weak (IC50:10^3nM) while α-adrenergic agents are more potent (IC50:100nM) with a rank order of potency consistent with an α_1-adrenergic receptor. These findings are in contradistinction to those in rat or human striatum, where spiroperidol appears to be binding at a dopamine receptor also, or the rat frontal cortex where such binding appears to occur at $5HT_2$ receptors. ^{3}H-Prazosine has been shown to label high affinity α_1-adrenergic sites in rat and calf frontal cortex ($K_D \simeq 0.1$nM, $B_{max} \simeq 100$ fmol/mg protein). We now report that ^{3}H-prazosine appears to specifically bind to a saturable and apparently homogeneous set of sites in human pre-frontal cortex ($K_D \simeq 0.1$nM, $B_{max} \simeq 150$ fmol/mg protein). Competition of ^{3}H-prazosine binding in this region parallels that observed in rat and calf: IC50 of α-antagonists ≃1nM, α-agonists ≃1μM and dopamine ineffective. Spiroperidol competes ^{3}H-prazosine binding with an IC50 of 0.1nM. The correlation coefficient for the competition of ^{3}H-prazosine binding versus ^{3}H-spiroperidol binding is 0.98 for the selective α-adrenergic agents. These findings suggest that ^{3}H-spiroperidol is possibly binding at an α_1-adrenergic receptor in human prefrontal cortex. Serotonin and tryptamine appear to have unusual interactions with ^{3}H-spiroperidol binding sites in this region which may not involve an interaction at the ^{3}H-spiroperidol binding site per se. ^{3}H-LSD was used to label 5HT sites in human prefrontal cortical homogenates. Unlike the rat frontal cortex where both $5HT_1$ and $5HT_2$ sites are present, we have observed 75% specific ^{3}H-LSD binding in this region less than 30% of which was competed by even μM spiroperidol. These findings suggest that $5HT_1$ receptor types predominate in human prefrontal cortex and that spiroperidol does not have a high affinity for these sites. Taken together these data suggest that the monoaminergic receptor systems involved in butyrophenone action in human prefrontal cortex are neither dopaminergic or serotonergic, but rather α_1-adrenergic. Whether these are the receptors involved in the antipsychotic action of these drugs remains unclear, but the neurochemical demonstration of α_1-adrenergic actions for ^{3}H-spiroperidol in the prefrontal cortex suggest that such properties rather than dopamine antagonist properties may have significance for the treatment of the perceptual and cognitive dysfunctions in the psychoses.

5.6 Butyrophenone Binding Sites in Human Amygdala: Heterogeneity of High Affinity Sites Without Apparent Dopaminergic Selectivity, M.E. Maguire, L.E. Weber*, A.C. Andorn*, (SPON: J. Foley), Depts. of Psychiat. and Pharmacol., Case Western Reserve Univ., Schl. of Med. Cleveland, Ohio 44106

Butyrophenone binding has been previously studied with the ligand ^{3}H-spiroperidol (^{3}HSP) in human prefrontal cortex and caudate. ^{3}HSP binds with high affinity and specificity at monoaminergic receptors other than dopaminergic in the prefrontal cortex, and to dopaminergic and α_1-adrenergic binding sites in the caudate. We now report that ^{3}HSP binds with high affinity to at least two sets of sites in human amygdala, neither of which appear to demonstrate selectivity for dopamine. Amygdalar tissue was obtained at autopsy from individuals with no known neurologic or psychiatric illness. Following preparation with extensive hypotonic washing, membrane fragments were used in standard filtration assays employing ^{3}HSP(0.5nM), and competitors with 10 min incubations at 25°C. Saturation isotherms were consistent with the presence of multiple sites ($K_D \simeq 0.4$ and 1.5 nM) with relatively low density (125 fmol/mg protein and 350 fmol/mg protein respectively). Specific binding, defined as that in the presence of 100μM fluphenazine subtracted from that in its absence was 70% of total binding and stereoselective with regard to the enatiomers of butaclamol by 2.5 orders of magnitude. Antipsychotic antagonists competed specific ^{3}HSP binding with IC50 ranging from 0.1nM(fluphenazine) to 1000nM(molindone); α-adrenergic agents also competed specific binding with IC50 ranging from 10nM(WB4101) to 10,000nM(clonidine) with a rank order of potency consistent with an α_1-adrenergic site. Dopamine was an ineffective competitor even at 0.1mM and +/-10μM pargyline. Serotonergic agonists inhibited only 60% of specific binding observed with IC50 of micromolar (for that binding that was inhibited) while the serotonergic antagonists inhibited 95% of specific binding with IC50 of 100 nM. Similarly, α-adrenergic agonists inhibited less than 50% of total specific ^{3}HSP binding observed. These results suggest that ^{3}HSP may be binding with high affinity at an heterogeneous set of sites in the amygdala. The differences in competition by agonists and antagonists may be reflective of differences in the selectivity of the sets of sites observed. The lack of apparent inhibition of specific ^{3}HSP binding by dopamine suggests that some actions of antipsychotic drugs may not be mediated through binding at dopaminergic receptors.

5.8 DISTRIBUTION OF CATECHOLAMINE RECEPTOR BINDING SITES IN DISCRETE HYPOTHALAMIC REGIONS AND THE INFLUENCE OF FOOD DEPRIVATION ON BINDING. M. Jhanwar-Uniyal*, B. Dvorkin*, M.H. Makman* and S.F. Leibowitz (SPON: E.B. Gardner). Rockefeller University, New York 10021 and Albert Einstein College of Medicine, New York 10461.

Studies of direct injections of catecholamine agonists and antagonists into rat hypothalamus indicate that feeding behavior is stimulated by α-adrenergic (α) receptor activation in the paraventricular nucleus (PVN), and is suppressed by dopaminergic (DA) and β-adrenergic (β) receptor activation in the perifornical lateral hypothalamus (PF-LH). The present study examines the distribution of α, β and DA binding in discrete hypothalamic and extrahypothalamic areas, compares binding of agonists and antagonists, and examines in a preliminary investigation the impact of food deprivation on binding. Brain areas of male Sprague-Dawley rats (350 g) were dissected using the micropunch technique. Binding studies were carried out: for α sites with 3nM ^{3}H-p-aminoclonidine (PAC) displaced by 10μM norepinephrine and 1nM ^{3}H-WB-4101 (WB) displaced by 10μM (+)butaclamol; for β sites with 3nM ^{3}H-dihydroalprenolol (DHA) displaced by 1μM l-propranolol; and for DA sites with 3nM ^{3}H-ADTN displaced by 10μM ADTN and with 1nM ^{3}H-spiroperidol (SP) in the presence of 1μM cinanserin and displaced by 20μM ADTN. The distribution pattern of α, β and DA binding sites is shown in the table. The ratio of agonist to antagonist sites for DA and α receptors varies in different regions, supporting the existence of receptor subclasses. This pattern of receptor binding for rats on ad libitum food is altered by 48 hrs of food deprivation. With deprivation, preliminary studies show that (1) binding of PAC to α receptors is specifically decreased in the PVN and VMH, while increased in other hypothalamic areas; (2) DHA (β) binding is selectively increased in the PF-LH; and (3) ADTN (DA) binding is generally increased throughout the hypothalamus, but most dramatically in the PF-LH.

5.9 EFFECT OF COPPER DEFICIENCY ON DOPAMINERGIC, β-ADRENERGIC AND MUSCARINIC RECEPTOR BINDING. Daniel J. Feller, Boyd L. O'Dell* and David B. Bylund, Departments of Pharmacology and Biochemistry School of Medicine, University of Missouri, Columbia, Missouri 65212.

There is evidence that cerebrospinal copper levels are altered in schizophrenic patients which suggests an involvement of copper or copper dependent enzymes in this disorder. Copper deficient animals exhibit pathologies resembling Parkinsonian symptoms and may possibly provide a model for the study of the syndrome. Dietary copper deficiency significantly reduces the concentration of dopamine in both the whole brain and corpus striatum of the rat, while whole brain levels of norepinephrine are depleted without a change in either hypothalamic or cerebellar NE. The decline in whole brain levels of both dopamine and norepinephrine have been correlated with a reduction in tyrosine hydroxylase activity. Recently, it has been suggested that changes in the density of neurotransmitter receptors are inversely related to changes in the effective concentration of neurotransmitter at the synapse. Thus it was of interest to characterize the changes in several neurotransmitter receptors in the copper deficient animal. Female rats received a low (<1 ppm) copper diet throughout gestation and lactation. Their offsprings were fed the same diet after weaning. Controls received the same diet supplemented with 10 ppm copper. Animals were sacrificed at 5 to 9 weeks of age. ^{3}H-Spiroperidol, ^{3}H-quinuclidinyl benzilate and ^{3}H-dihydroalprenolol were used to assay the dopaminergic, muscarinic and β-adrenergic receptors respectively. B_{max} values were determined from saturation exeriments and expressed as pmole/g protein. In the corpus striatum from deficient rats the density of the high affinity and low affinity DA receptor binding sites were decreased 55% and 45%, respectively ($p<.05$), while a 27% ($p<.005$) drop was observed in muscarinic binding sites. Furthermore the number of muscarinic receptors in the cerebral cortex was reduced 19% ($p=.05$) compared to only 6.5% ($p>.1$) in the cerebellum of animals receiving the copper deficient treatment. β-receptors increased 10% ($p>.1$) in the cerebral cortex and 13% ($.05<p<.1$) in the cerebellum. No significent differences were found in K_D values between the experimental and control rats. We suggest that the observed changes in receptor density are due to effects of copper deficiency not directly related to changes in neurotransmitter levels. Supported by NSF Grant BNS 7824715.

5.10 KAINATE LESIONS DIFFERENTIATE STRIATAL DOPAMINERGIC AGONIST AND ANTAGONIST BINDING SITES. S. Leff*, L. Adams and I. Creese (SPON: C.E. Spooner). Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093.

The neurotoxin kainic acid (KA) causes degeneration of treated neurons but not of axon terminals of distal afferents or of glia. Thus KA can be used to study the neuronal distributions of specific ligand binding sites in CNS nuclei. Striatal KA injections have been previously shown to decrease ^{3}H-butyrophenone binding sites by 50% while producing virtually a total loss of dopamine (DA) sensitive adenylate cyclase activity. Further studies demonstrated a larger loss (70%) of high-affinity binding of the DA agonist ^{3}H-apomorphine. We now report, in direct comparisons a greater loss of high affinity ^{3}H-agonist and ^{3}H-flupenthixol (an antagonist believed to label the DA-sensitive cyclase linked receptor) binding as compared to the loss of ^{3}H-butyrophenone sites after unilateral striatal KA lesions.

KA (2ug in 1ul 0.9% NaCl) was slowly infused through a 30g needle into the left striatum of anaesthesized rats positioned in a stereotaxic apparatus. Radioreceptor assays were performed on single striata dissected from animals sacrificed 3 weeks post-operatively. Binding of four ligands: ^{3}H-N-norpropylapomorphine (NPA), ^{3}H-spiroperidol, ^{3}H-domperidone, and ^{3}H-cis-flupenthixol, was assessed in lesioned and control (contralateral) striata. Specific binding was measured as the excess over blank tubes containing 1uM (+)-butaclamol. Specific binding of all ^{3}H-ligands was assessed using a concentration equal to their apparent K_D as determined in saturation experiments.

In lesioned striata the butyrophenone ^{3}H-spiroperidol and the butyrophenone-like ^{3}H-domperidone showed 56% and 59% losses of specific binding respectively. In contrast significantly greater decreases in binding were observed with ^{3}H-NPA and ^{3}H-flupenthixol which showed 79% and 73% losses of high-affinity binding respectively. The difference in the loss of ^{3}H-NPA vs. ^{3}H-flupenthixol binding in lesioned striata, however, was not significant; nor was there a significant difference in the loss of binding between ^{3}H-spiroperidol and ^{3}H-domperidone.

These findings lend further support to the hypothesis that there are multiple DA receptors in the striatum. The relatively greater loss of binding of ^{3}H-NPA and ^{3}H-flupenthixol parallels the nearly total loss of DA-sensitive adenylate cyclase activity, and suggests that these markers may identify the same receptors. The similar pharmacological specificities and kainate induced losses of ^{3}H-spiroperidol and ^{3}H-domperidone binding suggest that they identify identical receptors in the striatum. S.L. is an NSF predoctoral fellow, I.C. is an Alfred P. Sloan Fellow. Supported by PHS MH32990-01.

5.11 GENETIC DIFFERENCES IN CATECHOLAMINE RECEPTORS AND DOPAMINE-MEDIATED BEHAVIOUR IN RATS. D.M. Helmeste*, P. Seeman and D.V. Coscina. (SPON. M. Burnham). Pharmacology Department, University of Toronto and Bio-Psychology Unit, Clarke Institute of Psychiatry, Toronto, Canada.

In order to examine the hypothesis that behaviour may be correlated with receptor density, we examined two rat strains (F344, Buffalo) with known biochemical and behavioural differences. Previous studies have shown that adult F344 rats have higher levels of striatal and mid-brain tyrosine hydroxylase than Buffalo (BUFF) rats (1). An inverse relation between tyrosine hydroxylase levels and locomotor activity in these two strains has brought speculation that the primary factor responsible for the behavioural differences might be receptor sensitivity (2).

We measured alpha-adrenergic receptor densities (Bmax) in the frontal cortex, hippocampus and hypothalamus of these two strains using ^{3}H-clonidine to label alpha-2 sites and ^{3}H-WB-4101 to label alpha-1 sites. ^{3}H-Spiperone was used to label D-2 dopamine sites in the striatum and olfactory tubercle (O.T.). Significant differences in Bmax between strains were only found in the following areas.

ligand	area	$\frac{\text{Bmax F344}}{\text{Bmax BUFF}}$ ± S.E.
^{3}H-clonidine	frontal ctx.	1.20 ± 0.06
^{3}H-spiperone	striatum	1.34 ± 0.03
	O.T.	1.50 ± 0.19

Receptor affinities (K_D values) were not different between strains.

Behavioural testing of apomorphine-induced stereotypy in F344 and BUFF rats showed that F344 rats achieved higher levels of stereotypy compared to BUFF rats across the three doses of apomorphine used (0.25, 1.0, 2.5 mg/kg, s.c.).

The results of this study support the hypothesis that the higher density of D-2 receptors in the F344 strain may be related to the more sensitive responses to apomorphine. The increased sensitivity of BUFF rats to norepinephrine-induced locomotor activity [as previously shown (2)], may also be related to alpha receptor density.

6.1 HYPOXIA DECREASES THE METABOLISM OF THE GLUCOSE-DERIVED NEUROTRANSMITTERS. G. E. Gibson, C. Peterson*, and J. Sansone* (SPON: F. Plum). Cornell Med. Coll., Burke Rehab. Center, White Plains, NY 10605.

The molecular basis of the brain's sensitivity to mild decreases in oxygen is unknown. One possible explanation is that the synthesis of the glucose-derived neurotransmitters whose formation depends upon mitochondrial oxidation may be reduced by hypoxia. These neurotransmitters include acetylcholine (ACh), glutamate, aspartate and γ-aminobutyrate (GABA). Previously, we showed that ACh synthesis is decreased by levels of chemical or hypoxic hypoxia that do not reduce cellular ATP levels (J. Neurochem. 27:37; Neurosci. Abstr. 5:285). We have now compared the reduced ACh production to the formation of the amino acids GABA, glutamate, aspartate, glutamine, serine and alanine during chemical hypoxia. Their synthesis was determined after a pulse injection of [U-^{14}C]glucose (3 μCi/gm).

Mild chemical (anemic) hypoxia was induced with $NaNO_2$ to give the following % methemoglobins (MetHb): 0.7 (control), 12.1, 30.9, 59.2 and 83.8. The incorporation of [U-^{14}C]glucose into ACh (specific activities) declined as % of control from 100±1% (n=8) to 66±9 (n=8), 43±4 (n=5), 33±4 (n=7) and 16±6 (n=4) with the respective MetHb. There was a parallel decrease in the flux of glucose into the amino acid neurotransmitters dependent upon mitochondrial oxidation and into the non-neurotransmitter, glutamine, whose synthesis also depends upon mitochondrial metabolism. This is illustrated by the high correlation between the decrease in the incorporation of [U-^{14}C]glucose into ACh and its incorporation into GABA (r=0.98), glutamate (r=0.99), aspartate (r=0.93) and glutamine (r=0.99). However, the synthesis of the amino acids whose formation is not dependent upon mitochondrial oxidation did not correlate well with changes in ACh metabolism: serine (r=0.68), alanine (r=-0.19).

A standardized string test (Trans. Amer. Soc. Neurochem. 11: 159) was used to monitor behavioral changes during chemical hypoxia. The control score (7.8±0.2, n=6) did not vary in mice with the 12.1% MetHb (8.0±0.0, n=6) but was significantly altered with 30.9% MetHb (5.0±0.2, n=7) or 59.2% MetHb (0.6±0.4, n=5).

Thus, anemic hypoxia causes a parallel decrease in the synthesis of ACh and in the amino acid neurotransmitters which require mitochondrial oxidation. Decreases in neurotransmitter formation occur before any detectable changes in string test behavior. The relative importance of these alterations in different neurotransmitters in the production of impaired brain function in hypoxia or other metabolic encephalopathies remains to be determined. 6.2 DIFFERENCES IN THE STRUCTURE OF A AND B FORMS OF HUMAN MONOAMINE OXIDASE. *R.M. Cawthon, J.E. Pintar, F.P. Haseltine, M.S. Buchsbaum, D.L. Murphy, and X.O. Breakefield. Dept. Human Genetics, and Dept. Obstetrics and Gynecology, Yale Univ. Sch. Med., New Haven, CT 06510, Biological Psychiatry Branch and Clinical Neuropharmacology Branch, NIMH, Bethesda, MD 20014.

Monoamine oxidase (MAO) is a mitochondrial outer membrane enzyme which degrades amine transmitters in the nervous system. The irreversible inhibitor pargyline binds to the enzyme stoichiometrically, forming a stable adduct with the covalently bound flavin cofactor. Here sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) was used to analyze ^{3}H-pargyline-labeled MAO from human tissues with A and B activity. These two types of activity differ in their substrate selectivity, drug sensitivity, and tissue distribution. It is not clear to what extent these differences in MAO result from intrinsic variation in its structure or from extrinsic modulation by its membrane microenvironment. Recently, ^{3}H-pargyline-labeled polypeptides of MAO A and B from rat tissues were shown to have different apparent MW's and different one dimensional peptide maps by electrophoresis under fully solubilizing and denaturing conditions in SDS-polyacrylamide gels (studies by ourselves and by B.H. Callingham and D. Parkinson of Cambridge University). In the current studies the ^{3}H-pargyline-labeled polypeptides of human MAO A and B were compared using tissues from two individuals. In one case ^{3}H-pargyline was bound to MAO B in blood platelets from an adult male and to MAO A and B in a crude mitochondrial fraction from fibroblasts of the same individual. Specific labeling of only the A or the B forms of the enzyme from fibroblast cells was achieved by preincubation with selective A and B inhibitors. In the other case, ^{3}H-pargyline was bound to MAO B in umbilical cord blood platelets from a male newborn and to MAO A in a crude mitochondrial fraction from the trophoblast portion of the newborn's placenta. SDS-PAGE of samples containing MAO A activity revealed a labeled protein band of MW 63,000, and analysis of samples containing MAO B activity revealed a band of 60,000. Similar MW's have been reported for MAO A and B in rat tissues.

These findings demonstrate that distinct enzyme molecules are associated with the A and B types of human MAO activity. Whether the observed differences in structure arise from differential post-translational modification(s) of a single enzyme precursor or from divergent amino acid sequences coded by separate structural genes is under current investigation.

6.3 CHROMOSOMAL LOCATION OF GENES INVOLVED IN EXPRESSION OF MONOAMINE OXIDASE A AND B ACTIVITIES. John Pintar, James Barbosa, Uta Francke, Morris Hawkins Jr., Carmela Castiglione and Xandra Breakefield. Dept. Human Genetics, Yale Univ. Sch. Med., New Haven, Ct. 06510.

The chromosomal location of genes required for expression of type A and type B monoamine oxidase activities (MAO-A and MAO-B) has been studied in somatic cell hybrid lines. MAO-A activity was expressed in hybrid lines arising from fusion of a human fibroblast line (GM 316) that expressed both MAO-A and hypoxanthine phosphoribosyl transferase (HPRT) activities with a mouse neuroblastoma line (N1E-115TG2) that lacked both these activities. Subsequent growth of these lines in the presence of hypoxanthine, aminopterin, and thymidine (HAT) selected for hybrid cells that had retained the human X chromosome while randomly losing other human chromosomes; cell lines arising under these conditions continued to express MAO-A activity. Mouse and human MAO-A catalytic subunits were distinguished following specific and irreversible labelling with ^{3}H-pargyline and characterization by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. Although these proteins have the same MW, they have unique one dimensional peptide maps following limited proteolysis. Hybrid lines expressed the human form of the catalytic subunit of MAO-A, indicating the presence of the human structural gene for this protein. Moreover, selection of these cell lines in the presence of 6-thioguanine (that only allows survival of cells without HPRT activity) led to coordinate loss of the human X chromosome, human forms of X-linked enzymes, and MAO activity. In one case, however, a line containing a putative translocation lost a recognizable human X chromosome and some, but not all, human X-linked markers; yet retained MAO activity and produced a human catalytic subunit. Based on these observations, we have assigned the structural gene locus for the human MAO-A catalytic subunit to the X chromosome.

Fusion of a rat hepatoma line that expressed MAO-A, MAO-B, and HPRT activities with N1E-115TG2 gave rise to hybrids that continued to express both MAO-A and MAO-B activities. Three out of three hybrids resistant to subsequent 6-thioguanine treatment lost both types of MAO activity, while four out of four clones arising from growth on HAT retained both types of activity. This observation provided preliminary support for the idea that both MAO-A and MAO-B catalytic subunits are X-linked in the rat. Processing of MAO is currently being investigated and should help determine whether the MAO-A and MAO-B catalytic subunits are coded for by the same gene locus.

6.4 DEXAMETHASONE SELECTIVELY INCREASES MONOAMINE OXIDASE TYPE A ACTIVITY IN HUMAN DIPLOID FIBROBLASTS. Susan B. Edelstein and Xandra O. Breakefield. Dept. Human Genetics, Yale Univ. Sch. of Med., New Haven, CT 06510.

Cultured human diploid fibroblasts express both the A and B types of monoamine oxidase (MAO) activity. Studies on the effects of culture conditions on MAO suggest that heat-sensitive and dialyzable factors present in serum can markedly affect levels of activity. The effects of several hormones known to affect MAO activity in vivo have been studied using cultured fibroblasts. Cells were grown in medium supplemented with serum until several days past confluency and then placed in serum-free medium for 24 hr prior to exposure to hormones for 6 or 24 hr. Estradiol, progesterone, testosterone and tri-iodothyronine increased MAO activity only 10-50%, whereas dexamethasone (DEX) consistently increased levels 200-300%.

Although DEX increases MAO activity over a broad range of concentrations (1nM to 1μM), the greatest increases are observed after exposure to physiologic concentrations of DEX with an optimum near 50 nM. MAO activity increases linearly with time at this concentration. No apparent lag is observed (even at times as short as 6 hr) and levels are elevated nearly 6-fold by 5 days and 10-12 fold after 8-9 days of exposure to DEX.

Preliminary studies in which cultures were exposed to 50nM DEX for 8-9 days indicate that increases in MAO activity result from an increase in the number of MAO molecules: 1) Kinetic analysis reveals that DEX does not alter the affinity of MAO for tryptamine but increases the maximum velocity about 10-fold. 2) Dose response curves with selective MAO inhibitors indicate that DEX changes the proportion of A and B activity in living cells--e.g. using clorgyline (a selective A inhibitor), the proportion changes from 50% A:50% B in control cultures to 90% A:10% B in cultures exposed to DEX. 3) When the irreversible inhibitor ^{3}H-pargyline is used to stoichiometrically radiolabel the active sites of MAO A and B in crude mitochondrial preparations prior to SDS polyacrylamide electrophoresis, it is found that DEX does not alter the electrophoretic mobility of the labeled bands corresponding to MAO A (63K) and MAO B (60K). However DEX increases the amount of ^{3}H-pargyline-labeled MAO A about 10-fold but only increases ^{3}H-pargyline-labeled MAO B about 2-fold.

Thus, the increase in MAO activity induced by DEX in cultured fibroblasts appears to be almost entirely accounted for by an increase in the number of MAO A molecules.

6.5 CHARACTERISTICS OF RAT PHEOCHROMOCYTOMA TYROSINE HYDROXYLASE IN THE PRESENCE OF cAMP-DEPENDENT PHOSPHORYLATING CONDITIONS. J. Meligeni* and N. Weiner (Spon: J. Masserano). Dept. Pharmacology, Univ. Colorado Sch. Med., Denver, CO 80262

Tyrosine hydroxylase has been purified from rat pheochromocytoma tumor tissue by salt fractionation (28-42% ammonium sulfate, pH 7.8), ion exchange chromatography (phosphocellulose cation exchange, pH 6.2; DE-52 anion exchange, pH 7.8), and sucrose density gradient centrifugation (6-20% sucrose, pH 8.2). With this source of purified tyrosine hydroxylase, some physical characteristics of the enzyme, as well as alterations of those physical and functional characteristics consequent to exposure to protein phosphorylating conditions (ATP, Mg^{++}, purified catalytic subunit of cyclic AMP-dependent protein kinase), have been investigated in our laboratory. Tyrosine hydroxylase has a molecular weight of approximately 240,000 daltons as determined by polyacrylamide gradient gel electrophoresis, and probably exists as a tetramer with subunits of similar or identical size of approximately 60,000 daltons (Vulliet et al, PNAS, 77: 92-96, 1980). Two peaks of tyrosine hydroxylase activity at isoelectric points of approximately pH 5.4 and pH 5.2 can be detected by isoelectric focusing in flat-bed polyacrylamide gels (pH range 4-7). When purified tyrosine hydroxylase is exposed to ATP-γ-^{32}P and cAMP-dependent enzymatic phosphorylating conditions, ^{32}P is incorporated into both peaks of enzyme activity, and both peaks exhibit enhanced enzyme activity. Only minor shifts in the isoelectric points occur consequent to phosphorylation. Similarly, isoelectric focusing of crude pheochromocytoma supernatant reveals two peaks of tyrosine hydroxylase activity, and increases in enzyme activity and incorporation of ^{32}P into the regions of the gel which correspond to the sites of enzyme activity are observed when the crude tyrosine hydroxylase is incubated in the presence of ATP-γ-^{32}P, Mg^{++} and catalytic subunit of cAMP-dependent protein kinase. These data suggest that cAMP-dependent protein kinase can enhance tyrosine hydroxylase activity and that there may be more than one site at which the enzyme is phosphorylated in vitro. Rapid separation techniques, such as isoelectric focusing, may prove useful in further studies of the regulation of tyrosine hydroxylase both in situ and in vivo. Supported by USPHS grants NS 07927, NS 09199 and AA 03527.

6.6 DEBRISOQUIN, A PERIPHERAL MONOAMINE OXIDASE INHIBITOR AND ANTI-HYPERTENSIVE AGENT, REDUCES CORTICAL MHPG IN RATS. S. E. Hattox, A. C. Swann*, D. Jablonis* and J. W. Maas. Departments of Psychiatry and Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510

Debrisoquin sulfate is a monoamine oxidase inhibitor (MAOI) which does not cross the blood brain barrier. It has been clinically effective in lowering blood pressure. Although early reports confirm that debrisoquin has no effect on central aminergic neurons, more recent work has demonstrated a decrease in whole brain release of 3-methoxy-4-hydroxyphenethylene glycol (MHPG), a major metabolite of norepinephrine, in non-human primates treated chronically with debrisoquin (Maas et al., Biochem. Pharmacol. 28: 3153, 1979). In order to further examine the effect of debrisoquin on central monoaminergic systems, we have treated rats with various doses of debrisoquin and measured cortical MHPG at various times after treatment.

Rats were treated with 1, 5, 10 or 40 mg/kg debrisoquin, i.p., and sacrificed at 1 or 6 hours post injection. A second series of rats was treated with 10 mg/kg, b.i.d., for 24 hours and sacrificed 6 hours after the last injection. Conjugated plus free MHPG were measured in right cortical hemispheres by the mass spectrometric technique of selected ion monitoring employing deuterated internal standards, homogenization in sodium acetate buffer, ethyl acetate extraction and formation of the trifluoroacetyl derivative. Ions at m/e 358 and 360 were monitored, derived from endogenous and isotope-labelled MHPG, respectively. Caudate nucleus 5HIAA and HVA were also measured as indicators of central MAO inhibition or more generalized central effects. Again a selected ion monitoring procedure was used, employing deuterated internal standards, homogenization in 1 M formic acid, ethyl acetate extraction and formation of the pentafluoropropionyl derivatives. Ions at m/e 438 and 440 were monitored for 5HIAA while ions at m/e 460 and 462 were monitored for HVA.

Cortical MHPG was significantly lowered at 6 hr with 1, 5, and 10 mg/kg debrisoquin (N=5, $p < .01$, .02, .02) to 78, 78, and 74%, respectively of saline-treated control values. MHPG was not found to be significantly lowered, however, at 1 hr and had returned to control levels by 24 hours. Caudate nucleus 5HIAA and HVA were found to be unchanged at 6 hr regardless of dose. These data suggest that debrisoquin, in a time-dependent fashion, decreases central noradrenergic activity either indirectly via peripheral afferents or by a direct mode of action such as the formation of an active metabolite which can enter the brain. Further studies are underway to elucidate the mechanism by which debrisoquin decreases CNS MHPG. (Supported in part by grants from USPHS: Grants # MH-24393 and MH-25642.)

6.7 **DEPENDENCE OF BRAIN 3,4-DIHYDROXYPHENYLETHYLENEGLYCOL (DHPG) ON BRAIN NORADRENERGIC NEURONAL ACTIVITY. J. J. Warsh, P. P. Li*, D. D. Godse*, and S. W. Cheung*. Section of Biochemical Psychiatry, Clarke Institute of Psychiatry, University of Toronto, Toronto M5T 1R8, Canada.**

Using a direct gas chromatography-mass fragmentography (GC-MF) procedure, we have previously confirmed and extended earlier observations that in addition to 3-methoxy-4-hydroxyphenylethyleneglycol (MHPG), DHPG is also a major norepinephrine (NE) metabolite in rat and mouse brain (Soc. Neurosci. 9:575 1979). Moreover, GC-MF determination of significant although lower amounts of DHPG in human CSF (2.19 ± 0.57 ng/ml; N=6) compared to MHPG (9.92 ± 1.15 ng/ml; N=8) suggests that DHPG is also formed in human central nervous system (CNS). Although a variety of data suggest that brain MHPG production is dependent upon the functional status of CNS NE activity, the relationship of brain DHPG formation to NE neuronal activity is not as well established.

To characterize the functional significance and site of formation of brain DHPG, rat brain NE neuronal activity was modified pharmacologically followed by simultaneous determination of brain regional DHPG and MHPG levels by GC-MF. In rats given the α-adrenergic agonist clonidine (10 or 250 μg/kg, i.p.) 2-hr prior to sacrifice, cortical and spinal DHPG and MHPG concentrations were significantly decreased by 20 and 30%, respectively. On the other hand, the α-adrenergic antagonist yohimbine (1-10 mg/kg, i.p.), induced a parallel and dose dependent increase in cortical and spinal DHPG (130-200%) and MHPG (170-410%) concentrations compared to controls. Pretreatment with desipramine (10 mg/kg, i.p.) 30 min prior to yohimbine antagonized the yohimbine-induced elevation of DHPG levels in these same regions leading to a shift to the right of the log dose response curves. In contrast, desipramine augmented the effects of yohimbine on cortical and spinal MHPG levels resulting in a shift to the left of the dose response curves and a significant increase in the slopes. Desipramine alone significantly reduced cortical DHPG (23%) and not MHPG levels.

The parallel yohimbine and clonidine induced increments and decrements, respectively, of DHPG and MHPG indicate that DHPG is also sensitive to changes in brain NE neuronal impulse flow. Secondly, the differential effect of desipramine on the yohimbine-induced increments of brain DHPG and MHPG support the notion that brain DHPG and MHPG are formed in separate metabolic compartments, DHPG being formed in a presynaptic intraneuronal location and MHPG in a postsynaptic compartment.

6.8 Glucocorticoids increase β-adrenergic receptors in fetal rabbit lung in vivo and in vitro. James M. Roberts*, John B. Cheng*, Jeffrey Schwartz*, Robert Goldfien*, Philip L. Ballard*, Alan Goldfien*, (SPON: Cynthia L. Bethea). Depts. Ob. Gyn. & Reprod. Sci., Ped., & CVRI, U. CA at San Francisco, San Francisco, CA 94143.

Heterologous receptor regulation is an important mechanism of hormone action. We asked whether heterologous regulation of adrenergic receptors might have a role developmentally. Activation of pulmonary β-adrenergic receptors increases surfactant release and decreases lung water and is important in preparing the fetus for extrauterine existence. Glucocorticoid treatment accelerates lung maturation and also increases β-adrenergic receptors in adult lung. To determine if glucocorticoids might increase fetal lung β-receptors as one aspect of lung maturation, we used [^{3}H] dihydroalprenolol (DHA) to directly examine β-receptors in fetal lung. DHA binds to particulate preparations of fetal rabbit lung in a manner compatible with β_1-adrenergic interactions, and agonist affinities are similar to those in adult lung (isoproterenol K_I = .28±0.7μM; > epinephrine K_I = 4.1±1.7μM; = norepinephrine K_I = 6.6 ±2μM). We quantitated fetal pulmonary β-receptors throughout gestation and compared these to fetal free cortisol concentrations reported previously (Mulay, et al. Endoc. 93:1342, 1973). The concentration of DHA binding sites increased between 28 & 31 days gestation:

Gestational Age	[β-Receptors]	fmol/mg prot. ($\bar{x}$ ± SEM)
24 days	35.6± 6.5	
26 days	43.6± 7.4	
28 days	66.0± 7.0	($p < .001$)
31 days	138.7±17.7	
neonate	153.8±14.3	

This increase follows the increase in fetal free cortisol by 24 hours. To determine if the changes in glucocorticoid and β-receptors were causally related, we treated maternal rabbits at 25 days gestation with betamethasone (.17mg/kg) and found that glucocorticoid treatment increased β-receptors from 43.6±7.4 fmol/mg prot to 77.9±5.8 fmol/mg prot ($p<.001$) in lungs of fetuses removed 24 hours after treatment. We examined β-receptors in fetal lungs maintained in organ culture for 48 hours in the presence or absence of .1μM dexamethasone to determine if this increase was a direct effect of glucocorticoid and to provide a system for examining mechanisms of receptor increase. Lungs cultured with dexamethasone demonstrated an increase in β-receptor concentration (106 ±8fmol/mg prot) compared to lungs prepared prior to culture (36±9 fmol/mg prot), or lungs cultured without glucocorticoid (56±13fmol /mg prot) ($p<.05$). We conclude that heterologous regulation of pulmonary adrenergic receptors are an important developmental mechanism. Organ culture of fetal lung should provide a system in which mechanisms of receptor regulation can be evaluated

6.9 PUTRESCINE AS A METABOLIC SOURCE OF GABA. P.C. Caron*, L.J.Cote, L.T. Kremzner*. Depts. of Pathology, Neurology, and Rehabilitation Medicine. College of Physicians and Surgeons, Columbia University, New York, NY 10032.

Until recently, γ-aminobutyric acid (GABA) was considered to be formed solely by the enzymatic decarboxylation of glutamic acid. Although the concentration of GABA is highest in the central nervous system, low levels are found in non-neural tissues such as pancreas, adrenal, and kidney; (Gerber, J.C. and Hare, T.A. Diabetes 28: 1073, 1979) and glutamine acid decarboxylase activity has been found in these tissues. However, Seiler (Brain Res. 28: 371, 1971) found that putrescine was a precursor to GABA, as well as to spermidine and spermine. In the present communication the relative contribution of putrescine as a source of GABA in neural, as well as non-neural tissues, is assessed.

Female Sprague-Dawley rats (150-175 g) were injected with physiological levels of 1,4 ^{14}C-putrescine (S.A. 96.4 mCi/m mole) intraventricularly (0.4 μCi) or intraperitoneally (10 μCi). The animals were killed at 15, 30, 60, 120 and 300 min. The tissues were homogenized in 4 vol of 0.4 M PCA and the extracts were analyzed for radioactive GABA, putrescine, spermidine, spermine, and other GABA metabolites, using an amino acid analyzer. In addition, inhibitor studies using aminoguanidine (60 mg/kg), injected i.p. 6 hrs before putrescine administration, were performed.

Intraventricular injections of labelled putrescine showed little conversion (≤ 1%) to GABA. In contrast, more than 25% of the radioactivity was found in spermidine in the telencephalon and brain stem by 2 hrs. Low levels of ^{14}C-spermine were also found after 2 and 5 hrs.

Intraperitoneal injections of ^{14}C-putrescine showed marked differences in the uptake of radioactivity in neural and non-neural tissues. A significant conversion of putrescine to GABA occurred in the pancreas and adrenal gland, accounting for 5-10% of the total endogenous GABA in one hour. Smaller, but detectable levels of ^{14}C-GABA were also found in the brain, liver, heart, kidney, and skeletal muscle. After the administration of aminoguanidine, an inhibitor of diamine oxidase, as much as a 95% inhibition of GABA formation was found.

These studies show that a "significant" amount of GABA may have its origin in putrescine in some tissues. The role of GABA in non-neural tissue is unclear and needs further clarification. Perhaps GABA in the periphery plays a regulatory role by altering membrane permeability to anions. Alteration in GABA levels having its origin in the polyamines may provide clues to the function of GABA in neural and non-neural tissues.

6.10 EFFECT OF ANTIGANGLIOSIDE (ANTI-G_{M1}) ANTIBODY ON GABA RELEASE IN BRAIN SLICES. Brina Frieder* and Maurice M. Rapport., Div. of Neuroscience, N.Y. State Psychiatric Inst. and Depts. of Biochem. and Psychiatry, Columbia Univ., New York, N.Y. 10032.

Intracerebral injections of antibodies to G_{M1} ganglioside result in the perturbation of several CNS functions (induction of epileptiform spiking, inhibition of passive avoidance learning, blockade of morphine analgesia, etc.). Since the mechanism of action of these antibodies is not known, the present study was undertaken to determine the effect of such antibodies on transmitter release. Slices (0.7mm) of rat brain cortex were loaded with [^{3}H]-GABA (1 μCi/ml; 15 nM) for 15 min in 0.4 ml of aerated balanced salt medium. Slices were placed in fresh medium (containing 10 μM AOAA to block GABA metabolism), and medium was replaced at 5 min intervals. The effect of anti-G_{M1} ganglioside antibodies was studied using immunoglobulin (Ig) fractions from antiganglioside serum (in 10 μl PBS -- equivalent to the original volume of antiserum). As a control, Ig fractions were obtained from antiserum that had been absorbed with pure G_{M1} ganglioside to remove specific antibodies. Ig fractions were present in all replacement media. Spontaneous GABA release and release induced by K^+ (40 mM) and by veratrine (0.2 mM) were studied in the presence of GABA uptake inhibitors (50 μM 2,4-diaminobutyric acid plus 100 μM β-alanine). Four Ig fractions from four different antiganglioside sera (with anti-G_{M1} titers ranging from 350 to 750 using 4 C'50 units of complement) enhanced K^+-stimulated GABA release in the 1st (*) and 2nd (**) 5 min intervals (for which the K^+ effect on release is marked) by 82%* 82%**, 56%* 100%**, 37%* 60%** and 34%* 26%**. The two Ig fractions tested on veratrine-stimulated GABA release enhanced release by 32%* 12%** and 45%* 11%**. In contrast, spontaneous GABA release was inhibited (ca 25%) but only when uptake inhibitors were absent, suggesting that the reduction in spontaneous release of labeled GABA was the result of an increase in reuptake. It is concluded that antiganglioside antibodies can affect neurotransmitter release in the absence of complement since they enhanced depolarization-induced GABA release. The specificity of the action of antiganglioside antibodies warrants further study with respect to: 1) release of other transmitters, both spontaneous and depolarization-induced and 2) whether enhancement of release is a common effect.

Supported by a grant from NINCDS (NS-13762).

7.1 ACCUMULATION AND METABOLISM OF PIPECOLIC ACID IN THE BRAIN. H. Nishio*, J. Ortiz*, E. Giacobini, T. Schmidt-Glenewinkel*. Lab. of Neuropsychopharmacology, Dept. of Biobehavioral Siences, Univ. of Connecticut, Storrs, CT 06268.

Pipecolic acid (PA), an iminoacid related to lysine metabolism has been recently isolated in the mouse brain (Nomura, Y., Schmidt-Glenewinkel, T.,and Giacobini, E., Dev. Neurosci., 1:239-249, 1978). It occurs in appreciable amounts (18 + 4 pmoles/g), it is synthesized in vitro, it is taken up by a high affinity, Na^+ and temperature dependent mechanism into synaptosomes (K_m = 3.90 + 0.17 x 10^{-7}M) (Giacobini, E., Nomura, Y. and Schmidt-Glenewinkel, T., Cellular & Molecular Biology, 25:1-9, 1980). and it is released from rat brain slices by means of a Ca^{++} dependent, high potassium-induced release mechanism (Nomura, Y., Okuma, Y., Segawa, T., Schmidt-Glenewinkel, T. and Giacobini, E., J. Neurochem. 33:803-805, 1979). We have now studied the transport and accumulation of PA into the brain of the mouse-

About 1% of the (^{3}H)PA injected i.v. or i.p. (5.5-5500 nmole) in the mouse is rapidly accumulated in the brain from where it is slowly eliminated (T 1/2 = 6.7 hrs). In liver and kidney (^{3}H)PA is accumulated more rapidly than in the brain. Probenecid (200 mg/kg i.p.) produces a significant increase in brain accumulation. After 30 min. following i.v.injection approx 80% of (^{3}H) is found in the brain as (^{3}H)PA while the remaining part is constituted by metabolites. 80% of (^{3}H)PA injected i.v. is secreted in the urine as such after 30 min. The brain/plasma ratio following i.v. injection, is approximately 0.25 at 1 hr. and almost 1 at 6 hrs.

In summary we can say that PA is rapidly accumulated in the brain following i.p. or i.v. injection from where it is slowly eliminated. Probably, the brain is able to metabolize PA. The liver, on the contrary, does not seem to contribute substantially to PA metabolism. The existence of BBB for PA seems to be supported by our results. The transport of PA to the brain is similar to the one for its precursor aminoacid lysine. The BBB for PA seems to be more permeable than for 6-OH dopamine but less than for tyrosine.

Acknowledgment. This study was supported by U.S. Public Health Service Grant No. NS-11430-01 and 02, and NS-15086-01 to Ezio Giacobini and by grants from the University of Connecticut Research Foundation.

7.2 THE GLUTAMIC ACID DECARBOXYLASE OF LAMPREY CNS - DEVELOPMENTAL CHANGES AND EFFECTS OF CORDOTOMY. N.R. Krieger, U. Wald* and M.E. Selzer. Dept. of Pharmacology, University of Pennsylvania, School of Medicine, Philadelphia, PA 19104.

The presence of glutamic acid decarboxylase (GAD) was demonstrated in the CNS of the sea lamprey (Petromyzon marinus). A microassay based on the release of $^{14}CO_2$ from (1-^{14}C) L-glutamic acid was used. The enzyme had similar characteristics in brain and spinal cord and in larvae and feeding stage adults. It had a sharp temperature optimum at 27-30°C. Optimum pH was 6.8. The Km for glutamic acid, measured at 27°C, pH 7.1 in the presence of 0.1 mM pyridoxal phosphate, was 5 mM.

In large larvae (3-5 years old) homogenates of brain had approximately 2.5 times the GAD specific activity of homogenates of cord (63 vs. 26 nmol. CO_2/mg protein/hr.). In feeding stage adults the brain showed approximately 8 times the specific activity of the cord (236 vs. 29 nmol. CO_2/mg protein/hr.). Thus between larval and adult stages the brain showed an almost 4-fold increase in GAD activity, while the spinal cord showed no statistically significant increase.

GAD activity was the same in rostral, middle and caudal thirds of the larval spinal cord. Following transection of the spinal cord of larvae at the level of the 6th gill, the GAD activities rose sharply in brain and in all three regions of spinal cord. The maximum increase was observed one week after transection, at which time activities in all regions were 5-6 times normal. By the fourth week GAD activities had returned to normal. GAD activity persisted in brain and cord at approximately control levels for at least seven weeks following cordotomy. Thus Wallerian degeneration, which is known to occur in the lamprey spinal cord, did not eliminate the GAD activity either rostral or caudal to the transection. We conclude that GAD activity does not originate exclusively in cells of either brain or spinal cord, but must be synthesized independently by cells of both structures.

7.3 A unique action of 2-amino-4-phosphonobutyrate on the ON pathway in the mudpuppy retina. Malcolm M. Slaughter* and Robert F. Miller, Departments of Ophthalmology, Physiology, and Biophysics, Washington University School of Medicine, St. Louis, Missouri

Glutamate and aspartate have been proposed as photoreceptor synaptic transmitter candidates since Murakami, et al ('75) demonstrated that these excitatory amino acids depolarize OFF bipolar cells and hyperpolarize ON bipolar cells in fish. Recently, Wu and Dowling ('78) have reported that aspartate mimics the action of the photoreceptor transmitter on carp horizontal cells and both actions are blocked by DL α amino adipate. We have examined a number of glutamate and aspartate agonists and antagonists and report here on a selective action of 2-amino-4-phosphonobutyrate (APB), a glutamate analog, on the ON pathway in the mudpuppy retina. Intracellular recordings were obtained from all classes of retinal neurons in the superfused mudpuppy eyecup. In the outer retina, application of micromolar concentrations of APB blocked the light evoked response (LER) of the depolarizing bipolar cells while leaving unaffected the LER of receptors, horizontal cells, and hyperpolarizing bipolars. This blocking action was complete and reversible. In the inner retina, APB eliminated the LER of the ON amacrine and the ON component of the ON-OFF amacrine cells while the response of OFF amacrines persisted. APB blocked the ON but not the OFF IPSP of ganglion cells and also blocked the LER of ON ganglion cells. We have undertaken experiments to determine the mechanism of the APB action by superfusing with cobalt (3 mM) to clock synaptic transmission, a treatment which depolarized the ON bipolars. Application of APB superimposed on the cobalt block caused a hyperpolarization of the ON bipolar, consistent with the idea that APB is a transmitter agonist. A three carbon analog of APB, 2-amino-4-phosphonopropionate, did not block the ON pathway in concentrations up to 1 mM. Assuming that a single transmitter is released by photoreceptors, this selective effect of APB suggests that the transmitter receptors on depolarizing bipolar cells are unique and distinct from those on the two other types of second order neurons in the mudpuppy retina.

7.4 LOCAL CEREBRAL GLUCOSE UTILIZATION (LCGU) FOLLOWING SYSTEMIC ADMINISTRATION OF GABAERGIC AGONIST AND ANTAGONIST DRUGS. E.D. London, J.M. Palacios, S.I. Rapoport and M.J. Kuhar. Lab of Neurosciences, Gerontology Research Center, National Institute on Aging, Baltimore City Hospitals, Baltimore, MD 21224 and Departments of Pharmacology and Experimental Therapeutics and Psychiatry and the Behavioral Sciences, Johns Hopkins School of Medicine, 725 N. Wolfe Street, Baltimore, MD 21205.

Using radioligand binding and autoradiographic techniques, it has been observed that high affinity γ-aminobutyric acid (GABA) binding sites are heterogeneously distributed throughout the rat brain (Palacios et al., P.N.A.S. 77: 670, 1980). In order to assess the functional significance of these high affinity binding sites, we employed the autoradiographic ^{14}C-2-deoxy-D-glucose (DG) technique of Sokoloff et al. (J. Neurochem. 28:897, 1977) to study local cerebral glucose utilization (LCGU) in the conscious rat. Animals were injected i.v. with one of several doses of GABAergic agonist (muscimol, 1-7 mg/kg; 4,5,6,7,-tetrahydroisoxazolo[5,4-c] pyridin-3-ol,THIP, 12 and 24 mg/kg) or antagonist (bicuculline) drugs prior to the administration of 125 μCi/kg of DG. GABA agonists induced dose-dependent depressions in LCGU in most brain regions assayed. Decreases in LCGU were most dramatic in forebrain regions, especially cerebral cortex, caudate nucleus and thalamic nuclei. There were variable reductions in LCGU within the hippocampus. In contrast, LCGU in the red nucleus was increased by up to 100% with a high dose of muscimol (7 mg/kg). A subconvulsant dose of bicuculline (294 μg/kg) increased LCGU in several regions, notably the auditory cortex and inferior colliculus.

These observations support the proposed general inhibitory function of GABA in the central nervous system. Enhanced LCGU in the red nucleus may result from GABAergic inhibition in the cerebellum, thalamus and/or cerebral cortex; these areas have high densities of GABA receptors. There is no simple correlation between the magnitude of response in LCGU to GABAergic agonist and antagonist drugs and the density of high affinity GABA binding sites. Thus, LCGU following specific pharmacologic stimulation depends on the presence of relevant receptors for the administered drugs, but is influenced also by the neuronal circuitry of any region studied. 7.5 GLUTAMINE AND α-KETOGLUTARATE AS METABOLIC PRECURSORS OF AMINO ACID NEUROTRANSMITTERS. R. P. Shank and G. LeM. Campbell*, Franklin Research Center, Philadelphia, PA 19103.

As part of a project aimed at elucidating the mechanism by which the neurotransmitter pools of glutamate, GABA and aspartate are maintained and regulated we have examined the uptake and metabolism in vitro of glutamine, α-ketoglutarate and a variety of other compounds by cellular and subcellular fractions derived from the cerebellum of 1 to 3 week old mice. The cerebellar tissue was dissociated using a combination of enzymatic treatment (mild trypsinization and DNA ase) and mechanical agitation. Five cellular and subcellular fractions were obtained using a series of linear density gradients formed with Percoll. Four of the fractions were comprized almost entirely of cell bodies, one of which was enriched in granule cells. On fraction contained predominantly sub-cellular material. In this fraction nerve terminals were prevalent, but there were few, if any, free mitochondria.

Glutamine and α-ketoglutarate were both taken up comparatively fast by the fraction enriched in nerve terminals, but only glutamine was readily taken up by all five fractions. Both glutamine and α-ketoglutarate were rapidly converted to glutamate subsequent to being taken up by the nerve terminal enriched fraction. Much of the glutamate formed from these precursors was metabolized to GABA and aspartate. The transport of both glutamine and α-ketoglutarate appears to be mediated by high and low affinity systems; the K_t values for α-ketoglutarate (approximately 15 and 50 μM) being lower than those for glutamine (approximately 50 and 200 μM). The uptake of both glutamine and α-ketoglutarate by the fraction enriched in nerve terminals was inhibited by glutamate, aspartate, GABA and cGMP when this fraction was pre-incubated with those substances at concentrations of 0.2 to 2 mM. There was no apparent mutual interaction between glutamine and α-ketoglutarate transport.

Our observations support the concept that both glutamine and α-ketoglutarate derived from non-synaptic sources are instrumental in replenishing the molecules of glutamate, GABA and aspartate lost from nerve terminals during synaptic activation. Our data further suggest that the regulation of glutamine and α-ketoglutarate uptake is an important factor in the regulation of intracellular levels of glutamate, aspartate and perhaps GABA.

7.6 RATES OF GABA ACCUMULATION IN VARIOUS BRAIN REGIONS AFTER IRREVERSIBLE INHIBITION OF GABA-TRANSAMINASE IN VIVO AND IN BRAIN SLICES. M.J. Iadarola, and K. Gale. Department of Pharmacology, Schools of Medicine and Dentistry, Georgetown University, Washington, D.C. 20007.

The production of GABA in different rat brain regions was evaluated in brain slices maintained in vitro. Fresh tissue slices (225u) from cerebellum, cerebral cortex, caudate nucleus, superior colliculus and substantia nigra were incubated at 37°C for various times (5-90min) in the presence of 10^{-4}M gamma-vinyl-GABA (GVG), a specific and irreversible inhibitor of GABA transaminase. In slices prepared and maintained in Krebs-Ringer phosphate (bubbled with 100% O_2 for 20min) GABA levels started to rise after a latency of 15min after addition of GVG. The rate of accumulation of GABA was linear between 20 and 70min; during this period we took time points at 10min intervals. Under these conditions the rate of accumulation of GABA was found to be in the range of 0.2-0.6nmoles/mg protein/min; these values were similar to those obtained in vivo after administration of GVG (600mg/kg i.p.). In general, brain regions with low initial steady-state levels of GABA (cerebellum, cortex and caudate) had lower rates of GABA accumulation than regions with high initial steady-state GABA (superior colliculus and substantia nigra). However, the rates of accumulation of GABA were not found to be proportional to the glutamic acid decarboxylase (GAD) activity measured in cell-free homogenates of the various regions. Similarly, in vivo accumulation of GABA in the various brain regions after GVG was not proportional to either control steady-state GABA levels or to GAD activity. These findings may be related to our previous observation that a large portion of the GABA increase after GVG occurs in a glial-perikarya-metabolic compartment of GABA (Gale and Iadarola, Science 208: 288, 1980). Consistent with this, we found that slices obtained from kainic acid-lesioned caudates generated GABA at a rate comparable to that obtained in intact tissue.

In addition, we found that the initial rate (5-30min) of GABA accumulation in the slices could be accelerated by addition of CO_2 or bicarbonate to the Krebs-Ringer buffer. Under these conditions, differences in rates between the various brain regions were accentuated.

7.7 SPECIFIC BINDING OF [^{3}H]-GLUTAMATE AND [^{3}H]-KAINATE IN THE GRANULO-PRIVAL MOUSE CEREBELLUM. J. Slevin*, M. Johnston, K. Biziere and J.T. Coyle. Dept. of Pharmacol. and Expt. Therapeut., Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

To examine the relationship between receptor binding sites for [^{3}H]-glutamic acid and [^{3}H]-kainic acid and cerebellar (Cb) circuitry, the effects of granule cell ablation on neurotransmitter receptors and neuronal presynaptic markers were examined in mice rendered granule cell deficient by treatment with methylazoxymethanol acetate (MAM). On the day of birth, Blu/HA mice received a single, subcutaneous injection of MAM (30 mg/kg), an alkylating agent that selectively kills mitotically active cells. In adult treated mice, the Cb mass was reduced by 47% as compared to saline treated litter-mates. Nissl-stained sections of the lesioned Cb revealed a profound loss of granule cells; the Purkinje cells, which did not appear reduced in number, had an abnormal distribution.

The specific activities of choline acetyltransferase and glutamate decarboxylase were increased significantly ($p<0.001$) by 46% and 59% respectively, resulting in a slight decrease in total activities per MAM Cb. The specific activities of the Na^+ dependent synaptosomal uptake for [^{3}H]-GABA was increased by 52% ($p<0.001$) whereas the uptakes of [^{3}H]-L-glutamic acid and of [^{3}H]-L-aspartic acid were reduced by 45% ($p<0.001$) and 28% ($p<0.05$) respectively. Congruent with these results, the concentration of GABA was elevated by 29% ($p<0.05$) whereas the concentration of glutamate was reduced by 29% ($p<0.001$); endogenous norepinephrine was increased by 67% ($p<0.001$).

In MAM Cb the specific binding of [^{3}H]-quinuclidinyl benzilate, a muscarinic receptor antagonist, and of [^{3}H]-dihydroalprenolol, a beta receptor antagonist, were unchanged. For contrast, the specific binding of ^{3}H-GABA was significantly reduced by 32% ($p<0.001$) per mg protein. The specific binding of [^{3}H]-kainic acid (50 nM; 2°C incubation) was not altered in the lesioned cerebellum per mg protein but total binding was significantly reduced by 47% ($p<0.001$). In contrast, the specific binding of [^{3}H]-L-glutamic acid (600 nM; 37°C incubation) was incrased by 106% ($p<0.001$) per mg tissue protein; as a result, the total amount of specific binding per MAM Cb was increased by 41%.

The data indicate that the MAM treatment results in a marked reduction in Cb granule cells and their pre-synaptic glutamatergic markers; the specific binding of ^{3}H-glutamate increased considerably, which suggests a postsynaptic localization and possible denervation supersensitivity. The binding site for [^{3}H]-kainate responds to the lesion differently than that of [^{3}H]-glutamate but similarly to the muscarinic and beta receptors.

7.8 EXCITATORY AMINO ACID RECEPTORS ARE ENRICHED IN SYNAPTIC JUNCTIONS. A. C. Foster*, E. E. Mena*& C. W. Cotman. Dept. of Psychobiology, Univ. of Calif., Irvine, CA. 92717.

Dicarboxylic amino acids have been shown to cause excitations when applied to mammalian neurons, and electrophysiological evidence suggests that multiple receptors for such amino acids exist in the CNS. The multiplicity of such receptors may reflect the presence of extra-junctional, as well as junctional receptors, as has been demonstrated for glutamate in the invertebrate nervous system. Binding studies with excitatory amino acids reported to date have used crude synaptic membranes, which would be expected to contain both junctional and extra-junctional receptors.

We have investigated the binding of L-[^{3}H]-glutamate, L-[^{3}H]-aspartate and [^{3}H]-kainic acid to purified synaptic junctions from rat brain. For all three ligands, specific binding (defined as displaceable binding in the presence of 10^{-4}M unlabelled ligand) was enriched as the purity of synaptic junctions increased i.e. homogenate < P_2 < synaptic plasma membranes < synaptic junctions. The highest specific binding was found in synaptic junctions, which for all three ligands was enriched approx. 10-15 fold over that in homogenate. Microsomal, mitochondrial and myelin fractions were found to have appreciably less binding than the synaptic fractions.

These results suggest that the use of synaptic junction preparations in the study of excitatory amino acid binding may allow differentiation between junctional and extra-junctional receptors for these compounds. (Supported by grant -- NIH no. NS 08597-11.)

7.9 BIOCHEMICAL PHARMACOLOGY OF KOJIC AMINE, A GABA RECEPTOR AGONIST. J.W. Ferkany,* M.F. Browner* and S.J. Enna. Depts. Pharmacol., Neurobiol. and Anat., Univ. Texas Medical School, Houston, Texas 77025

Kojic amine (2-aminomethyl-5-hydroxy-4H-pyran-4-one), a structural analogue of γ-aminobutyric acid (GABA), selectively inhibits ^{3}H-muscimol binding to GABA receptors in rat brain membranes (IC_{50}=4μM) and, when applied iontophoretically, hyperpolarizes cerebellar Purkinje cells, an action which is blocked by bicuculline (Arch. Int. Pharmacodyn. Therap. 241:266, 1979). These data suggest that this agent may be a direct-acting GABA receptor agonist. In the present study, experiments were undertaken to further explore and define the interactions of kojic amine with the GABA receptor and to determine whether this compound will activate this receptor system following systemic administration.

Like GABA, kojic amine enhances ^{3}H-diazepam binding to rat brain benzodiazepine receptors in vitro, though it is some 10 fold weaker (EC_{50}=64μM) than GABA in this regard. In addition, chronic administration of kojic amine (18 mg/kg b.i.d. for 15 days) induces a significant increase in dopamine receptor and a decrease in GABA receptor binding in the rat corpus striatum. Furthermore, acute administration of kojic amine (30 mg/kg) causes a significant increase in synaptosomal high affinity choline uptake in the corpus striatum. The results of these ex vivo experiments are qualitatively similar to those previously found after chronic administration of more established GABAergic agonists such as THIP and γ-acetylenic GABA.

These findings indicate that kojic amine is a GABA receptor agonist following systemic administration, suggesting that this compound may be a useful tool for defining the behavioral, biochemical and physiological effects of the GABAergic system. (Supported in part by USPHS grants NS-13803, NS-00335 and MH-07688).

7.10 RELEASE OF ENDOGENOUS AMINO ACIDS FROM NORMAL AND GRANULE AND STELLATE CELL DEPLETED RAT CEREBELLUM. R.S. Flint*, M.A. Rea* and W.J. McBride, Depts. Psychiatry & Biochemistry, Inst. Psychiatric Res., Indiana Univ. Sch. of Med., Indianapolis, IN 46223

The release of endogenous amino acids from rat cerebellum was studied using 300 x 300 μm diced tissue embedded in Sephadex G-50 columns. In preliminary studies, the whole cerebella from adult, male Wistar rats were used to ascertain the time course of release of glutamate (Glu), aspartate (Asp), GABA, taurine (Tau), glycine (Gly) and alanine (Ala). The tissue was perfused first for 30 minutes with a Ca^{++} free physiological saline medium containing 1 mM EGTA, then for 25 minutes with Ca^{++} free medium containing 55 mM K^+, and finally with medium containing 55 mM K^+ plus 2.5 mM Ca^{++}. After the initial 10-15 minute wash-out period, a small constant rate of spontaneous efflux was observed. Elevation of K^+ in the absence of Ca^{++} caused a slight increase in efflux of Glu and Asp without altering the efflux of GABA, Tau, Gly or Ala. Addition of 2.5 mM Ca^{++} to the medium containing 55 mM K^+ caused a peak release above baseline of 25-fold for Glu, 5-fold for Asp, 10-fold for GABA and 2-fold for Ala. The efflux of Tau and Gly was not increased by addition of Ca^{++} to the 55 mM K^+ medium. In a second study, male Long-Evans rats were used. One group (N=4) was exposed to x-irradiation treatment at 12-15 days following birth (12-15x group) which prevented the acquisition of late-forming granule cells; a second group (N=5) was exposed to a schedule of x-irradiation which prevented the acquisition of granule and stellate cells (8-15x group). Unirradiated littermates (N=11) were used as controls. Animals were killed at 90-120 days of age. The cerebellum was quickly removed; the vermis was dissected free, diced and perfused as described above. With respect to control values, there was a significant reduction in the K^+-stimulated Ca^{++}-dependent release from the 12-15x cerebellar vermis of (a) 50% for Glu; (b) 50% for Asp; and (c) 57% for Ala. With regard to control data, there was a significant reduction in the K^+-stimulated Ca^{++}-dependent release from the 8-15x group of (a) 77% for Glu; (b) 67% for Asp; (c) 55% for GABA; and (d) 92% for Ala. The reduction in the release of Glu from the granule cell deficient cerebella supports the hypothesis that it may be the excitatory transmitter released from these interneurons. The reduced release of GABA from the granule and stellate cell deficient cerebella supports the idea that GABA is the transmitter released from stellate cells. The fact that no increased release of Tau or Gly occurred in the elevated K^+ plus Ca^{++} medium could be taken as evidence against a neurotransmitter role for these two amino acids in the cerebellum. (Supported in part by NS 13925 and MH 00203).

7.11 ASPARTATE AS THE NEUROTRANSMITTER FOR THE PERFORANT PATHWAY OF THE HIPPOCAMPUS. A. Di Lauro* and J. L. Meek* (SPON: L. M. Neckers). Lab. Preclin. Pharmacol., NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

It has been reported that glutamate and/or aspartate could be the transmitter of the perforant pathway (PP), the pathway from the entorhinal cortex to the fascia dentata (FD) and to the hippocampus proper (Nadler et al., 1976, Nature 260:539). In order to determine the role of aminoacids in the PP we examined in the target areas of this pathway the changes in the concentration of various aminoacids (Tau, Gly, Ala, Glu, Asp, GABA) after unilateral entorhinal cortex lesion in rats.

At various survival time (1,3,7,15 days) after a radiofrequency lesion, the rats were killed by means of focused microwave irradiation. The hippocampus was excised from the lesioned side and from the contralateral side and the FD dissected. Aminoacids were separated on a cation exchanger by high pressure liquid chromatography and detected fluorimetrically. The lesion caused a decrease in the aspartate content of the homolateral FD. This decrease reached its maximum (70% of control; $P<0.001$) after three days; at longer survival times (7-15 days after the lesion) we observed a slow recovery toward control values. This recovery is probably due to the known sprouting process that starts early after this lesion (West et al., 1975, Brain Res. 97:215). In the contralateral FD and in the hippocampus proper we observed only slight variations in the aspartate concentration. We were unable to detect any significant difference between control and lesioned rats in Glu or in the other aminoacids tested. In order to determine whether this decrease of aspartate is presynaptic or postsynaptic we injected kainic acid in the hippocampus of 10 rats at a dose (0.75 μg) able to destroy granule cells; the following day half of rats received entorhinal cortex lesion while the remaining rats (KA alone) were used as controls. Three days after the PP lesion we observed a significant decrease in aspartate content of FD when compared to rats treated with KA alone. The decrease in FD aspartate after PP lesion was not, therefore, due to granule cells but to degenerating presynaptic terminals of PP. In conclusion though our experiments do not prove that aspartate is the neurotransmitter of the PP, they strongly support this hypothesis.

8.1 ELECTROGENESIS OF THE EVENT-RELATED SLOW POTENTIAL DETERMINED BY INTRACELLULAR RECORDING IN THE CONSCIOUS CAT BRAIN, G. L. King*, and J. E. Skinner.

Frontocortical neurons in the conscious cat brain manifest slow membrane potential and input resistance shifts in parallel with an extracellular event-related slow potential, all of which are evoked by a tone that forewarns a cutaneous shock. The biophysical responses of each cell were recorded with a new "floating-micropipette tip" technique that enabled intracellular impale ments to be maintained when the animal was presented the previous ly conditioned stimuli. Two classes of cells were recorded, those with large resting membrane potentials and action potentials that manifested overshoot of the extracellular zero potential (overshoot cells) and those with small resting potentials and small action potentials that did not overshoot the extracellular zero potential (undershoot-cells).These two classes of cells are easily distinguished by their resting input resistances and other cable properties. Both the cable properties and the location of inject ed dye suggest that the undershoot cell records are from dendritic impalements. Individual cells of both cell classes manifested different patterns of responses to the tone and to the shock. The predominant response patterns of the undershoot-cells were input resistance decreases accompanied by depolarizations (rD-re sponses) and input resistance increases accompanied by hyperpolar izations (RH-responses). One other group of undershoot-cells showed responses following the shock that were different from those following the tone (MM-responses). The overshoot cells showed similar response patterns, although no RH-responses were recorded. These input resistance and membrane potential responses of the cells were not correlated in time; they showed different latencies to onset and peak amplitude. Some cells of both class es were recorded for a long enough time to permit the recording of the responses of the cells to repeated conditioning trials. It was observed that the cell responses during the repeated trial were not always the same response as during the first trial.

All of these data have been interpreted to suggest that a neuronal mechanism underlies the electrogenesis of the event-related slow potential. Furthermore, the response patterns of these neurons, which manifest themselves only in the conscious state, may be the basis for a type of neural integration that is characteristic of information processing in a higher cerebral brain system.

8.2 TWO CLASSES OF SPONTANEOUS MINIATURE SYNAPTIC POTENTIALS IN CA3 HIPPOCAMPAL NEURONS. Thomas H. Brown and Daniel Johnston, Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010, and Department of Neurology, Baylor College of Medicine, Houston, TX 77030.

Spontaneous miniature synaptic potentials were recently detected in CA3 neurons of the hippocampus (Brown et al., Brain Res. 177, 194, 1979). In the present study, we have examined the amplitude and polarity of miniature potentials in these cells, at membrane potentials ranging from -150 to +50 mV, to address the following two questions: Can inhibitory miniature potentials be detected when the cells are depolarized? What is the approximate reversal potential of the excitatory miniature potentials?

Recordings were made in the in vitro slice preparation which was continuously perfused with oxygenated normal saline containing 1 μg/ml tetrodotoxin (TTX) and 2 mM $MnCl_2$. Current was injected and voltage recorded through a single micropipet using a 3 KHz time-share system. Pipets were filled with either 3 M KCl, 4 M KAc or 1 M $CsSO_4$. At membrane potentials between -150 and -50 mV, only depolarizing events were observed, their amplitudes being greater at more hyperpolarized potentials. In many cells, at about -40 mV, both hyperpolarizing and depolarizing events were present. At membrane potentials between -30 and 0 mV, the events were always hyperpolarizing. These hyperpolarizing events appeared to be spontaneous inhibitory miniature potentials, since they were abolished by adding to the bath putative inhibitory blockers (10 μM bicuculline, 10 μM picrotoxin, or 2 mM penicillin). With the blockers in the bath, the usual depolarizing events were still present at membrane potentials between -150 and -50 mV. In the presence of these agents, hyperpolarizing events were not observed unless the membrane was depolarized beyond +30 mV. The amplitude of these hyperpolarizing events increased as the cells were further depolarized. These events appeared to be reversed excitatory miniature potentials. Their apparent reversal potential was near 0 mV, but the value could not be determined accurately because the events could not be resolved above the background noise when the membrane was within ±30 mV of the estimated reversal potential. All of the above results were duplicated in parallel studies in which TTX and $MnCl_2$ were omitted from the bath. In these studies, the only apparent difference was that the synaptic events were larger, presumably because they consisted of both spontaneous and evoked release.

The ability to resolve both inhibitory and excitatory miniature potentials in these cells should be useful in neuropharmacological studies as well as in testing hypotheses concerning the mechanism of long-term potentiation in these cells. (Supported by NIH grants NS15772 and NS11535.)

8.3 REVERSAL POTENTIAL FOR EXCITATORY SYNAPTIC EVENTS IN HIPPOCAMPAL CA3 PYRAMIDAL NEURONS. D. Johnston, T. H. Brown, J. J. Hablitz and F. J. Lebeda. Dept. of Neurology, Baylor Coll. of Med., Houston, TX 77030 and Div. of Neurosciences, City of Hope Research Inst., Duarte CA 91010.

Reversing the direction of excitatory postsynaptic potentials (EPSPs) with an accurate measure of the membrane potential at the reversal point has proved a difficult task in mammalian CNS neurons. In this study we have attempted to demonstrate a reversal of mossy-fiber EPSPs in CA3 pyramidal neurons from in vitro hippocampal slices in order to address the following questions: Is the mossy-fiber EPSP entirely chemical in origin? If a reversal is obtained, what is the apparent reversal potential, and therefore what ions might be carrying the synaptic current? Are the synaptic endings electrically distributed on the postsynaptic neuron? Does concomitant inhibition play a role in the mossy-fiber EPSP?

Intracellular recordings were made using pipettes filled with 4M KAc or 2M Cs_2SO_4. Current and voltage clamping were performed using a single microelectrode system. Several procedures (including high Mg and low stimulus strengths) were used to reduce the recurrent inhibition obtained with mossy-fiber stimulation. The traditional recurrent IPSP was still occasionally present, but was distinguishable from the EPSP on the basis of a slower time course. However, the mossy-fiber EPSP was found to reverse direction completely at a single and very negative membrane potential (about -50 mV). Moreover, under voltage clamp conditions all reversal potentials and extrapolated reversal potentials of the inward current were only 10 to 30 mV depolarized from the resting potential. Since these reversal potentials seemed unreasonable for an EPSP, putative inhibitory blockers (10 μM bicuculline, 10 μM picrotoxin, or 2 mM penicillin) were added to the bath in an attempt to separate possible occult inhibitory components in the normal EPSP. With one of these agents in the bath, the mossy-fiber EPSP reversed direction completely at or near 0 mV. If the mossy-fiber terminals are electrotonically remote from the recording site, then this apparent reversal potential may be an overestimate of the true synaptic equilibrium potential.

The results suggest, however, that the mossy-fiber ending is a chemical synapse producing a conductance increase, that the terminals are not electrotonically distributed on the postsynaptic neuron, and that the normal EPSP is contaminated by a large occult inhibitory component of similar time course. The data suggest also that a measured reversal potential is a better test of a pure EPSP than the separation of events on the basis of time course. (Supported by NIH Grants NS15772, NS11535 and the Epilepsy Foundation of America.)

8.4 SPONTANEOUS IPSPs IN HIPPOCAMPAL PYRAMIDAL CELLS. R. A. Nicoll and B. E. Alger, Depts. of Pharmacology and Physiology, Univ. of Calif., San Francisco, CA 94143.

In CA1 pyramidal cells of rat in vitro hippocampal slices, intracellular recording with 3 M KCl-filled electrodes reveals many small (1 - 10 mV) spontaneous depolarizing potentials on the baseline. These potentials vary in frequency from one to about 20 Hz and appear to be chloride (Cl^-) dependent, as they are not seen in CA1 cells with electrodes filled with potassium salts of impermeant anions. Since Cl^- dependence is a property of hippocampal inhibitory post-synaptic potentials (IPSPs), and not EPSPs, we have considered the hypothesis that these small depolarizations are spontaneous, reversed IPSPs.

Because the major hippocampal inhibitory transmitter is probably γ-aminobutyric acid (GABA) we have tested the sensitivity of these spontaneous depolarizations to various drugs known to affect GABA-mediated events. Experiments were done on single cells (24) impaled with KCl electrodes in a normal bathing medium and then switched, while the impalement was held, to different experimental media. GABA antagonists bicuculline, picrotoxin and penicillin abolish the spontaneous events. Excitatory transmission is not blocked with these drugs. When GABA antagonists are applied to cells recorded with KCl electrodes the membrane hyperpolarizes and the input impedance increases, as expected when a spontaneous inhibitory input is blocked. Pentobarbital, an anesthetic which in low doses (10^{-4} M) has a very selective effect of enhancing GABA-mediated events, markedly prolongs the spontaneous depolarizations. Pentobarbital has a depressant effect, if any, on EPSPs. From their Cl^- dependence and responses to drugs which affect both GABA actions and synaptic inhibition, we conclude that the small spontaneous depolarizations are reversed, GABA-mediated IPSPs.

Spontaneous IPSPs are also blocked by tetrodotoxin and calcium antagonists. Since true "quantal" release processes are ordinarily immune to such treatment, it appears that "spontaneous" IPSPs in CA1 pyramidal cells are actually activity-dependent, and result from spontaneous firing of inhibitory interneurons. Consistent with this interpretation is the finding that analysis of the distribution of these potentials does not agree with predictions based on a random release process.

Besides its intrinsic interest, study of spontanous IPSPs has practical usefulness for investigating modulation of inhibitory synaptic transmission. For example, we have recently found that these small spontaneous IPSPs and the evoked IPSP are blocked by the opiate peptide d-ala^2-met^5-enkephalinamide. Since responses to iontophoretically applied GABA are not blocked by enkephalin, we conclude that the site of IPSP blockade by enkephalin must be presynaptic on the inhibitory interneurons.

8.5 INHIBITORY ACTION OF GABA IN RAT HIPPOCAMPUS. K. Krnjević, Y. Ben-Ari and W. Reinhardt*. Anaesthesia Research and Physiology Depts., McGill University, Montreal, Canada H3G 1Y6.

Although there is plenty of evidence from extracellular studies that GABA inhibits hippocampal cells and that it is probably synthesized in (and released from) inhibitory interneurons such as basket cells (Storm-Mathisen, Prog.Neurobiol. 8, 119, 1977), there has been no systematic comparison between IPSPs and the effects of GABA.

In rats under urethane, we have recorded intracellularly from cells in the CA1 and CA3 area, usually with KCl (but also some K citrate) -containing microelectrodes. IPSPs were evoked by stereotactic stimulation of the ipsilateral fimbria or entorhinal cortex. GABA and other agents were tested by microiontophoretic release from a second, closely adjacent extracellular microelectrode. In addition to the membrane potential and IPSPs, we also monitored continually the neurons' input resistance at "rest" and during IPSPs, by injecting regularly repeated series of known current pulses through the recording electrode.

In spite of quite variable conditions of intracellular recording, in most cases a marked conductance increase was readily detected near the peak of IPSPs (mean of +155% for 84 different cells) evoked by 10 V, 0.5 ms stimulating pulses. In a selected group of 11 cells, having resting potentials of at least -55 mV (mean -65.0), the mean input resistance was 10.3 MΩ and the mean fall in resistance near the peak of the IPSP -72.7%. There was no significant difference in time course or in reversal potential between IPSPs evoked by entorhinal or fimbrial stimulation. Iontophoretic applications of GABA (mean dose 108 nA) caused a large increase in conductance (mean +245%, for $n = 55$), as well as a change in potential that followed the direction of IPSPs. Indeed, a comparison of the calculated IPSP reversal potential (E_i) for the period immediately preceding the release of GABA and the reversal potential for the maximum potential change evoked by GABA (E_G) revealed a very high positive correlation ($r = 0.893$, for $n = 44$) and a mean difference between corresponding values of E_i and E_G of only 0.78 mV (SE = 1.25, for $n = 44$). By contrast glycine was almost totally ineffective in evoking either inhibition of unit firing or any significant conductance increase. As in the cerebral cortex and elsewhere, the action of GABA showed a pronounced "fading", the conductance increase diminishing within a few seconds to a sharply lower plateau. This change was often associated with a parallel diminution in the conductance increase that accompanies EPSPs. These effects of GABA are fully in keeping with its probable role as the transmitter responsible for the most prominent IPSPs observed in the hippocampus.

8.6 INCREASE IN MUSCARINIC BINDING SITES AT PRIMARY AND SECONDARY FOCI AFTER HIPPOCAMPAL KINDLING. F. Morrell, A. Hitri*, T. J. Hoeppner*, D. Bergen*, E. Kessler*, and S. Fleming*. Dept. of Neurological Sciences, Rush Medical College, Chicago, Il 60612.

Male Sprague-Dawley rats were implanted with stimulating electrodes in the left perforant path and recording electrodes in right and left CA_3 region of the hippocampus. Animals were stimulated twice daily with 60 Hz for 2 sec at a current which produced a brief after-discharge (6-12 sec). Stimulation was continued until the development of generalized seizures. Animals were sacrificed 18 hrs. after the last convulsion, the brain quickly removed, rapidly frozen and the hippocampi dissected out at 4°C. Muscarinic cholinergic receptors were measured with a radioligand binding assay using tritium labeled quinuclidinyl benzilate (QNB) according to the method of Yamamura and Snyder (Proc. Natl. Acad. Sci. 71:1725-1729, 1974). Specific binding was defined as the difference in total QNB binding obtained in the absence and presence of 1 μM atropine. Results indicated more than two-fold increase on the stimulated and more than three-fold increase on the unstimulated side compared to the intact controls. Both of these differences were significant ($p < 0.01$). There were no significant differences in the dissociation constants; thus, no change in receptor affinity was demonstrated.

Our findings imply that hippocampal kindling may depend upon an increase in muscarinic cholinergic receptors. These observations are consistent with the iontophoretic studies of Burchfiel et al. (Science 204:1096-1098, 1979) and with the chemical stimulation experiments of Wasterlain et al. (Neurology 28: 346, 1978) both of which also imply an augmentation of muscarinic cholinergic responsiveness in kindling. Differences between these data and the report of McNamara (Brain Res. 154: 415-420, 1978) may reflect the substantial variations in both the kindling technique and the method of measuring QNB binding.

8.7 THE EPILEPTIFORM BURST DISCHARGE IS ASSOCIATED WITH A CALCIUM-DEPENDENT AFTERHYPERPOLARIZATION. B. E. Alger and R. A. Nicoll, Depts. of Pharmacology and Physiology, Univ. of Calif., San Francisco, CA 94143.

Intracellular recording from cells in experimentally produced epileptic foci reveals an interictal spike ("burst") potential and an afterhyperpolarization (AHP). We have found the burst and AHP are produced by synaptic activation of pyramidal cells in rat in vitro hippocampal slices during blockade of synaptic inhibition by γ-aminobutyric acid (GABA) antagonists picrotoxin and bicuculline, in concentrations which block responses to iontophoretically applied GABA. GABA is the major hippocampal inhibitory transmitter candidate. The synaptically evoked AHP is 8.6 ± 3.4 mV in amplitude and lasts 2.9 ± 1.2 sec ($n = 16$); it is associated with a conductance increase of 36 ± 12 %, and is functionally inhibitory. Previous work has suggested the interictal spike AHP is either an unusual form of inhibitory post-synaptic potential (IPSP) or a calcium (Ca)-dependent potassium potential. However, there is as yet little direct evidence on this point. Our data favor the latter hypothesis.

In our experiments the AHP usually appears as an all-or-none potential following an epileptiform burst. In addition we find the AHP is independent of chloride (Cl^-) movements, as it can be elicited in cells in which the Cl^- gradient has been reversed. These properties are not expected of IPSPs. Indeed we have compared the synaptically activated AHP (AHP_s) seen with GABA antagonists, with the AHP which follows a train of action potentials produced by direct depolarizing current injection into a cell (AHP_d). The AHP_d has been shown by Hotson and Prince (1980) to be an intrinsic, Ca-dependent potential. We have found both AHP_s and AHP_d are similarly depressed by barium, which is known to depress Ca-dependent potassium potentials in several other systems. Finally, in many cases we have been able to reverse both AHP_s and AHP_d by hyperpolarizing the membrane potential. Both potentials reverse at about -86 mV. These reversal potentials are, moreover, dependent on the extracellular potassium concentration $[K^+]_o$, there being a -50 mV shift in reversal potential per decade change in $[K^+]_o$. This is very close to the -60 mV shift predicted by the Nernst equation for a purely potassium dependent potential.

Our evidence therefore supports the hypothesis that the AHP associated with a synaptically elicited epileptiform discharge in the presence of GABA antagonists is a Ca-dependent potassium potential. This demonstration has direct implications for understanding the neurophysiology of epilepsy.

8.8 EGTA REDUCES THE AFTERHYPERPOLARIZATION (AHP) FOLLOWING CURRENT-INDUCED AND SPONTANEOUS BURSTING BUT NOT AFTER EPILEPTIFORM DISCHARGES IN HIPPOCAMPAL NEURONS. C. E. Stafstrom and P. A. Schwartzkroin. Depts. of Physiol. & Biophysics, and of Neurol. Surgery, Univ. of Wash. School of Medicine, Seattle, WA 98195.

Calcium has been shown to increase membrane conductance to potassium ions and to activate a long-lasting hyperpolarization in both vertebrate and invertebrate neurons. This Ca^{++}-mediated K^+ flux may serve to limit prolonged depolarization. The present experiments, employing intracellular injection of EGTA, investigate the role of Ca^{++} in this conductance mechanism in vertebrate cortical neurons. Transverse slices of guinea pig hippocampus (400 μm) were maintained in vitro using standard techniques. Control recordings were made using 4M K-acetate electrodes. Pyramidal cells from the CA3 region exhibited spontaneous bursting behavior consisting of 2-20 spikes riding on a slow wave of depolarization; similar burst discharges could be elicited by current injection. Membrane conductance increased during the AHP following both types of bursts as well as during IPSPs.

When impaled with 0.2M K-EGTA electrodes, CA3 pyramidal cells showed prolonged discharges with broader spikes both spontaneously and in response to a depolarizing current pulse. These effects were presumably due to the chelation of free Ca^{++} by the diffusing EGTA. The AHP after both bursts was reduced, and the conductance change under both conditions was decreased. The prolonged bursting in CA3 cells could be reset with a hyperpolarizing pulse. Conductance during the IPSP did not differ from the control penetration using K-acetate electrodes.

Addition of 2mM Na-penicillin to the bathing medium led to spontaneous epileptiform bursting. These bursts could be distinguished from spontaneous or EGTA-bursts on the basis of their rhythmicity (the same as that of epileptiform field potentials), and their resistance to blockage with hyperpolarizing current. The AHP following epileptic bursts was not affected by EGTA, and the conductance increase was maintained. These results are inconsistent with the hypothesis that AHPs following epileptiform bursts are mediated by the same mechanisms as those following spontaneous or current-induced bursts.

8.9 SPONTANEOUS EPILEPTIFORM DISCHARGES AND CLINICAL SEIZURES OCCUR EARLY IN HIPPOCAMPAL KINDLING. L. deToledo-Morrell* and F. Morrell (SPON: M. M. Cohen). Dept. of Neurological Sciences, Rush Medical College, Chicago, IL 60612.

Three and twenty-seven mos. old Fisher 344 strain rats were subjected to hippocampal kindling as part of a project concerned with alterations in neuronal plasticity during ageing. Stimulating electrodes were placed in the perforant path and recording electrodes in the ipsilateral dentate gyrus and on the cortical surface bilaterally. Depth electrode placement was accomplished using stereotaxic coordinates initially and then correcting until single pulse stimulation of the perforant path yielded a "population spike" (Lømo, Exp. Brain Res., 12: 18-45, 1971) of dentate gyrus granule cells. Animals were kindled with either once daily or twice daily stimulations with parameters (60 Hz, 2 sec.) and current levels sufficient for production of an after-discharge (AD) under 10 sec. In addition to the usual augmentation of AD duration, we observed the development of spontaneous epileptiform potentials arising primarily in the dentate electrode and unaccompanied by clinical signs. Such observations confirm the findings of many other workers.

We now report a further, previously undescribed phenomenon. Beginning usually after the seventh stimulation, often after a delay of ten or more min. following the AD, electrographic seizures were seen having an origin in the region of pyriform or entorhinal cortex. Within 2-3days, these electrical discharges were associated with clinical attacks which usually consisted of behavioral arrest, rhythmic head shaking, and clonic jaw movement. The electrographic seizure grew in frequency and duration as stimulations continued. Eventually, these discharges occurred throughout the day, were unrelated to stimulation times, and were often seen prior to the first stimulation of the day. All the criteria of true spontaneous epilepsy were fulfilled. Records obtained simultaneously from the stimulating electrodes revealed frequent triggering by cortical ictal spikes. The time relationships were such as to raise the possibility that antidromic activation of cortical neurons may play a role in this form of epileptogenesis.

8.10 Are the Epileptogenic Effects of γ-Hydroxybutyrate Secondary to its Dopaminergic Actions? O. Carter Snead, III. Dept. Pediatrics and The Neuroscience Program, Univ. Alabama in Birmingham Sch. Med. B'ham.

γ-hydroxybutyrate (GHB) is a naturally occurring substance which produces profound EEG and behavioral changes as well as elevation of striatal dopamine when administered to animals. The evidence for a cause-effect relationship between the dopaminergic and the EEG and behavioral actions of GHB is contradictory (Snead, Neurology 28:1179, 1973). The GHB-induced EEG changes represent a model for petit mal epilepsy, hence such a cause-effect relationship would have important ramifications for this disorder.

Using γ-butyrolactone (GBL) the pro-drug of GHB, we investigated the relationship of the dopaminergic to the EEG effects of this compound in a number of ways. Rats were implanted with permanent epidural cortical electrodes to permit recording of the electroencephalogram (EEG), which was quantitated by a computerized frequency analysis system. A flurometric assay was used to determine striatal dopamine concentration. Dose response curves for the dopaminergic and EEG effects of GBL were compared as was the time course of each action of the drug. Animals were also sacrificed at various time points during evolution of specific changes induced in the EEG by GBL and striatal dopamine determined. In addition the effect of ethosuximide, trimethadione, and sodium valproate, drugs known to abort GHB-induced EEG abnormalities (Snead et al, Neuropharmacology 19:47, 1980), on the GBL-induced elevation of striatal dopamine was determined.

The GBL-induced EEG changes occurred at lower doses, had an earlier onset and lasted longer than the GBL-induced elevation in striatal dopamine concentration. There were marked sequential changes in EEG and behavior in the face of normal striatal dopamine concentrations in animals administered 400 mg/kg GBL. Ethsuximide, sodium valproate and trimethadione were all effective in aborting or decreasing the rise in striatal dopamine concentration produced by GBL. We conclude that the elevation in brain dopamine produced by GBL is not responsible for the EEG or behavioral effects seen with this substance.

8.11 EXTRACELLULAR SEROTONIN INHIBITS ELECTRICALLY STIMULATED SEROTONIN RELEASE FROM MOUSE CEREBELLUM SLICES. H.R. Figueroa*, P.B. Yurgens* and T.R. Hall*. (SPON: D. Czech). Dept. of Biology, Marquette University, Milwaukee, WI 53233.

Mouse cerebellum slices, preincubated with ^{3}H-5 hydroxytryptamine (5HT, serotonin), were superfused in a lucite chamber with a physiological solution of Krebs-Ringer-Phosphate (KRP) at a flow rate of 4 ml/min. Fractions of 1 or 4 min of the superfusate were collected throughout the whole experiment. After the first 22 minutes of superfusion the slices received a first electrical stimulus (S_1) with square monophasic pulses of 2 ms duration, 50 HZ and 100mA, for 1 minute. After S_1 the slices were superfused for a further 22 minutes with either KRP alone or with KRP containing 1 μM 5HT, 1 μM 5HT plus 20 μM Methysergide or 1 μM 5HT plus 10 μM Methiothepin. Then the slices received a second stimulus S_2 identical to S_1. At the end of the superfusion the slices were solubilized and the radioactivity in the slices and superfusate samples was determined by liquid scintillation counting. Fractional ^{3}H release was calculated for S_1 and S_2. S_2/S_1 fractional release ratio was found to decrease significantly ($p<.001$) in the presence of 1 μM extracellular 5HT, with respect to the control group. The presence of 20 μM methysergide did not alter the effect of 1 μM 5HT on tritium release. However the simultaneous administration of 10 μM Methiothepin antagonized the inhibitory effect of 5HT, ($p<0.05$). A first order kinetic analysis of basal tritium efflux from slices showed that the efflux rate constant was significantly more negative ($p<0.02$) during the superfusion with 1 μM 5HT compared with that obtained with KRP alone, indicating that extracellular 5HT increases the basal, unstimulated cellular 5HT efflux. These results suggest that 5HT modulates its own release from central serotoninergic neurons via a negative feedback mechanism, probably mediated through the activation of presynaptic 5HT autoreceptors.

8.12 NERVE FIBER DEGENERATION IN THE BRAIN OF RATS FOLLOWING A SINGLE CEREBRAL CONCUSSION. L. C. Parsons, M. Skinner*, B. Fitzgerald*, and M. Guthrie. Physiology Lab., Univ. of Va., School(s) of Nursing and Medicine, Charlottesville, VA 22903.

Adult laboratory rats of both sexes, between the ages of 40 and 75 days and weighing between 235 and 375g. were used for the purpose of initiating an acceleration cerebral concussion (ACC). Single measured blows varying between 26 and 40 PSI were delivered to the reinforced calvarium of each rat by use of a calibrated, rigidly fixed spring coil concussion gun. The severity and duration of each ACC were measured using the behavioral manifestations of length of convulsive seizure(s), loss of corneal reflex and loss of voluntary motor reflexes as criteria. These data were then correlated with morphological changes as demonstrated through use of the silver staining technique of Fink-Heimer II, a method used to show nerve fiber and terminal degeneration in the cerebrum, cerebellum and brainstem. The extent of whole brain injury as analyzed in a rostral to caudal manner provided evidence and verification for three sites of injury resulting from a single ACC. Nerve fiber and terminal degeneration were closely correlated with injuries likely to have been received at coup, contrecoup and craniocervical junctional sites in this rat model. The extent of nerve fiber degeneration associated with coup injuries involved structures of the corticospinal tract, and intrinsic nerve fibers of the cerebellum, while injury at the contrecoup site showed nerve fiber degeneration in the optic nerve pathways and selected forebrain structures. Widespread nerve fiber degeneration was shown in fiber tracts traversing the medullary, pontine and mesencephalic brainstem and suggested an injury occurring at the craniocervical junction which resulted from the rapid and extreme flexion of the neck as a consequence of the ACC. The severity and duration of the ACC were correlated positively with the extent of injury as measured by number of neuroanatomical structures showing nerve fiber and terminal degeneration.

8.13 HIPPOCAMPAL POTENTIATION IN VITRO: EFFECTS OF HIGH Mg-LOW Ca MEDIA AND OF DURATION OF INCUBATION. Philip W. Landfield, Dept. Physiol. Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103

Substantial data indicate that facilitation (potentiation) in peripheral systems is due to increased transmitter release, and depression to transmitter depletion. Elevating the extracellular $(Mg^{++})/(Ca^{++})$ ratio can increase facilitation during or after repetitive stimulation (stim.) by retarding transmitter depletion. Ca^{++} appears necessary both for facilitation in peripheral systems and for hippocampal long-term potentiation (LTP). However, it has been questioned whether hippocampal frequency potentiation (FP) and LTP depend on mechanisms similar to those in the periphery. This study examines whether Mg/Ca balance affects hippocampal potentiation in a manner analogous to its effects on peripheral facilitation. Data from 37 hippocampal slices from young-mature rats are described for CA1 population spike amplitudes during and after stimulation of stratum radiatum afferents. Slices were simultaneously incubated in 2 recording chambers containing either "normal" medium (Mg/Ca ratio of 1.3/2.4 (mM)) or high Mg/Ca ratio media (ranging from 2.7/1.0 to 4.0/2.4 (mM); osmotic balance maintained by altering NaCl). Paradigms for each slice were as follows: Continuous stim. at 6 Hz for 4 min (FP); 100 Hz stim. for 5 sec; 0.2 Hz stim. for 15 min (LTP assessment); 6 Hz stim. for 4 min. During 6 Hz stim. spike amplitude was measured every 15 sec. In slices studied 1-3 hrs after cutting, high Mg/Ca ratios moderately increased the percent of FP and sometimes of LTP, in comparison to slices from the same animal in normal medium. Threshold was elevated and control responses at 125% of threshold were reduced, so that absolute FP or LTP were not increased. LTP was sometimes completely blocked. However, in many slices incubated in elevated Mg and low Ca for 4 hr or more, striking increases in FP and LTP were seen (in comparison to normal medium slices), both in terms of absolute (e.g., 6-10 mV vs 2-3 mV) and percentage (e.g., 400-500% vs 50-100%) values. Persistence of FP was also increased. Fiber spike potentials were largely unchanged. Field EPSPs are still under study. Incubation for 4-6 hrs in all media lowered thresholds and increased control spike amplitudes, but this effect was not correlated with enhanced potentiation.

Dependence of the effect of elevated Mg/Ca ratios on duration of incubation may be due to several factors, including the intracellular accumulation of transmitter or of a minimum Ca level. Nevertheless, dramatic absolute value increases in potentiation were induced by an ionic manipulation which presumably increases transmitter stores. This suggests that enhanced transmitter release is an important, but not necessarily exclusive, factor in both FP and LTP in hippocampus. (Supported by AG01737).

9.1 SACCADES SERVE AS MARKERS FOR VISUAL INFORMATION. C.Torda
Res.Dpt.,N.Y.Center for PA Training, N.Y.,N.Y.,1028

Visual stimuli activate specific tunable photoreceptors located in the retina. Through automatically ongoing parallel processing the photic energy is transformed to spatial frequency codes. Coding is a gradual process whereby the chunks of photic information are substituted by parsimonious and efficient representations that permit to eliminate redundancies. During the passage from retina to higher CNS centers, the visual information undergoes repeated phase-coding (an analytical process) performed through generation of graded slow potentials. The prime function of the dendritic trees is weighted summation in the wave mode. The waves generate pulses at the dendritic and/or somatic trigger zones. The neuron is an unidirectional integrator and transmitter.It transmits the pulses to higher CNS centers where further analysis and synthesis occur under the organizing influence of decision making control systems and regulators (i.e. the hippocampus) before the information becomes part of the long-term memory system.--Concurrently with this coding process the visual stimuli also initiate a saccade (rapid eye movement) with a few msec delay. This saccadic system is a sampled data positional servomechanism. The activity necessary to produce saccades is coded in the firing rates of phasic units located in the rostral zone of the paramedian pontine reticular formation(PPRF). By integration of the phasic pulses from the PPRF,the periabducens neurons generate the tonic component of the saccades.

The here presented research addressed the possibility that the saccades contain a stimulus specific marker system that serves to facilitate allocation of the codes of the original visual stimulus during the process of coding, transformation, elaboration,storage and recall.Saccades seem to be excellently suited to serve as markers:(1) they are generated concurrently with the onset of the visual process;(2)the codes for saccades are simpler and the process is faster;(3)because of simplicity and speed they are suited fortracing and allocating codes; (4)the dual type of processing and transmission to higher CNS centers has already been demonstrated for the rapid eye movement contained in the PGO waves(Torda,Int.J.Neurosciences, 9:455 & 10:230,1979;Psychobiology of Memory & Dreams,Walters,1980). Bioelectric processes were extra-and intracellularly recorded from cat and rat from the rostral PPRF,the III & VI nuclei, the hippocampus,the visual-and infratemporal cortices.A technique has been developped that permits statistically valid comparison of the recall of a specifically designed visual stimulus. Comparison of results obtained from sham-operated animals and those with surgically and/or chemically eliminated rostral PPRF zone led to the conclusion that the saccade contains a marker of the original visual stimulus. In absence of this marker storage and recall is significantly delayed and is defective. By application of some lateralization techniques,human clinical data were obtained that supported the conslusions.

9.3 PULSE WIDTH NOT PULSE HEIGHT ERRORS CAUSE GLISSADES. A. Terry Bahill. Department of Electrical Engineering, Carnegie-Mellon University, Pittsburgh, PA 15213.

Saccadic eye movements with glissadic overshoot can be simulated by increasing either the pulse width (PW), or the pulse height (PH) of the motoneuronal controller signal. However, increasing the pulse height increases the peak velocity, whereas, increasing the pulse width does not. Human saccadic eye movements with glissadic overshoot have normal or less than normal peak velocities, suggesting that glissadic overshoots are caused by pulse width errors (Bahill, Hsu, and Stark 1978).

Our sensitivity analysis explains why this is so by showing that eye position is not sensitive to pulse width variations until near the end of the saccade, after the point of peak velocity. So, pulse width changes affect the size of the saccade, but not its peak velocity. On the other hand, eye position is sensitive to pulse height variations throughout the saccade. Therefore, pulse height changes do affect the peak velocity.

Our function minimization programs show that there must be variations in the pulse width rather than in pulse height in order to minimize the mean squared error between human and model saccadic eye movements with glissadic undershoot or glissadic overshoot. This was true for normal subjects as well as for patients with multiple sclerosis. When the parameter estimation routine was allowed to vary the pulse width and the pulse height, the only two physiological parameters that are likely to change between saccades, the best fit for a typical movement with glissadic undershoot, was obtained by decreasing the pulse width 16% below its nominal value while decreasing the pulse height 2.5% below its nominal value. Making these changes from the nominal values reduced the mean squared error by a factor of ten. When the estimation program was allowed to vary pulse width, pulse height and the four time constants, the mean squared error decreased by only 3%.

This means that the central nervous system makes more pulse width errors than pulse height errors. It must be harder to control the duration of a motoneuronal burst than the firing frequency and number of motoneurons recruited.

9.2 SACCADIC EYE MOVEMENT CHARACTERISTICS - AN AUTOMATED, LARGE DATABASE STUDY. L. A. ABEL* and B. TODD TROOST. Neurol. Control Systems Lab., Univ. Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

Most studies of the characteristics of normal human saccadic eye movements, have been performed on relatively restricted groups (1 - 25 subjects), have taken limited data from each subject (< 100 refixations), or have neglected the effects of age (subjects < 50). The present report describes the use of a microcomputer-based system for real time stimulus presentation and data collection. Large amounts of eye movement information can be immediately analyzed with results graphically displayed. We have attempted to cover a broad age range to delineate normal saccadic characteristics for the general population.

Fifty normal subjects ranging in age from 18 to 75 years viewed an array of light-emitting diodes driven by Digital Equipment Corp. MINC laboratory computer. Saccades of 3 deg to 30 deg were elicited by programmed LED switching. Target amplitude and direction were randomized to minimize anticipation. A total of 280 saccades were obtained from each subject. Eye movements were recorded using infrared reflectance with a vertical EOG channel to detect eye blinks. The two eye movement position channels and the blink trace were digitized at 200 Hz; if a blink occurred during the saccade, it was not stored and the trial was automatically repeated. Verbal encouragement was used to maintain subject alertness and the analog records were visually monitored for signs or fatigue or loss of calibration in which case the data was rejected. Thus, only noncontaminated data was stored for analysis. The entire process, including calibration, took less than 30 minutes per subject.

Data were stored on floppy disk and analyzed off-line by the microprocessor. Saccadic amplitude, velocity, duration, and latency for each eye in both horizontal directions were calculated and stored in disk files for each subject. This enabled us to plot results for individual subjects and to produce cumulative results for each age cohort and for the overall population. The relationship between saccadic amplitude and velocity showed considerable intersubject variability, even within a given age group. Intrasubject variability followed characteristic patterns for individual subjects: some showed little data scatter, others much more. Repeat trials with several subjects showed these characteristics to be reproducible. Results shown include examples of individual subject's saccadic characteristics and the cumulative results for different age cohorts. The study is continuing for further definition of normal characteristics.

9.4 THE VELOCITY OF SACCADIC EYE MOVEMENTS IN REM SLEEP AND THE AWAKE STATE. John H. Herman, Howard P. Roffwarg, Dept. of Psychiatry, David R. Barker*, Medical Computing, Southwestern Medical School, University of Texas Health Science Center, Dallas, Texas 75235.

The characteristics of saccadic eye movements have been reported to be vastly different in REM sleep as compared to the awake state in terms of velocity (Fuchs and Ron, 1968), patterning (Aserinsky, 1971), and prevalence of rotatory or oblique components (Jacobs, Feldman, and Bender, 1971). None of these reports included optimal awake state controls for REM sleep eye movements.

We studied the properties of saccades in three subjects in an auditory orienting task under the following conditions: (1) normal lighting, eyes open; (2) total darkness, eyes open; and (3) total darkness, eyes closed. These conditions were performed both when the head was free and when it was rigidly immobilized. Condition order was counterbalanced. Eye movements during awake state reenactments of dream scenes were compared to REM state saccadic activity. On-line computer analysis of horizontal electroculographic (EOG) signals, utilizing a 5-msec sampling rate and a visually validated 8-sample algorithm, provided peak velocity-amplitude relationships. Calibrations of the EOG were performed in the light and in the dark to permit compensation for the changing amplitude of the corneo-retinal potential.

Analysis of variance of the equality of slopes demonstrated that awake state eye movements in normal lighting were of a significantly greater velocity than those of similar amplitude performed with eyes open in the dark. Saccades in the dark with eyes open were, in turn, significantly more rapid than those executed awake with eyes closed. Head restraint increased all velocities. The velocity of REM sleep saccades was not significantly different from awake state, closed eye saccades, though their variability was significantly greater. Slow, rolling, oscillatory changes in eye position were continually present in REM sleep, but were observed only infrequently in head unrestrained, awake state conditions. The so-called "torsional" and oblique eye movements seen in REM sleep were observed in the awake state when the head was unrestrained. Visual reenactment of shifts of gaze in REM sleep dream scenes, while the subjects lay recumbent with eyes closed, yielded eye movement patterns that were similar to the REM sleep EOG.

The attenuated velocity of saccades in the absence of a visual target indicates that actual visual factors play an important role in oculomotor control. Secondly, the serial decrement whereby the velocities of waking eye movements, when eyes are closed, become similar to those of REM sleep suggests that the physical characteristics of the closed eyelid, or its effect upon neuromuscular mechanisms, plays a more important role in affecting saccadic velocities than does state of consciousness.

9.5 CEREBELLAR MODULATION OF AN INTRINSIC SACCADIC COUPLER DURING VISUAL FIXATION. J. R. Hotson, M.D. Department of Neurology, Stanford Univ. Sch. of Med., Palo Alto, CA 95070.

During visual fixation on a small target it is well known that small saccades and slow drift eye movements occur continuously. These fixation eye movements are often smaller than 10 min arc. Recently it has been shown in normal subjects that horizontal, but not vertical, fixation saccades larger than 10 to 15 min arc may couple spontaneously and form square waves or saccadic oscillations (J. Hotson, Neurosci. Abstr. #1249, 1979). The mean duration between these coupled saccades is less than 200 msec and can be as brief as 50 msec. Horizontially coupled saccades with no intersaccade interval also occur in normal subjects and are called flutter movements.

These observations led to the proposal that an intrinsic saccade coupling mechanism functions in normal subjects during visual fixation and that it is activated by particularly large fixation saccades. Therefore if a disorder of supranuclear oculomotor control systems, such as the cerebellum, causes an enlargement of fixation saccades, it should also increase the frequency of saccade coupling. To test this postulate fixation eye movements as small as 1 min arc were recorded with a purkinje image eyetracker in four human subjects with pan-cerebellar disorders and compared to control subjects.

In subjects with cerebellar disorders the mean amplitude of fixation saccades and velocity of slow drift was significantly increased ($p<0.008$) compared to control subjects. However the frequency of horizontal, but not vertical, fixation saccades was less ($p<0.03$) in the cerebellar group. In contrast, both the amplitude ($p<0.009$) and frequency ($p<0.04$) of square waves and the frequency of saccadic oscillation ($p<0.04$) were increased in cerebellar subjects when compared to controls. Vertical square waves and saccadic oscillations did not occur in cerebellar subjects and flutter movements did not happen with greater frequency.

These results indicate that disorders of the cerebellum may limit the ability to reduce the size of fixation saccades below 10 min arc and thereby increase the activation of a horizontal saccade coupler. A decreased frequency of uncoupled saccades and an increased frequency of square waves and saccadic oscillations results. The frequency of flutter, however, was not increased by the loss of cerebellar control. Flutter eye movements, therefore, appear to be activated by a different mechanism than square waves.

9.6 DISCHARGE OF SUBSTANTIA NIGRA NEURONS DECREASES BEFORE VISUALLY-GUIDED SACCADES. O. Hikosaka* and R. H. Wurtz. Lab. of Sensorimotor Research, NEI, NIH, Bethesda, MD 20205.

Recent anatomical evidence has shown that the pars reticulata of the substantia nigra projects to the layers of the superior colliculus where cells discharge before saccadic eye movements. In order to determine the relation of pars reticulata neurons to the initiation of saccadic eye movements, we recorded the discharge of single cells as rhesus monkeys made saccades to visual targets. The location of cells was histologically verified.

Pars reticulata neurons had a steady rapid discharge rate usually averaging between 40 and 100 spikes per second. We found at least two types of cells related to saccades both of which decreased their discharge rate before onset of saccades.

In the first type of cell, a decrease in the discharge rate occurred in closer temporal relation to the onset of the saccade than to the onset of the visual target. The discharge rate usually decreased about 100 msec before and continued for 100 msec after a saccade. These cells have limited movement fields with the most pronounced decrease in activity usually associated with saccades to the contralateral visual field.

The second type of cell showed a decrease in discharge rate better correlated to the onset of the visual target than the saccade. They showed a decrease in discharge rate to the spot of light even when the monkey did not make a saccade to the target. These cells have visual receptive fields usually also primarily on the contralateral side and have a latency of 70-140 msec.

Some of these visual cells showed a more pronounced suppression of their discharge rate when the visual stimulus was the target for a saccadic eye movement. This enhancement effect has been reported for cells in superior colliculus and frontal eye fields, but these pars reticulata neurons showed a modulation not seen in other structures: when the monkey made a saccade to a target outside of the visual receptive field, the suppression effect of the stimulus in the receptive field was reduced.

The anatomical connections and temporal relation of cell discharge to saccades suggest that some cells in pars reticulata of the substantia nigra are possible precursors of the saccade-related cells in the superior colliculus and are involved in the initiation of visually-guided saccadic eye movements.

9.7 INFORMATION IN THE MESENCEPHALIC RETICULAR FORMATION (MRF) RESPONSIBLE FOR HORIZONTAL VISUALLY GUIDED OR VISUALLY INDUCED RAPID EYE MOVEMENTS. V. Matsuo*, B. Cohen, T. Raphan, J. Fradin* and D. Dennett*. Dept. of Neurology, Mount Sinai School of Medicine, CUNY, New York, New York 10029.

The MRF appears to be an important region for processing activity that originates in the visual system and reaches the paramedian zone of the pontine reticular formation (PPRF) to induce horizontal saccades and quick phases of nystagmus. Microstimulation of the MRF in alert monkeys elicited only rapid eye movements. This indicates that this region is associated with production of saccades and quick phases of nystagmus, not slow phases or pursuit movements. If stimulating currents and frequencies were above threshold (8-10 μA and 100-125 Hz), the size of the induced eye movements was dependent only on the region of the MRF that was stimulated. Fixed-amplitude saccades were elicited from dorsal portions of the MRF. Deeper in the MRF saccades or quick phases were evoked whose size depended on initial eye position, being larger from positions on the side of stimulation. At dorsal loci, a constant number of pulses was required to trigger saccades, causing the latency of the induced movements to be longer at lower frequencies of stimulation. Stimulation at frequencies below threshold affected the excitability of the mechanism that generated rapid eye movements in the PPRF. OKN quick phases were either facilitated or suppressed by MRF stimulation, depending on the direction of the quick phases. The frequencies necessary for quick phase suppression increased with slow phase velocity. This indicates that there are neurons in the MRF whose activity is related to the velocity of the eyes during slow phases. The data suggest that neurons in the MRF act to trigger saccade generating networks in the pons. Above threshold the amplitude of the rapid movements that are induced is dependent on the region of the MRF that is active rather than on the parameters of stimulation. A similar dependence of size and direction of eye movement on locus of stimulation is found in the superior colliculus and frontal eye fields. This is in contrast to the PPRF where there is a direct relationship between parameters of unit activity or of stimulation frequency, and size of rapid eye movements that are induced. It suggests that activity in descending visual-oculomotor areas is organized into channels that trigger saccades of specific sizes. Moreover it would appear that a transformation from a spatial code to a frequency code characteristically takes place between suprapontine pathways and the PPRF to induce rapid eye movements in the horizontal plane.

9.8 INHIBITORY BURST NEURONS IN THE ALERT CAT. C.R.S. Kaneko and A.F. Fuchs. Regional Primate Research Center and Dept. Physiol. and Biophys., Sch. Med., Univ. Washington, Seattle, WA 98195.

Neurons in the pontine and medullary reticular formations of the cat exhibit a burst of action potentials for saccadic eye movements. Recent studies have suggested that many of the pontine burst neurons (EBNs) provide monosynaptic excitatory connections to abducens motoneurons while the medullary burst neurons (IBNs) provide monosynaptic inhibition. To investigate whether EBNs and IBNs play different functional roles in the generation of saccades, we have recorded from and stimulated in the region containing IBNs in alert cats trained in visual tracking tasks. The quantitative and correlative analyses of IBN discharge characteristics in relation to saccadic eye movements and eye movements during electrical stimulation are reported here.

In most of their discharge properties, IBNs are similar to EBNs. IBNs discharge only with saccades and are otherwise silent. Saccades in a preferred ("on") direction are accompanied by the greatest maximum average discharge frequnecy although IBNs discharge over a broad range of saccade directions. On-directions are always ipsilateral to the recording site. Latencies from the burst onset to the onset of an on-direction saccade are typically 10 to 20 msec. In contrast to EBNs, during on-direction saccades, IBNs discharge at higher peak and average firing rates, have bursts of longer duration and consequently also have a greater number of action potentials within a burst than do EBNs. For example, IBNs have maximum on-direction average discharge rates of about 190 spikes/sec compared with 120 spikes/sec for EBNs.

Preliminary statistical analyses suggest that IBNs, like EBNs, show the highest correlations between average discharge frequency and number of action potentials in the burst on the one hand and the size and maximum velocity of the on-direction component of the saccade on the other. However, unlike EBNs, IBNs have high correlations between burst duration and the duration of the on-direction component of the saccade.

Stimulation through the recording microelectrode results in an assymetric saccade interruption. For the contralateral eye, saccades in the contralateral direction are most profoundly effected. Within as little as 10-15 msec after a stimulus train (30 msec,30μA),contralateral saccades of the contralateral eye show a decrease in velocity which often reaches zero. On average, contralateral saccades during stimulation exhibit lower peak velocities and longer durations. During ipsilateral saccades of the contralateral eye stimulation produces only a modest (if any) decrease in velocity at a much longer latency (20msec). During stimulation, ipsilateral saccades of the ipsilateral eye are relatively normal whereas contralateral saccades are interrupted. The most likely pathway for mediating this effect is via internuclear neurons. Thus IBNs probably inhibit both contralateral abducens motoneurons and internuclear neurons.

9.9 INTRACELLULAR INJECTION OF HRP INTO OMNIPAUSE NEURONS IN THE ALERT CAT. C. Evinger, R.A. McCrea & R. Baker, Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016

Extracellular recordings from alert cats have shown that omnipause neurons are tonically active cells which cease firing for all saccades regardless of either direction or amplitude for a period proportional to saccade duration. Their frequency is not modulated during optokinetic and/or vestibular induced eye movement. Since microstimulation in the omnipause area of the brainstem prevents the occurrence of saccades, but does not interrupt smooth eye movements, it was suggested that omnipause neurons inhibit neurons that exhibit a burst of spikes during saccades. In spite of the wealth of physiological data concerning the activity of these neurons little is known about their axonal trajectory and termination areas. To examine this question we identified omnipause neurons according to the above physiological criterion in the alert cat and then intracellularly injected HRP. The cell bodies of these neurons (30-40 μm) were located within .2 mm of the midline rostral to the abducens nucleus even though the dendrites extended a considerable distance from the soma (up to 1 mm). The parent axons bifurcated near the soma and sent branches to both sides of the brainstem. These branches gave off many smaller collaterals with en passant and terminal boutons in the pontine reticular formation. These branches further gave rise to large collaterals which ascended and descended throughout the brainstem. The caudal-going branches passed medial to the VIth nerve rootlets and terminated in the medullary reticular formation between the abducens nucleus and MLF as well as more posteriorly in the dorso-medial reticular region. The axons could be followed caudally to the level of the inferior olive. The rostral ascending branches gave rise to terminal collaterals in the pontine reticular formation up to the level of the Nucleus reticularis tegmenti pontis and continued rostrally to the level of the trochlear nucleus where they could no longer be traced. In the pontine and medullary reticular formation the termination zones were in those areas known to contain excitatory and inhibitory burst neurons which had been identified by HRP staining in other alert cats. The combined anatomy and physiology of omnipause neurons strongly supports prior suggestions that these neurons specifically gate burst neurons involved in both horizontal and vertical saccades. It is interesting to note the lack of evidence for omnipause neuron collateralization in the vestibular and perihypoglossal nuclei or any brainstem area not linked in some fashion with eye movement. Therefore, we suggest that omnipause neurons are not only specific for oculomotor function, but also are uniquely involved with saccadic eye movement. Supported by NS-13742 and EY-02007.

9.10 ACTIVITY OF IDENTIFIED MOTONEURONS IN THE ABDUCENS AND ACCESSORY ABDUCENS NUCLEUS OF THE ALERT CAT DURING EYE MOVEMENT AND RETRACTION. J. Delgado-Garcia*, C. Evinger and R. Baker. Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York 10016.

In the cat, motoneurons from both the abducens (Abd) and accessory (Ac) Abd nucleus innervate the retractor bulbi muscle which retracts the eye into the orbit causing the nictitating membrane to sweep up over the globe. Retraction most often occurs reflexly in response to mechanical stimuli applied directly to either the eye or the periorbital region. Prior electrophysiological studies suggested that all motoneurons in the Ac Abd nucleus received strong disynaptic excitation from trigeminal activation, especially the cornea, but little or no response to vestibular nerve stimulation. Exactly the opposite synaptic effects were found in motoneurons of the Abd nucleus. We investigated the hypothesis that motoneurons of the Ac Abd nucleus would only be active during retraction and exhibit little, if any, activity during rotational eye movement and that motoneurons in the Abd nucleus would respond in the opposite fashion. Extracellular recordings were made from antidromically identified motoneurons in the Abd and Ac Abd nucleus of alert cats equipped with two scleral eye coils, one measuring rotational eye movement and the other retraction. Bursts of spikes were produced in every Ac Abd motoneuron from 5-10 msec after onset of the air puff and approximately 6 msec prior to eye retraction. Ac Abd motoneurons were silent during all classes of rotational eye movement (saccadic, vestibular, etc.). Although tonic activity has not yet been observed in any Ac Abd motoneuron, repetitive dendritic spike activity as well as a remarkable enhancement in active dendritic responses coincident with subthreshold adequate stimulation has been observed. In contrast, all antidromically identified Abd motoneurons (and internuclear neurons in the Abd nucleus) exhibited a burst and/or pause in activity both preceding and during saccades as well as a tonic activity proportional to eye position. When the air puff stimulus was tested in motoneurons and internuclear neurons of the Abd nucleus, both exhibited weak, but consistent, responses; yet they did not occur until at least 5 msec after the onset of retraction. Given the latency of the responses and ability to condition its occurrence with an auditory stimulus, we conclude that all neurons in the Abd and Ac Abd nuclei may participate in general 'alerting' responses associated with eye retraction and blinking during withdrawal behavior; however, Ac Abd motoneurons are active prior to, and during, 'reflex' and 'alerting' retractions. Since Ac Abd motoneurons were not modulated during any rotational eye movements, we also conclude that eye movement responses described in retractor bulbi muscle must result from innervation by motoneurons in the Abd nucleus. (Supported by NS13742 and EY02007).

9.11 DIFFERENTIAL LOCALIZATION OF ACETYLCHOLINESTERASE IN CAT ABDUCENS MOTONEURONES AND INTERNUCLEAR NEURONES. R.F. Spencer (SPON: W.I. Rosenblum). Dept. of Anat., Med. Coll. of Virginia, Richmond, VA 23298.

The cat abducens (Abd) nucleus contains coextensive populations of lateral rectus (LR) and retractor bulbi (RB) motoneurones (MNs) and internuclear neurones (INs) that project to the medial rectus (MR) subdivision of the oculomotor (Oc) nucleus. Although the morphological features of Abd INs are quite different from the MNs, both populations of neurones receive the same types of afferent synaptic connections and exhibit qualitatively similar behaviors during eye movement. The extent to which the different ultrastructural features of ABd MNs and INs is related to differences in neurotransmitters utilized by these neurones is unknown.

Cat Abd MNs and INs were labelled by retrograde transport of horseradish peroxidase (HRP). Vibratome sections through the Abd nucleus were incubated either separately or sequentially for the histochemical localization of acetylcholinesterase (AChE) and/or HRP. Electron microscope examination revealed dense AChE reaction product associated the granular endoplasmic reticulum (GER) of MNs. AChE reaction product also was observed extracellularly on the MN soma-dendritic membrane in association with all (e.g., ipsi- and contralateral vestibular) synaptic endings, regardless of synaptic vesicle morphology. In each case, AChE reaction product was absent from sites of presumed synaptic contact indicated by pre- and/or postsynaptic membrane specializations and accumulations of synaptic vesicles along the presynaptic membrane, and from sites of neuroglial appositions and capillary basal laminae.

By contrast, no AChE reaction product was observed within the GER or any other cytoplasmic organelle within Abd INs. AChE reaction product furthermore was absent extracellularly between the IN soma-dendritic membrane and synaptic endings whose morphology was similar to those contacting the MN soma-dendritic membrane.

The intracellular localization of AChE in Abd MNs is consistent with the synthesis of this enzyme within the MN soma with subsequent axonal transport to the neuromuscular junction for the hydrolysis of acetylcholine (ACh) released from the motor end-plate. The absence of AChE from Abd INs thus suggests that ACh is not the neurotransmitter involved in mediating the excitatory IN synaptic effects upon contralateral MR MNs. The extracellular localization of AChE on the MN soma-dendritic membrane, by contrast, may subserve a trophic function upon presynaptic supranuclear neurones. Given the different soma-dendritic architectures of Abd MNs and INs, this may represent one mechanism by which afferents during development selectively establish synaptic connections with the MNs and INs. A similar function could be postulated for the re-establishment of synaptic connections with regenerating MNs following axotomy. (Supported by U.S.P.H.S. Grant EY 02191).

9.12 LOCALIZATION OF THE MOTONEURONS WHICH INNERVATE THE RETRACTOR BULBI MUSCLE IN THE RABBIT. T. S. Gray*, S. E. McMaster*, J. A. Harvey and I. Gormezano. Dept. of Psychol., Univ. of Iowa, Iowa City, IA 52242

Recent studies employing the horseradish peroxidase (HRP) method have suggested that the retractor bulbi muscle (RBM) of the cat may be innervated by the paraabducens nucleus (PAbN) rather than the abducens nucleus (AbN). Since the rabbit's nictitating membrane reflex, a response mediated by contraction of the RBM, has been used extensively in neurobehavioral research, it was important to determine the precise location of the motoneurons which supply this muscle.

Adult, New Zealand, albino rabbits (n=24) were injected with a 50% HRP and 2% dimethyl sulfoxide solution (5μl per muscle slip) into the following extraoccular muscles: one or four slips of RBM, lateral rectus (LRM), medial rectus, superior rectus, or superior oblique. After 48 hour survival times, 60μm sections of the brainstem were processed by the tetramethyl benzadine method.

Injections of HRP into all four slips of the RBM resulted in consistent labeling of neurons throughout the rostrocaudal extent of the ipsilateral AbN. Inconsistent labeling was seen in the occulomotor, trochlear and facial nuclei. However, a group of labeled neurons were observed ventrolateral to and extending rostral to the ipsilateral AbN. Since the axons of these neurons were seen to course dorsomedially to join the VI nerve, we concluded that this group of motoneurons is the homologue of the PAbN reported in the cat. The mean number of labeled RBM motoneurons in the PAbN was 100 as compared with 290 in the AbN. Reactive neurons within the PAbN and AbN were of the same size and shape averaging 30μm in diameter. Similar results to above were seen after single medial or superior slip RBM HRP injections. After LRM injections neurons were labeled throughout the rostrocaudal extent of the ipsilateral AbN. Labeled neurons were never observed in the PAbN; however, reactive cells were sometimes present in the occulomotor, trochlear or facial nuclei. The per cent of AbN neurons labeled after LRM injections was 33 as compared with 70 after four slip, 59 after medial slip and 35 after superior slip RBM injections. HRP placements into the medial rectus, superior rectus or superior oblique muscles resulted in reliable labeling of areas in the occulomotor-trochlear complex as previously described for the rabbit, but the PAbN and AbN were free of reaction product.

The results demonstrate that the retractor bulbi muscle in the rabbit is innervated by motoneurons located in both the paraabducens and abducens nuclei. Thus, the PAbN projects only to the RBM while the AbN sends axons to the RBM and LRM.

10.1 BUFFERING OF INTRACELLULAR CALCIUM IN MOLLUSCAN NEURONS. Z. Ahmed*, F. Jung* and J. A. Connor. Dept. of Physiology and Biophysics, Univ. of IL, Urbana, IL 61801.

The relationship between calcium influx and increase in cytoplasmic free calcium, $\Delta[Ca_I^{2+}]$, has been examined using the intracellular Ca-indicator Arsenazo III (Ar) and voltage clamp membrane current. Comparisons of the incoming Ca during voltage pulses estimated from the absorbance change of Ar with the amount of entering calcium computed from I_{Ca}^{2+} indicate that only 15 - 30% of the incoming Ca is sensed by Ar. The remaining fraction is presumably bound extremely rapidly by cytoplasmic buffers. Cytoplasmic Ca-buffer capacity (B C_{cell}) during a voltage clamp pulse was measured by injecting calibrated amounts of EGTA and using the relation B C_{cell} = [B C_E/($\frac{\Delta pCa'}{\Delta pCa''}$ - 1)] - B C_{Ar}, where B C_E and B C_{Ar} are buffer capacities of measured amounts of EGTA and Ar respectively. $\Delta pCa'$ and $\Delta pCa''$ were calculated from the absorbance changes of Ar before and after injection of EGTA. The rate of recovery of Ca^{2+} (rate of Ar absorbance decrease) following the termination of a voltage pulse was examined with different Ca loads induced by changing either the duration or amplitude of the voltage pulse. For larger loads of Ca (within physiological limits) the initial rate of Ca^{2+}-recovery increased, suggesting a recruitment of slower buffering or sequestering processes. Injecting small quantities of EGTA accelerated the rate of absorbance recovery in addition to reducing peak absorbance change for a given calcium load. A computational model based upon calcium diffusion and experimental measurements of Ca-buffer capacity was developed. This model reproduces several important aspects of the Ar absorbance time course and suggests that diffusional movement of Ca within the strongly buffering cytoplasm may play a significant role in the regulation of Ca^{2+} levels. Supported by PHS-NS15186.

10.2 VOLTAGE DEPENDENT, EARLY OUTWARD CURRENT IN A PHOTORECEPTOR OF HERMISSENDA CRASSICORNIS. J.J. Shoukimas* and D.L. Alkon. Lab. of Biophysics, NINCDS, NIH, Marine Biological Laboratory, Woods Hole, MA 02543.

The response of Type B photoreceptors of Hermissenda crassicornis to paired light and rotation stimuli has been implicated in associative training of this animal. A voltage clamp study of the Type B photoreceptor is in progress with the intent of fully characterizing light and voltage dependent conductances. Step clamp commands from a holding potential of -60 mV elicit an early, transient outward current that appears to be carried predominantly by K+ ions. Both steady state activation (peak value) and inactivation of the conductance are voltage dependent. Activation shows a maximum, "e"-fold change/12.5 mV over the range of -20 to +10 mV. The outward current shows inactivation from a relative value of 1 at -70 mV to zero at about -10 mV. -30 mV is the voltage at which the current is half inactivated at steady state. Unlike some other gastropod neurons in which similar currents have been reported, such as Anisodoris (Connor, J.A. and Stevens, C.F., 1971, J. Physiol. 213:21), the kinetics of inactivation, like the steady state value, show voltage dependence. The decline of the outward current during sustained depolarization can be fitted by two exponentials, one with a comparatively short time constant which declines from about 130 msec at -20 mV to about 50 msec at +10 mV. The longer time constant (> 1 sec) may reflect the behavior of another outward conductance.

The early outward current is strongly activated at the time that the light induced sodium current is rising (Alkon, D.L., 1979, Science 205:810). The temporal position of these two currents suggests that possible extrinsic control of resting potential by paired stimulus presentations could influence the rising phase of the generator potential by setting the degree of early outward current inactivation.

10.3 VARIABILITY IN MOLLUSCAN NEURON SOMA CURRENTS. E.E. Serrano* and P. A. Getting. Department of Biological Sciences, Stanford University, Stanford, CA 94305.

This study focuses on the characterization of variability in neuron soma currents between and within identifiable cell types. The transient outward potassium current (A-current) was studied under voltage clamp. This current is particularly suitable for these measurements because it can be activated, by using the appropriate voltage paradigms, in isolation from other membrane currents without the need for pharmacological agents.

Somata from identifiable neurons of Archidoris montereyensis and Anisdoris nobilis were isolated and voltage clamped at 10°C with a two microelectrode voltage clamp. Variability was examined in:

a) magnitude of A-current
b) voltage dependence of steady state activation and inactivation
c) time constant for onset of inactivation (T_{BA})
d) time constant for removal of inactivation (T_{REM})
e) membrane capacitance

Variability in A-current parameters was measured by comparing data from the same identifiable cell in different animals. Comparison between cells within and across species was then possible.

The magnitude of A-current obtained from a given cell in different animals shows a variation of 30% about the mean. Membrane capacitance may vary by ten-fold between cells. The normalized steady state voltage dependence of activation and inactivation is highly conserved. This implies that the steady state voltage dependence of the A-current channel is relatively invariant between cells. The time course of inactivation (as characterized by T_{BA} and T_{REM}) shows considerable variation.

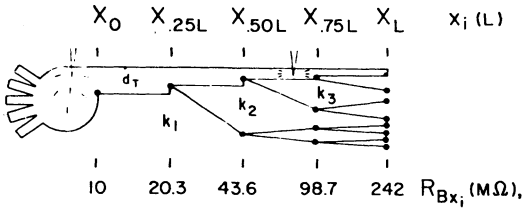
In conclusion, the major variability in A-current appears to reside in the time course of inactivation while the steady state voltage dependence of activation and inactivation is relatively invariant. Current values normalized to input capacitance show as much as eight-fold variation between cells. If the specific capacitance of the cells is assumed to be similar, the data suggests variation in channel density and/or unit channel conductance. Across species, the most striking difference is in the magnitude of A-current which can be from four to eight times larger in Anisdoris than in Archidoris.

10.4 SLOW POTENTIALS IN THE SECONDARY CELLS OF THE APLYSIA EYE. K.J. Markowitz* and J.W. Jacklet. (SPON: J. Schmidt). Dept. of Biol. Sci. and Neurobiology Res. Ctr., SUNY Albany, Albany, N.Y. 12222.

The isolated eye of Aplysia expresses a circadian rhythm of compound action potentials (CAP) frequency recorded in the optic nerve. The CAP's are produced by ~ 1,000 secondary cells which are electrically coupled to one another as well as to the primary photoreceptors. The axons of the secondary cells, photoreceptors and other cell types comprise the optic nerve. To better understand how the circadian clock controls this membrane activity, further studies of the electrophysiological properties of the secondary cells were undertaken. CAP's as well as graded potentials were recorded from the optic nerve with a sucrose gap. A suction electrode on the cornea was used to electrically stimulate the eye and record the electroretinogram (ERG). The ERG closely mirrors light evoked potential changes in the photoreceptors. In the dark spontaneous activity recorded with the sucrose gap consists of bursts of CAP's and underlying slow wave potentials similar to those recorded from identified bursting neurons in the central nervous system. The CAP burst terminates with a depolarizing hump similar to a DAP followed by a post-burst hyperpolarization. The burst duration and the interburst interval are considerably longer than those recorded from single central bursting cells. Electrical stimulation of the cornea evokes a CAP followed by a depolarizing after potential (DAP) in the gap recording. The DAP is not blocked by high Mg^{++} low Ca^{++} indicating that chemical synapses are not involved in its production. The amplitude of the DAP increases as the size of the electrically evoked secondary cell CAP increases. When only the low threshold H cell axons are stimulated, the DAP is absent. This indicates that the DAP is produced in the secondary cells. Similar DAP's were described for central bursting neurons in Aplysia and other gastropods (Thompson and Smith, J. Neurophysiol. 39: 153-161, 1976), and appear to be absent from other cell types. A potential similar to the DAP is triggered by depolarizing input from the receptors. The light evoked slow potential recorded by the sucrose gap is biphasic. An early depolarization is correlated with the ERG and represents receptor depolarization. A latter phase associated with the CAP has no correlate in the ERG and closely resembles the electrically evoked DAP. These results show that the secondary cells have many of the electrophysiological properties exhibited by bursting neurons, including a voltage sensitive slow depolarization. These membrane properties may be modulated by the circadian clock. Supported by NSF BNS 11154.

10.5 EVIDENCE SUPPORTING DENDRITIC IMPALEMENT OF CORTICAL NEURONS IN THE CONSCIOUS CAT BRAIN: CABLE PROPERTIES AND DYE INJECTION. J. E. Skinner and G. L. King*. Neurophysiology Section, Neurology Department and Neuroscience Program Baylor College of Medicine, Houston, Tx 77030.

Frontocortical neurons in the conscious cat brain manifest slow membrane potential and input resistance shifts, in parallel with an extracellular event-related slow potential, in response to a tone that forewarns cutaneous shock. The biophysical responses of each cell were recorded with a new "floating-micropipette tip" technique that enabled intracellular impalements to be maintained when the animal was presented the previously conditioned stimuli. Two classes of cells were recorded, those with large resting mem brane potentials and action potentials that manifested overshoot of the extracellular zero potential (overshoot-cells) and those with small resting potentials and small action potentials that did not overshoot the extracellular zero potential (undershoot-cells) These two classes of cells were also easily distinguished by their resting input resistances. The undershoot-cells are suggested to represent dendritic impalements based on two observations. The first is that electrophoretic injection of small amounts of Lucifer Yellow dye into cells with undershoot-cell properties always results in dye located in a dendritic process near the termination of the microelectrode track in the tissue. The second observation is that 1) input resistance, 2) action potential amplitude, 3) voltage-time integral of the action potential and 4) reduction in action potential amplitude during steady-state current injections through the recording electrode, all are observed in the undershoot-cells to be within the range of values predicted by Rall's mathematical model of the neuron dendrites. The figure below shows the range of values of input resistance predicted by the model that is identical to the range actually recorded. The average input resistance for the overshoot-cells was 10MΩ; the range for the overshoot-cells was 15-98 MΩ.



10.6 SPONTANEOUS HYPERPOLARIZATIONS AT THE MEMBRANE OF MOUSE DORSAL ROOT GANGLION CELLS IN TISSUE CULTURE. David A. Mathers* and Jeffery L. Barker (Sponsor: H.G. Wagner) Laboratory of Neurophysiology, National Institute of Neurological and Communicative Disorders and Stroke, National Institutes of Health, Bethesda, Maryland, 20205.

We report here the occurrence of spontaneous hyperpolarizations at the membrane of mouse dorsal root ganglion (DRG) neurons grown in tissue culture.Cells were obtained from 13 day old mouse embryos and maintained for 8-12 weeks in modified Eagle's culture medium.DRG cells were distinguished from co-cultured spinal cord cells by established morphological and electrophysiological criteria. Intracellular recordings were made from DRG cells (18-30μ M in diameter) bathed in Hank's Balanced Salt Solution containing 5.3mM KCL, 142mM NaCl, 1mM $CaCl_2$ and 1mM $MgCl_2$ at pH 7.4 (temperature 23-27°C). DRG cells were invariably electrically excitable but showed no spontaneous action potential activity. Spontaneous hyperpolarizing potentials of amplitude 0.5-6mV and frequency 1-20Hz were observed at the resting potential (-42 ± 6.7 mV) of 34/69 cells studied. In the remaining cells, no resolvable discrete potential events were seen.Voltage clamp recordings showed that the spontaneous outward currents underlying the potential fluctuations were reduced in amplitude and apparent frequency at more negative membrane potentials and were not detectable at potentials in the range -75 to -85mV.These current events were reversibly abolished by 5mM TEA but not by 1μM tetrodotoxin or 10mM Mg^{++} ions. Power density spectra of membrane current fluctuations were compared for DRG cells lacking and possessing the spontaneous outward currents.In cells of the former population, spectral intensity S(f) was generally proportional to 1/f (frequency) over the potential range -40 to -70mV. In cells showing spontaneous activity the power density spectrum was frequently better approximated by a Lorentzian term ($S(f) \propto 1/f^2$) when measured at the normal resting potential (-30 to-50mV). Hyperpolarization of the membrane of these cells led to the suppression of this Lorentzian component concomitant with the loss of the spontaneous outward currents.It remains unclear whether these currents reflect processes exogenous to the DRG cell(e.g. quantal release of a transmitter) or are an endogenous property of some DRG cell membranes.Spontaneous hyperpolarizations have been observed in motoneurons of the mudpuppy cardiac ganglion while spontaneous depolarizations occur at the membrane of several types of photoreceptors.The relationship of the events seen in DRG cells to these phenomena is unknown.

10.7 CALCIUM-DEPENDENT ACTION POTENTIALS IN MAMMALIAN SPINAL CORD AND DORSAL ROOT GANGLION NEURONS IN PRIMARY DISSOCIATED CELL CULTURES. E.J. Heyer, R.L. Macdonald, G.K. Bergey and P.G. Nelson. Dept. of Neurology, Univ. of Michigan, Ann Arbor, MI 48109 and LDN, NICHD, NIH, Bethesda, Maryland 20014.

Action potentials (APs) dependent on sodium and potassium conductance changes are elicited in normal medium in mouse spinal cord (SC) and dorsal root ganglion (DRG) neurons in primary dissociated cell (PDC) cultures. DRG neurons have, in addition, a prominent calcium conductance that contributes to their longer AP duration. No calcium conductance has been described in APs from SC neurons. We have demonstrated a calcium conductance in SC neurons that can produce calcium-dependent action potentials.

PDC cultures of dissected spinal cord from 12-14 day old fetal mice were grown by conventional techniques. After 4-6 weeks, intracellular recordings with 4M KAc-microelectrodes were made in neurons bathed in Tris buffered saline with 5 mM calcium (TBS). Addition of tetraethylammonium (TEA) was compensated by an equal molar decrease in the sodium concentration.

Short duration APs were evoked by intracellular stimulation in SC and DRG neurons in normal TBS. Addition of 3 μM tetrodotoxin (TTX), a sodium conductance blocker, eliminated APs in most SC neurons but did not alter APs in DRG neurons. In bathing medium containing 100 mM TEA, a potassium conductance blocker, long-duration APs lasting many hundreds of milliseconds were generated in both SC and DRG neurons. These APs had three phases: a rapidly rising depolarization; a long duration plateau; and an afterpotential that might be depolarizing, hyperpolarizing, or depolarizing followed by hyperpolarizing. Calcium dependency was proven by the following results: (1) AP overshoot varied linearly as a function of the extracellular calcium concentration $[Ca^{+2}]_0$ (a ten-fold change in $[Ca^{+2}]_0$ produced a 27.5 mV change in the overshoot). (2) Maximum rate of depolarization varied as a function of $[Ca^{+2}]_0$. (3) Pressure ejection of 10 mM calcium onto neurons in low calcium containing bathing medium raised the AP plateau and prolonged its duration. (4) Application of 5 mM manganese, a calcium conductance blocker, lowered the AP plateau and decreased its duration. Supported by the Grass Foundation (R.S. Morison Fellowship) (E.J.H.), NINCDS grant (NS 15225), and NINCDS Research Career Development Award (NS 00408) (R.L.M.).

10.8 DEVELOPMENT OF CALCIUM SPIKES IN MOUSE HIPPOCAMPAL CELL CULTURES. J.H. Peacock and C.R. Walker. Dept. of Neurology, Stanford University Medical School, Stanford, CA 94305.

Intracellular recordings from mature hippocampal cultures in media containing Na^+ (140 mM) and Ca^{++} (8 mM) show well-developed actions potentials (APs) and bursts of APs frequently superimposed on depolarizing events lasting up to 500 msec. After the addition of tetrodotoxin (TTX; 1 μg/ml), intracellular stimulation elicits slow, graded APs in up to 84% of the cells tested despite marked variability in different culture series. This variability is eliminated by recording from cells in defined media containing Na^+, 14 mM, and Ca^{++}, 8 mM, with TTX as above and tetraethylammonium chloride, 5-20 mM. Cultures prepared from 18 day fetuses were examined between 18 hours and 43 days in culture. The incidence of cells with calcium AP activity is as follows: 46% (n = 35) from 18 hours to 2 days; 89% (n = 38) from 3 to 7 days; 83% (n = 53) from 10 to 16 days; and 83% (n = 6) at 43 days. These data suggest that the incidence of calcium mediated APs remains relatively constant after two days in culture. The lower incidence of calcium potentials recorded from cultures less than two days old could indicate either that these cells have not yet acquired calcium spikes or that this property has been temporarily lost in culture preparation. The latter possibility seems most likely because 91% (n = 22) of cultured neurons equivalent in age to intact neurons in 16-18 day fetuses have calcium APs.

Special features include the following. (1) Calcium APs are optimally developed when the membrane potential is depolarized to about -40 mV by steady electrical current. (2) AP morphology suggests multiple generator sites may exist in some cells. (3) Up to 25% of the cells in selected cultures have rhythmic pacemaker-like, calcium APs with a frequency which increases linearly from about 1 to 7 Hz with increasing steady current injection.

These calcium dependent APs are reversibly blocked by cobalt, 10 mM, and are absent in defined medium containing up to 2 mM calcium and equimolar amounts of nickel. Manganese does not block and may even enhance these APs suggesting that manganese may traverse the same channel as calcium in these cells.

Sodium dependent APs can be demonstrated in cells which have calcium APs by use of local perfusion of medium containing Na^+ (140 mM). These dual AP mechanisms persist within the same cell throughout the time span of the cultures studied here.

In summary, our data show that cultured hippocampal neurons have the capability for calcium electrogenesis which can be recorded within a day of plating and persists in high incidence for at least six weeks in culture.

10.9 EFFECTS OF BLOCKERS OF POTASSIUM CONDUCTANCE ON SPINAL NEURONS OF A VERTEBRATE. R. J. Bookman* and M.E. Selzer. Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

The effects of 40 mM tetraethylammonium chloride (TEA), 1 mM 4-aminopyridine (4-AP), and 1 mM 3,4-diaminopyridine (3,4-DAP) were tested on spinal neurons of the sea lamprey (Petromyzon marinus). On dorsal cells (DCs) and giant interneurons (GIs) these drugs produced a dramatic broadening of the action potential. The prolonged plateau could be permanently interrupted by a brief pulse of hyperpolarizing current. The current threshold for this all-or-none repolarization decreased as the pulse was applied later in the plateau. This long lasting potential could be produced in tetrodotoxin but was blocked by 0 Ca^{++} or 5 mM $MnCl_2$. It was associated with an increased input conductance, which lessened progressively during the plateau. In 3,4-DAP, the potential was clearly regenerative since the threshold voltage for activation was well below the peak depolarization of about +10 mV. Thus in the presence of these drugs DCs and GIs appear to develop voltage-dependent, regenerative Ca^{++} conductances.

The giant Müller's and Mauthner's axons never developed these spike prolongations. This is striking because these unbranched axons form their synapses en passant and require Ca^{++} for transmitter release. Smaller axons also did not show Ca^{++} spikes in TEA. In one case we recorded simultaneously from the cell body of a GI and its axon. The soma showed TEA-induced spike prolongation while the axon did not.

Stimulation of DCs and GIs at frequencies greater than 0.02 Hz produced progressive shortening of the action potential until a steady spike duration was reached. This duration decreased with increasing stimulus frequency up to 0.2 Hz. Frequencies faster than this did not usually shorten the duration further. However, when pairs of action potentials were elicited in GIs at very short intervals (40-100 msec.), the second spike was prolonged relative to the first. This facilitating effect was not seen in DCs. It is interesting that the EPSP produced in one GI by stimulation of a second GI shows facilitation at short interstimulus intervals. However, the EPSP of a GI, seen in response to stimulation of a DC, does not facilitate. Therefore, it is possible, though still speculative, that increased Ca^{++} conductance plays a role in synaptic facilitation.

10.10 REGIONAL DIFFERENCES IN THE TEA SENSITIVITY OF A VERTEBRATE INTERNEURON. C. Kaars* and D.S. Faber. Div. Neurobiology, Dept. Physiol., SUNY at Buffalo, Buffalo, NY 14214.

Recent voltage clamp data (Chiu et al., J. Physiol., 298: 171-184, 1980; Brismar, J. Physiol., 298:171-184, 1980) indicate that axons of two mammalian species, unlike those of amphibian axons (Hille, J. gen. Physiol., 50:1287-1302, 1969), lack voltage sensitive K^+ conductance. TEA and 3-AP are potent blockers of voltage sensitive K^+ conductance. We have examined the distribution of TEA and 3-AP sensitivity in a vertebrate interneurone, the goldfish Mauthner cell. Our results indicate that TEA and 3-AP sensitivity is restricted to the axon hillock and initial segment while the axon is insensitive to TEA. Intrasomatic iontophoresis of TEA results in a marked broadening of the antidromic action potential recorded intracellularly in the soma and extracellularly in the axon cap surrounding the axon hillock-initial segment. The prolonged spike often evokes a second action potential of short duration, presumably generated in the axon. Similar effects are observed following intra- or extracellular application of 3-AP.

In order to determine if axonal and axon hillock-initial segment membranes are differentially sensitive to TEA, we examined its effects on the action potentials generated in these two regions. The axon spike, which can be isolated by blocking antidromic invasion of the axon hillock-initial segment with hyperpolarizing current, is unaffected by intra-axonal TEA iontophoresis at sites from 0.5 to 2.0 mm distal to the axon hillock. The axon hillock-initial segment action potential can be isolated by axonal hyperpolarization during orthodromic activation. Intra-axonal iontophoresis up to 2 mm distal to the axon hillock typically increases the duration of the axon hillock-initial segment spike by ≥ 2, without altering its rise time. Increased duration is associated with prolongation of the slow phase of repolarization, resulting in a spike with a pronounced shoulder. Topical application of 5% $CoCl_2$ partially reverses the effect of TEA on the axon hillock-initial segment spike. This suggests an inward calcium current may contribute to the prolonged axon hillock-initial segment action potential.

In summary, our findings suggest voltage sensitive K^+ channels contributing significantly to the repolarizing phase of the action potential are limited to the axon hillock-initial segment of the Mauthner cell. Thus, rapid repolarization of axonal membrane in the absence of voltage sensitive potassium currents may not be limited to the nodes of mammalian peripheral axons. (Supported in part by NIH Grant No. 1 R01 NS15335.)

10.11 ELECTROPHYSIOLOGICAL LOCALIZATION OF ACTIVE MEMBRANE SITES IN THE GOLDFISH MAUTHNER AXON. Paul G. Funch and Donald S. Faber, Div. Neurobiology; Dept. Physiology; SUNY at Buffalo, Buffalo, NY 14214.

The myelinated axon of the goldfish Mauthner cell makes synaptic contact every 0.2 to 0.3 mm with motoneurons and interneurons. No interruptions in the axon's myelin sheath have been observed, other than at the terminations of the short collaterals where the synaptic contacts are made. The lack of typical nodes of Ranvier has led to an hypothesis that the collateral terminals are the active membrane sites which support impulse propagation. However, we have analyzed the components of the axonal action potential, and our results indicate that distinguishable active sites are spaced only about every 2½ mm along the rostral portion of the axon.

During simultaneous intracellular recordings from the Mauthner axon, hyperpolarizing currents applied through the distalmost electrode (fixed locus) were used to block all-or-nothing components of the orthodromically initiated axonal impulse. Spike component amplitudes at the critical blocking current levels were measured at proximal sites with the second electrode (variable locus). In one experiment, detailed spatial profiles of the voltage output from individual active sites were obtained. These exhibit sharp maxima separated by roughly 2 mm; decays to either side of the maxima are consistent with the passive electrical characteristics of the axon. Furthermore, in eight experiments, the critical hyperpolarizing currents required to block the apparent active sites were (nA; mean ± S.E.): 77.7 ± 5.2, 124.7 ± 8.7, and 223.0 ± 31.0. The average ratio of these currents at adjacent active sites is thus 1.70, indicating an electrotonic decrement, in a semi-infinite cable, over a distance of 0.53 space constants (λ). The λ of the Mauthner axon is estimated to be 4.8 ± 0.7 mm. Therefore the average spacing between the apparent active sites is roughly 2.5 mm.

In summary, the active sites in the Mauthner axon are spaced at distances of about 0.53 λ, which is comparable to nodal spacing in peripheral fibers; in contrast, collateral spacing is on the order of 0.05 λ. Therefore either specific clusters of collateral terminals function collectively as an active membrane site, or the morphological correlate of a discrete active site remains to be identified. (Supported in part by NIH Grant No. 1 R01 NS15335.)

10.12 SITE OF IMPULSE INITIATION IN NEURONS. J.W. Moore, N. Stockbridge*, M. Westerfield*†. Dept. of Physiology, Duke University, Durham, NC 27710.

Computer simulations have been carried out in order to determine how a neuron's shape and membrane excitability affect the locus of apparent impulse initiation. We simulated a neuron as a 10 µm diameter unbranched axon attached to a 50 µm diameter soma and lumped equivalent cylinder dendrite 2800 µm long. Any segment of membrane could be made passive or excitable (Hodgkin-Huxley description) and synaptic current could be injected at any location.

We found that, when the whole neuron including the dentritic tree was made active, an impulse was always initiated at the site of the synaptic stimulation. However, when excitability was restricted to the axon and soma, the apparent site of initiation moved out beyond the soma and into the initial segment of the axon. This finding was true for synaptic locations throughout the soma-dendrite and results from the fact that the very heavy electrical load of the passive dendritic tree restricts the voltage excursions in the active cell body. Therefore the full-size impulse occurs first in the less heavily loaded axon.

Thus we have shown that uniform channel density and membrane properties in the soma and axon are sufficient to give impulse initiation in the axon initial segment.

Current efforts are under way to extend these conclusions to neurons with myelinated axons.

11.1 CELLULAR IMMUNE RESPONSES (CMI) TO CNS MYELIN BASIC PROTEIN (MBP) FOLLOWING STROKE IN THE GUINEA PIG, B. Gran*, Z. Latif, W. Sheremata. Depts. of Neurology and Microbiology, Univ. of Miami Sch. of Med., Miami, FL 33101.

Immune responses to damaged tissue are a recognized factor in the induction of autoimmune disease. Immune responses following nervous system injury might theoretically contribute to the morbidity of such injury, but experimental evidence for or against this is lacking. We have therefore studied CMI 2 weeks after experimental embolic stroke in Hartley guinea pigs. The direct macrophage migration inhibition factor (MIF) assay was used with 1 μg-25 μg/ml MBP or 10 μg/ml peripheral nerve myelin P_2 protein as antigens. Eighteen of 24 guinea pigs survived operation and were assayed concomitantly with 19 normals. Mean normal % migration of peritoneal exudate macrophages from 12 animals (in 10% guinea pig serum supplemented TC199) was 102 ± 5.40 for MBP 10 μg/ml and 104 ± 3.62 for P_2 10 μg/ml. Stroke animals gave % means of 98 ± 4.21 for MBP, and 99 ± 3.62 for P_2. Two of 10 animals showed significant responses ($p < 0.01$) to MBP only. Additionally 8 stroked animals and 7 normals were studied utilizing 10% fetal calf serum supplemented TC199. Mean % migrations was 100 ± 3.93 in normals, and 102 ± 6.27 in stroke animals at 1 μg/ml MBP, 104 ± 6.19% in controls and 103 ± 4.12% at 10 μg/ml MBP, and 103 ± 3.48% in controls and 102 ± 4% stroke animals at 25 ug/ml MBP. Three of these 8 stroke animals gave a significant response to MBP but only one to P_2. Positives in both groups occurred in the smallest animals suggesting age may be a factor in determining CMI to encephalitogenic MBP and other neural antigens. A factor in normal guinea pig serum may protect against such a response. However, the clinical significance of such in vitro responses remains to be determined.

11.2 T-CELL BLASTOGENIC RESPONSES TO MYELIN BASIC PROTEIN (MBP) IN MULTIPLE SCLEROSIS (MS), William Sheremata, Diana Lopez*, and Mario A. Moscarello. Dept. of Neurology and Microbiology, U. Miami Sch. of Medicine, Miami, FL 33101, and Neurological Research Unit, Univ. of Toronto, Toronto, ONT.

Preliminary results from our laboratory revealed that T-cells from MS patients in acute attacks underwent marked blastogenic responses to low MBP concentrations. Unseparated peripheral venous blood mononuclear and T-cell responses to MBP and the mitogens Con-A, and PHA have now been studied in 10 MS patients in acute attacks, 24 during recovery and in 35 controls. Based on the preliminary data, concentrations of 2.5 and 5 μg/ml MBP, 4 μg/ml Con-A, and 10 μg PHA were utilized. Normals gave values (X 1000) of -0.2 ± 0.06 for unseparated cells, 0.2 ± 0.6 for T-cells, and 0.1 ± 0.3 for non T-cells. Acute MS patients results were 9.0, 15.3, and 1.0; other MS patients 0.5, 0.3, and 0.2; and other neurological diseases (OND) 0.1, 1.2, and -2.0 respectively. Con-A results were lower in MS exacerbation but PHA results were not. T-cells from 7 of the 10 acute MS patients gave marked responses not seen in any normals or OND. Alterations in B cell function may impair effective suppressor T function. However, these results probably indicate that, in addition to suppressor T- cells, non E-rosetting cells - probably B cells - play an important part in regulating immune responses to neural antigens.

11.3 EFFECTS OF TUNICAMYCIN ON GLYCOPROTEIN SYNTHESIS IN PNS MYELIN. M. E. Smith. Dept. of Neurology, Veterans Administration Medical Center, Palo Alto, and Stanford University School of Medicine, Stanford, CA 94305

PNS myelin contains at least four glycoproteins in molecular weights of 100,000 (MAG), 27,000 (P_0), 23,000, and 19,000 daltons. Biosynthesis of these glycoproteins in PNS myelin was studied in vitro using radioactive precursors. Spinal roots or sciatic nerves from 21 day rats were incubated with a [^{3}H] or [^{14}C] amino acid mixture or with [^{3}H] fucose, in Krebs Ringer bicarbonate buffer, then purified myelin was prepared from the incubated tissues. The myelin was delipidated, and the proteins separated on SDS polyacrylamide gel electrophoresis. The gels were stained with fast green, scanned, and cut into slices which were counted for their radioactivity. The separated stained myelin proteins on the gels corresponded to definitive radioactive peaks showing good incorporation of labeled amino acids and fucose. Tunicamycin, an inhibitor of protein glycosylation, when incubated with the spinal roots or sciatic nerves, inhibited the uptake of [^{3}H] fucose into all the glycoproteins. Tunicamycin did not inhibit uptake of [^{3}H] amino acids into protein to any great extent, but the radioactive peak corresponding to the main structural PNS myelin protein, P_0, was displaced to a position corresponding to about 25,000 daltons. When tissue was incubated with tunicamycin, [^{14}C] amino acids and [^{3}H] fucose, the new protein was labeled with [^{14}C] but not with [^{3}H]. We propose that this 25,000 dalton protein is the P_0 protein which has remained unglycosylated. No new forms of the other glycoproteins were apparent on the gels. Although glycoprotein function is usually associated with "recognition," it appears that the association of P_0 with the PNS myelin membrane can proceed in the absence of the carbohydrate side chain. Supported by the Veterans Administration and by Grant #NS-02785 from the NIH.

11.4 THE ALTERATION OF FUCOSE/LEUCINE INCORPORATION INTO PNS MYELIN BY ISONIAZID NEUROPATHY. M. P. Colip*, S. Baughman*, and R. G. Peterson. Anatomy Department, Indiana University School of Medicine, Indianapolis, IN 46223.

The ratio of [^{3}H]fucose to [1-^{14}C]leucine incorporation into rat sciatic nerve during in vitro incubation has been previously studied in Wallerian degeneration and in diabetic neuropathy by this lab (submitted for publication). This model was applied to a clinically relevant and morphologically well studied experimental toxic neuropathy produced by isoniazid (INH) to further quantify altered protein-glycoprotein metabolism. Male Sprague-Dawley rats, weighing 200g, were injected daily I.P. with INH 150mg/kg (10% INH in 0.9% NaCl) and controls with a comparable volume of 0.9% NaCl. After 1, 2, 4, and 7 days, sciatic nerves were harvested for metabolic studies and posterior tibial nerves for morphological comparison. Sciatic nerves were stripped of their epineurium and individually incubated at 37°C in 0.5ml of a solution composed of: Krebs-Ringer bicarbonate (KRB); complete amino acid mixture (Tolman et al., J. biol. Chem. 248: 4552, 1973); 3% BSA; 0.2% glucose; 50uCi/ml [^{3}H]fucose; and 5uCi/ml [1-^{14}C]leucine (NEN). After 3hr the nerves were washed in iced KRB, glycerinated, and frozen in liquid nitrogen. Myelin was purified according to Wiggins (Brain Res. 89: 99, 1975). Delipidated myelin protein was solubilized in SDS by sonication. Aliquots of the supernatant were taken for protein assay (Lowry) and liquid scintillation counting. Both DPM/ug protein of each incorporated precursor and the DPM ratio (fucose/leucine) were compared to control values. At 7d the ratio for the four INH treated rats was 2.23 ± 0.14 (S.D.), statistically significant ($p < 0.001$) from the four controls at 3.03 ± 0.17. The decreased ratio reflected a concomitant decrease in fucose and increase in leucine incorporation into myelin of about equal specific activity. 14.3 ± 7.4% of fibers teased from tibial nerves of the 7d INH rats showed ovoid formation as the criterion of degeneration (Lubinska, Brain Res. 130: 49, 1977) as compared to no degeneration in controls. This 7d data along with earlier time periods, especially at 4d, suggest that lower DPM ratios correlated with higher percent degeneration. This model thus appears to be a quantitative indicator of modified protein-glycoprotein synthesis and of nerve fibers undergoing degeneration induced by INH. Supported by NSF BNS 78-00616.

11.5 POSTNATAL SYNTHESIS OF MYELIN AND BRAIN SUBCELLULAR MEMBRANE FRACTIONS FOLLOWING POSTNATAL PHENYTOIN ADMINISTRATION. Philip N. Patsalos* & Richard C. Wiggins. Dept. of Neurobiol. & Anat., Univ. Texas Med. Sch., Houston, Texas 77025

Long Evans rats were administered intraperitoneally with various concentrations of phenytoin (PHT) during the period from birth through 17 days postnatal age. Synthesis of brain subcellular membrane proteins was examined by double isotope methodology as we have previously described in detail.

At age 21-24 days ^{3}H-leucine and ^{14}C-leucine were injected intraperitoneally into pairs of test and control rats respectively. Brains of experimental and control pups were combined and subcellular fractions prepared. For each subfraction $^{3}H/^{14}C$ (test/control) ratios were determined and normalized to corresponding microsomal value for that double brain homogenate. The resultant percentage values obtained are a measure of relative synthesis for each subfraction of the experimental pup.

Relative Synthesis (percentage; Mean±SEM)

	PHT dose (mg/kg)					
Subcellular Fraction	5.0		15.0		45.0	
Myelin	94±1[c]	(N=6)	82±3[b]	(N=11)	91±2[d]	(N=5)
Nuclear	81±4[c]	(N=6)	80±2[a]	(N=11)	91±4	(N=5)
Synaptosomal	97±5	(N=6)	96±1	(N=11)	97±4	(N=5)
Mitochondrial	97±2	(N=6)	95±1	(N=11)	97±2	(N=5)
Microsomal	100	(N=6)	100	(N=11)	100	(N=5)

a,b,c, and d represent $p<0.001$, $p<0.005$, $p<0.01$ and $p<0.025$ respectively.

The myelin ratio was consistantly low at 20-24 days postnatal age, the period of most rapid myelin synthesis, reflecting a 10-20 percent relative reduction in synthesis. Synthesis of nuclear membrane protein was also decreased. Myelin and nuclear membrane protein synthesis deficits occurred at all PHT concentrations studied. No significant change in relative synthesis of the synaptosomal and mitochondrial protein fractions was observed.

This research supported by PHS Grants NS-14355, NS-13799 and NS-00474 awarded to RCW.

11.6 INCREASED MYELINATION IN CULTURES OF MYELIN-DEFICIENT CEREBELLUM WITH ADDED NORMAL OPTIC NERVE GLIA: MORPHOLOGICAL STUDIES. Susan Billings-Gagliardi, Lori H. Adcock*, Gail B. Schwing* and Merrill K. Wolf. Department of Anatomy, University of Massachusetts Medical Center, Worcester, MA 01605

CNS myelination is severely reduced in mice with the single-gene mutation myelin synthesis deficiency (jp^{msd}) (Billings-Gagliardi et al., '80a). The jp^{msd} abnormality is reproduced in organotypic cultures of cerebellum (Billings-Gagliardi et al., '80b). The defect could be the result of primary abnormalities in the axon, oligodendrocyte, and/or some third cellular element. To test these ideas, cerebellum from 0-day jp^{msd} mice was co-cultured with 0-14 day normal mouse optic nerve to permit normal optic nerve glia to invade jp^{msd} cerebellum. Each cerebellum was cut into 8 parasagittal slabs which were cultured in pairs. Optic nerve was added to the lateral and medial cultures from one half of each cerebellum. The corresponding cultures from the other half served as controls. After 21-30 days in vitro, when cultures of normal cerebellum would be fully myelinated, cultures were fixed and studied by light and electron microscopy.

Quantitative study of ten jp^{msd} cultures with added optic nerve demonstrates that myelination is substantially greater than in the corresponding control cultures without optic nerve. The proportionate increase in myelination ranges from 1.5x to 25x, with an average approximating 10x (Wolf et al., '80). In jp^{msd} cultures with increased myelination, the optic nerve and cerebellar explants are fused. Separation of optic nerve and cerebellum by as little as 0.2 mm prevents increase of myelination, presumably by preventing invasion of optic nerve glia. Myelinated axons in jp^{msd} cultures with added optic nerve usually occur in long, broad tracts close to the optic nerve, whereas myelin segments in control jp^{msd} cultures form small, randomly distributed clusters. Oligodendrocytes are more numerous and myelin sheaths are usually thicker than in controls. Thus myelin in cultures with added optic nerve looks like normal rather than like jp^{msd} myelin.

These findings are difficult to explain on the basis of a diffusible factor made by normal optic nerve, but are simply explained by assuming that the additional myelin is directly made by the added normal oligodendrocytes. This suggests (1) that oligodendrocytes from normal optic nerve are competent to myelinate axons of jp^{msd} cerebellum, and (2) that the mutant axons are receptive to myelination by normal oligodendrocytes. Supported by NIH Grant NS-11425.

11.7 MYELINOGENIC GENE EXPRESSION IN LONG-TERM CULTURES OF PURIFIED RAT OLIGODENDROCYTES. C. Shama Bhat*, E. Barbarese*, and S.E. Pfeiffer. Dept. of Microbiology, Univ. of Connecticut Health Center, Farmington, CT 06032.

Oligodendrocytes are isolated from 11 day old primary cultures prepared from 19-21 day fetal or 1-2 day neonatal rat brain cerebral hemispheres by shaking them from the primary cultures followed by lysis of other contaminating cells in Hepes buffered balanced salt solution at pH7.2. More than 99% of the isolated cells are viable and can be cultured as monolayers for over 60 days. At least initially the oligodendrocytes synthesize DNA and divide. The isolated oligodendrocytes are characterized by: (a) morphological parameters (phase contrast, Nomarski, and transmission electron microscopy); (b) immunofluorence labelling with antisera to myelin basic protein and galactosyl-ceramide; and (c) biochemical analyses for myelin basic protein, 2',3'-cyclic nucleotide 3'-phosphohydrolase, and sulfogalactocerebroside synthesis (450 pmoles/mg protein; 6 umoles/min/mg protein; and 6 nmoles/24h/mg protein, respectively, at 32 total days in culture). Since these values are similar to the peak activities of these parameters observed in mixed primary cultures of the same age, in which the cellular "specific activity" of oligodendrocytes is estimated to be about 1/10 that in the purified cultures (by staining with anti-myelin basic protein antisera), the data suggest that either the maximal levels or the rates of development of the expression of these parameters requires non-oligodendrocyte positive signals for optimal expression of myelin-related differentiated function by the oligodendrocytes.

Supported by grants from the National Institutes of Health (10861), National Multiple Sclerosis Society (RG-1231-A-2), and The Kroc Foundation.

11.8 PARALLEL RIDGES IN FREEZE FRACTURED CNS MYELIN FROM A MYELIN DEFICIENT MOUSE R.G. Miller and J.-M. Matthieu* 20 Rue Ecole de Médecine, 1211 Geneva and Service Pédiatrie, Centre Hospitalier Universitaire Vaudois, 1011 Lausanne, Switzerland.

The myelin deficient mouse, "MLD", is a mutant which, in the homozygote, contains a reduced amount of total myelin and only 3-4% (on the basis of total protein) of the normal amount of myelin basic protein (MBP). Although such myelin appears normal in the PNS, in the CNS it lacks a compact major dense line which is normally derived from the cytoplasmic surfaces of the oligodendrocyte and the number of lamellae are less than 8. (Matthieu, Ginalski, Friede, Cohen, and Doolittle, Brain Res. v.190, in press, 1980). Since the depletion of a major myelin protein can be expected to alter the ultrastructure of myelin membranes, we have used freeze fracture to determine the fine structural differences between the myelin from the MLD mice and their heterozygote littermates which contain an approximately normal amount of MBP.

Optic nerves from 30-38 day mice were removed under pentobarbital and either immediately quenched in Freon on a specimen stub, or were fixed in glutaraldehyde (2% in PBS at RT) and infiltrated in 20% glycerin before quenching. The description which follows applies equally to the freshly frozen and fixed/cryoprotected tissue.

The most striking observation is that there is a hitherto unreported membrane configuration on MLD myelin, consisting of shallow (less than 4nm), parallel ridges. Their low profile made their detection very labile to shadow angle and, thus, it is not certain whether all or just some portions of MLD myelin contained these ridges. Ridges are propagated across the interperiod line to the adjacent fracture plane. Typically, they appeared roughly parallel to the major axis of the axon. These ridges resemble neither the usual paranodal junction nor other specializations which are present in other tissues. Another difference between the MLD and Normal myelin is an abundance in MLD of patches (ca .1 micron in diameter) of "paranodal" specializations which were not associated with paranodal regions and were not organized into regular arrays as they are in normal tissue.

11.9 MYELINATION-DEPENDENT AND INDEPENDENT MEMBRANE SPECIALIZATIONS AT THE NODE OF RANVIER, DEMONSTRATED IN INSUFFICIENTLY MYELINATED NERVES OF THE DYSTROPHIC MOUSE. Clayton A. Wiley-Livingston and Mark H. Ellisman, Dept. of Neuroscience, U. Calif. at San Diego, La Jolla, CA 92093

"Dystrophic" mice of the 129/ReJ-Dy strain have a genetic defect affecting Schwann cell proliferation. Spinal nerve roots of these animals contain myelinated and unmyelinated axons in addition to groups of large "amyelinated" axons. In affected regions of the spinal roots, myelinated axons are missing their myelin sheaths. Where the myelination terminates or begins, half-nodes are created. Freeze-fracture analysis of these half-nodes shows a patch of particles in the nodal fracture faces similar to the annulus of particles around the axon of normal nodes. Rows of dimeric-particles (putative Na^+ channel) in the P-face of the paranode are seen only on the myelinated side. The P-face on the amyelinated side contains a dense, even distribution of particles, many of which are the size of dimeric-particle subunits, but only a few of which are arranged in rows.

The E-face of the completely amyelinated axons are comparatively particle-free except for infrequent patches of particles. These patches are very similar to the patches present at half-nodes, and are similar to, but smaller than, annuli of particles at the node of Ranvier. We conclude that the paranodal rows of dimeric-particles are dependent upon myelination for their organization. In contrast, the positioning of the nodal patches of particles is independent of myelination.

11.10 A CROSS SPECIES COMPARISON OF 2',3'-CYCLIC NUCLEOTIDE 3'-PHOSPHODIESTERASE. T. J. Sprinkle* and M. R. Wells. Neurochem. Lab. V. A. Med. Ctr. Res. Service (151) Augusta, GA 30904 and Lab. of CNS Injury and Regeneration. V. A. Med. Ctr. Washington, D.C. 20042.

The enzyme 2',3'-cyclic nucleotide 3'-phosphodiesterase (EC 3.1.4.37, CNP) has been purified from human and bovine white matter and from myelin in the rat, guinea pig, and rabbit. Purifications were accomplished primarily by column chromatography (ionic-exchange, hydrophobic, gel filtration and affinity). In all of the species examined, purified CNP appeared on polyacrylamide SDS slab gels as 2 major protein bands in the region of 46-50,000 daltons separated by a distance of 2-3,000 daltons. There was a tendency for CNP to appear in higher molecular weight forms in all species to a varying degree. The relative intensities of the two major protein bands of CNP varied between species in a manner consistent with the contention (Sprinkle and Wells, Trans. Am. Soc. Neurochem. Abstr. 11: 214, 1980) that the enzyme is at least a major component of the Wolfgram proteins W1 and W2 described in myelin (Waehneldt and Malotka, Brain Res. 189: 582, 1980).

11.11 DEVELOPMENT OF AN ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA) FOR BOVINE WHITE MATTER PROTEOLIPID APOPROTEIN. Wendy B. Macklin* (Spon: Marjorie B. Lees) E.K. Shriver Center, Waltham, Ma 02154 and Harvard Med. School, Boston, Ma 02115

An indirect microtiter plate ELISA has been developed to quantitate anti-proteolipid antibodies produced upon immunization of rabbits with the bovine white matter proteolipid apoprotein (APL). APL is a hydrophobic membrane protein which tends to aggregate and precipitate in aqueous solution. This microtiter plate procedure reduces the problem of APL aggregation since the APL need not be radioiodinated or chemically treated. APL binds avidly to many surfaces, and is thus well suited for microtiter immunoassay. The protein is prepared as a chloroform-methanol soluble protein free of complex lipids which can be converted to a water soluble form. Antibodies to the water soluble form of APL were produced by immunization of rabbits with APL in the presence of bovine serum albumin (BSA). The presence of anti-BSA antibodies in these animals precluded the addition of BSA or calf serum to the microtiter plates to reduce non-specific binding of immune serum or second antibody to the wells. The only protein tested which reduced the non-specific background without binding the anti-BSA antibodies in the immune serum was ovalbumin. In this assay, water soluble APL was bound to the microtiter plate wells, followed by ovalbumin. After washing the plates with phosphate buffered saline, pH 7.6, containing Tween 20, immune and control sera were added in the presence of ovalbumin plus Tween 20. After washing, second antibody, goat anti-rabbit IgG antibody conjugated to horseradish peroxidase (HRP), was added in the presence of BSA plus Tween. The sensitivity of enzyme-conjugated second antibody was compared to that of ^{125}I protein A.

This assay has permitted quantitation of anti-APL antibodies produced by several different immunization protocols. A comparison of the crossreactivity of the water soluble and chloroform-methanol soluble forms of APL was made using this assay. Preliminary experiments suggest that the assay can be adapted to quantitate the apoprotein rather than antibody. Since APL is the major myelin protein, comprising 50% of the total myelin protein, a quantitative assay for both the apoprotein and its antibody would be useful in screening sera and CSF of animals and/or patients with various neurological disorders, particularly demyelinating disorders.

12.1 MOTONEURON POOLS OF PRIMATE FORELIMB MUSCLES LABELED BY HORSERADISH PEROXIDASE R.F. Martin and E.E. Fetz, Dept of Physiology and Biophysics and Regional Primate Research Center, Univ of Washington, Seattle, WA 98195

Cervical motoneuron pools of specific forelimb muscles of Macaca mulatta were retrogradely labeled with horseradish peroxidase (HRP) to determine their relative location and size. In most cases HRP was applied in a cuff attached over the proximal end of the severed muscle nerve, for direct uptake by cut motoneuron axons. Alternately, HRP (Worthington, 30%) was injected into small hand muscles for uptake via motoneuron synaptic terminals. After 72-hour survival monkeys were perfused (1% paraformaldehyde and 1.25% glutaraldehyde in 0.1 M phosphate buffer). Serial 80 um cord sections were reacted with tetramethyl benzidine (TMB). HRP-labeled motoneurons were counted only if their nuclei were visible. In two monkeys motoneurons of extensor digitorum communis (EDC) were labeled with an HRP cuff. In both animals, labeled motoneurons extended from the caudal portion of C7 segment to the rostral portion of T2. 495 EDC motoneurons were labeled in one animal, 374 in the other. In one of these animals, contralateral flexor digitorum profundus (FDP) motoneurons were also labeled by HRP cuff. The rostrocaudal extent of the 269 FDP motoneurons was virtually identical to that of the EDC pool, but FDP motoneurons lay more dorsally in the lateral ventral horn. In another monkey, a cuff applied HRP to the median nerve at the wrist, to identify its motoneurons of intrinsic hand and finger muscles; the 582 labeled neurons extended from the C7/C8 junction to the rostral portion of T2. Several labeled motoneuron pools appeared at slightly different positions in dorsolateral ventral horn. In one monkey, motoneurons of abductor pollicus brevis (APB), an intrinsic thumb muscle innervated by the median nerve, were labeled by HRP muscle injection on the left side and by HRP nerve cuff on the right. The muscle injection produced 271 densely labeled neurons, while the nerve cuff labeled 135 neurons less densely; this difference may have been due to compromised HRP transport in the six nerve twigs of APB. The rostrocaudal extent of both labeled APB pools was identical with that obtained by cuffing the entire median nerve at the wrist, but the APB motoneurons were more localized in the ventral horn.

For some muscles, motoneurons appeared to be preferentially grouped within the rostro-caudal extent of the pool. Motoneuron soma diameters ranged from 15-70 μm. The TMB reaction product was no denser in the smaller γ motoneurons than in the α motoneurons, making it impossible to assess the relative number of γ and α motoneurons, particularly in the intermediate range of soma diameters (30-40 μm). The TMB product labeled the axons of many motoneurons, and revealed surprisingly tortuous axon trajectories in the ventral horn, which have proven to be characteristic of particular motoneuron pools. Instead of exiting the lateral ventral horn by the shortest route, many axons travel ventro-medially for a considerable distance, and then exit the gray matter in the ventral direction.

12.2 ANATOMY OF THE FLEXOR DIGITORUM PROFUNDUS MOTOR NUCLEUS IN THE CAT SPINAL CORD. G.A. Iwamoto, J.A. Dixon* and W.J. Gonyea*. Depts. of Internal Medicine and Cell Biology, Univ. of Texas Health Science Center, Dallas, TX 75235.

As a necessary step in our ongoing examination of the structural and functional bases of prehensile motor activity in the cat forelimb, the motor nucleus of the flexor digitorum profundus (FDP), was mapped in detail. As described by Reighard and Jennings (Anatomy of the Cat, 1901) the muscle is composed of five distinct heads. The heads are commonly held (McClure, Dallman and Garrett, Cat Anatomy, 1973) to be innervated by the median nerve (heads 2,3,4,5) and the ulnar nerve (heads 1 & 2).

The FDP was injected with a 30% solution of horseradish peroxidase utilizing a microliter syringe. To isolate the contributions of individual heads of this muscle, injections of the entire muscle on one side of each animal were accompanied by injections of a selected head on the contralateral side. Following a 48-72 hr survival period, the animals were perfused with a 0.4% paraformaldehyde -2.5% glutaraldehyde solution. Frozen serial sections from the C_5-T_2 spinal segments were cut at 50 μm and reacted with tetramethyl benzidine after the method of de Olmos, Hardy and Heimer (J. Comp. Neurol. 181:213-244).

The overall distribution of the FDP motor nucleus extends from the mid C_6 to caudal T_1 levels. The cells are grouped on the dorsolateral border of the ventral spinal gray matter for the rostral half of this distribution. However, the caudal half of the nucleus, in addition to the large main group on dorsolateral border, shows a division of more scattered cells situated just ventromedial to the main group. The highest density of cells occurs in the mid C_8 to mid T_1 regions. Individual heads contribute thusly: Head 1 is concentrated between C_8 and T_1 while head 5 extends from C_6 to T_1. These results are similar to those reported previously for flexor carpi ulnaris (FCU) and flexor carpi radialis (FCR), respectively (Iwamoto et al, Anat. Rec. 196:85-86A). Head 5, however, does not show a high density of cells in the C_7 area (as in FCR), but reveals a higher concentration of cells in the C_8 and T_1 regions as is the case with all heads of the FDP. Heads 2, 3, and 4 show distributions which are intermediate (in varying degrees) between the patterns shown by 1 and 5. The data show that many similarities exist in motor cell groupings for muscles synergically involved with wrist flexion. The data also suggest that a possible basis for synergy between muscles involved in radial or ulnar deviation movements during prehensile motor activity may exist since the motor nuclei involved seem to be spatially grouped and selectively innervate medial or lateral antibrachial musculature. (Supported by NIH Grants AM-17615 and HL-07360.)

12.3 ELECTRICAL STRUCTURE OF MOTOR NEURONS: INFORMATION FROM THE RESPONSE TO A PULSE OF CURRENT. D.H. Edwards, Jr. and B. Mulloney. Dept. of Zoology, University of California, Davis, CA 95616.

The electrotonic structure of a neuron is the foundation on which the integration of all its synaptic currents and active responses rests. The electrotonic structure also determines what can be recorded from a given site in the neuron, and how effectively the potential of the neuron can be controlled.

We have developed a method that uses the voltage response of a neuron to a brief pulse of current to build a compartmental model of the electrotonic structure of the cell (Rall, 1962). We have used this method to study the electrotonic structure of neurons in the lobster's stomatogastric ganglion.

The method treats the recovery phase of the voltage transient as a series of exponentials, each of which has a coefficient and time constant. The terms of this series can be separated by "peeling." We have developed algebraic formulae that relate these coefficients and time constants to the resistances and capacitances of a compartmental model of the injected neuron that has one compartment for each term in the series. This model will accurately predict the linear voltage response of the cell to any waveform of current injected at the recording site (Perkel and Mulloney, 1978).

The input resistance of the neuron can be calculated from the pulse response. This method has the advantage that voltage is measured after current is injected, so bridge-balance is not a problem. The total capacitance, and therefore the surface area, of the injected region of the neuron can also be calculated from the pulse response.

Each of the identified stomatogastric neurons we have studied with these methods has a characteristic electrotonic structure. Their input resistances at the soma and their membrane time constants vary through a wide range, but these neurons share some common features. The soma of each neuron is its most resistive region; therefore, the soma is an excellent place to record voltage responses to synaptic currents. The axon of each neuron is its major current sink; most currents flow out of the integrative region down the axon. There is a significant coupling resistance between the soma and the neuron's integrative segment; therefore, it is not possible to space-clamp the neuron with a voltage clamp applied to the soma.

12.4 MOTONEURONAL POOLS INNERVATING FIN MUSCLES IN THE ATLANTIC STINGRAY, DASYATIS SABINA. M.H. Droge and R.B. Leonard. Marine Biomed. Inst. and Dept. of Physiol. & Biophys., Univ. of Texas Med. Br., Galveston, TX 77550.

Pectoral fin muscles in the stingray consist of a series of antagonist sets of dorsal and ventral muscles separated by cartilaginous bars. The radially arranged muscles have distinct superficial and deep components in both the dorsal and ventral masses. The localization of motoneuron pools innervating the various portions are being investigated using retrograde transport of horseradish peroxidase (HRP). Dorsal or ventral muscle is split by gentle dissection to expose the interface of adjacent muscle bundles (myotomes?). The desired portion is injected along its radial length with 4-6μl of 30-40% HRP. Following 3-4 days of survival, animals are perfused with 1.25% gluteraldehyde and 0.75% paraformaldehyde. Serial frozen sections of the appropriate spinal cord levels are reacted with tetramethylbenzidine histochemistry.

Two groupings of relatively large neurons can be distinguished in the ventral horn of Nissl stained material in the region previously shown to contain motoneurons (Leonard et al., J. Neurophysiol., 41:108, 1978). One group of prominent cells extends in a loose row from the central canal ventrolaterally across the gray matter. The second consists of large cells scattered beneath the first group; particularly ventrolaterally. Labelled somata in both groups range in diameter from 20-45 μm with a unimodal distribution. This is expected from the absence of well organized muscle spindles with efferent innervation. Motoneurons innervating the ventral muscles are located dorsomedially in the first cell group. Dorsal muscles are supplied by motoneurons in the more scattered, ventrolateral second group. There appears to be some overlap among neurons to dorsal and ventral muscles. Preliminary evidence indicates more overlap among neurons to the superficial and deep components within the dorsal muscle mass. Following injection of a single muscle bundle, motoneurons are found over about two spinal cord segments (about 2.0 mm).

12.5 MONOSYNAPTIC SUPRASPINAL INPUTS TO LONG DESCENDING PROPRIOSPINAL NEURONS IN CATS. R. D. Skinner and R. S. Remmel. Depts. of Anatomy and of Physiology, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

The cell bodies of origin and the peripheral inputs to long descending propriospinal (LDP) neurons were recently reported by this lab (J. Comp. Neurol. 188 (1979) 443; Brain Res. (in press); Soc. Neurosci. Abst. 4 (1978) 563). Adult cats were intercollicularly decerebrated under ether and then the ether was discontinued. Blood pressure, temperature and expired CO_2 were maintained within physiological limits. The midline cerebellum was removed. The cat was either paralyzed with gallamine or else unparalyzed for EMG recordings. The action potentials of LDP neurons were recorded in the cervical enlargement on the left side with extracellular micropipettes (1-3 MΩ, filled with 4M NaCl). LDP neurons were identified by means of antidromic excitation from the lumbar cord. In order to study inputs from the brain, monopolar stainless-steel electrodes were placed into the left medial longitudinal fasciculus (MLF) at 5 mm rostral of the obex and into the left lateral vestibular nucleus (LVN). Stimulating currents were ≤100 μA and 0.1 msec duration. Trains of 1-3 shocks at 300/sec were used.

Thirty-four of 50 (68%) LDP neurons were fired by ipsilateral supraspinal stimulation. Some responded to only one input (15 to MLF only, 4 to LVN only), but inputs from MLF and LVN converged upon 15 cells. Using the criterion that a response ≤1.0 msec following the arrival of the axonal volly (detected by a cord dorsum electrode) indicated a monosynaptic input, 24 neurons were monosynaptic. (The 10 longer-latency neurons might have had a monosynaptic input.) Seventeen (34%) were monosynaptic to MLF stimulation and 9 (18%) were monosynaptic to LVN. Only 2 were monosynaptic from both inputs. Some LDP neurons received both antidromic and orthodromic excitation from the lumbar cord.

The spontaneous "walking" rhythm of these neurons could in general be modulated by the lateral vestibulospinal tract, the MLF, somatosensory input from the forelimbs and/or lower parts of the body (see abstract by Remmel and Skinner, this volume). The LDP cells are hypothesized to synchronize the walking of the forelimbs with the hindlimbs.

Supported by NIH grant NS-10304.

12.6 "WALKING" RHYTHMS IN LONG DESCENDING PROPRIOSPINAL NEURONS IN CATS. R.S. Remmel and R.D. Skinner. Depts. of Physiology and of Anatomy, Univ. of Ark. for Med. Sci., Little Rock, AR 72205.

The accompanying abstract (Skinner and Remmel, this volume) and papers referenced therein describe the cell bodies of origin and the peripheral and brainstem inputs to long descending propriospinal (LDP) neurons. This abstract describes "walking" rhythms in these neurons.

Methods were similar and most cats yielded data on both "walking" and on synaptic connections. The cat was either paralyzed with gallamine or else unparalyzed for EMG recording. The responses of LDP neurons antidromically excited from the lumbar cord were recorded extracellularly in the cervical enlargement. In order to study effects of brain stimulation upon the "walking" rhythm, both the medial longitudinal fasciculus (MLF) and the lateral vestibular nucleus (LVN) were stimulated, as described elsewhere. The spontaneous bursting ("walking") rhythm of spike trains and of the EMGs from arm extensor muscles were recorded on an FM tape recorder.

LDP and other cervical neurons often developed a "walking" rhythm for 6 or more hours. Forelimb stepping movements and EMGs confirmed that the single-unit rhythms were indeed "walking" rhythms. The average and standard deviation of at least 10 interburst periods were calculated. The average period was 0.61 ± 0.04 sec for one neuron. It was 1.19 ± 0.12 sec for a second neuron (23 ± 9 spikes/burst); this period, however, increased to 1.8 ± 1.0 sec and the number of spikes/burst decreased to 7.4 ± 4.6 when the ipsilateral digits were squeezed. It was 0.62 ± 0.04 sec for a third neuron; this period decreased to 0.49 ± 0.03 when the ipsilateral forepaw digits were squeezed and the period was increased when the contralateral paw was squeezed. The period was 1.6 ± 0.3 sec for a fourth neuron (3.3 ± 1.3 spikes/burst), but the firing rate increased when the skin over the triceps muscle of the contralateral forelimb was pinched. Thus for these and other neurons the rhythm could be modulated or in some cases stopped by stimulation of the LVN or the MLF or by natural stimulation (squeezing) of the pads, skin or muscles of the arm or of other body parts.

For one neuron the firing was correlated with the EMG recorded from the triceps muscle of the ipsilateral forelimb. Both the EMG and the LDP neuron fired at a period of 0.59 ± 0.04 sec, with the beginning of the neuronal burst leading the beginning of the EMG activity by 65 ± 18 degrees. This neuron fired 0 to 3 spikes/burst.

The LDP cells are hypothesized to synchronize the walking of the forelimbs with the hindlimbs. Supported by NIH grant NS-10304.

12.7 THE EFFECTS OF APOMORPHINE ON SPINAL CORD MONOSYNAPTIC TRANSMISSION. J.S. Carp* and R.J. Anderson (SPON: J.G. Kenimer). Dept. of Pharmacol., Geo. Washington Univ., Washington, D.C. 20037.

The effects of i.v. administration of the dopamine agonist apomorphine and the catecholamine antagonists haloperidol and phentolamine on spinal cord neurotransmission were evaluated in spinal cats. Compound action potentials of monosynaptic latency evoked by supramaximal stimulation of L_6, L_7 or S_1 dorsal roots were recorded from the appropriate ventral root during slow repetitive stimulation (2N response) and during posttetanic potentiation (PTP response).

The results of these experiments are summarized in the table below. Apomorphine (2 mg/kg) significantly depressed the amplitude of the 2N but not the PTP response. However, this depressant effect of apomorphine was not observed in animals pretreated with the dopamine receptor antagonist haloperidol (2.5 mg/kg). This dose of haloperidol alone depressed the amplitudes of the 2N and PTP responses to 90±4% and 82±5% of the predrug control, respectively. Pretreatment with phentolamine (1 mg/kg), an α-adrenergic antagonist, did not alter apomorphine's depressant effect on the 2N response. This dose of phentolamine alone had no effect on spinal monosynaptic transmission.

These data demonstrate a depressant effect of apomorphine on spinal cord transmission. This appears to be mediated by a dopaminergic mechanism, since the dopamine receptor antagonist haloperidol, but not the α-adrenergic receptor antagonist phentolamine, prevented the depressant effect of apomorphine on the 2N response.

Effect of Apomorphine
(mean % of predrug amplitude)

Pretreatment	none + apomorphine	haloperidol + apomorphine	phentolamine + apomorphine
2N	75 ± 5*	96 ± 5	76 ± 1*
PTP	96 ± 4	96 ± 3	90 ± 7
	n = 10	n = 5	n = 3

*$p < 0.01$, significantly different from predrug response

12.8 RECOVERY OF MOTOR FUNCTION FOLLOWING LESIONS OF THE DORSAL COLUMN NUCLEI, DORSAL COLUMNS, AND DORSAL ROOTS. A.J. Berman, D. E. Teodoru, and T.A. Tran.* Dept. of Neurosurgery, V.A. Hospital, Bronx, New York 10468.

This study was undertaken to further explore the role of the dorsal column medial lemniscal system (DCMLS) in recovery of motor function after dorsal rhizotomy (DR). A total of 14 monkeys were subjected to lesion of the dorsal column nuclei (DCN). Of these, five underwent DR six months later; six underwent dorsal columns section (DC) three months after DCN lesion, and of these, three were subjected to a third lesion, DR, after a further three months. Thus, all DR procedures were carried out six months after DCN lesion. All operative procedures were bilateral. Animals were trained on each of two tasks before the initial surgery, and all were retested starting two weeks after the final surgery except for two of the DCN plus DR animals, which were not retested until six months after the last surgery. One task involved reaching into a moving cylinder to remove a piece of food, and the other necessitated reaching for a small food pellet nested atop a narrow stationary platform.

DC section ameliorated the finger discoordination resulting from DCN lesion. The amelioration, however, is not as great as that seen when DR follows DCN lesion. On both tasks, reaching was more severely affected by DC than by DCN or by DCN plus DC lesion, confirming previous results of Melzack and Bridges. On the moving cylinder test, monkeys that had undergone lesion of DCN, followed by lesion of DC, then DR, exhibited a more rapid recovery than monkeys that had only undergone lesion of DCN then DR. On the stationary platform test, however, rate of recovery was similar for both groups of animals.

Melzack and Bridges have proposed that after DC lesion, intrinsic circuits in DCN are released from ascending control and are driven to fire aberrantly by descending cortical input, thus providing "misinformation" to motor centers. They proposed that lesion of DCN eliminates such misinformation. We suggest that our results, involving DR, can be interpreted similarly. After DCN lesion, spinocerebellar pathways within DC are still intact. DR may release intrinsic circuits of the spinal relay nucleus of this system from ascending control, thus sending "misinformation" to the cerebellum. Tracking performance, as on the moving cylinder test, is sensitive to spinocerebellar input, and would, therefore, be severely impaired by such misinformation.

12.9 EFFECTS OF DORSAL RHIZOTOMY AND DORSAL COLUMN MEDIAL LEMNISCAL SYSTEM INTERRUPTION ON PERFORMANCE OF A BIMANUAL TASK. T.A. Tran,* D.E. Teodoru, and A.J. Berman. (SPON: R. Hawkins). Dept. of Neurosurgery, V.A. Hospital, Bronx, New York 10468.

Dorsal rhizotomy (DR) is not only a "sensory" lesion depriving the CNS of peripheral information; it is also a motor lesion, for it interrupts the γ loop, debilitating those motor functions dependent on "α-γ coactivation"(Granit, 1976). Dorsal column medial lemniscal system(DCMLS) interruption is more of a sensory lesion for it deafferents the sensorimotor cortex (SMC) (Brinkman, et.al., 1978) without interrupting the γ loop. The present study seeks to differentiate the chronic effects of DR from those of DCMLS interruption. Three monkeys underwent unilateral DR and two, bilateral DCMLS lesions followed by unilateral DR. They were tested 18 months post-operatively on two bimanual tasks requiring proximal strength from one limb and digital coordination from the other. Each monkey had to pull a tray against a 6 lb. (heavy) or a 2 lb. (light) counterweight and to hold it while removing pellets from a flat surface (easy task) or from a dexterity board (hard task) which required use of a coordinated precision grip. All monkeys used the non-DR limb exclusively to pull the tray towards themselves. When the counterweight was light, the uDR monkeys switched hands: the intact limb pulled the tray and the DR limb held it while the intact hand grasped the pellets on both easy and hard tasks. When the weight was heavy, the DR limb was used to grasp the pellets on both hard and easy tasks, while the intact limb held the tray. The two monkeys with DCMLS interruption on one side and DR on the other used the limb on the DCMLS-lesioned side to hold the tray and the DR limb to remove the pellets on both hard and easy tests, when the weight was light as well as heavy. The strategy used by the unilateral DR monkeys indicates that the strength of the DR limb was inadequate to hold the tray when the weight was heavy but finger coordination was adequate to perform the hard tasks. This observation is consistent with the results of Hepp-Raymond, et.al. (1973), suggesting that coordinated movements can be executed via the "α route," but the development of strength requires α-γ coactivation. Since these uDR monkeys had undergone maximal recovery from post-DR ataxia, we conclude that chronic disuse of the DR limb is due to weakness and not discoordination. Exclusive use of the DR limb to grasp pellets by the monkeys subjected to DR on one side and DCMLS interruption on the other suggests that while post-DR digital coordination greatly improves, after DCMLS interruption it remains permanently impaired.

12.10 THE ROLE OF ATTEMPTED MOVEMENTS IN RECOVERY FROM UNILATERAL DORSAL RHIZOTOMY. D.E. Teodoru and A.J. Berman. Dept. of Neurosurgery, V.A. Hospital, Bronx, New York 10468.

After unilateral dorsal rhizotomy (uDR), the deafferented limb of monkeys was found not to be used purposefully in the free situation unless the intact limb was immobilized or amputated at the wrist. However, if the intact hand was covered, uDR monkeys could eventually be trained to use the DR limb to reach into a box and remove crackers. Furthermore, we observed spontaneous use of the DR limb in postural support, ambulation, and climbing by some uDR monkeys several years after surgery. The present study has sought to examine the pattern of spontaneous recovery of uDR monkeys (C2 to T3) after rendering the intact limb functionally useless. A hollow, transparent, lightweight polyethelene ball, 11.4 cm. in diameter, was placed over the intact hand permitting free movement of the hand within it. This was done to 3 uDR monkeys 3-1/2 months after surgery and to four at surgery. The ball was temporarily removed 1, 2, or 3 months after being put on in some cases and permanently 4 months later in all cases. Food could only be obtained by reaching blindly into a box through a hole 6.4 cm. in diameter. Animals were kept in a large "gym" cage and observed daily for over two years. Before the intact limb was covered, it performed all purposive movements; the DR limb only exhibited associated movements. Irrespective of when the DR limb was covered, all uDR monkeys exhibited almost the same pattern and rate of recovery. A sudden shift to exclusive use of the DR limb followed initial abortive attempts to use the covered intact limb. Early DR limb movements were very ataxic. During such movements, the intact limb exhibited associated movements inside the ball. Recovery followed a distal to proximal course (e.g., finger coordination preceeded accurate reaching). Each movement recovered in strength only several weeks after it recovered in form. When the ball was removed, bimanual cooperation was immediately evident in eating, climbing, ambulation, and other manipulative tasks. If removal occurred after more than 4 months, interlimb coordination persisted; if after less than 4 months, it deteriorated in days,and disuse of the DR limb resulted. We propose that higher centers substitute reefferent for reafferent feedback in order to regain control of lower centers disrupted by DR. Such internal feedback is available only when movements are attempted so that the post-operative period of disuse does not contribute to recovery. We feel that adjustment of the same motor circuits that are used to produce movements in intact monkeys would be responsible for post-DR recovery and not retraining to use alternate circuits as proposed by Chambers.

12.11 SUPRASPINAL FACILITATION OF SHORT LATENCY POLYSYNAPTIC EPSPs PRODUCED BY LOW THRESHOLD SURAL NERVE AFFERENTS IN MEDIAL GASTROCNEMIUS α MOTONEURONS. M. J. Pinter*, R. E. Burke, M. J. O'Donovan* and R. P. Dum. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Electrical stimulation of low threshold (<5xT) afferents in the sural nerve (SN) produces mixed polysynaptic PSPs in ankle extensor α motoneurons (MNs). The shortest-latency components are excitatory (EPSPs) and these are predominant in the SN PSPs recorded in fast twitch (type F) medial gastrocnemius (MG) MNs but are much smaller and often absent in slow twitch (type S) cells (J. Physiol. 207:709, 1970). The polysynaptic PSPs produced in the same MNs by stimulation of the red nucleus (RN) are qualitatively similar, suggesting that SN afferents and rubrospinal axons may converge upon the same spinal interneurons (op. cit.). This hypothesis was tested using intracellular recording from MG MNs in cats anesthetized with α-chloralose. Ventral roots were intact and MG MNs were identified by antidromic invasion from the cut MG nerve on the left side. The right RN and the pyramidal tract (PT) were separately stimulated (5 to 8 pulses, 0.2 msec duration at 500 Hz, 30 - 100 μA) with sharpened tungsten monopolar electrodes placed stereotaxically, guided by antidromic field potentials evoked from the left dorsolateral spinal cord quadrant at T13 (right half of the cord cut and dorsal columns removed at T13). Final RN and PT electrode positions were adjusted for point of minimum threshold for facilitation of the disynaptic group Ia IPSP (tibialis anterior nerve stimulation; Hongo et al., Exp. Brain Res. 7:365, 1969). Supraspinal conditioning trains to RN or PT preceeded the test SN PSP by 20 - 50 msec (train onset). Resulting PSPs were averaged by interleaving individual sweeps of test, conditioning alone, and conditioning plus test trials in different quadrants of the averager memory. RN and PT conditioning both produced net facilitation of the short-latency EPSP components in the SN response, which was particularly clear when SN stimulation was 1.1-1.5 x T (threshold for cord dorsum N wave and compound action potential in the intact sciatic nerve). At these low levels of SN stimulation, PT conditioning produced relatively clean increase in SN EPSP components while the effect of RN was complicated by considerable facilitation of SN IPSP components. Maximum SN EPSP facilitation was found in MG MNs with fast conduction velocity and short afterhyperpolarizations, presumed to be type F MNs. The existence of this excitatory convergence suggests that rubro- and corticospinal axons can modulate transmission in a polysynaptic cutaneous excitatory pathway that appears to be organized to produce differential control of fast and slow twitch motor units (see Exp. Brain Res. 29:57, 1977).

12.12 PATTERNS OF SPIKE GENERATION OF LUMBAR MOTONEURONS DURING SLEEP AND WAKEFULNESS. F. Morales*, S. O'Brien*, and M. Chase (SPON: J. Segundo). Departments of Physiology and Anatomy and the Brain Research Institute, Univ. of California, Los Angeles, CA 90024.

The present report describes the patterns of spike generation of lumbar alpha motoneurons during sleep and wakefulness. Intracellular experiments utilizing micropipettes filled with 3M K-citrate were performed on six chronic, undrugged, normally respiring adult cats according to procedures previously described (Morales and Chase, Exp. Neurol. 62:821-827, 1978). The patterns of motoneuron discharge in the chronic cat during wakefulness (W) and quiet sleep (QS) were similar to that reported during synergistic muscle stretch in the acute preparation: small depolarizing potentials summated, which resulted in sustained depolarization. When a critical level of depolarization was reached, rhythmic discharges appeared. The membrane potential time course between spikes, i.e., its "trajectory," was similar in W and QS to that reported for motoneurons discharging in the primary range in the acute preparation. Some lumbar motoneurons were continuously active during W or QS while others discharged sporadically.

When the animal entered AS, spontaneous activity ceased entirely. Concomitant with periods of intense rapid eye movements, large rhythmic depolarizing potentials often developed (4-6 waves in each episode with a wave duration of 100 to 200 msec and an amplitude of 6 to 8 mV). In spite of their large amplitude these potentials did not always spontaneously produce spike activity. Indeed, in most of the cases, discharge threshold was not reached. If a depolarizing bias was added (outward current injected through the microelectrode), spike doublets or triplets were observed riding on the summit of these rhythmic potentials. When these potentials were above threshold, two or three spikes appeared in conjunction with each wave.

Two types of action potentials were noted during AS. The first type was characterized by full sized spikes whose amplitudes were similar to those which appeared during QS and W. The main difference consisted of the almost complete abolition of afterhyperpolarization. The second type was characterized by partial spikes whose amplitudes were in the order of magnitude of an "A" spike. Typically "normal" motoneuron spikes could always be induced by orthodromic and/or antidromic excitation both before and after periods of rapid eye movements.

We postulate that the depolarizing potentials of AS may be due to phasic excitatory influences acting on spinal cord motoneurons during periods of rapid eye movements, and that the small spikes possibly originate in a pacemaker region other than the soma membrane. Supported by grants from the USPHS (NS 09999) and the NSF (BNS 79 12897).

13.1 SIMILARITIES AND DIFFERENCES IN THE STRUCTURE OF SEGMENTALLY HOMOLOGOUS NEURONS CONTROLLING HEARTBEAT IN LEECH. M. R. Shafer* and R. L. Calabrese. The Biological Laboratories, Harvard Univ., Cambridge, MA 02138.

The central pattern generator for heartbeat in the leech, Hirudo medicinalis, comprises an ensemble of synaptically interconnected heart motor neurons (HE cells) and heart interneurons (HN cells). We have investigated the structure of these neurons by iontophoretic injection of the dye Lucifer Yellow.

Bilateral pairs of HE cells have been identified in segmental ganglia 3-19 of the nerve cord. Their structure was found to be nearly identical from ganglion to ganglion and from animal to animal.

Bilateral pairs of HN cells have been identified in segmental ganglia 1-7 of the nerve cord. Their structure was found to vary from ganglion to ganglion. These segmental differences among HN cells were consistently observed from animal to animal. The HN cells also show segmental differences in the types of electrical activity recorded in their cell bodies and in their synaptic connections with the other neurons of the network. Some of these physiological differences were found to correlate with the observed structural differences.

No postsynaptic potentials can be recorded from the cell body of the heart interneuron in the second ganglion, cell HN(2). This observation correlates with the cell's lack of dendritic arbor in that ganglion. Cells HN(3) and HN(4) show similar electrical activity and have similar input and output connections. However, cell HN(3) connects monosynaptically with the ipsilateral heart motor neuron in its own ganglion while cell HN(4) does not. This difference is reflected by the presence of a well developed anterior branch in cell HN(3) that projects into the dendritic arbor of the ipsilateral cell HE(3). Such a branch is not present in cell HN(4).

Some physiological differences among the heart interneurons are not reflected in their dendritic structures. Cells HN(3) and HN(4) inhibit their contralateral homologues while cells HN(6) and HN(7) do not. However, the dendritic arbors of each of the neurons overlaps to the same extent with that of its contralateral homologue.

13.2 SPIKE TRAIN ANALYSIS OF IDENTIFIED SIPHON MOTONEURONS IN INTACT APLYSIA AND SUBSEQUENTLY REDUCED PREPARATIONS. Lewis Eberly and Harold Pinsker. Marine Biomedical Institute, Depts. of Physiology and Psychiatry, UTMB, Galveston, Texas 77550.

To examine how a simple nervous system mediates different patterns of behavior, implanted cuff electrodes are used to record spontaneous and triggered activity from whole nerves in intact Aplysia californica. Firing patterns of individual units are characterized by analysis of 2-channel recordings based on spike amplitudes and conduction velocities. To record intracellularly from members of the same population, the intact animal is then anesthetized, restrained and surgically reduced to a semi-intact preparation in which the abdominal ganglion is lifted onto a stage. The spike train analysis must recognize the same units in the semi-intact preparation in order to trace the activity of these identified units back to the intact animal.

Electrical activity was recorded from the siphon nerve of intact animals during quiescence and reflex activation of siphon withdrawal. Computer analyzed siphon nerve samples typically contain 8 to 10 units with well isolated spike amplitudes and conduction velocities. After reduction to the semi-intact preparation, siphon nerve activity was again recorded and the same population of units could typically be recognized. Representative members of the population of siphon motoneurons were then identified by intracellular impalement and their extracellular spikes characterized in terms of amplitude and conduction velocity. Once characterized in the semi-intact samples, the same unit could be identified in samples from the intact animal using spike amplitude and conduction velocity as criteria. Additional criteria such as similar responses (excitation or inhibition) during spontaneous Interneuron II contractions and visual inspection of unitary waveforms aid in making the connection between the semi-intact preparation and the intact animal.

This approach will be used to characterize the firing patterns of identified neurons in intact animals and to specify the changes in firing at different stages of the experiment. For example, siphon motoneurons often fire more regularly in the semi-intact preparation and occasionally show prolonged spontaneous bursts, quite unlike their activity in the intact animal. We also hope to fill siphon motoneurons intrasomatically to label their axons in the nerve and to correlate axon diameter and infolding with the amplitudes and conduction velocities used to identify units by spike train analysis. (Supported by NSF grant BNS 76-17480 and NIH grants 16087 and 11255).

13.3 CENTRALIZED CONTROL OF DISTRIBUTED MOTOR NETWORKS IN PLEUROBRANCHAEA. C. S. Cohan* and G. J. Mpitsos (Spon: P. Crago). Dept. of Anatomy, Case Western Reserve Univ., Cleveland, OH 44106.

Coordination of cyclical appendage movements in the marine gastropod mollusc Pleurobranchaea californica has been explained by the coupling of multiple oscillatory centers distributed in the nervous system (Davis, W. J., Siegler, M. V. S., and Mpitsos, G. J., J. Neurophysiol. 36: 258, 1973). The neural responses, which were assumed to represent feeding behavior, were obtained from isolated nervous systems by electrical stimulation of the stomatogastric nerve (STGn), paracerebral command neurons (PCN), and the connective between the cerebral and buccal ganglia (CBC). In studying the mechanisms for coordination of activity between ganglia we first reexamined the evidence for distributed oscillators. The following results were obtained when activity in the CBCs was blocked by means of anodal electrical currents or sucrose gap perfusions: a) blockage during STGn stimulation immediately stopped cerebral ganglion rhythms but did not affect buccal ones; b) short duration blocks did not shift the phase relationship between cerebral and buccal activity; c) blockage during PCN stimulation stopped all cerebral and buccal rhythms. Tonic stimulation of the CBCs produced rhythmic activity in isolated cerebral ganglia as originally reported. In some instances, bursts in the CBC occurred simultaneously with the cerebral bursts, but, when individually isolated, the same CBC produced rhythmic activity to tonic electrical stimulation. Taking these observations together, we conclude that the patterned activity necessary for driving the distributed motor networks in isolated nervous systems arises only from loci in the buccal ganglion.

Intracellular recordings from PCN has shown that these cells are functionally heterogeneous in the types of motor patterns they produce. Moreover, corollary discharge neurons (CDN) in the buccal ganglion are activated during PCN or STGn stimulation, and, in turn, drive specific cerebral motoneurons. In addition, we have found that the body structures innervated by the buccal and cerebral ganglia participate in at least 5 different behaviors (feeding, regurgitation, rejection, defensive bite, and gill grooming), all of which appear to be produced by similar motor patterns, except for the active phase of regurgitation (McClellan, A. D., Soc. for Neurosci., 1978 and 1979). By our present hypothesis, these behaviors might be produced by different "command system requests" that turn on the buccal oscillator(s) and selectively orchestrate the movement of the anterior body structures through the CDN. (NSF BNS 76-8123)

13.4 Leech swimming:effects of interrupting the intersegmental path of swim-initiating vs. pattern generating neurons, and the ability of single ganglia to produce swim bursts. Janis C. Weeks. Dept. of Biology, Univ.Ca.San Diego, La Jolla, Ca. 92093

Two functionally distinct groups of segmentally iterated interneurons participate in leech swimming: 1) "oscillator" interneurons, whose intra- & interganglionic connections have been proposed to comprise the swim central pattern generator, & 2) swim-initiating interneurons. Both classes send interganglionic axons for considerable distances in anatomically separate connectives: oscillator interneuron axons run in the paired, lateral connectives, whereas swim-initiating interneuron axons run in the medial connective, Faivre's Nerve. Thus, section of the medial or lateral connectives interrupts functionally distinct neuronal pathways. The initiation and coordination of the swim motor pattern in isolated nerve cords was studied after producing such lesions in midbody segments. Faivre's Nerve section did not affect intersegmental coordination of the pattern, but interfered somewhat with the simultaneous initiation of the pattern along the cord in response to swim-initiating interneuron stimulation. After section of the lateral connectives, stimulation of a swim-initiating interneuron in either end of the nerve cord caused normally coordinated simultaneous swim activity in both ends, but individual swim cycles in the two ends were randomly phased with respect to each other. Thus, intersegmental coordination is normally mediated by axons running in the lateral connectives.

When cut away from the rest of the nerve cord, pairs of ganglia were able to produce the swim motor pattern, but individual ganglia were not. However, single ganglia left attached to the remainder of the nerve cord by one or both Faivre's Nerves produced swim bursts in response to swim-initiating interneuron stimulation anywhere in the nerve cord. Thus, intersegmental connections among oscillator interneurons are not required for rhythmic pattern generation by single ganglia.

13.5 FLIGHT ACTIVITY EVOKED BY INTRACELLULAR STIMULATION OF GIANT INTERNEURONS IN THE COCKROACH PERIPLANETA AMERICANA.
R.E. Ritzmann, C.R. Fourtner And M.L. Tobias. Dept. of Biology, Case Western Reserve University, Cleveland, Oh 44106.

Stimulation of giant interneurons (GIs) in the cockroach Periplaneta americana evokes a motor output which is believed to be associated with running in the wind-mediated escape response (Ritzmann and Camhi, J. comp. Physiol. 125: 305, 1978, Camhi and Tom, J. comp. Physiol. 128: 104, 1978). However, when none of the cockroach's legs are in contact with a surface, wind stimuli directed at the animal's cerci evoke flying movements rather than running movements. The initiation of both of these behaviors could be controlled by the GIs, if a switch were interposed between the GIs and the pattern generators for flying and running. The position of this switch would be determined by sensory information on leg contact. To test this hypothesis, we performed experiments to determine whether or not stimulation of GIs can in fact initiate flight in the absence of leg contact.

All legs were removed except the right metathoracic leg, which was left intact to allow for recording from leg nerves. In this leg,nerve 5, which contains the major sensory axons of the leg, was severed. Under these conditions an animal pinned to a cork will perform vigorous flight activity in response to gentle wind puffs. This is characterised as follows: 1. The wing stubs unfold and beat at 20-40Hz, 2. EMG recordings from flight muscles are indistinguishable from those recorded during tethered flight, 3. Leg levator motor neurons burst approximately in phase with wing elevator and depressor muscle potentials. This levator activity is probably involved in maintaining the proper leg posture during flight.

Under these conditions trains of current pulses (73 msec duration/2.0 - 3.5 msec interpulse interval) delivered intracellularly to any dorsal GI will evoke flight activity identical to that described above. This is a dramatic change from the response evoked by the same stimulus to the same GIs when leg contact is maintained. GI stimulation only evokes vigorous flying when nerve 5 of all 6 legs is severed. Moreover, even when they are all severed, stimulation of a single nerve 5 during GI stimulation prevents flight activity from occurring. Thus, the dorsal GIs are capable of initiating at least two completely different locomotor behaviors. The choice of which behavior is initiated at any given time is based, at least in part, on sensory activity in nerve 5 of each leg.

13.6 CENTRAL EFFECTS OF OCTOPAMINE AND SEROTONIN ON POSTURAL MOTOR SYSTEMS IN THE LOBSTER.
R. Harris-Warrick, M. Livingstone* and E. Kravitz. Dept. of Neurobiology, Harvard Med. Sch., Boston, MA 02115

Injection of octopamine into freely moving lobsters (Homarus americanus) causes the animals to assume a rigid, sustained posture characterized by hyperextension of all extremities. Serotonin injection induces flexion. These opposite postural effects are not due to excitatory effects of the amines directly on exoskeletal muscles: on muscles, amines have a synergistic action. Rather, the postures are generated by activation of diametrically opposite centrally co-ordinated motor programs. In root recordings from isolated abdominal ganglia, we have shown that bath application of octopamine selectively excites motor neurons to slow (postural) extensor muscles and the inhibitory neuron to slow flexors while simultaneously inhibiting activity of motor neurons to slow flexors and the inhibitory neuron to slow extensors. Serotonin activates an opposite pattern (Livingstone et al., Science 208:76 (1980).

To understand the mechanisms by which the amines generate these complex motor programs, we have recorded intracellularly from identified motor neurons in abdominal ganglia, primarily I1, the inhibitory neuron to slow flexors, and M15, an excitatory motor neuron to slow extensors. Recording from the somata, we can detect attenuated epsp's and ipsp's, and action potentials arising from the distal spike initiation zone. At least part of the amine effect appears to be on pre-synaptic inputs to the motor neurons: in both I1 and M15, octopamine increases the spontaneous epsp frequency (+255%) while serotonin decreases epsp frequency (-25%). These changes could be due to direct amine effects on the input resistance of the cells; this would raise or lower the signals into the noise level of the recording, causing only an apparent change in epsp frequency. We believe this is not correct for the following reasons: 1) spontaneous and evoked epsp's and ipsp's do not change in amplitude; 2) the ipsp frequency does not change; 3) the attenuated spike recorded in the soma does not change in amplitude; 4) the input resistance and resting potential recorded in the soma do not change. In addition to pre-synaptic effects, octopamine also lowers the apparent threshold for action potential generation in I1 when the spike is induced by current injection into the soma. At this time it is not known whether this effect is a direct action on I1 or results from increased excitatory input localized at the I1 spike initiation zone.

The motor patterns elicited by octopamine and serotonin are strikingly similar to those observed upon stimulation of command fibers for abdominal extension and flexion in crayfish (Evoy and Kennedy, J. Exp. Zool. 165:223 (1967)). Our results support a role for octopamine and serotonin in directing or modulating postural commands in Crustacea. Supported by NIH #NS-07848 and MDA.

13.7 SEROTONIN INCREASES THE PROBABILITY THAT THE LEECH NERVOUS SYSTEM WILL PRODUCE THE SWIM MOTOR PROGRAM.
Alan L. Willard* (SPON: W.B. Kristan, Jr.). Biology Dept., B-022, UCSD, La Jolla, CA 92093.

The isolated nerve cord of a leech can produce episodes of the swim motor program but usually does so only in response to stimulation of peripheral nerves or of swim-initiating interneurons (Kristan & Calabrese, J. exp. Biol., 65: 643, 1976; Weeks & Kristan, J. exp. Biol., 77:71, 1978). I have found that isolated nerve cords produce episodes of the swim motor program in the absence of such stimulation when they are exposed to $5x10^{-8}$-10^{-5}M serotonin. Such "spontaneous" episodes first occur 2-30 min after serotonin is added to the saline bathing an isolated nerve cord or one or a few ganglia within an isolated nerve cord. They continue to occur for as long as 2-3 hr after washing out the serotonin.

Each segmental ganglion has 7 serotonin-containing neurons. These cells are electrically coupled (Lent & Fraser, Nature, 266: 844, 1977) and include the Retzius cells, which are the largest neurons in the leech. Stimulation of the Retzius cells in a pair of ganglia of an isolated nerve cord is followed by "spontaneous" episodes of the swim motor program if the volume of saline around the ganglia containing the stimulated cells has been reduced to about 50 µl or less. This requirement for a reduced volume in order to see an effect of Retzius cell stimulation on the probability of occurrence of a swim episode suggests that serotonin may act as a circulating effector in the leech.

To test the physiological relevance of the effect of serotonin on isolated nerve cords, intact leeches were injected with 100 µg of serotonin. Swimming behavior of these and of control leeches (both uninjected and saline-injected animals) was recorded by an observer who did not know what treatment the animals being observed had received. In the absence of experimental stimulation, control animals swam relatively infrequently (about once per 10 min observation period per 2 animals), while leeches which had been injected with serotonin swam about 7 times per 10 min observation period. This effect of serotonin injections lasted 5-8 hr.

Thus, either administration of exogenous serotonin to isolated nerve cords or to intact leeches or stimulation of serotonin-containing neurons in isolated nerve cords can result in increased probability that the leech nervous system will produce episodes of the swim motor program. Experiments are in progress to find the neuronal basis for this phenomenon. (Supported by NIH fellowship 1 F32 NS 06182-01 to ALW and by USPHS grant 1 R01 NS14410-01A1 to WBK.)

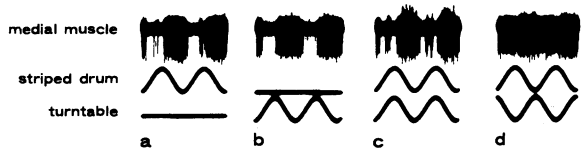
13.8 CEREBRAL CONTROL OF THE EXTRINSIC FEEDING MUSCLES IN APLYSIA.
Steven Fredman and Behrus Jahan-Parwar. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

Feeding in Aplysia is the result of the coordinated cyclical activation of both the intrinsic and extrinsic muscles of the buccal mass. The former control the several steps involved in each bite and are innervated by buccal ganglia neurons, while the latter are largely responsible for the overall protraction and retraction of the buccal mass itself and are innervated, at least in part, by several identifiable cerebral ganglion neurons. We have examined the control of two of the extrinsic buccal mass protractors using an isolated brain-muscle preparation. Cerebral neurons innervating these muscles were identified by simultaneous intracellular, extracellular and tension transducer recordings. Cerebral innervation of the protractors is via the upper labial nerve (ULAB) and includes a single ipsilateral B cluster neuron and several neurons in the E clusters. Excitatory motor neurons had axons in the ULAB branches innervating the protractors; caused muscle contractions when depolarized by current injection and 1:1 extracellularly recorded potentials at the muscle. The B neuron is a strong exciter and could produce measureable muscle contractions at firing rates as low as 4 Hz. There are at least 2 excitatory E neurons. In addition 2 E cluster neurons appear to be inhibitory motor neurons for one of the muscles. Intracellular stimulation of these neurons produced no tension changes when the protractor was relaxed, but caused measureable decreases in tension when the muscle had contracted either spontaneously or following intracellular stimulation of an excitatory motor neuron. While the mechanism by which the inhibitory motor neurons produce their effect is not yet known, two possibilities are direct action at the muscle and/or presynaptic gating. E cluster neurons display cyclic firing, with the excitatory motor neurons firing during the rising phase of protractor contractions and the inhibitors firing during the falling phase. Both excitors and inhibitors exhibit synaptic input and firing which is coordinated with the firing of units recorded from the buccal roots and with individual intracellularly recorded buccal ganglia neurons. The mechanisms by which the neurons controlling the intrinsic and extrinsic buccal muscles are coordinated is under investigation. (Supported by Grant NS14388 to BJ-P).

13.9 OCULOMOTOR ACTIVITY DURING COMBINED OPTOKINETIC AND PROPRIOCEPTIVE STIMULATION OF THE CRAYFISH. Richard F. Olivo and DeForest Mellon Jr. Dept. Biol. Sci., Smith College, Northampton, MA 01063 and Dept. Biology, Univ. of Virginia, Charlottesville, VA 22901.

The crayfish's horizontal eye movements are driven by inputs from the visual system (the optokinetic response) and from proprioceptors in the legs; the two inputs add algebraically. We report here on experiments in which we recorded from the muscles that move the eye in the horizontal plane. Crayfish (Procambarus clarkii) were clamped above a turntable on which their legs rested and were surrounded by a striped drum. Fine wire electrodes were inserted in the medial and lateral muscle of the eye. The turntable and striped drum were oscillated sinusoidally through 38° at frequencies from 3 to 23 cycles/min (0.05 to 0.38 Hz), under four conditions: stripes moving with turntable clamped, turntable moving with stripes covered and clamped, stripes and turntable moving together (in phase), and stripes and turntable moving in opposite directions (out of phase).

Preliminary analysis of the data confirms the results of prior experiments on eye movements: optokinetic stimulation is most effective at low frequencies, proprioceptive stimulation is most effective at high frequencies, and the response to combined (in phase) stimulation is greater than the responses to either stimulus alone. Out-of-phase stimulation, which evokes very small movements of the eyes, evokes substantial motor activity. This surprising result is illustrated in the recordings below from a unit in the medial muscle of the right eye. The unit responds to counterclockwise (downward) movement of the stripes (a), the turntable (b), or both together (c). (Brief bursts during the clockwise phases of (a) and (c) correspond to flickbacks of the eye.) The unit's response to out-of-phase stimulation (d) is continuous, as if the unit were driven independently by the counterclockwise phases of each stimulus. This suggests that the reduced eye movements during out-of-phase stimulation are due to simultaneous activation of antagonist muscles, and it implies that at least some of the algebraic summation of visual and proprioceptive stimuli occurs at the level of the muscles themselves.



(Supported by a grant from the Whitehall Foundation).

13.10 Thoracic leg control of abdominal extension in the crayfish, Procambarus clarkii. Charles H. Page. Dept. of Physiology and Bureau of Bio. Research, Rutgers Univ., Piscataway, NJ, 08854.

Postural extensions of the abdomen of the crayfish, Procambarus clarkii can be evoked by mechanical stimulation of single thoracic legs. Movement of a single leg joint is sufficient to initiate an extension response. Vigorous abdominal extensions are initiated either by depression of the whole leg (WLD) or by flexion of the mero-carpal joint (MCF). Similar stimulation of the chelipeds does not elicit an abdominal extension response.

Single frame analysis of motion pictures of crayfish responding to WLD or MCF stimulation showed that the responses evoked by the two different stimulus situations are nearly identical. They differ principally in the responses of the leg located contralateral to the stimulated leg.

Movements of most of the cephalic, thoracic and abdominal appendages accompany the abdominal extension response. Only the eyes remained stationary throughout the response. The mean values of the latencies for the initiation of appendage movement ranged from 125 to 204 msec; abdominal movement had a mean latency of about 220 msec.

The abdominal extension reflex results from the activity of the tonic superficial extensor muscles. The deep phasic extensor muscles are silent during the response. The mean latencies for the initiation of superficial extensor muscle activity by WLD and MCF stimulation were 53.7 msec and 50.0 msec respectively. Supported by NIH grant NINDS #12262.

14.1 ALPHA-ADRENERGIC BINDING SITES IN BOVINE ANTERIOR PITUITARY GLAND AND CONTROL OF ACTH SECRETION IN RAT ANTERIOR PITUITARY CELLS IN CULTURE. L. Beaulac-Baillargeon*, T. Di Paolo*, V. Raymond*, V. Giguère* and F. Labrie* (SPON: C. Radouco-Thomas) School of Pharmacy & Dept. of Mol. Endocrinology, CHUL, Quebec G1V 4G2, Canada.

Three α-adrenergic ligands were used to identify and characterize α-adrenergic binding sites in bovine anterior pituitary membranes. The assay was performed as described (Caron et al., J. Biol. Chem. 253: 2244, 1978). [^{3}H]clonidine binds to a single class of high affinity binding sites at a K_D value of 0.45 ± 0.1 nM with a number of binding sites of 15 ± 4 fmol/mg protein. Specific binding measured in the presence or absence of 1 μM unlabeled clonidine (65% of total binding) is rapid, saturable and stereospecific. The specificity is characteristic of an alpha-adrenergic receptor: clonidine > epinephrine > norepinephrine > dopamine > isoproterenol. Yohimbine is much more potent than prazocin which has no effect below 10^{-6}M. The α-adrenergic antagonists phentolamine (K_D = 6 nM) and dihydroergocryptine (DHEC) (K_D = 15 nM) compete for binding while WB-4101 is less potent (K_D = 60 nM). The β-adrenergic antagonist propranolol and serotonergic agents do not interfere with [^{3}H]clonidine binding. No high affinity sites could be demonstrated for [^{3}H]WB-4101 at concentration up to 60 nM. As assessed in the presence or absence of 100 nM spiroperidol, 10-15% of total [^{3}H]DHEC binding is alpha-adrenergic and can be displaced by α-adrenergic agents. [^{3}H]clonidine binds with high affinity in rat anterior pituitary homogenate. A good correlation is observed between the potency of a series of adrenergic agents to displace [^{3}H]clonidine binding from bovine adenohypophyseal membranes and to modulate ACTH secretion, in rat anterior pituitary cells in primary culture. (-) norepinephrine, (-)epinephrine and clonidine induce a dose-dependent stimulation of ACTH secretion (6- to 8-fold) which can be reversed by phentolamine, yohimbine and DHEC. Isoproterenol and dopamine do not stimulate ACTH secretion up to 1 μM while phenylephrine has little effect. The present data demonstrate the presence of an α_1-adrenergic receptor in bovine anterior pituitary membranes which shows a close correlation with the control of ACTH secretion in rat adenohypophyseal cells in culture. This system should be a useful model to study the mechanisms of action of α-adrenergic receptors.

14.2 [^{3}H]SPIROPERIDOL LABELS DOPAMINE RECEPTORS IN THE BOVINE PARS INTERMEDIA PITUITARY. T. Di Paolo*, P. Poyet* and F. Labrie* (SPON: S. Radouco-Thomas) Department of Molecular Endocrinology, CHUL, Quebec, G1V 4G2, Canada.

Pars intermedia cells secreting ACTH- and β-LPH-related peptides are under stimulatory and inhibitory control by β-adrenergic and dopaminergic agents, respectively. Since the secreted peptides can be measured with precision by specific radioimmunoassays, this system could become a useful model to study the interactions between β-adrenergic and dopaminergic receptors. We have thus used [^{3}H]-spiroperidol, a potent dopaminergic antagonist, to study the dopamine receptor in membranes prepared from the pars intermedia obtained from adult bovine pituitaries. The binding assay was performed as described (Caron et al., J. Biol. Chem. 253: 2244, 1978) using 10 μM (+)butaclamol to determine non-specific binding. [^{3}H]spiroperidol binding shows high affinity with a single class of binding sites (K_D value = 0.7 ± 0.1 nM), saturability (number of binding sites = 300 ± 20 fmoles/mg protein) and reversibility. At 25°C, the second order association rate constant (k_1) is 1.1 ± 0.2 x 10^7 min^{-1} while the first order dissociation rate constant (k_2) is 5.1 ± 1.0 x 10^{-3} min^{-1}, thus giving a ratio (k_2/k_1) of 0.5 ± 0.2 nM, a value in good agreement with that obtained by equilibrium binding data. The rank order of potency of various agonists to compete with [^{3}H]spiroperidol binding sites is consistent with a dopamine receptor: apomorphine > dopamine >(-)epinephrine =(-)norepinephrine > isoproterenol = clonidine. Competition for binding of the tritiated ligand shows stereoselectivity,(+) butaclamol being 1,000 times more potent than (-)butaclamol. Dopaminergic antagonists compete for [^{3}H] spiroperidol binding at nanomolar concentrations whereas adrenergic (phentolamine, propranolol, clonidine, (-)epinephrine, (-)norepinephrine and isoproterenol) and serotonergic (serotonin, cyproheptadine and methysergide) drugs do not compete or are only weak competitors at micromolar concentrations. GTP decreases the affinity of the agonists apomorphine and dopamine for [^{3}H]spiroperidol binding but does not change the potency of unlabeled dihydroergocryptine or spiroperidol. The influence of GTP suggests that the dopaminergic receptor of the pars intermedia pituitary is associated with a dopamine-sensitive adenylate cyclase. The present data show the presence of a typical dopaminergic receptor in pars intermedia and suggest that this system, in analogy with the adenohypophyseal mammotrophs where binding to the dopamine receptor can be correlated with prolactin secretion, could be a useful model where changes of receptor binding could be correlated with changes of secretion of ACTH- and β-LPH-related peptides.

14.3 EFFECTS OF LONG TERM DOPAMINERGIC TREATMENT ON PROLACTIN REGULATION IN THE RAT.
G. A. Jawahir* and G. M. Brown. Neuroscience Dept., McMaster University., Hamilton, Ontario L8N 3Z5.

Evidence suggests that tonic hypothalamic inhibition of pituitary prolactin (PRL) secretion is mediated by pituitary dopamine receptors responding to dopamine (DA) released from tuberoinfundibular neurons into portal blood. Prompted by an interest in observing the effects of a long term increase in DA stimulation on the regulation of PRL, we performed the following experiment. Male Wistar rats were given 16mg/kg of the DA agonist apomorphine in the form of a diester pro-drug apomorphine dipivaloyl ester (ADPE), for 12 days. Following 3 drug free days animals were decapitated and anterior pituitaries and trunk blood collected. Hemipituitaries were pre-incubated for 1 hour in medium 199 at 37°C in a shaking incubator under 95% O_2, 5% CO_2, then transferred to fresh medium. One of each pair was incubated for 3 hours in medium containing 250 nM DA, the other in drug free medium. Media were sampled at 90 mins. and 3 hrs., following which pituitaries were sonicated in saline.

Results of PRL radioimmunoassay revealed (1) lowered serum PRL levels, (2) reduced PRL secretion into drug free medium and (3) reduced pituitary PRL content, in animals pre-treated with ADPE. ADPE treated animals also showed a smaller percentage inhibition of PRL secretion in vitro in response to 250nM DA, but this was not a consistent observation and may simply be a reflection of the greatly lowered basal levels.

In earlier studies on the effect of long term DA agonist treatment, DA agonists have been shown to inhibit growth of cultured mammotrophs and cause tumor shrinkage in vivo. Our results indicate that either mammotroph PRL content or mammotroph numbers are lowered following long term dopaminergic stimulation in vivo, and suggest that downregulation of mammotroph proliferation and prolactin content may be a physiological role of DA.

14.4 CEREBELLAR INFLUENCES ON BASAL AND STRESS-INDUCED CORTICOSTERONE AND ACTH SECRETION IN THE RAT. J. P. Allen and T. Kepic*. Dept. of Neurosciences, Peoria Sch. of Med., Peoria, IL 61656.

The cerebellum is known to have an inhibitory influence on several CNS systems. Its possible role in neuroendocrine regulation is incompletely understood. Therefore, we studied the effects of midline and lateral cerebellar lesions on basal and stress-induced corticosterone (B) and ACTH secretion in 200 gm male Sprague Dawley rats. The study was accomplished by completely removing midline cerebellar (ML) structures or a portion of the left lateral cerebellar (LL) hemisphere using a vacuum operated suction apparatus. Four days following surgery the rats were decapitated immediately at 0700 h (AM) or 1600 h (PM) or following the exposure to a diethyl ether atmosphere for 2.5 min. Trunk blood was collected and plasma B and ACTH concentrations were measured by sensitive and specific radioimmunoassays. There was a reduction ($P < 0.05$) in the mean AM but not PM basal plasma B concentration in those with ML lesions compared to those with LL lesions. In each group there was preservation of the normal diurnal difference in plasma B concentration; however, there was no diurnal difference in plasma ACTH levels. Following the ether stress, mean plasma B levels were significantly higher ($P < 0.01$) in the ML group compared to the LL group. Similarly, the mean plasma ACTH levels were slightly but not significantly higher in the ML compared to LL group. We conclude from our data that an inhibitory outflow from midline cerebellar structures may modify both basal and stress-induced corticosterone secretion in the adult male rat. Moreover, the cerebellum does not appear to significantly alter the pattern of diurnal secretion of corticosterone or ACTH.

14.5 THE OLFACTORY BULB IS RICH IN TRH IMMUNOREACTIVITY. M.S. Kreider*, A. Winokur, N.R. Krieger, Departments of Pharmacology and Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA 19104

The tripeptide thyrotropin releasing hormone (TRH) was originally isolated from hypothalamic tissue. Its presence was subsequently demonstrated throughout the central nervous system, including retina, cortex, brain stem and spinal cord. We report that the rat olfactory bulb is rich in TRH immunoreactivity. Tissue was homogenized in 0.15 M NaCl, 0.01 M NaH_2PO_4, pH 7.5 at 0°C, diluted 5 fold with methanol and centrifuged for 10 minutes at 2000 rpm. The supernatant was dried and redissolved in 0.25% bovine serum albumin/PBS at 25°C. TRH content was determined according to the radioimmunoassay method of Bassiri and Utiger (Endocrinol, 90:722 - 727, 1972). The concentration (mean ± S.E.M., n=10) of TRH in olfactory bulb (60 ± 10 pg/mg wet weight) was 23% of the concentration in the hypothalamus, and was at least twice that of other brain regions examined. The 2 olfactory bulbs (mean wet weight 65 mg/2 bulbs) contained 3.9 ± 0.3 ng TRH. The TRH immunoreactivity could be separated into high and low molecular weight forms. The high molecular weight form sedimented at 15,000 xg and eluted in the void volume after gel filtration on Sepharose 4B. The low molecular weight form co-chromatographed with authentic TRH (MW 362) on gel filtration and thin layer adsorption chromatography and caused the release of thyrotropin from pituitary tissue incubated in vitro. The neuronal organization and functions of the olfactory bulb are well described. Studies of the localization and metabolism of TRH in this region may help clarify the role of this tripeptide in the central nervous system.

14.6 IMMUNOCYTOCHEMICAL ANALYSIS OF MAGNOCELLULAR ELEMENTS IN RAT HYPOTHALAMUS: DISTRIBUTION AND NUMBERS OF NEUROPHYSIN, OXYTOCIN, AND VASOPRESSIN CELLS. C. H. Rhodes*, J. I. Morrell and D. W. Pfaff. The Rockefeller University, New York, NY 10021.

A cell by cell analysis of the magnocellular elements in hypothalami of forty Long-Evans (normal) and Brattleboro (diabetes insipidis) rats was done using the unlabeled antibody enzyme technique (PAP) with primary antisera directed against oxytocin (OXY), vasopressin (ADH), and the neurophysins.

In the Long-Evans rat the supraoptic nucleus (SON) has, on the average (uncorrected for section thickness), 3849 OXY and 7729 ADH cells; the paraventricular nucleus (PVN) has 3130 OXY and 2602 ADH cells; and the accessory magnocellular groups in the hypothalamus have 3393 OXY and 1473 ADH cells. The Brattleboro strain animal has similar numbers of cells in these nuclei. (The cells which contain ADH in normal animals were identified in the Brattleboro rat as large, neurophysin negative cells.) Thus, a large fraction of the magnocellular oxytocin and vasopressin producing cells in the rat are located outside of the PVN and SON. One accessory cell group in particular, the anterior commissural nucleus, has 1643 OXY cells, or about 50% as many as PVN. In each nucleus the sum of the numbers of OXY and ADH cells was approximately the number of neurophysin cells.

SON is divided by the optic tract into the principal part and retrochiasmatic SON. In retrochiasmatic SON a majority of the cells contain vasopressin. Within the principal part oxytocin producing cells tend to be found rostrally and dorsally while the vasopressin cells are more ventral. PVN can be divided into three subnuclei, the medial, lateral (as described by Hatton et al., Br. Res. 108:187, 1978), and posterior subnuclei, on the basis of cellular morphology and peptide content. The magnocellular cells of the medial and lateral PVN are closely packed together and nearly round, while those of posterior PVN are more separated and are fusiform in shape with their long axis running in a medio-lateral direction. Medial PVN consists primarily of oxytocin producing cells while lateral PVN is formed of a core of vasopressin producing cells with a rim of oxytocin cells. Posterior PVN contains largely oxytocin producing cells. Both ADH and OXY cells are found in the accessory nuclei.

14.7 Selective Depletions of Somatostatin in Discrete Brain Nuclei by Hypophysectomy, Periventricular Hypothalamic and Medial Basal Amygdaloid Lesions. L.C. Terry and W.R. Crowley. Depts Neurol. and Pharmacol., Univ. Tenn., Memphis, TN 38163.

Several hypothalamic and extrahypothalamic sites that have high concentrations of somatostatin (SRIF)-positive nerve terminals and/or cell bodies are important in the regulation of growth hormone (GH) secretion. GH is capable of inhibiting its own secretion under certain prescribed conditions and a short-loop regulatory feedback mechanism may involve SRIF systems. Immunohistochemical studies have demonstrated the presence of SRIF-positive cell bodies in the periventricular nucleus of the hypothalamus (PVN) and in the medial basal amygdala (MBA). It has been suggested that SRIF in the median eminence (ME) derives from cells located more rostrally because large lesions of the preoptic area (POA) and anterior hypothalamus, or deafferentation of the medial basal hypothalamus reduces SRIF within the ME. It is unclear whether these effects are due to destruction of the PVN SRIF system or to interruption of SRIF-containing fibers from other forebrain structures. The objectives of the present investigations were: 1) to determine the effect of GH removal by hypophysectomy on SRIF in discrete brain nuclei, and 2) to define more precisely the specific projection patterns of the PVN and MBA SRIF-positive cell groups by employing the biochemical mapping approach. To these ends, SRIF was measured in individual nuclei microdissected from frozen sections of the hypothalamus and other forebrain structures in: 1) hypophysectomized (hypox) and sham-operated rats, and 2) animals with discrete lesions placed in the anterior PVN and MBA. The tissue content of SRIF was determined by a specific radioimmunoassay.

The content of SRIF in the ME of hypox rats was reduced significantly by 38%, compared to sham-operated controls (278 ± 53 vs 447 ± 57 pg/ug protein, respectively). Significant reductions of SRIF in the MPOA (50%), arcuate (33%) and periventricular (30%) nuclei were also observed in hypophysectomized animals. No significant changes were detected in the ventromedial, suprachiasmatic, medial, central or cortical amygdaloid nuclei nor in the nucleus interstitialis stria terminalis. Bilateral destruction of the PVN significantly reduced SRIF in the ME (72%)and the rostral PVN(44%) MPOA (33%) and arcuate nuclei (50%). Bilateral MBA lesions significantly decreased SRIF in the ME (36%) and suprachiasmatic nucleus (28%). Similar depletions were also observed following lesions of the stria terminalis.

These data suggest: 1) GH may exert "feedback" effects on specific hypothalamic nuclei that involves SRIF-containing systems, and 2) both the periventricular and amygdaloid SRIF systems may participate in such regulation of GH secretion via their projections to the ME and other hypothalamic nuclei.

14.8 SYNTHESIS OF SOMATOSTATIN PROHORMONES IN CEREBRAL CORTICAL CELL CULTURES. Richard J. Robbins* and Seymour Reichlin. Endocrine Div., Tufts-New England Med. Center Hospital, Boston, MA 02111.

We have previously reported that dissociated monolayer cultures derived from fetal rat telencephalon produce progressively increasing amounts of immunoreactive somatostatin (IRS) (Delfs et al, Nature 283:676). To demonstrate that this represents de novo synthesis, we exposed the cultures to labeled amino acid precursors of the peptide. During the period of rapid IRS accumulation (Day 13), the cultures were deprived of phenylalanine for 18 hours, and then incubated with ^{3}H-Phe for 15-120 min. This was followed by a "chase" incubation in normal medium (MEM-10% Heat Inactivated Horse Serum) for 0-180 min. Cells were then harvested in 1N acetic acid (HAc), heated to 100°C for 7 min., sonicated, and centrifuged. The supernatant was purified on an anti-somatostatin affinity column and subjected to gel filtration and high performance liquid chromatography (HPLC).

HPLC analysis revealed an IRS which comigrated with cyclic somatostatin-14, and 2 more polar species, eluting earlier on a reverse phase C_{18} column. After a 15 min. pulse, only the most polar peak of IRS was labeled; following 30-60 min. chase the predominant form was an IRS of intermediate polarity. After a 2 hour pulse and a 60 min. chase, the least polar peak of IRS, which comigrated with cyclic somatostatin-14, was labeled.

On a calibrated Biogel P-10 sizing column, eluted with 2N HAc, four types of IRS were noted. The largest form had an apparent molecular weight of 11.5-12.5 K, the intermediate form migrated in the 7.5-8.5 K range, the third species comigrated with cyclic somatostatin-14, and the final IRS was apparently smaller, in the 1200-1400 dalton range.

We conclude that cerebral cortical cells can synthesize somatostatin de novo and that there are two prosomatostatins in these cultures which are precursors in the biosynthetic pathway, as well as a smaller form of IRS which may represent a somatostatin metabolite or a separate type of somatostatin, as has recently been reported in catfish islets.

14.9 EFFECTS OF THE ABLATION OF THE LEFT CEREBRAL CORTEX ON T-CELL NUMBER AND CELL-MEDIATED RESPONSES IN THE MOUSE. K. Bizière, G. Renoux*, M. Renoux*, L. Gyenes*, D. Degenne*, J.M. Guillaumin*, P. Bardos*, and Y. Lebranchu*. Laboratoire d'Immunologie, Faculté de Médecine, B.P. 3223, 37032 Tours Cedex, FRANCE. Laboratoire de Pharmacologie, Faculté de Médecine. Tours.

The nervous system and the immune system are both involved in the maintenance of homeostasis and body integrity in relation to the external environment. They both possess recognition, memory and cell to cell learning through the production of mediators. Several investigators have observed relationships and mutual influences between the thymus and the pituitary gland or the hypothalamus. In the present report we describe the effects of a partial cortical ablation on T-cell differentiation and immune function of female C3H/He mice.

The amount of circulating T-cell selective inducer, relative and absolute numbers of splenic Thy-1-2$^+$ and sIg$^+$(B) cells, direct (IgM) and indirect (IgG) primary α-SRBC responses, cytotoxic (NK, CML, ADCC) responses, lymphoproliferative responses to mitogens (PHA, Con A, PWM) were evaluated and compared to those of sham operated controls, 8 weeks after a partial left decortication.

Cortical ablation : a) suppressed the production of the hormone active on T-cells and, concomitantly a sharp reduction in the number of spleen T-cells, b) depressed the IgG α-SRBC response c) depressed the mitogen-induced lymphoproliferations d) inhibited the NK activity, e) suppressed the CML response to allogeneic cells, and f) increased the ADCC, probably associated with an intact macrophage population.

Our results can hardly be attributed to an increased secretion of glycocorticosteroid hormones resulting from surgical stress and anesthesia. In mice, an excess of steroid hormones induces a reduction in spleen weight, and a depletion of the number of spleen lymphocytes, without altering the functional capacity of a constant number of live splenocytes and preferentially depresses the B cell responses and macrophage activity. In the present study, the spleen and organ weights, the number and viability of spleen lymphocytes, and the number and the activity of B cells were identical in decorticated and sham operated animals, and the macrophage-mediated cytotoxicity (ADCC to CRBC) of spleen cells from decorticates was found above that of controls.

The present findings strongly suggest that, in the mouse, the neocortex plays an important role in maintaining body integrity in response to environment through the control of T cell recruitment and function.

14.10 EFFECT OF CHOLINERGIC AND ADRENERGIC INHIBITION ON THE ADRENAL CORTEX REGENERATION, M. O. Udoye* and K. F. A. Soliman. School of Pharmacy, Florida A&M University, Tallahassee, Florida 32307.

In these experiments, adult Sprague-Dawley male rats weighing 150-250 grams were used. In one experiment animals were sympathectomized by chronic treatment with guanethidine (Ismelin Sulfate). Two groups of rats received daily injection of 30 mg/kg of guanethidine (i.p.) for a period of 7 weeks, while another two groups were placed on the drug vehicle. Adrenal enucleation and sham surgery were performed following the end of the 5th week of guanethidine without interrupting the treatment. Animals were sacrificed by decapitation at 2, 7, and 11 days post-surgery. Plasma and adrenal tissue were assayed for corticosterone. Significantly high levels of plasma and adrenal tissue corticosterone were observed in the 2 day group post-surgery in the guanethidine treated animals in contrast to the low levels of plasma and adrenal tissue corticosterone seen in the 7 day groups of rats. The result from 11 day post-surgery guanethidine treated animals, indicates that guanthidine treatment had no significant effect on corticosterone levels in the plasma or in the adrenal tissue. In another experiment the peripherally acting antimuscarine drug propantheline bromide was used. Adrenal enculeation and sham surgery were performed prior to treatment. Four groups of rats received daily injection of 5 mg/kg of propantheline bromide (i.p.) while the other four groups were placed on the drug vehicle. All treatments started 1 day post-surgery and continued till the animals were sacrificed by decapitation. Plasma and adrenal tissue corticosterone were determined at the high (1800 h) and low (0600 h) points of the circadian rhythm in control rats and in propantheline bromide treated animals 7 and 11 days post-surgery. The obtained results indicate the adrenal tissue corticosterone was significantly lower in propantheline bromide treated groups of rats than in the control animals at 7 and 11 days after surgery. The regenerating adrenal mass was also found to be reduced significantly by propantheline bromide treatment. From these studies, therefore, it seems that cholinergic, and not adrenergic, neural function is probably involved in the regeneration of adrenal cortex. (Supported by a grant from NASA NSG #2183)

14.11 CHANGES IN NORADRENERGIC TRANSMISSION ALTER THE CONCENTRATION OF CYTOPLASMIC PROGESTIN RECEPTORS IN HYPOTHALAMUS. B. Nock*, J.D. Blaustein and H.H. Feder*. Inst. of Animal Behavior, Rutgers University, Newark, NJ 07102

Experiments were designed to determine whether changes in noradrenergic (NA) transmission alter steroid action within hypothalamic target cells in female guinea pigs. We first examined the effects of the dopamine-β-hydroxylase inhibitor U-14,624 on cytoplasmic progestin receptors (PR, measured using a [^{3}H]R 5020 binding assay) in hypothalamus (HYPO) of estradiol benzoate (EB)-primed females. At 12 h after U-14,624 injection, the concentration of PR was 35 % less in HYPO (PR in other brain areas were not affected by U-14,624) in drug treated than in non-drug treated controls. Activation of α-adrenergic receptors with clonidine reversed the effects of U-14,624 on PR in HYPO of EB-primed females, although clonidine had no effect on PR when administered alone. Blockade of α-receptors by either intraperitoneal or intraventricular injection of phenoxybenzamine (Pb) resulted in a reduction of the concentration of PR in HYPO of EB-primed females. There was a 3 - 4 h delay between the blockade of α-receptors by Pb (determined using a [^{3}H]WB 4101 binding assay) and a significant effect on the concentration of PR in HYPO. The lower concentration of PR in HYPO after drug treatment did not appear to be due to the release of adrenal progesterone (P). The concentrations of P in plasma at .5, 2, 4 and 12 h after Pb and at 12 h after U-14,624 injection were not different from control values. Furthermore, the concentration of PR was lower only in HYPO after Pb and U-14,624 treatment, whereas injection of 100 µg P caused a reduction in the concentration of PR in all brain areas examined. The lower concentration of PR in HYPO after drug treatment might be due to interference with the EB-induced increase in the concentration of PR. This hypothesis is supported by the finding that Pb had no effect on HYPO PR in the absence of EB priming. Changes in NA transmission, therefore, might alter EB action in HYPO, in addition to altering target cell sensitivity (through effects on PR concentration) to progestins.

These results indicate that neurotransmitters affect target tissue sensitivity to steroids. The existence of such a relationship may provide a means by which environmental, behavioral, and emotional events could rapidly influence steroid-dependent behaviors and anterior pituitary function.

14.12 DIFFERENTIAL EFFECTS ON WARM AND COLD AMBIENT TEMPERATURE ON BLOOD LEVELS OF BETA-ENDORPHIN AND PROLACTIN IN RATS. W.T.Deeter, III* and G.P. Mueller. Dept. of Physiology, Uniformed Services University of the Health Sciences, Bethesda, MD 20014.

Recent findings indicate that beta endorphin (B-END) may be involved in the stimulatory control of pituitary prolactin (PRL) secretion. To further investigate the neuroendocrine mechanisms controlling pituitary B-END and PRL release, the effects of warm and cold ambient temperature on blood levels of immunoreactive B-END and PRL were studied. Mature male rats were accustomed to daily handling for five days and then placed in lighted and ventilated chambers maintained at either 36°C or 4°C. All blood samples were collected by rapid decapitation and plasma concentrations of B-END and PRL were estimated by RIA. The B-END RIA used here can detect 10 pg of B-END and does not cross-react with related peptides including B-LPH (<3%) (Mueller, Endo,A518,1979). The results of a representative experiment are shown in the table below.

Treatment	B-END (ng/ml)	PRL (ng/ml)
Controls (22°)	0.35±.06	12±1
36° for 30 min	1.08±.10	54±7
4° for 60 min	0.89±.18	6±1

It was observed that exposure to warm ambient temperature evoked significant ($p<0.05$) increases in blood levels of both B-END and PRL. By contrast, cold exposure increased circulating B-END ($p<0.05$) and decreased PRL ($p<0.05$). To better characterize the effects of cold ambient temperature on blood levels of B-END and PRL, a time-course experiment was carried out. In this study blood samples were collected after 7½,15,30,60,180, and 360 min exposure to 4°C. Circulating levels of B-END were maximally elevated (3 fold,$p<0.05$) by 30 and 60 min and then returned to control values (.38±.02 ng/ml) by 180 and 360 min cold exposure. Plasma levels of PRL were significantly decreased from a control mean of 38±10 ng/ml to 23±4 ng/ml by 15 min cold exposure. At the later time intervals circulating PRL was further decreased to a mean of 10±1 ng/ml by 360 min.

Together these results show that warm ambient temperature stimulates the release of both B-END and PRL whereas acute cold exposure stimulates the release of B-END but inhibits the release of PRL. Thus, cold ambient temperature constitutes an enviromental stimulus which has opposite effects on the secretion of B-END and PRL. Although this finding does not preclude a role for opiate peptides in the stimulatory control of PRL, under the condition of cold exposure the acute release of pituitary B-END does not enhance the release of PRL.

15.1 GABA INJECTED INTO THE GLOBUS PALLIDUS ATTENUATES WATER INTAKE ELICITED BY CENTRAL ADMINISTRATION OF ANGIOTENSIN II BUT NOT CARBACHOL. D. L. Jones, D. Sztorc* and G. J. Mogenson. Depts of Physiolgy and Faculty of Medicine, University of Western Ontario, London, Canada N6A 5C1.

The globus pallidus has been shown to receive GABAergic projections from the nucleus accumbens, implicated in the initiation of locomotor activity (Jones and Mogenson, 1980, Am. J. Physiol., 238: R63-R69). The nucleus accumbens has been shown to contribute to oral-motor performance and ingestive behaviors as well as to locomotor activity. Whether the nucleus accumbens to globus pallidus projection also contributes to ingestive behaviors is unknown. The present study investigated the possibility that the nucleus accumbens to globus pallidus GABAergic projection contributes to the initiation of drinking, elicited by the dipsogens angiotensin II and carbachol, injected into the ventricles of chronically cannulated rats.

Rats were prepared with guide tubes implanted above the lateral cerebral ventricle and globus pallidus. Injections of angiotensin II or carbachol made into a lateral ventricle of the rat routinely elicited copious drinking, averaging 10 ml in 15 min, with latency of onset usually less than 3 min. Pretreatment of the globus pallidus with GABA produced a dose-dependent decrease in the volume of water consumed, the number of laps taken during the test interval and an increase in the latency to drink. These responses did not appear to be nonspecific motor effects. There were no effects on lap volume at any dose. Following injections of GABA, the animals continued to explore the home cage and drinking spout and often were observed sniffing at the drinking spout without drinking. In contrast, the administration of GABA into the globus pallidus was without effect at any dose on water intake stimulated by the ventricular administration of the dipsogen, carbachol. There were no alterations in the latency to drink, the amount consumed or the number of laps taken during the test interval.

These results suggest that GABAergic projection from the nucleus accumbens to the globus pallidus is involved in the control of water intake stimulated by central angiotensin II administration but not by carbachol administration. Further, they are consistent with the suggestion that these projections may be part of the interface between the limbic and motor systems necessary for the initiation of the behavior.

15.2 BRAIN STEM MECHANISMS IN CONTROL OF SALT INTAKE AND BLOOD PRESSURE. Robert J. Contreras & Paul W. Stetson.* Dept. of Psychol., Yale University, Box 11A Yale Station, New Haven, CT 06520.

Area Postrema (AP) and the nucleus of the solitary tract (NST) are two adjacent structures in the dorsal medulla. In rats, the AP is a midline structure at the caudal end of the 4th ventricle; it has been implicated as a chemoreceptor trigger zone for integration of emetic responses. The AP can be influenced chemically via the blood stream due to the absence of a blood brain barrier in this region, and possibly via the cerebrospinal fluid. Ventrolateral to the AP is the NST, which receives incoming afferents from gustatory and visceral receptors. The AP and the NST, together, due to their location, composition and proximity to each other, may integrate information from a variety of sources. More recent reports suggest a role for the AP and NST in cardiovascular function. Damage to these structures produced a chronic labile hypertension, although the relative contribution of each structure to the syndrome is a subject of controversy. We have obtained the following data that may speak to this conversy.

18 experimental rats received lesions to the AP while 6 control rats received sham lesions. After the lesions, we gave the animals a two-bottle preference test between water and various molar concentrations of NaCl (.03, .1, .3, .5), glucose (.1, .3) or KCl (.1, .3) solutions. We found that AP lesioned rats exhibited a significant increase in intake of the NaCl solutions, but their intakes of glucose and KCl solutions were unchanged. These changes in intake were apparently not secondary to changes in output. Urinary sodium and potassium levels were the same for both groups of rats while on a control, sodium replete diet or on a sodium free diet. Histological observations of the brains revealed a significant correlation between the lesion and the salt intake behavior of the rat. Rats, with lesions restricted to the AP, showed an enhanced salt intake. When the AP was partially spared or when the lesion extended well into the NST, the rats did not, however, exhibit an increased salt intake.

We believe that these changes in intake are secondary to the hemodynamic effects of the lesions. From our data as well as data from other labs, we propose that hypertension results from damage to the NST, not to the AP. AP ablations result in hypotension and hypovolemia and the animals may try to compensate by drinking more saline. It would be counterproductive for a hypertensive, NST lesioned rat to increase its saline intake, inasmuch as excessive salt intake leads directly to hypertension in rats. Our data suggest that the AP and the NST may operate synergistically to maintain sodium balance and normal blood pressure.

This research was supported by NIH, NHLBI Grant HL-24732.

15.3 EXAGGERATED SODIUM APPETITE AND ANGIOTENSIN-ELICITED DRINKING BY AREA POSTREMA-LESIONED RATS. Gaylen L. Edwards and Robert C. Ritter, Department of Veterinary Medicine, University of Idaho, Moscow, ID 83843 and Department of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

Recently we reported that lesions of the area postrema (AP) enhanced ingestion of glucose solutions and preferred foods (Edwards and Ritter, Neurosci. Abstr., Vol. 5, p. 215, 1979; Ritter and Edwards, Neurosci. Abstr., Vol. 6, 1980). These findings implicate the AP in the control of food intake. Several reports also suggest AP involvement in control of fluid and electrolyte balance. In order to investigate potential AP participation in the behavioral control of fluid and electrolyte regulation, we have tested AP-lesioned rats for drinking in response to AII, isoproterenol, cell dehydration and water deprivation. Our results show that AP-lesioned rats drink more than two times as much distilled water as intact rats when treated with subcutaneous AII. For example, AP-lesioned rats drank 8.6 ± 2.6 ml while intact rats drank 3.2 ± 0.9 ml in response to subcutaneous AII (2 mg/kg). Lesioned rats also drank more than intact rats in response to isoproterenol (50, 100 and 150 ug/kg). This difference was most evident during the first 60 min of a 120 min test. Drinking by AP-lesioned rats in response to water deprivation or cell dehydration did not differ from that of intact rats. These results suggest a role for the AP in control of extracellular thirst.

Because sodium intake, as well as water intake, is essential for maintenance of extracellular fluid volume, we examined sodium balance and sodium appetite in AP-lesioned rats. Plasma sodium concentrations, plasma AII concentrations, sodium intake and sodium excretion are indistinguishable for AP-lesioned and intact rats maintained on lab chow and distilled water. Furthermore, 24 hr sodium excretion and urine volume does not differ between intact and AP-lesioned rats deprived of food. Nevertheless, the NaCl preference threshold of AP-lesioned rats is one to two orders of magnitude below that of intact rats. Lesioned rats also consumed significant amounts of 2.5% and 3.0% NaCl. These salt concentrations were virtually rejected by intact rats.

Our data suggest that the AP is involved in inhibition or modulation of extracellular thirst and sodium appetite. AP-lesions may result in release from inhibition and enhancement of extracellular thirst and sodium appetite. Further studies concerning the neuroendocrine and chemosensory role of the AP in mediating these behavioral responses are in progress.

15.4 NEW EFFERENTS AND AFFERENTS OF THE SUBFORNICAL ORGAN: A STRATEGIC NEURAL CIRCUITRY FOR THE CONTROL OF WATER BALANCE BEHAVIORALLY AND PHYSIOLOGICALLY. Richard R. Miselis. Animal Biol., Sch. Vet. Med., Inst. Neurol. Sci., Univ. of Penn., Phila. PA 19104.

The subfornical organ (SFO), one of the circumventricular organs of the brain, has attracted attention because of its role in drinking behavior, water balance and cardiovascular function. The SFO mediates drinking to angiotensin II (AII) and perhaps contributes to drinking to hypovolemia. Lesions of the anteroventral third ventricular area (AV3V) which includes the nucleus medianus (NM) and the organum vasculosum of the lamina terminalis (OVLT), cause drinking deficits, plasma Na and osmolality imbalances and transient hypertension. In previous work we described efferent projections from the SFO which were appropriate for these functions (Sci. 205:1022, 1979). It projects to the NM, OVLT and supraoptic nucleus (SON). Further work where ^{3}H leucine and ^{3}H proline were slowly infused into the SFO and adjacent structures shows additional projections from the SFO and some afferents to it. Efferent projections were observed passing to the NM, OVLT, SON (anterior and tuberal) the entire paraventricular nucleus (PVN), nucleus circularis, dorsal perifornical area and periventricular area of the hypothalamus. Precommissural fibers of passage emerging from the SFO remain on the midline and either descend along the anterior border of the NM or enter the periventricular area beneath the anterior commissure. Postcommissural fibers enter the columns of the fornix and then separate with the ventral stria medullaris (SM) as it descends into the hypothalamus. It separates from the SM to pass medially and laterally to the column of the fornix at the anterior dorsal level of its course through the hypothalamus. Small injections into the dorsal area of the medial septal nucleus and the anterior ventral triangularis nucleus of the septum (TS) resulted in labelling of the SFO, implicating these nuclei as afferent sources to the SFO. However, small injections into the dorsal TS did not label the SFO. The connectivity described above reveals the strategic relationship between the SFO and the magnocellular neurosecretory system of the hypothalamus. With its lack of a blood brain barrier giving it a view of the plasma and its connectivity, the SFO can modify water balance via an influence on ADH secretion. Its projection to the AV3V area and hypothalamic areas such as the PVN known to have a considerable projection field other than its projection to the posterior pituitary may provide the neural substrate for the behavioral response.

15.5 IMPAIRED DRINKING RESPONSES OF RATS WITH LESIONS OF THE SUBFORNICAL ORGAN: NONSPECIFIC FEATURES. Jean A. Hosutt*, Neil Rowland*, and Edward M. Stricker. Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15260.

Electrolytic lesions of the subfornical organ (SFO) in rats are known to abolish their drinking response to intravenous (iv) infusion of angiotensin II(AII). Such lesions also attentuate drinking to 20% polyethylene glycol solution (PEG; 5 ml sc), suggesting that AII may play an important role in mediating thirst during hypovolemia. However, we now report that rats with SFO lesions, which showed impaired drinking in response to 20% PEG, usually drank normal amounts when larger plasma volume deficits were caused by 30% PEG treatment. They also drank normally in response to 20% PEG when pretreated either with caffeine (12.5 mg/kg, ip) or with a small dose of hypertonic saline (0.5 ml of 1 M NaCl, ip). These results indicate that rats with SFO lesions are not incapable of drinking when hypovolemic, but may simply require a greater amount of stimulation before they do so.

A second series of experiments reexamined the drinking response of lesioned rats to AII. Although rats with SFO lesions usually did not drink after AII administration (up to 128 ng/min for 60 min, iv), they did drink when pretreated with caffeine (12.5 mg/kg, ip). Furthermore, the lesioned rats usually failed to drink in response to a low dose of hypertonic saline (0.5 ml of 2 M NaCl, iv) which provoked drinking in control rats, but drank normally when given a larger dose (2 ml of 2 M NaCl, iv). In general, the same rats that showed drinking deficits in response to AII also had impaired responses to hypertonic saline. These results indicate that the drinking impairment in rats with SFO lesions may not be specific to AII receptor loss. Instead, the lesioned animals seem to be insensitive to relatively low levels of all thirst-provoked stimuli, but can be induced to drink water either by raising the level of such stimulation or by increasing the general activation of the animals.

15.6 KNIFE CUTS BETWEEN THE SUBFORNICAL ORGAN (SFO) AND ANTERO-VENTRAL THIRD VENTRICLE (AV3V) BLOCK DRINKING TO PERIPHERAL ANGIOTENSIN II. R. Wallace Lind and Alan Kim Johnson, Department of Psychology & the Cardiovascular Center, University of Iowa, Iowa City, IA 52242

Ablation and injection studies (Johnson and Buggy, AJP,234(3): R122-R129, 1978; Simpson, et al., JCPP,92(4):581-601,1978; Phillips, et al., Fed.Proc.,38:438,#1204, 1978) have implicated the SFO, the organum vasculosum of the lamina terminalis (OVLT), and the periventricular tissue of the AV3V in the dipsogenic action of angiotensin II. Anatomical studies by Miselis et al. (Science, 205: 1022-1024, 1979) have identified efferents from the SFO to the AV3V and electrophysiological data from Buranarugsa and Hubbard (J. Physiol. (Lond), 291:101-116, 1979) suggest that these fibers may reside in the columns of the fornix. The present experiment examined angiotensin-induced drinking in rats with knife-cuts separating these circumventricular organs from the dorsal AV3V.

Eighteen rats were tested before and after surgery for drinking responses to subcutaneous injections of hypertonic saline (12%, 1 ml/100 g) and angiotensin II (2 and 4 mg/kg). A Knigge knife was used to make a circular cut of approximately 3 mm diameter between the SFO and anterior commissure (AC) in six animals and between the OVLT and dorsal AV3V in six others. The approximate size and position of these cuts are represented in the figure below. The remaining six rats served as controls.

The controls and the rats with the ventrally placed knife-cuts evidenced no long-term deficits in drinking to either dipsogen following surgery. However, the rats that received cuts between the SFO and AC manifested a specific and persistent abolition of drinking responses to angiotensin II. Drinking to hypertonic saline was unaffected. These animals were found to have bilateral interruptions of the columns of the fornix ventral to the SFO with inconsistent damage to the septum, dorsal thalamus, and fibers of the stria medullaris. These findings converge with the work cited above to suggest that the subfornical organ is a receptor site for the dipsogenic action of peripheral angiotensin with efferents passing via the columns of the fornix to the dorsal AV3V.

15.7 LESIONS OF THE ORGANUM VASCULOSUM OF THE LAMINA TERMINALIS INHIBIT HYPERTONIC NaCl AND ANGIOTENSIN INDUCED DRINKING IN DOGS. T. N. Thrasher*, J. B. Simpson, L. C. Keil* and D. J. Ramsay. Department of Physiology, University of California, School of Medicine, San Francisco, CA 94143 and Ames Research Center, NASA, Moffett Field, CA 94035

The tissue surrounding the anteroventral region of the 3rd ventricle (AV3V) has been suggested to play a role in body fluid regulation. The importance of this region in drinking and vasopressin (AVP) secretion in response to angiotensin II (20 ng/kg/min, iv) and 5% NaCl (3.8 ml/min, iv) was tested before and after electrolytic destruction of the AV3V in dogs. In addition, maintenance of salt and water balance was examined in these dogs. Accurate placement of the lesion was accomplished by injecting contrast media (Conray) into the third ventricle and taking an X-ray photograph which allowed visual verification of the electrode position. In 5 dogs histological examination indicated damage confined to the midline, bounded superiorly by the anterior commissure and inferiorly by the floor of the 3rd ventricle and included destruction of the organum vasculosum of the lamina terminalis, anteriorly. Mean intake of water in response to hypertonic NaCl was 210 $\pm$ 37 ml and fell to 54 $\pm$ 37 ml after lesioning. Angiotensin-induced drinking fell from 188 $\pm$ 26 ml to 83 $\pm$ 42 ml after lesioning the AV3V. The effect of the lesion on daily salt and water balance in these dogs was variable. One dog was completely adipsic but would readily lap a commercial liquid beverage mix. Other dogs showed a reduction in water intake and a mild elevation in plasma osmolality or no change at all. The increase in plasma AVP induced by hypertonic NaCl appeared blocked by AV3V destruction but the lesion did not alter the AVP secretion in response to angiotensin.

Subfornical organ (SFO) lesions in the dogs block angiotensin-induced drinking but not drinking in response to hypertonic NaCl. Lesioning the AV3V blocked NaCl induced drinking and also reduced drinking to angiotensin. In order to account for these two sets of results, we suggest that the SFO is essential for angiotensin-induced drinking and that the AV3V region contains osmoreceptive elements which are important in NaCl induced drinking. We have previously shown that intracranial osmoreceptors must lie outside of the blood-brain barrier (Thrasher et al., 1980, Am. J. Physiol.). Large lesions of the AV3V destroy these elements and also cut fibers from the SFO, thus affecting angiotensin induced drinking. Small lesions of the AV3V, specifically affect NaCl drinking leaving angiotensin drinking intact.

15.8 KNIFE CUTS OF THE ANTERIOR STALK OF THE SUBFORNICAL ORGAN PRODUCE DRINKING DEFICITS TO ANGIOTENSIN II BUT NOT TO OTHER DIPSOGENIC CHALLENGES. Ricardo Eng, Richard R. Miselis, and Gitta Salanga*. Inst. Neurol. Sci., Anim. Biol., Sch. Vet. Med., Univ. of Penn., Philadelphia, PA 19104.

The subfornical organ (SFO) and the anteroventral third ventricular (AV3V) area have been shown to play a role in the dipsogenic action of angiotensin (AII). Lesions of either of these structures abolish AII-induced drinking. Anatomical studies from this laboratory have demonstrated SFO efferents which pass via its anterior stalk to the nucleus medianus and the organum vasculosum of the lamina terminalis (OVLT), which are within the AV3V area, the supraoptic nuclei (SON), the paraventricular nuclei, the nucleus circularis, the periventricular area, and the perifornical nucleus. In the present study we made wire knife cuts of the anterior stalk to test the role of SFO efferents in mediating the drinking response to AII. The anterior stalk of the SFO in adult male albino rats was cut using a retracting 2 mm. wire knife made from a modified Hamilton one microliter syringe. An intrajugular catheter was implanted and externalized through a head cap. After a brief recovery period, the rats were remotely infused with AII (192 ng/kg/min. for 20 min. i.v.). In other drinking tests, the rats were challenged with hypertonic saline (10% NaCl, 1cc/rat, s.c.), 20-hr. water deprivation or 24-hr. food deprivation. At the conclusion of these experiments the rats were perfused, the position of the catheter tip was verified, and the brains were processed in celloidin (40 µm sections, cresyl violet) for histological analysis. Rats that did not drink to AII (1/2 hr. test, 3 tests each on different days) had transections of the anterior stalk (6 rats). Rats with cuts sparing the stalk drank 1.6 $\pm$ .3 ml. and intact brain rats drank 1.7 $\pm$ .2 ml. In the two hours after hypertonic saline, rats with cuts of the anterior stalk drank 6.3 $\pm$ 1.3 ml., rats with control cuts drank 7.4 $\pm$ 1.1 ml. and intact brain rats drank 7.2 $\pm$ 1.7 ml. In the first two hours of water access after a 20-hr. water deprivation rats with the anterior stalk cut drank 21.6 $\pm$ 3.0 ml., rats with control cuts drank 18.3 $\pm$ 6.7 ml. and intact rats drank 17.0 $\pm$ 2.3 ml. During 24 hours of food deprivation rats with anterior stalk cuts drank 54.8 $\pm$ 4.8% control cut rats drank 56.5 $\pm$ 10.2%, and intact brain rats drank 33.8 $\pm$ 5.5% of their respective mean intakes when food was available. These results support a role for the anterior stalk SFO efferents in i.v. AII-induced drinking and exclude a primary role for SFO neurosecretion in mediating the behavioral response. 15.9 ANGIOTENSIN-INDUCED SODIUM APPETITE: EFFECTS OF SODIUM BALANCE AND POSSIBLE SYNERGY WITH MINERALOCORTICOIDS.

Steven J. Fluharty*, Scott Manaker*, and Alan N. Epstein.
Depts. of Psychology and Biology, Univ. of Pennsylvania, Philadelphia, PA 19104.

Continuous intracerebroventricular infusion (cICV) of angiotensin II (AII) elicits ingestion of both water and Na^+ solutions (Bryant et al., Fed. Proc. 37:1978; Avrith and Fitzsimons, J. Physiol. 282:1978). The salt intake is dose-related and specific for Na^+. However, cICV AII also results in excessive Na^+ loss (Severs et al., Pharmacol. 6:1971) and thus the Na^+ ingestion may be a behavioral compensation for this loss. We therefore examined the temporal relationship between Na^+ ingestion and urinary Na^+ loss during cICV AII. Animals were housed in metabolism cages with water and 3% NaCl available ad lib but without food. Intakes and urinary Na^+ loss were monitored every 1/2 hr during an 8hr infusion of either AII (60ng/5µl/hr; n=10) or isotonic saline (5µl/hr; n=7).

Na^+ ingestion is increased within the first 1/2 hr of the AII infusion and by 2 hrs is approximately 540µEq Na^+. During this time intake exceeds urinary Na^+ loss and consequently the AII-infused animals are in positive Na^+ balance. However, during the next 6hrs, the rate of Na^+ ingestion slows while urinary loss continues and the AII-infused animals descend rapidly into negative Na^+ balance (-2.1mEq Na^+ at 8hrs). When the AII infusion is extended to 24hrs Na^+ ingestion is markedly increased.

When 8hr of cICV AII is combined with a mineralocorticoid (DOCA; 2mg sc), the negative Na^+ balance is reduced although not completely abolished (-1.1mEq Na^+ at 8hrs). Nevertheless, 24hr Na^+ intake during this combined treatment remains unchanged. Moreover, when the AII infusions and DOCA treatments are continued for three successive days an excess Na^+ intake is elicited by as little as 60pg/hr of AII which is two orders of magnitude less than the minimally effective dose when exogenous mineralocorticoid is not given. Intake increases with increasing dose of AII. The magnitude of the intake exceeds the sum of the intakes that are produced by the DOCA and the AII acting alone, and is therefore potentiated.

Thus, 1) cICV AII alone elicits an early phase of Na^+ ingestion that is not the result of prior Na^+ loss but the magnitude and maintenance of the sodium appetite is probably affected by Na^+ loss. And 2) when DOCA is combined with AII, at a dose which attenuates the AII-induced Na^+ loss, the appetite is potentiated. Therefore, since both endogenous AII and mineralocorticoids are concurrently elevated during sodium deficiency, the sodium appetite may be aroused by a synergy of the peptide and steroid. Supported by NS-03469 & MH07753-02.

15.10 ATTENUATION OF SPONTANEOUS AND ANGIOTENSIN STIMULATED DRINKING DURING OESTROUS CYCLE OR CENTRAL OESTROGEN TREATMENT.

J. Danielsen and J. Buggy. Dept. of Physiol., Univ. of South Carolina, Columbia, SC 29208.

In adult female rats with continuous access to water and 1.8% NaCl, 24 hr. ad lib fluid intakes were reduced on the day of oestrus compared to other days of the cycle. When thirst and sodium appetite were acutely stimulated by intracerebroventricular [ICVT] injections of angiotensin II (AII, 100 ng/ul), both water and saline intakes were again depressed on the day of oestrus, mirroring the fluctuating pattern of fluid intakes seen with spontaneous drinking. The ratio of saline to water intake remained constant, however, for both AII-stimulated and ad lib conditions. In contrast, after ICVT injections of carbachol (CARB, 200 ng/ul) which acutely stimulated water but not saline intake, the volume drunk was similar regardless of the day of oestrous cycle. These data provide two functional contrasts between CARB-stimulated versus AII-stimulated and ad lib drinking, namely, sodium preference and variation of amount drunk across the oestrous cycle. Since oestrogen levels peak the day before oestrus and since drinking evoked by central AII injection as well as ad lib drinking is depressed at oestrus, we decided to determine whether an action of oestrogen directly on the brain could modulate certain thirst states. Adult male and adult, ovariectomized female rats with chronic cannula terminating in the anteroventral third ventricle at the preoptic-hypothalamic level (AV3V) were used. Thirst states were each studied for four consecutive days. On the second day of each test series, 1 ug of oestradiol benzoate or vehicle was injected into AV3V 2 hrs before the test period. CARB (125 ng/ul, AV3V) or hypertonic saline (5 ml of 12% NaCl/kg, SC) induced drinking was unaffected by central oestrogen treatment. In contrast, 24 hr. ad lib and AII-induced (100 ng/ul, AV3V) drinking were depressed one day but not two days after central oestrogen treatment in overiectomized females (but not males!). The time course of central oestrogen effect is consistent with a delayed time course for expression of steroid action. The full recovery 2 days after oestrogen treatment implies a rapidly reversible central effect; subcutaneous injection of this dose of oestradiol had no effect. Preliminary data suggest that the effect of oestrogen on central AII mechanisms is not limited to the thirst response since pressor responses to AV3V injections of AII are also attenuated the day after central oestrogen treatment. From these studies, we conclude that oestrogen reversibly affects female brain sites to modulate certain forms of thirst, perhaps through an action on central AII receptors. Supported by American Heart Association.

16.1 DUPLICATION BY LANTHANUM OF SOMATOTOPIC AND OTHER OPIATE ANALGESIA EFFECTS WITH TOTAL NALOXONE REVERSIBILITY. P. Keresztes-Nagy* and J.P. Rosenfeld, Cresap Neuroscience Lab., Dept. of Psychology, Northwestern University, Evanston, Illinois 60201.

1μ mole of Lanthanum (La^{3+}) was microinjected into midbrain Periaqueductal Gray (PAG) of rats. Latency to paw lick (hot plate test), tail flick, and face-rub (to noxious heat; Rosenfeld, J.P., et al., Physiol. Behav., 21:287, 1978), and aversive reaction to midbrain Dorsal Central Gray stimulation were tested. Compared to saline controls, La^{3+} increased the response latency to hot-plate and tail-flick by 180% ($p<.05$), and the latency to left and right face-rub by at least 250%. Many rats' responses were totally blocked. The difference between the face-rub and tail flick effects was significant at beyond the $p<.01$ level. However La^{3+} had no effect on aversive midbrain stimulation. The analgesic effect of La^{3+} on hot-plate, tail-flick and face-rub was completely blocked by coinjection of 1μ mol Ca^{2+}, or by 15 min. pre-treatment with 20 mg/kg naloxone. These findings support the existence of a descending inhibitory analgesia system since La^{3+}, like morphine (Rosenfeld and Holzman, Brain Res. (1977) 124:367-372) and enkephalin (Rosenfeld and Keresztes-Nagy, Pain, 1980, in press) does not alter central nociceptive thresholds even while producing profound peripheral analgesia. The striking duplication by La^{3+} of both somatotopic (face vs tail effects) and differential central-peripheral effects of opiates, and their complete naloxone and Ca^{2+} reversibility suggest that both types of substance produce analgesia by interfering with Ca^{2+} metabolism specifically at opiate receptor neurons.

(Supported by NIH grant GM23696. ENDO supplied Naloxone)

16.2 ALTERATIONS IN RAT CENTRAL NERVOUS SYSTEM ENDORPHINS FOLLOWING TRANSAURICULAR ELECTROACUPUNCTURE. L. Ng, R. Dionne, E. Bragin,* C. B. Pert and A. Pert. Biological Psychiatry Branch, NIMH and Neurobiology and Anesthesiology Branch, NIDR, Bethesda, MD 20205

Several lines of evidence suggest that acupuncture may induce some of its analgesic actions by activating, at least in part, the endogenous pain suppression mechanism encoded by opioid peptides. We have evaluated the effects of auricular electroacupuncture in rats on levels of endorphins in the cerebrospinal fluid (CSF), plasma and various brain regions. Electroacupuncture, sufficient to induce analgesia, produced a significant increase in cerebrospinal fluid levels of endorphins as assessed by the radioreceptor assay. Gel filtration chromatography revealed that rat CSF contains only endogenous opiate ligand material with enkephalin-like molecular weight. This ligand was not only increased by acupuncture treatment, but was also shifted slightly toward higher molecular weight fragments. Concomitant with an increase of endorphins in CSF, there was also a decrease of endorphins in the hypothalamus, medial thalamus and periaqueductal gray matter as assessed by the radioreceptor assay. The radioimmunoassay for β-endorphin revealed only a decrease in β-endorphin-like immunoreactivity in the hypothalamus and medial thalamus. These data, taken together, suggest that acupuncture may activate the central endorphin systems coded by both β-endorphin and enkephalins. This activation results in a depletion of both opioids in strategic brain regions as well as a concomitant increase in the CSF of enkephalin-like material. While auricular acupuncture had a significant effect on brain endorphins, no change was seen in plasma endorphins as assessed by the radioreceptor assay. This seems to rule out the participation of the hypophyseal endorphin system in acupuncture analgesia.

16.3 ADRENALECTOMY ENHANCES ENDOTOXIC SHOCK SUSCEPTIBILITY AND ALTERS THE THERAPEUTIC EFFECTS OF CENTRALLY OR PARENTERALLY INJECTED NALOXONE. John W. Holaday and Alan I. Faden. Dept. of Med. Neurosci., Div of N.P., Walter Reed Army Inst. of Res., Wash. DC 20012

In prior work, we have shown that naloxone reverses the hypotension and improves recovery from shock produced by endotoxemia, hemorrhage, spinal transection, and spinal injury in a variety of species. Hypophysectomy was shown to block the therapeutic effects of naloxone in rat hemorrhagic shock (Neurosci. Abs. 5:528, 1979), suggesting that pituitary endorphins were involved in shock hypotension. Adrenalectomy (adrex) is known to elevate pituitary endorphins (Guillemin et al, Science 197:1367, 1977). The purposes of the present studies were to evaluate the effects of adrex upon endotoxic shock susceptibility and to determine the therapeutic efficacy of centrally and parenterally administered naloxone in sham-adrex and adrex rats.

One to two weeks following adrex or sham-adrex in male Sprague Dawley rats (250-350 g), cannulae were surgically placed in the tail artery and external jugular vein; a guide-tube was affixed to the cranium for drug injections into the lateral ventricle (ivt). Conscious rats were studied. Adrex itself resulted in a significant decrease in mean arterial pressure (MAP) of 20 mm Hg and increased heart rate (HR) 60 beats/min. Sham-adrex rats were injected intravenously (iv) with 15.0 mg/Kg lipopolysaccharide endotoxin which was 50% lethal in 24 h. All adrex rats injected with as little as 0.25 or 1.0 mg/Kg endotoxin died within 2 h. When MAP fell 20-30 mm Hg, 30 μg naloxone was injected ivt. This central injection produced a robust increase in MAP only in rats with intact adrenal glands. Fifteen min later, all rats received a second dose of naloxone (3.0 mg/Kg naloxone iv). This parenteral naloxone dose had therapeutic effects in both adrex and sham-adrex rats.

These results show that endotoxic shock is reversed by centrally injected naloxone only in rats with intact adrenal glands. From these studies we conclude that the enhancement of endotoxic shock suceptibility produced by adrex in rats is not solely a consequence of the feedback-mediated elevations in pituitary endorphin levels, but may also involve the absence of adrenal corticosteroids and/or catecholamines.

16.4 THE EFFECTS OF CHRONIC HEAT EXPOSURE ON OPIATE CHALLENGE AND THE OPIATE-LIKE EFFECTS OF ELECTROCONVULSIVE SHOCK (ECS) IN RATS. G.L. Belenky, V.E. Bates and J.W. Holaday. Dept. of Med. Neurosci., Walter Reed Army Inst. of Res., Washington, DC 20012.

We have previously shown that electroconvlusive shock (ECS) produces naloxone sensitive, opiate-like effects in rats. Prior work has also indicated that naloxone challenge in acutely or chronically heat-exposed rats produces opiate withdrawal-like signs (Holaday et al, PNAS 75, 2923, 1978). Because of the putative activation of endorphin systems by these two stressors, we were interested in evaluating the possible alteration of the opiate-like effects of ECS following chronic heat exposure. Additionally, we have shown that repeated ECS sensitizes rats to opiate challenge and, in a complimentary study, chronic morphine exposure sensitizes rats to the opiate-like effects of ECS. A further purpose of these present studies was to determine if chronic heat exposure, like chronic ECS, also potentiates the effects of challenging doses of opiates.

Our subjects were male, Sprague Dawley rats (250-300g). Transauricular ECS was delivered for 2 sec. at 160 v, 60Hz in rats maintained at 23°C or 35°C for 5 days. The duration of tonic-clonic seizures following ECS was significantly reduced in the heat-exposed rats (23.2 + 2.5 sec at 23°C; 15.2 + 1.0 sec at 35°C, $p<.01$). Heat alone significantly diminished both hot-plate escape latencies and tail-flick latencies and increased both colonic temperature and respiratory rates. The increased hot-plate escape latencies, increased colonic temperatures, and decreased respiratory rates produced by ECS were not significantly modified by chronic heat exposure when adjusted for the altered baseline values characteristic of heat-exposed rats. However, the transitory increase in tail-flick latencies produced by ECS was completely blocked by chronic heat exposure. Additionally, when these same rats were tested for catalepsy following ECS, there was evidence for a diminished cataleptic response in the heat-exposed animals. The decrease in some of the opiate-like effects of ECS produced by heat exposure suggests the possibility of cross-tolerance to some of the effects produced by these two stressors. In additional studies, we found that chronically heat-exposed rats were sensitized to the analgesic and cataleptic effects produced by central or parenteral opiate injections, a finding consistent with the cross sensitization between repeated ECS and responses to subsequent opiate challenge (vide supra).

Collectively, these findings suggest that the physiological activation of endorphin systems may result in cross-tolerance to some measures across stress systems. However, these same stressors (heat or ECS) potentiate the pharmacological effects of challenging doses of opiates.

16.5 CHRONIC NALOXONE INDUCES ABSTINENCE-LIKE SYNDROME. David H. Malin, Michael P. Layng* and Paul R. Swank*. Univ. of Houston at Clear Lake City, Houston, Texas 77058.

Prolonged blockade of endorphin receptors eventually produced a state which resembled an opiate abstinence syndrome, without any exposure to opiates. Rats were injected with 0.6 mg/kg naloxone sub. cut. twice a day for six days or with injection vehicle alone. They were observed under blind conditions twice a day for four subsequent days. The naloxone-pretreated rats developed symptoms resembling morphine abstainence syndrome. Their "wet dog" body shakes, head shakes, scratches and total symptoms were significantly elevated over controls.

Analysis of variance (one repeated measure) of total symptoms revealed a significant effect of pretreatment (naloxone versus water), and of days, but not of interaction (pretreatment x days). Symptoms were dramatically reversed by a small dose of morphine but not by naloxone.

In a second experiment, rats were injected for 10 days with the same dose of naloxone. The abstinence-like syndrome began after 6 days of naloxone and continued for several days after cessation of injections. Total symptoms, body shakes, scratches and aggression were significantly elevated over controls.

Analysis of variance of total symptoms (one repeated measure) revealed a significant effect of pretreatment (naloxone versus water) as well as days and interaction (pretreatment x days). In view of the significant interaction, an analysis of Simple Main Effects was performed, indicating significant effects on days 8 and 10 of the treatment period and day 1 of the post-treatment period.

These results suggest that organisms may depend on endogenous endorphin receptor stimulation to prevent abstinence-like discomfort. However, the fact that at least six days of receptor blockade were required to produce the syndrome suggests that continuous receptor stimulation is not necessary to prevent this syndrome, but that occasional cyclical or episodic stimulation will suffice.

16.6 DIFFERENTIAL BEHAVIORAL EFFECTS OF TYPE I AND TYPE II OPIATE RECEPTOR ACTIVATION IN RAT BRAIN. K. Trujillo* and A. Pert (SPON: L. Ng). Biological Psychiatry Branch, NIMH, Bethesda, MD 20205

There are at least two different subclasses of opiate receptors through which opiates and opioid peptides exert their pharmacological and physiological effects. One class of receptors appears to be coupled to adenylate cyclase (Type I) and the other appears to be uncoupled (Type II). There is a distinct regional distribution for each receptor subclass in brain. Regions of the brain that appear to be involved in mediating the analgesic and depressant actions of opiates (e.g., periaqueductal gray matter) have a higher concentration of Type I than Type II receptors. Type II receptors appear to be associated predominantly with limbic forebrain structures such as the nucleus accumbens, amygdala and hypothalamus through which the excitatory and euphorogenic actions of opiates are mediated. Morphine has a preferential affinity for the Type I receptor, while D-Ala^2-D-Leu^5-enkephalin (DADL) has a preferential affinity for Type II receptors. Intraventricular injections of 1, 5 or 25 µg of DADL produced a dose-dependent increase in locomotor activity, which was only partially antagonized by naloxone. Intraventricular injections of morphine produced a dose-dependent depression of locomotor activity which was antagonized by naloxone. Injections of morphine into the periaqueductal gray matter also produced a dose-dependent depression of locomotor activity, while injections of DADL into the same structure produced no effect or slight hypermotility. Injections of DADL as well as morphine into the nucleus accumbens increased locomotor activity without depression. DADL, however, was considerably more potent. Injections of DADL into the caudate nucleus produced contralateral rotation behavior which increased in intensity with repeated injections and was relatively resistant to antagonism by naloxone. Morphine had no apparent effect in this structure. The data suggest that Type I and Type II opiate receptors located in various brain regions mediate different behavioral actions of opiates.

16.7 β-ENDORPHIN: EFFECTIVENESS IN SUPPRESSING ACUTE WITHDRAWAL IN MORPHINE-DEPENDENT MONKEYS BY INTRAVENTRICULAR INJECTION. E.F. Domino, Dept. of Pharmacology, Univ. of Mich., Ann Arbor, MI 48109 and C.H. Li*, Hormone Res. Lab., Univ. of Calif., San Francisco, CA 94143.

The evidence that β-endorphin is a narcotic agonist when given intraventricularly to rodents is impressive. The fact that many drugs are reported to be effective in suppressing morphine abstinence signs in rodents and even in humans but not in morphine dependent monkeys makes additional studies in primates imperative. Six female monkeys, weighing from 3 to 5 kg, were made dependent upon morphine with daily injections of 3.0 mg/kg of morphine sulfate s.c. every 6 hr. at 7:00 a.m., 1:00 p.m., 7:00 p.m., and 1:00 a.m. for periods up to 2 yr. Each animal was prepared surgically under ketamine anesthesia with a chronic indwelling stainless steel needle which contained a rubber septum covered with silastic for sterility. Evidence that the needle was in the lateral ventricle was obtained by withdrawal of ventricular fluid and via skull x-rays obtained after injection of 0.2 and 1.0 ml of the radiocontrast medium metrizamide (250 mg of iodine/ml). At approximately 1 to 4 week intervals the animals were subjected to 14 hr. abstinence in which the 1:00 and 7:00 a.m. doses of morphine were omitted. Each experiment began at about 9:00 a.m. or 14 hr. after the previous 7:00 p.m. dose of morphine. Abstinence signs were scored before drug injection and at various times thereafter. Morphine and synthetic human β-endorphin were dissolved in artificial cerebrospinal fluid. To maintain sterility, all solutions were passed through separate disposable millipore filters prior to injection. Each substance was given intraventricularly in doses of 10, 32, 100, 320, 570 and 1000 µg total or /kg i.v. in a random fashion. The drug dosages were compared with equal volumes of artificial cerebrospinal fluid. Abstinence scores were obtained using an 8 point scale. Signs were grouped in the following categories: general behavior in the home cage, facial, trunk and extremity characteristics, autonomic signs, and those signs elicited by a handling routine. The handling routine was by far the most sensitive means of measuring abstinence. Both β-endorphin and morphine, in a dose dependent manner given intraventricularly, suppressed the signs of 14 hr. acute morphine abstinence. On a molar basis, β-endorphin was more active than morphine. β-endorphin, in comparable abstinence suppressing amounts, also produced more central nervous system depression and no gross convulsions, in contrast to morphine. Morphine, given i.v., suppressed morphine abstinence but β-endorphin in equivalent doses did not, indicating that the latter does not readily cross the blood-brain barrier in this species.

16.8 CHRONIC LITHIUM INDUCES APPARENT ANALGESIA AND HYPERSENSITIVITY TO OPIATE ANTAGONISTS. SHIMON AMIR and RABI SIMANTOV*. Isotope Department, The Weizmann Institute of Science, Rehovot, Israel.

Lithium is commonly used in treatment of manic depressive patients. However, its mechanism of action is not entirely clear. Increased levels of methionine enkephalin in specific brain regions has been observed in rats treated chronically with lithium (Gillin et al., PNAS, 75, 2991-2993, 1978). Lithium also affects the binding of opioid peptides and alkaloids to opiate receptors. In the present study we investigated the effect of chronic lithium on pain sensitivity and responsiveness to the opiate antagonists, naloxone and naltrexone.

Male C57Bl/6 mice were chronically fed with lithium containing diet, and at the day of the test they were injected intraperitoneally with saline which contained different concentrations of naloxone or naltrexone. Pain sensitivity to thermal stimulus was assessed in a modified hot plate test at 46°. Ten days feeding with lithium diet increased the latency and reduced jumping (by 56%) but had no such effect on grooming and rearing. Injection of 0.156-160 mg/Kg naloxone caused only 0-20% increase in jumping response in control mice, whereas 0.156 mg/Kg naloxone caused > 100% increase in jumping of lithium treated mice. The effect of naloxone observed in lithium treated mice was increased in a dose dependent fashion. A similar dose dependent relationship was obtained also with naltrexone, except that the highest dose of this alkaloid (160 mg/Kg) caused marked depression in all behavioral measures in both groups. The increased jumping in the naloxone treated mice was accompanied by a decrease grooming and rearing. It is concievable that the lithium induced reduction in pain responsiveness is a behavioral correlate of the increased levels of endogenous methionine enkephalin. However, since this increase was observed only in the nucleus caudatus and the globus pallidus, other mechanisms such as alteration in the opiate receptor cannot be excluded. The hypersensitivity to naloxone and naltrexone in the lithium treated mice may reflect an increase in endogenous enkephalins. The possibility that chronic lithium causes an apparent dependency to the increased levels of endogenous enkephalins will be discussed.

16.9 BEHAVIORAL EFFECTS OF INTRAVENTRICULARLY ADMINISTERED DYNORPHIN-(1-13) AND D-ALA2-DYNORPHIN-(1-11) IN RATS. B.H. Herman* and A. Goldstein, Addiction Res. Fdn., 701 Welch Rd., Palo Alto, CA 94304.

Lateral intraventricular (LV) or cerebral aqueduct (CA) administration of the opioid peptide, dynorphin-(1-13), induced catalepsy and analgesia in rats. Onset was earlier and duration shorter than with morphine or B_C-endorphin. The dose required to induce analgesia was reduced at least tenfold when dynorphin-(1-13) was administered into CA rather than LV. An analogue, D-Ala2-dynorphin-(1-11), produced a comparable degree of catalepsy and even more profound analgesia at one-tenth the dose. These effects of dynorphin-(1-13) and D-Ala2-dynorphin-(1-11) were significantly antagonized by naloxone pretreatment. Rats treated with dynorphin-(1-13) or a high dose of D-Ala2-dynorphin-(1-11) exhibited bizarre postures immediately following LV admistration with limb rigidity and "barrel rolling". These effects were not blocked by naloxone.

16.10 STUDIES ON THE BEHAVIORAL AND NEUROCHEMICAL INTERACTIONS BETWEEN NALOXONE, AMPHETAMINE AND APOMORPHINE. J. Curell*, B. Hitzemann*, H. Loh* and R. Hitzemann (SPON: D. Garver). Lab. of Psychobiology, Dept. of Psychiatry, Univ. of Cincinnati Coll. of Med., Cincinnati, OH 45267.

The effects of naloxone, in the absence of analgesics, on behaviors generated by activation of the mesolimbic and/or nigrostriatal dopamine (DA) systems has received some attention. Naloxone has been found to block d-amphetamine-induced increases in motor activity (Holtzman, S., J. Pharmacol. Exp. Ther., 189, 51, 1974; Dettmar et al, Neuropharmacol. 17, 1041, 1978) and to potentiate the effects of low doses of apomorphine and ET-495 on conditioned behavior (Harris et al, Eur. J. Pharmac., 43, 243, 1977). In the present study we have confirmed and extended the observations on the interactions between naloxone, amphetamine and apomorphine in Sprague-Dawley rats. Naloxone in doses of 0.3 to 10mg/kg, s.c. antagonized the increase in ambulation and rearing induced by 1mg/kg of d-amphetamine. When the dose of d-amphetamine was increased to 3mg/kg, naloxone (3mg/kg) specifically antagonized rearing activity. No dose (0.3 to 10mg/kg) of naloxone significantly affected the quality of d-amphetamine or apomorphine induced stereotyped behavior. However, naloxone (3mg/kg) significantly augmented the apomorphine (1mg/kg) induced increase in ambulation. Naloxone (3mg/kg) decreased ambulation in a novel environment and enhanced the rate decreasing effects of apomorphine (0.03mg/kg) in the same paradigm. Naloxone was administered chronically via pellet-implantation. Tolerance developed to the inhibition of d-amphetamine induced rearing but not ambulation. Naloxone in concentrations as high as 10^{-5}M had no significant effect on [^{3}H] spiroperidol binding in both the nucleus accumbens and caudate nucleus. Similarly, naloxone did not effect [^{3}H]-DA synaptosomal uptake in the nucleus accumbens and caudate nucleus. However, naloxone (10^{-6} to 10^{-5}M) was found to block the d-amphetamine (10^{-6} to 10^{-5}M) induced release of [^{3}H]DA from caudate slices. At 10^{-7} to 10^{-6}M naloxone decreased the spontaneous release of [^{3}H]DA but increased release at 10^{-5}M. The significance of these and additional findings in terms of the naloxone effects on d-amphetamine and apomorphine induced behaviors will be discussed. This study was supported in part by grant MH-25487.

16.11 FAILURE OF MORPHINE TO PRODUCE PHYSICAL DEPENDENCE FOLLOWING CENTRAL ADMINISTRATION DURING HIBERNATION. Alexander L. Beckman and Carmen Llados-Eckman*. Alfred I. duPont Institute, Wilmington, DE 19899.

Previous work in our laboratory demonstrated that non-hibernating (ie., euthermic) ground squirrels (Citellus lateralis), treated with subcutaneously implanted morphine (M) pellets, developed a strong and characteristic abstinence syndrome following naloxone (Nx) administration. By contrast, animals failed to show any abstinence syndrome when treated with M in this way during deep hibernation and given Nx immediately after arousal to the euthermic state. In considering the possibility that peripherally administered M did not enter the brain during deep hibernation, we have examined the development of physical dependence on M following intracerebroventricular (icv) infusion during this natural state of CNS depression.

Euthermic C. lateralis of either sex were implanted under light ether anesthesia in the interscapular region with a miniature osmotic pump. The pump delivered M (55µg/µl) through a previously implanted cannula guide tube to the lateral cerebral ventricle at a rate of 50-55µg/µl/hr for periods of 24, 48, or 72 hr. Hibernating animals received the same administration of M, with osmotic pump activation provided by sustained immersion in a container of 0.9% saline (in place of interscapular implantation). In all animals, morphine abstinence was precipitated by Nx (1mg/kg, s.c.) during euthermia and was characterized by quantifying the occurrence of signs displayed in the 30 min period following Nx injection.

Animals exposed to M during euthermia displayed a strong abstinence syndrome consisting of exploratory behavior, nesting, grooming, vocalization, shakes, yawning, chewing, chromodacryorrhea, digging, dyspnea, eyetwitch, flattened posture, ptosis, and forward-extended tail. Animals exposed to M during deep hibernation, however, displayed no abstinence signs following arousal to the euthermic state and immediate testing with Nx. Some hibernating animals displayed M-induced stereotypy following arousal to the euthermic state. Euthermic and hibernating saline control experiments were without effect.

These data support our earlier findings (Soc. Neurosci. Abstr. 5:599, 1979) and demonstrate that, whereas exposure of the brain to M during euthermia results in physical dependence, similar exposure to M during deep hibernation does not. It therefore appears that CNS mechanisms underlying the development of physical dependence on M are altered during this depressed state. (Supported by the A.I. duPont Institute and NIDA grant DA 02254).

17.1 FINE STRUCTURAL ANALYSIS OF AXONS ENTERING THE EPIDERMIS WITHIN THE RECEPTIVE FIELD OF HIGH-THRESHOLD MECHANORECEPTIVE MYELINATED AFFERENTS. L. Kruger, E. R. Perl and M. J. Sedivec.* Depts. of Anatomy, Anesthesiology and Brain Research Institute, UCLA Center for Health Sciences, Los Angeles, CA and Dept. of Physiology, University of North Carolina, Chapel Hill, NC.

Myelinated hindlimb afferents in the cat conducting at velocities of 10-35 m/sec. and subserving high-threshold mechanoreceptors, possess receptive fields consisting of a number of spot-like responsive areas separated by regions unresponsive to the same stimuli. It has been suggested that these receptors constitute a class of myelinated 'nociceptor' partially involved in the sensitivity to mechanically induced pricking pain (Burgess and Perl, '67).

Following electrophysiological mapping of receptive field 'spots,' fine steel pins were inserted perpendicularly into the epidermis at a distance of $\sim$ 0.5 mm in order to bracket the responsive points. The cats were then aldehyde perfused, each receptive field spot was carefully blocked, osmium treated, embedded in plastic and trimmed. Semi-thin sections were cut within the delineated area for orientation and tracing of single thinly-myelinated axons penetrating into the papillary layer of the dermis. Axonal profiles enter the epidermal basal lamina displaying clear pleomorphic and a few dense-core vesicles at the penetration site. They are surrounded by Schwann cell processes that lose their basal lamina within the epidermis; the axon ultimately becoming completely enveloped by basal keratinocytes. These axonal profiles can generally be distinguished from Langerhans cell 'dendrites.' The low density of this pattern in cat hindlimb hairy skin and its consistent presence in the marked areas of focal responsiveness suggest that nociceptors with thinly myelinated fibers possess unmyelinated terminal branches penetrating the basal epidermis where the Schwann cell loses its basal lamina in the zone where vesicles are found and displays marked pinocytotic activity. This pattern forms a receptive apparatus within the basal epidermis which appears to correlate with the distribution of delta nociceptor spots.

17.2 SYNAPTOLOGY OF PHYSIOLOGICALLY IDENTIFIED, HRP-STAINED, NEURONS IN THE SUPERFICIAL DORSAL HORN OF CATS. A. R. Light, M. Réthelyi*, E. R. Perl. Dept. of Physiology, Univ. of North Carolina, Chapel Hill, N.C. 27514.

The activity of neurons in the marginal zone (MZ) and substantia gelatinosa (SG) of the cat's spinal cord was recorded with HRP-filled microelectrodes. On the basis of physiological characteristics (localization and size of the receptive field, nature of cutaneous stimuli activating the neurons), the neurons could be subdivided into three broad groups: group 1 - neurons activated by noxious mechanical stimuli; group 2 - neurons activated by innocuous mechanical stimuli; group 3 - neurons activated by both noxious and innocuous stimuli (Neurons most commonly observed were of groups 1 or 2). Following physiological identification, the neurons were stained by iontophoretic injection of HRP. A histological analysis was carried out on 50 µm thick Vibratome sections cut in the sagittal plane and subsequently serially cut into ultrathin sections. The location and shape of perikarya and the arborization pattern of dendrites and axons varied considerably among the neurons. Nevertheless, relations were consistently seen: group 1 neurons were mostly confined to the MZ and to the outer layer of the SG, group 2 neurons to the inner SG and to the dorsal part of the nucleus proprius; group 3 neurons showed widespread dendritic and axonal arborizations. With few exceptions the dendrites of the neurons were richly supplied with long, often complicated appendages. Presynaptic axon terminals were found to make contact with a labeled neuron all along its dendritic shafts, and consistently on the enlarged heads of the dendritic appendages. Although these axon terminals varied in size, vesicle content and synaptic connections, an axon terminal of a particular ultrastructure was often found to synapse repeatedly with the dendrites of the same neuron. It appears probable that these repeated connections provide a structural basis for the occurrence of a large number of neurons in the superficial dorsal horn with no, or minor, convergence of various sensory modalities. In addition to axon terminals, vesicle containing, dendritic-like profiles often made synaptic contact with labeled dendrites of all three groups in MZ and SG. Similar profiles were also both pre and postsynaptic to axon terminals that synapsed with labeled neurons. All three functional groups displayed vesicles inside labeled dendritic appendages. These were common in the inner substantia gelatinosa, and less numerous in the marginal zone. Thus, dendritic interactions may modify the input of MZ and SG neurons at, or before, the first synapse.

17.3 CARDIOPULMONARY INPUTS ONTO THORACIC SPINOTHALAMIC NEURONS IN THE PRIMATE. R.W. Blair, R.N. Weber*, and R.D. Foreman. O.U. Hlth. Sci. Ctr., Dept. of Physiology & Biophysics, Oklahoma City, OK. 73190.

During angina pectoris or the onset of a myocardial infarction in man, pain is often felt in the left arm and shoulder, a phenomenon known as "referred pain." Previous work from this laboratory has demonstrated that thoracic cells of origin of the spinothalamic tract (ST) receive convergent input from the cardiopulmonary region and the left forelimb. This viscerosomatic convergence was suggested as the mechanism whereby referred pain could occur. The present study was performed to quantify the visceral input onto ST cells in the thoracic spinal cord. Monkeys (Macaca mulatta and Macaca fascicularis) were initially anesthetized with ketamine and chloralose, and were maintained at a constant level of anesthesia with an infusion of pentobarbital. They were paralyzed with gallamine. Neurons of the ST in the T_3-T_5 segments of the thoracic gray matter were antidromically activated from the contralateral ventral posterior lateral thalamic nucleus. All cells reported were antidromic, and all received visceral and somatic inputs. Visceral input to the ST neurons was elicited with electrodes placed on the left ansa subclavia and sympathetic chain between the T_2 and T_3 rami communicantes. A total of 32 ST cells were examined; their antidromic conduction velocity (CV) was 23.4 $\pm$ 2.1 (SE) m/s. The spinal cord location for 25 of the cells was histologically determined; 8% of the ST neurons were found to be in lamina I, 36% in lamina IV, 32% in lamina V, and 24% in lamina VII. The mean antidromic CV of the neurons in the different laminae was not significantly different. The classification of visceral fibers activating the ST neurons was inferred from both the minimum afferent conduction velocity (MACV) and the threshold for cell activation. MACV was determined for 28 cells; the average MACV was 9.0 $\pm$ 1.3 (SE) m/s, which indicates that the ST neurons received input from Aδ fibers. For 21 cells the stimulus intensity was increased sufficiently to activate C-fibers if they were present. Ten ST neurons were found to receive C-fiber input; MACV was 0.65 $\pm$ 0.16 m/s, and the stimulus threshold for cell activation by C-fibers was 28.3 $\pm$ 6.3 times greater than for activation by Aδ fibers. One additional ST cell received only C-fiber input. Preliminary data also suggests that some ST cells in the T_3-T_5 segments receive Aδ and C input from afferents coursing in the greater splanchnic nerve. This study demonstrates the following: (1) ST spinal neurons in the T_3-T_5 segments receive input from both Aδ (primarily) and C-fibers, and (2) thoracic ST neurons are found about equally in laminae IV, V, and VII, with a fewer number in lamina I.

17.4 RESPONSES OF PRIMATE SPINOTHALAMIC TRACT NEURONS TO NATURAL STIMULATION OF THE TESTICLE AND URINARY BLADDER. R.J. Milne, G.J. Giesler, Jr. and W.D. Willis, Jr. Marine Biomed. Inst. and Depts. of Physiol. & Biophysics and of Anatomy, Univ. TX Med. Branch, Galveston, TX 77550

Compression of the testicle and overdistension of the urinary bladder produce intense pain. One characteristic of this visceral pain is its pattern of referral to the skin of the flank and inguinal area, suggesting possible convergence of inputs transmitting nociceptive information from skin and viscera. We report spinothalamic tract neurons in the primate which respond to graded natural stimuli to the testicle and/or urinary bladder, and also to the cells' cutaneous receptive fields.

Male monkeys (Macaca fascicularis) were anesthetized with α-chloralose (80 mg/kg) and an infusion of sodium pentobarbital (4 mg/kg/hr), paralyzed with gallamine triethiodide and artificially ventilated. Extracellular single unit activity was recorded with glass capillary microelectrodes from lower thoracic or upper lumbar spinothalamic tract neurons identified by antidromic activation of the contralateral ventral posterolateral nucleus of the thalamus. Each unit responded with an increased firing rate to innocuous stimuli (brushing the hair or skin) and more vigorously to noxious stimuli (pinching or noxious heat) applied within its cutaneous receptive field. In addition, each unit received excitatory input from the urinary bladder and/or the ipsilateral testicle.

Distension of the urinary bladder under constant pressure (0 to 60 cm H_2O) or constant volume (10 to 50 cc) conditions evoked an increase in firing rate which was graded with stimulus strength. Compression of the testicle with forces in the range 200 to 1200 gm-wt likewise induced responses which were graded with the applied force. Application of noxious heat to the testicle induced a vigorous response. Activity elicited by either somatic or visceral stimuli reached its peak rapidly and declined, usually within 1 minute, close to background levels. We conclude that spinothalamic tract cells which display a wide dynamic range of responses to somatic stimuli also have powerful excitatory visceral inputs. Such viscero-somatic convergence may provide a neural substrate for pain referred from visceral structures.

17.5 ELECTROPHYSIOLOGICAL ANALYSIS OF THE RESPONSES OF SPINAL NEURONES IN RATS TREATED WITH CAPSAICIN. J.A. Pearson, M.C. Green*, W.A. Staines and H.C. Fibiger. Department of Physiology and Division of Neurological Sciences, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

A reduction in responsiveness to thermal noxious stimuli, and a 50% depletion of spinal substance P levels, has been demonstrated in rats tested 12 weeks after neonatal treatment with capsaicin (Nagy, J.I. et al. Brain Res. 186, 1980, 435-444). It is suggested that this analgesia is a consequence of the neurotoxic effect of capsaicin on nociceptive substance P-containing sensory neurones. The present study was undertaken to determine whether treatment with capsaicin influences the responses of spinal neurones to cutaneous stimulation.

Two-day old, male, Wister rats were given subcutaneous injections of either capsaicin (50 mg/Kg) or vehicle (10% ethanol, 10% Tween-80 in 0.9% saline). Electrophysiological experiments were carried out 4-5 months later. Rats were anaesthetized with Urethane (1.5 g/Kg) and a laminectomy was performed to expose the lumbar enlargement of the spinal cord. Neurones, situated in the dorsal horn, were classified according to their responses to mechanical stimuli applied to their cutaneous receptive fields. Type I cells were driven only by weak, presumably non-noxious, stimuli. Type II cells could only be activated by intense stimuli and neurones of Type III responded to both non-noxious and noxious mechanical inputs. In rats which had received injections of vehicle, the number of cells which were classified as Types I, II and III were 47, 17 and 77 respectively (32, 12, 55%). After capsaicin treatment, the proportion of cells in each category (43, 16, 50 ie 39, 15, 46%) did not differ significantly ($p>0.05$) to that seen in control animals. In contrast to its lack of effect upon the sensitivity to mechanical stimuli, capsaicin treatment resulted in a reduced ability to respond to noxious thermal stimuli ($p<0.01$). Heat pulses (45^{o}C for 15 secs) applied to the skin excited 26 out of 51 cells (51%) in control animals but only 10 out of 49 (20%) in capsaicin treated rats.

It is concluded that the neurones which are disrupted by neonatal administration of capsaicin are involved in thermal rather than mechanical nociception.

17.6 AFFERENT AND EFFERENT CONNECTIONS OF PERIAQUEDUCTAL GREY IN THE MONKEY. Patrick W. Mantyh*. (SPON. S. Hockfield) Dept of Anat., University of California, San Francisco, CA 94143.

Combined horseradish peroxidase (HRP) and tritiated amino acid injections ranging from .01-.1ul were stereotaxically placed in various regions of the periaqueductal grey (PAG) of 10 squirrel monkeys. After a 2-4 day survival time the monkeys were perfused and alternate frozen sections processed for either HRP histochemistry (Mesulam '78) or autoradiography (Cowan et. al. '72).

From this study it appears the PAG receives wide ranging afferents from the rostralmost pole of the frontal cortex to the sacral spinal cord. HRP positive cells were found in the following areas: Frontal granular cortex; Amygdala; central and basal lateral nuclei; Substantia innominata; Hypothalamus: ventromedial, supraoptic, suprachiasmatic, dorsomedial, lateral, paraventricular, periventricular, posterior, peri-arcuate; Zona incerta; Mesencephalon: superior colliculus, cuneiformis, PAG; Pons: raphe magnus, locus coeruleus; Medulla: parvo-, gigantocellular reticular, spinal trigeminal nuclei; Spinal cord. Of all these areas the hypothalamus and zona incerta have the heaviest projection to the PAG. The afferent connections revealed here implicate the PAG as a visceral, nociceptive, and cognitive integrator.

Efferent projections were observed in the following nuclei after tritiated amino acid injections into the PAG: Bed nucleus of the stria terminalis; Hypothalamus: ventromedial, supraoptic, suprachiasmatic, dorsomedial, lateral, periventricular, posterior, supramammilary, preoptic area; Dorsal thalamus: centromedian, parafascicularis, medialis pars medialis, paraventricular thalami, centralis medialis, reuniens, rhomboidalis; Ventral tegmental area of Tsai; Zona incerta; Mesencephalon: cuneiformis, PAG, superior colliculus; Pons: raphe magnus, raphe pallidus, locus coeruleus; Medulla: parvo- and giganto-cellular reticular formation. Efferent and afferent connections of the PAG show a significant degree of overlap. This reciprocity is especially evident in the hypothalamic and brainstem areas.

Afferent and efferent connections remain quite constant from one animal to another even though the area of the PAG injected varied. These findings, along with Nissl, Weil, and Golgi analysis of the PAG (Abols and Mantyh, Neurosci. Abst. '80) do not support the division of the PAG into distinct cell groups, each with its own cytoarchitecture and connectivity. (Supported by H.J. Ralston NS-11614 and W.R. Mehler NASA task 199-05-02-07.)

17.7 RESPONSE OF NUCLEUS RAPHE MAGNUS NEURONS TO IONTOPHORETICALLY APPLIED SUBSTANCE P. Scott L. Pomeroy and Michael M. Behbehani. Dept. of Physiology, Univ. of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

The medullary nucleus raphe magnus (NRM) appears to be an important location of neurons which inhibit nociception when the periaqueductal gray matter (PAG) is stimulated. Stimulation of PAG can influence the activity of NRM neurons; little is known about the neurotransmitter which mediates these responses. Substance P is present in nerve terminals within the NRM and produces analgesia when injected intracerebrally.

To test the hypothesis that substance P is the neurotransmitter of the PAG to NRM projection, we compared the response of NRM neurons to PAG stimulation with response to iontophoretically applied substance P in urethane anesthetized Sprague-Dawley rats. Post-stimulus time histograms were recorded from NRM neurons while electrically stimulating PAG with bipolar tungsten electrodes (parameters: 40μsec, .5-.10 mA, 1Hz). It was found that NRM neurons responding to PAG stimulation with either excitation or inhibition were more likely to be excited by substance P than neurons which did not respond to PAG stimulation. Thirty-three of the sixty-three NRM neurons studied were excited by PAG stimulation; twenty-three of these neurons were excited by substance P. Eight NRM neurons were inhibited by PAG stimulation; seven of these neurons were excited by substance P. Twenty-two neurons did not respond to PAG stimulation; five of these were excited by substance P. A Chi-square test for inhomogeneity found this distribution of responses to have a significant interaction ($X^2 = 15.6$, $df = 2$, $p<.001$). No NRM neurons were inhibited by substance P. Substance P does not appear to be the neurotransmitter of this projection since neurons inhibited by PAG stimulation were excited by the putative transmitter.

To test the hypothesis that substance P may modulate the response of NRM neurons to PAG stimulation, substance P was iontophoretically applied to NRM neurons while stimulating PAG. Thirteen responding neurons were studied: the responses of three were inhibited by substance P. One neuron was inhibited at low currents, but had a potentiated response at higher currents. Substance P may, therefore, have a modulating role in the NRM.

17.8 THE ROLE OF NOREPINEPHRINE IN THE INTERACTION BETWEEN THE PERIAQUEDUCTAL GRAY (PAG) AND NUCLEUS RAPHE MAGNUS (NRM). M.M. Behbehani and S.L. Pomeroy. Dept. of Physiology, Univ. of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

In recent years the involvement of a descending system in analgesia produced by morphine and by electrical stimulation of the brain has been well documented. It has been shown that interaction between the PAG and NRM is an important functional aspect of this descending system. Several neurotransmitter substances are known to be involved in analgesia produced by morphine and electrical stimulation but it is not known which one of these transmitters are involved in the interaction between the PAG and NRM. Histochemical experiments have shown that norepinephrine containing cell bodies and terminal are found in the PAG and NRM. The object of the experiments reported here was to determine how those cells in the NRM that respond to PAG stimulation respond to iontophoretically applied norepinephrine. Male Sprague-Dawley rats weighing 250-300 grams were used. After surgical procedure under urethane anesthesia, activity of single cells in the NRM was recorded using a recording electrode glued to a five barrel drug electrode. The PAG was stimulated monopolarly with 40μsec, 0.5 to 1.5 mA constant current pulse. Norepinephrine HCL (100mM), Sotolol HCl 500 mM, piperoxan chlorhydrate (PIP) 100 mM and sodium acetate were iontophoresed as needed.

Seventy percent of the cells in the NRM responded to PAG stimulation; 51% responded by excitation and 19% responded by inhibition. Of those cells that responded to PAG by excitation, application of NE produced 30% excitation, 35% inhibition and no response in 35% of the cells. Of the cells that responded to PAG stimulation by inhibition, NE application caused 28% excitation, 42% inhibition and no response in 30%. The onset of response to NE was slow and at current of 30 nA usually the response became noticeable after at least 10 seconds of drug application. The inhibitory effect of NE had a slower time course than the excitatory effect. The response to NE could be partially blocked by sotolol but seldom could be affected by PIP. In 15% of the cells application of sotolol alone caused an increase in the firing rate. Statistical analysis showed no correlation between response to PAG stimulation and NE response. It is concluded that although the cells in the NRM can respond to NE by excitation the more dominant response is inhibition. Furthermore, it seems unlikely that the NE is the transmitter which mediates the interaction between the PAG and NRM.

17.9 A PHARMACOLOGICAL STUDY OF INHIBITION OF PRIMATE SPINOTHALAMIC TRACT CELLS FROM PERIAQUEDUCTAL GRAY AND NUCLEUS RAPHE MAGNUS. R.P. Yezierski, T.K. Wilcox and W.D. Willis. Marine Biomedical Institute and Departments of Physiology & Biophysics and of Anatomy, University of Texas Medical Branch, Galveston, TX 77550

It has been previously shown by our laboratory that activity of primate spinothalamic tract (STT) cells is inhibited by stimulation in nucleus raphe magnus (NRM). We have now shown that a comparable inhibition is obtained by stimulation in the periaqueductal gray (PAG). The present experiments were undertaken to study the pharmacology of descending inhibitory pathways activated by stimulation in these brain regions.

Monkeys (Macaca fascicularis) were anesthetized with α-chloralose and pentobarbital, paralyzed and artificially ventilated. STT cells were identified by antidromic activation from the contralateral thalamus and functionally characterized. Cells used in the present study were classified as wide dynamic range or high threshold. Stimulating electrodes were placed in both NRM and PAG. Pre-drug inhibitory effects of NRM and PAG stimulation on evoked activity of STT cells were determined. Stimulus parameters consisted of long and short duration trains delivered at 333 Hz with currents of 50-200 microamps. Inhibition was observed following NRM or PAG stimulation of spontaneous activity as well as STT cell activity evoked by non-noxious and noxious cutaneous stimulation, and responses to C-fiber volleys from the ipsilateral sural nerve. A tendency was noted for PAG inhibition to be greater on STT cell activity evoked by noxious than by non-noxious cutaneous stimulation.

The results of this study showed PAG inhibition to be antagonized by intravenous administration of the serotonin antagonists methysergide (2-5 mg/kg) and metergoline (2-4 mg/kg). This effect was seen when stimulating electrodes were located in the PAG at the level of the third or fourth cranial nerve nuclei. The opiate antagonist naloxone (0.2-0.4 mg/kg) and the α-blocker phentolamine (1-3 mg/kg) had no antagonistic effects on PAG inhibition. NRM inhibition was not antagonized by these various monoaminergic or opioid antagonists. The results of these experiments will be discussed in relation to the involvement of endogenous opiates and monoamines in descending inhibition.

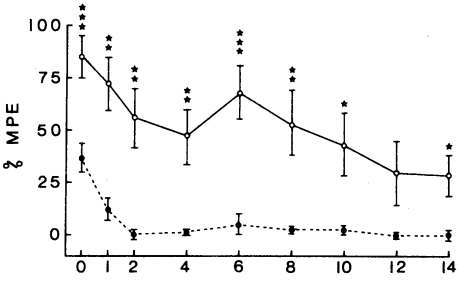
17.10 DORSOLATERAL FUNICULUS (DLF) LESIONS BLOCK FOOT-SHOCK PRODUCED OPIATE ANALGESIA. LR Watkins*, DA Cobelli* & DJ Mayer (SPON: JH Johnson) Dept Physiol, Med Coll Va, Richmond, VA 23298.

The analgesic effects of systemic morphine, intracerebral morphine & electrical stimulation of the periaqueductal gray are greatly attenuated following lesions of the DLF. In contrast, bilateral DLF lesions do not reduce footshock produced analgesia (FSA) elicited by shocking rats on all 4 paws. Recently we suggested that FSA involves both opiate & non-opiate mechanisms since naloxone antagonizes FSA produced by front paw (FP) but not hind paw shock. In order to provide further support for the involvement of an endogenous opiate mechanism in FSA, the effect of DLF lesions on this analgesia was examined.

Two groups were tested: bilateral DLF lesioned rats (vertebral T2) & sham operated rats. Lesions were made with a carbon dioxide laser. Six days after surgery rats were tested for baseline tail-flick (TF) latencies & FP shocked 90 sec (1.5 mA, rms).

Immediately post-shock, TF latencies were significantly elevated above baseline for both DLF & sham operated rats. At 1 min post-shock, the TF latency of DLF rats was no longer significantly above baseline ($p>0.05$). In contrast, the TF latency of sham operated rats remained significantly elevated throughout testing.



Bilateral DLF lesions greatly reduce the effects of FSA produced by FP shock. We conclude that the DLF plays an important role in this FSA. It is of interest that DLF lesions do not completely eliminate the increased TF latency measured immediately post-shock. This is in agreement with the observation that naloxone also fails to prevent significant analgesia from FP shock for the first 2 min following shock. These results strongly indicate that the same endogenous opiate analgesia system is activated by morphine & electrical stimulation of the brain. PHS Grant DA-00576.

17.11 A STUDY OF THE RESPONSE PROPERTIES OF MEDIAL BRAINSTEM CELLS PROJECTING TO THE SPINAL CORD IN MONKEYS. T.K. Wilcox, R.P. Yezierski, K.D. Gerhart and W.D. Willis. Marine Biomedical Institute and Departments of Physiology & Biophysics and of Anatomy, University of Texas Medical Branch, Galveston, TX 77550

Electrical stimulation within the medial brainstem has been shown to inhibit responses of spinothalamic tract (STT) cells to noxious and innocuous cutaneous stimuli. A similar inhibition of STT cells by periaquaductal gray (PAG) stimulation has been demonstrated by our laboratory. The present study examines the effect of PAG stimulation on and the receptive field properties of cells in the medial brainstem which have projections to the lumbrosacral spinal cord.

Monkeys (M. fascicularis) anesthetized with α-chloralose and pentobarbital were paralyzed and artificially ventilated. Stimulation sites in the PAG were selected on the basis of inhibition of evoked activity in STT cells (50-500 μA pulses, 100 ms trains, 333 Hz). Spinothalamic tract cells were antidromically activated from the ventral posterior lateral nucleus of the thalamus. Medial brainstem cells were antidromically activated by stimulation of the left dorsolateral fasciculus of the spinal cord (L4) and 100 μsec current pulses not exceeding 1 mA. The conduction velocities of these cells ranged from 7-81 m/s.

The cutaneous receptive fields of medial brainstem cells were large and often included the entire body. Both excitatory and inhibitory fields were found. Most cells responded only to noxious mechanical and/or thermal stimuli. Some brainstem cells were unresponsive to cutaneous stimulation. Stimulating electrodes were placed in contact with the left sural nerve to examine further the response properties of these cells. Stimulation of A and C fibers in the sural nerve elicited noticeable changes in the activity of those medial brainstem cells having cutaneous input from the sural region. Responses of cells to electrical stimulation in the PAG were mostly excitatory, although inhibition of spontaneous and evoked activity was sometimes observed. These responses were obtained using stimulus parameters similar to those used to inhibit evoked responses in STT cells.

Results of this study of the response characteristics of medial brainstem cells projecting to the spinal cord will be discussed in relation to the mechanism of descending inhibition.

This work was supported by research grants NS 09743 & NS 11255, by postdoctoral fellowship NS 06193 to R.P.Y. from the National Institutes of Health and by a grant from the Moody Foundation.

17.12 THE EFFECTS OF NUCLEUS RAPHE MAGNUS AND ADJACENT RETICULAR AREAS ON THE RESPONSES OF NUCLEUS CAUDALIS NEURONS TO NOXIOUS AND NON-NOXIOUS STIMULI IN CATS. J.O. Dostrovsky and Y. Shah*, Department of Physiology, Univ. of Toronto, Toronto, Canada M5S 1A8.

The nucleus raphe magnus (NRM) and possibly the nucleus reticularis magnocellularis (RMC) have been implicated as components of a descending pathway involved in the inhibition of nociceptive transmission in the spinal cord and trigeminal subnucleus caudalis. Raphe neurons have been shown to project via the dorsolateral funiculus and terminate in the dorsal horn of the spinal cord and in nucleus caudalis. There is also evidence that the dorsolaterally located nucleus gigantocellularis (NGC), which has a descending projection by a different pathway, the ventral lateral funiculus, is involved in the inhibition of sensory input. Here we report a comparison of the effects of these areas on the neuronal responses of caudalis neurons to noxious and non-noxious stimuli.

Experiments were done on chloralose anesthetized cats. Concentric bipolar electrodes were stereotaxically positioned in the NRM, NGC and RMC and histologically verified. Bipolar electrodes were also implanted in the teeth. Single units were recorded with glass-coated tungsten or carbon fibre microelectrodes. Units were categorized by sensory examination according to standard criteria as low threshold mechanoreceptive (LTM), wide dynamic range (WDR) and nociceptive specific (NS). Units were excited by just-suprathreshold stimulation intensities delivered to the skin (electrically or mechanically) or tooth pulps. The effects of stimulating the NRM, NGC or RMC (100 ms, 500 Hz, train 0.1 ms pulse width, delivered 130 ms prior to the test stimulus) on these peripherally elicited responses were determined.

Conditioning stimuli were tested on the cutaneous responses of 22 LTM, 14 WDR and 5 NS,and on the tooth pulp evoked responses of 24 units. 95% of these units were inhibited by NRM, NGC or RMC at stimulation currents less than 250 μA. No consistent difference was found between the stimulation thresholds necessary for NRM, NGC, or RMC induced inhibition. Furthermore there was no consistent difference between the thresholds required to inhibit cells in the various categories studied.

Thus the NGC, RMC and NRM appear to be equally effective in inhibiting responses to both noxious and non-noxious stimulation. These results do not support the idea of a nociceptive specific inhibitory pathway from the NRM.

This project was supported by grant #1R01 DE05404 from NIDR, DHEW.

18.1 EFFERENT SYNAPTIC ACTIVITY MODIFIES COCHLEAR MECHANICS SEEN IN EAR-CANAL ACOUSTIC DISTORTION PRODUCTS. J.H. Siegel and D.O. Kim. Dept. of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO. 63110.

The intermodulation-distortion products (f_2-f_1) and ($2f_1-f_2$), believed to originate in the cochlea, were monitored in the ear-canal sound pressure with a two-tone stimulus as previously described (Kim, Hearing Res. 2, 1980). Mountain (J. Acoust. Soc. Amer. 67: S89(A), 1980) has reported that shocking the crossed olivo-cochlear bundle (COCB) reduces the amplitude of the acoustic distortion product (f_2-f_1). In our experiments chinchillas were deeply anesthetized with Dial (70mg/kg) in urethane. Both middle ear muscles were completely severed from the ossicles to eliminate their influence during the shocks. 400-Hz shock trains were delivered through bipolar electrodes on the dorsal surface of the brainstem in the 4th ventricle. Depending on the primary stimulus frequencies, (f_2-f_1) or ($2f_1-f_2$) was increased, decreased, or unchanged during the shocks. For ($2f_1-f_2$) panel "A" below shows a 3dB increase (f_1=4500Hz, f_2=6000Hz, with SPL (re 20μPa) L_1=63dB, L_2=62dB) while panel "B" shows a 2dB decrease (f_1=2170Hz, f_2=2790Hz, L_1=64dB, L_2=66dB). For (f_2-f_1) panel "C" shows a 3dB increase (f_1=2170Hz, f_2=2790Hz, L_1=64dB, L_2=66dB) while panel "D" shows a 2dB decrease (f_1=2700Hz, f_2=4200Hz, L_1=69dB, L_2=62dB). The effect was completely blocked by perfusing the cochlea with artificial perilymph containing 10 μM d-tubocurarine, which did not itself alter the distortion amplitude. This clearly mechanical change is almost certainly mediated by efferent synaptic activity, presumably through the outer hair cells.

18.2 INCORPORATION OF ^{14}C-2-DEOXYGLUCOSE IN THE COCHLEA: EFFECTS OF ACOUSTIC STIMULATION. A. F. Ryan*, P. Goodwin*, N. K. Woolf and F. Sharp. Otolaryngology Research Laboratory, University of California at San Diego Medical School, San Diego, CA 92103.

Activation of cellular structures of the central auditory pathway can be demonstrated by the increased incorporation of ^{14}C-2-deoxyglucose (2-DG). However, this technique as employed in previous investigations does not lend itself to use in the cochlea. The bony capsule and large fluid spaces of the inner ear make it difficult to obtain and preserve frozen sections. We have developed an alternative technique which permits the visualization of 2-DG uptake in cochlear tissues.

2-DG (New England Nuclear) was suspended in tissue culture medium and injected intracardially (16 μCi/100 gm, in 0.1 ml) into adult mongolian gerbils. Animals were immediately placed in a double-walled, sound-attenuated chamber (IAC 1200A) with an anechoic lining, in the dark for one hour. Experimental subjects were exposed free-field to wide-band (0-100 kHz) noise delivered through a mid-range driver (JBL 2482) for the one-hour period, at an intensity of 25, 45, 65, 85 or 105 dB SPL. Control subjects were treated identically, but received no noise exposure. All animals were then sacrificed by decapitation. The brains were removed and frozen in isopentane at -20°C. The inner ears were dissected whole and frozen in Freon 12 cooled in liquid nitrogen to its freezing point (-160°C). The brains were sectioned at 20 μm, dried and exposed for 5-7 days on x-ray film. Inner ears were freeze-dried at -40°C for 72 hr, and the round and oval windows opened. Some specimens were vapor-stained over a 4% solution of osmium tetroxide for 3-10 min. Inner ears were then embedded in Epon or Spurr resin. No dehydration sequence was necessary, and only organic solvents (absolute alcohol, acetone and propylene oxide) were employed in the embedding procedures. Evaluation of the solvents employed indicated no loss of 2-DG during embedding. Once polymerized, the cochleas were cut in mid-modiolar section utilizing a 100 μm jeweler's saw and exposed on LKB Ultrofilm for 7-12 days. Exposures of brain sections revealed increased uptake of 2-DG during acoustic exposure in all of the structures of the central auditory pathway, although relatively modest activity was detected in medial geniculate nucleus and cortex. 2-DG uptake was maximal at exposure intensities of 85 and 105 dB SPL. Control inner ears showed maximum uptake of 2-DG in stria vascularis, with visualization of organ of Corti, spiral ganglion and VIIIth nerve possible. Vapor staining with osmium tetroxide appeared to have no effect on 2-DG distribution. Preliminary data from experimental inner ears indicate that 2-DG uptake increased during exposure to 85 and 105 dB, in spiral ganglion and VIIIth nerve.

18.3 POSTMORTEM EFFECTS AND SPECIES DIFFERENCE FOR ACOUSTIC INPUT CHARACTERISTICS AT THE EARDRUM OF THE CHINCHILLA AND THE CAT. D.O. Kim, J.H. Siegel and C.E. Molnar*. Box 8101, Washington University School of Medicine, St. Louis, MO 63110

A closed acoustic system containing a Beyer DT48 earphone and a probe microphone (Kim, Hearing Res. 2, 1980) was used in this study. The chinchillas and the cats were anesthetized with Dial (70 to 75 mg/kg) in urethane, and the bulla and septum were widely opened. In the chinchilla, both of the middle ear muscles were completely severed; in the cat, they were left intact. A notch at 115Hz, as shown in the figure, was seen in the antemortem chinchillas whether or not the middle ear muscles were severed, but not seen in the cat. This difference is not due to experimental apparatus—an identical set of apparatus was used for both species. Pronounced postmortem changes occurred over several hours after death. For example, the 115Hz notch is absent in the 13 Hr postmortem chinchilla curve. Prominent harmonic distortion products as large as -22 dB relative to the primary component, with primary level in the range of 55 to 90 dB SPL, were observed at this notch in the live chinchilla. The 115Hz notch may correspond to a resonance in the cochlear input impedance. The postmortem changes reported here may in part reflect changes in cochlear mechanics occurring over several hours after death, as observed by Rhode (Basic Mech. Hear., Möller, Ed., 1973) which are interpreted by Kim et al. (Psychophys., Physiol. & Behav. Stud. Hear., van den Brink and Bilsen, Eds., 1980) as possibly due to a loss of active mechanical energy source in the cochlear partition soon after death and to a later decrease in the partition stiffness.

18.4 Effects of kanamycin on the auditory system of the leopard frog (Rana pipiens). G. Rose* and R.R. Capranica, Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14853.

It is well known that the ototoxic drug kanamycin leads to irreversible loss of hair cells in the mammalian cochlea. To determine whether similar effects occur in cold-blooded vertebrates, kanamycin (12.5%) was infused (10 nl/g) directly into the fluid-filled inner ear of leopard frogs (Rana pipiens); a group of control animals received injections of equivalent amounts of amphibian Ringer's solution. Subsequently, multi-unit recordings from the midbrain (torus semicircularis) and recordings from single auditory nerve fibers were conducted. In recordings from the midbrain, large threshold elevations (up to 40 decibels) were encountered one to two days following a single injection of the drug. This elevation was most pronounced in the frequency range of 200 to 700 Hz, corresponding to the region of maximum sensitivity of the amphibian papilla. Single unit recordings from the eighth nerve confirmed that injection of kanamycin leads to a pronounced elevation in thresholds of the low- and mid-frequency sensitive fibers; high-frequency (1,000 - 1,800 Hz) sensitive fibers presumably from the basilar papilla showed a significant, although less marked, elevation in threshold. Furthermore, there was a clear correlation between threshold and Q_{10} value: fibers with high threshold in our treated animals had very broad tuning curves. Injection of Ringer's solution in our control group of animals failed to alter the response properties of the auditory system.

Our most recent results suggest that the deleterious effects of kanamycin on auditory function in anurans may be completely reversible. Threshold sensitivity and tuning sharpness recover to normal values within one to two weeks following a single drug injection. These results will be discussed with regard to the presence of a physiological vulnerable frequency filtering mechanism at the level of the auditory periphery.

This research was supported by NIH grant NS-09244.

18.5 POTENTIATION OF KANAMYCIN'S OTOTOXICITY BY AMINOOXYACETIC ACID. R. Cronin-Schreiber*, G. Bryant*, B. Melamed*, C. Norris and P. Guth. Dept. Pharmacology and Otolaryngology, Tulane Univ. Sch. of Med., New Orleans, LA 70112.

Aminooxyacetic acid (AOAA) has been shown to produce a reversible loss of hearing acuity, presumably by diminishing the endocochlear potential (Bobbin, R.P., et al., Nature, 223:70, 1969). Based on this finding Bobbin, et al. (Trans. Amer. Acad. Ophthal. Otolaryng., 82:299, 1976) investigated the possible protective effect of AOAA against noise-induced loss of cochlear hair cells, and found that AOAA did, indeed, protect against this type of hearing loss. We decided to study the possible protective effect of AOAA against kanamycin-induced loss of cochlear hair cells and found that rather than a protective effect AOAA potentiated kanamycin's ototoxicity. Single subcutaneous doses of AOAA at 8, 11, 15, and 25 mg/kg, which normally do not damage the cochlea, markedly potentiated kanamycin's ability to cause cochlear damage in the guinea pig. Kanamycin generally is given in subcutaneous doses of 400 mg/kg daily for 10-14 days to produce ototoxicity. When combined with AOAA, a single 400 mg/kg dose of kanamycin is sufficient to cause cochlear damage as measured electro- and histocochleographically. Twenty-one days after an injection of one dose each of AOAA and kanamycin, it is not possible to detect hearing thresholds electrocochleographically at 2, 4, 8, 12 and 16 kHz. The pattern of histological damage produced is somewhat different from that produced by kanamycin alone. The combination caused widespread destruction of both inner and outer hair cells, whereas kanamycin generally causes the loss of outer hair cells before many of the inner hair cells are destroyed. The mechanism of this unexpected interaction of AOAA and kanamycin is unknown but may involve the interference of glutamate metabolism by AOAA and the interference of glucose transport by kanamycin (Garcia-Quiroga, J., et al., Res. Commun. Chem. Pathol. Pharmacol., 22:535, 1978), thus depriving the cochlea of its chief energy sources.

Supported in part by NSF #11647 and NSF #07058-03.

18.6 ONTOGENY OF FREQUENCY SELECTIVITY AND SENSITIVITY OF THE PERIPHERAL AUDITORY SYSTEM OF THE POST-METAMORPHIC BULLFROG, RANA CATESBEIANA. William P. Shofner and Albert S. Feng. Dept. of Physiology and Biophysics, Univ. of Illinois, Urbana, IL 61801

During the post-metamorphic development of the bullfrog, there is a dramatic increase in the size of the tympanic membrane, middle ear bones, and middle ear cavities. Changes in the size of these structures presumably influence the efficiency of sound transmission at various frequencies. This raises the question as to whether the frequency selectivity and sensitivity of the bullfrog peripheral auditory system change during development.

Auditory responses to pure tone bursts were studied on over 200 single auditory fibers of the VIIIth cranial nerve of juvenile bullfrogs ranging in snout-vent lengths of 37-46 mm (2.5-12 g body weight) and compared to those of fully developed adults. The distribution of best excitatory frequencies (BEFs) from the juveniles indicated that at least three populations of auditory fibers exist: a low-frequency population centered around 100-300 Hz, a mid-frequency population had BEFs distributed between 900 Hz and 1600 Hz, and a high-frequency population had BEFs ranging from 1800 Hz to 2400 Hz. It is unknown at the present time as to which auditory papillae these populations innervate. The distributions of BEFs of the mid- and high-frequency populations found in the adult were lower than those observed in the juvenile. In the adult, the mid-frequency population had BEFs distributed between 500 Hz and 900 Hz, and the BEFs of the high-frequency population ranged from 1100 Hz to 1800 Hz. Furthermore, the majority of high-frequency sensitive fibers in the juvenile could be excited by tones as high as 4000-4500 Hz, whereas all high-frequency fibers in the adult could not be excited by tones beyond 3000 Hz even at intensities of 100 dB SPL. Thus, there appeared to be a downward shift in the frequency selectivity with development. A comparison of the distribution of thresholds at BEFs indicated that the sensitivity of the low-frequency fibers in the juvenile generally were poorer than those fibers found in the adult. The mechanisms responsible for these changes are currently being investigated.

Supported by NSF grant 79-12271, RIAS Study Grant SER 78-18244 from NSF, and NIH training grant HEW PHS GM 07283-05.

18.7 NEURAL DELAY IN THE AUDITORY SYSTEM DETERMINED USING AMPLITUDE MODULATED SOUNDS. A. R. Møller. Division of Physiological Acoustics, University of Pittsburgh School of Medicine, *Pittsburgh, PA 15213.*

Gross potential responses from the auditory nerve and the cochlear nucleus of anesthetized rats to tones and noise which were amplitude modulated with pseudorandom noise were compared with the responses to transient sounds such as tone and noise bursts. The responses to several periods of the amplitude modulated sounds were averaged and syncronized to the periodicity of the pseudorandom noise. The averages were cross correlated with one period of the pseudorandom noise. The wave morphologies of the cross correlation functions resembled those of the averaged responses to tone and noise bursts. However, the latencies of peaks obtained from cross correlation functions showed smaller decreases as the stimulus intensity increased than did the latencies of the peaks from responses to tone and noise bursts. The latencies of the peaks in the cross correlation function obtained from the gross potential responses had values that were close to those of single unit responses to the same types of stimuli. This indicated that the latencies obtained from the responses to amplitude modulated sounds were more accurate measures of synaptic and axonal delay than were the latencies of the responses to transient sounds such as tone or noise bursts.

18.8 THE FINE STRUCTURE OF STELLATE CELLS IN THE ANTERIOR DIVISION OF THE ANTEROVENTRAL COCHLEAR NUCLEUS (AVCN) OF THE CAT. N. Cant. Department of Anatomy, Duke University Medical Center, Durham, *N. C. 27710*

The anterior division of the AVCN contains at least two types of large neurons defined on the basis of their dendritic morphology in Golgi preparations--the bushy cells and the stellate cells. The fine structure and synaptic organization of the bushy cells has been described previously (e.g., Cant & Morest, '79), but no detailed description of the stellate cells is available. In the present study, stellate cells were observed with the electron microscope and the fine structure of their somas and proximal dendrites and of the synaptic terminals contacting them was described. Their synaptic organization was then compared to that of the bushy cells.

The stellate cells are identified by their somatic and dendritic size and shape, their distribution within the AVCN and the organization of their cytoplasmic organelles. They are distinguished from bushy cells by the absence of stacks of granular endoplasmic reticulum encircling the nuclear envelope. Although only one type of stellate cell has been identified in light microscopic preparations, two distinct types are found in electron micrographs. The type I stellate cells are large neurons with relatively pale cytoplasm and very few synaptic endings contacting the somatic or proximal dendritic surface. In contrast, their more distal dendrites are contacted by many terminals. The type II stellate cells are large neurons with many somatic spines and numerous axosomatic and axodendritic synapses. Both neuronal types receive synaptic endings from the cochlea as well as several types of non-cochlear endings, most of which resemble those that contact the bushy cells. However, the fine structure of a few of the non-cochlear terminals contacting the type II neurons appears to be different from that of terminals described previously. In addition, large end-bulbs of Held have not been seen contacting either type of stellate cell.

In summary, the anterior division of the AVCN contains at least three types of large neurons defined on the basis of their fine structure and synaptic organization. Since distinctive arrangements of cochlear and non-cochlear synaptic terminals could result in different response patterns to acoustic stimuli, each of these neuronal types may correspond to a different type of single unit, defined physiologically.

18.9 TYPES OF GIANT NEURONS IN DEEP DORSAL COCHLEAR NUCLEUS (DCN) OF CATS. Eileen S. Kane. Department of Anatomy, University of Massachusetts Medical School, Worcester, MA 01605

Giant neurons (average diameter > 22.0 μm) of the deep DCN (layers 3 & 4 of Lorente de Nó) have been identified by somatic shape, location, orientation and basal dendritic numbers and orientations in Nissl material. The major types (elongate bipolar, elongate multipolar, radiate, oriented and globular giants) correspond to distinct giant neurons studied in Golgi-impregnated cat deep DCN. Both types of elongate giant cells have smooth somata, but bipolars have a cylindrical dendritic field and smooth, long dendrites, parallel to the striae. Elongate multipolars have bowl-shaped dendritic fields and highly branched, appendage-covered dendrites. Radiate giants have ovoid-to-spherical, smooth somata and thin, appendage-covered, radiating dendrites. Oriented giants, with smooth, spherical somata, have stout, long dendrites extending a cone-shaped field into the superficial DCN. Globular giants have smooth, ovoid somata vertical to the DCN surface and one or two very thick, short primary and long secondary dendrites. Each giant cell type was first recognized in thick plastic sections and then identified in thin sections. All giant cell basal and primary dendrites receive very dense synaptic inputs. Somata of elongate multipolar, radiate and oriented giants have very dense synaptic coverage while elongate bipolar cell somata have less and globular giants have the sparsest coverage. Many large, primarylike terminals are found on basal dendrites of all giant cell types and notably, upon somata of elongate multipolar and radiate giant cells. Nauta preparations (after complete ipsilateral cochlear ablations and 2-14 day survival times) show primary inputs to all giant cell types. Elongate bipolar cells are always surrounded by peridendritic (not perisomatic), medium-caliber preterminal fragments but elongate multipolars have perisomatic and peridendritic fragments, as do radiate giant cells. Preterminal fragments are predominantly associated with basal and primary dendrites of both oriented and globular giant cells, but both have occasional perisomatic degeneration. Thus, giant cell types receive cochlear inputs of different densities and distributions; elongate multipolars and radiate giant cells receive the densest inputs. Since all giant cell types have observable (Golgi-impregnated) axons directed toward or into the striae, we conclude that all of these large neurons can transform and convey differently encoded primary information to higher auditory centers.

18.10 LOCALIZATION OF LABEL FROM H^3-GABA IN PARALLEL FIBERS IN THE OUTER MOLECULAR LAYER IN THE CAT DORSAL COCHLEAR NUCLEUS. I.R. Schwartz, Division of Head and Neck Surgery, UCLA School of Medicine, Los Angeles, CA 90024.

Light and electron microscopic autoradiography was performed on sections from fresh slice preparations of the cat dorsal cochlear nucleus following 20 minute room temperature incubation in oxygenated Ringers bicarbonate solutions containing micromolar amounts of different putative neurotransmitter amino acids. Some parallel fibers in the outer molecular layer were heavily labeled following incubation with H^3-GABA. Some terminals in the outer molecular layer were labeled following incubation with H^3-glutamic acid and H^3-glycine. However, after H^3-glutamic acid the labeled terminals were distributed deeper in the outer molecular layer and generally appeared to be larger than the parallel fiber endings. Labeled terminals were mainly found on cell bodies and dendrites after H^3-glycine. Virtually no endings were labeled after incubation with H^3-aspartic acid, H^3-taurine or H^3-alanine. Granule cell bodies were unlabeled after all the amino acids.

The localization of label derived from H^3-GABA in parallel fibers is consistent with its presumed role as an inhibitory neurotransmitter in the dorsal cochlear nucleus and the biochemical evidence of its higher concentration in the molecular layer (Godfrey et al., 1977). The label localization could be due either to an exchange with high endogenous concentrations or to a high affinity uptake. Moreover, given the level of preservation of the slice preparation produced by the tissue chopper, the label localization could reflect synaptosomal-like properties rather than properties of intact neurons. Further studies are underway to examine label localization in hand sliced sections in which there is improved preservation.

Supported by NS 09823 and 14503.

19.1 EFFECTS OF RESTRAINT ON DOPAMINE TURNOVER AND TYROSINE HYDROXYLASE ACTIVITY IN RAT FRONTAL CORTEX. Linda Toth Kennedy and Michael J. Zigmond. Department of Pharmacology, School of Pharmacy, and Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260.

Dopamine (DA) turnover in rat frontal cortex (FC) has been shown to increase following footshock. We wished to confirm these results using a second stressor, restraint, and to determine whether the increased turnover was accompanied by an increase in tyrosine hydroxylase (TH) activity.

Adult, male Sprague-Dawley rats (Zivic-Miller Labs) were housed one per cage and were handled daily for at least one week. Rats were then subjected to 15 minutes of restraint, and DA turnover estimated by measuring dihydroxyphenylacetic acid (DOPAC) levels or the rate of DA depletion following synthesis inhibition. Fifteen minutes of restraint increased DOPAC levels in FC by 30% (control = .046 ug/g; restraint = .060 ug/g; $p<.05$), suggesting an increase in DA turnover in that structure. In a second experiment, rats were subjected to 15 minutes of restraint immediately prior to the administration of the DA synthesis inhibitor alpha-methyltyrosine (AMT; 250 mg/kg, i.p.), and were sacrificed 15 minutes post-injection. The turnover rate of DA in FC of non-stressed rats was 0.035 ug/g/h, while that of stressed rats was 0.118 ug/g/h. Similar results were obtained if rats were treated with AMT prior to restraint, and sacrificed immediately after the 15 minute stress period.

We next examined the ability of restraint to increase TH activity in FC. Tissue was homogenized in 50 mM Tris-HCl, pH 6.0, and the 20,000 x g supernatant assayed for TH activity in a Tris-acetate buffer (pH 6.2) in the presence of subsaturating concentrations of tyrosine and cofactor. No significant change in TH activity was observed using either the synthetic cofactor, 6MPH4, or the presumed natural cofactor, biopterin. Moreover, no difference in TH activity was observed between samples from control and restrained animals incubated in the presence of the phosphatase inhibitor, NaF. TH activity could be increased *in vitro* by incubating the tissue under phosphorylating conditions (cAMP, ATP, magnesium, and protein kinase), implying that TH activity was not maximally active in crude homogenates.

These data thus support previous suggestions that stress increases DA turnover in rat FC. However, although TH from FC could be activated *in vitro*, *in vivo* activation could not be detected following restraint-induced stimulation of DA turnover. (Supported in part by USPHS Grants MH-29670 and MH-00058.)

19.2 ACUTE HEAT STRESS LOWERS BRAIN STIMULATION REWARD THRESHOLD. R.W. Phelps* and M.J. Lewis. Dept. of Psychology, Tufts University, Medford, MA. 02155.

The effects of acute heat stress were investigated on brain stimulation reward (BSR), and food and water intake in adult male albino rats. All rats were implanted in the medial forebrain bundle(MFB) with bipolar platinum electrodes. Each received extensive training to press a lever for stimulation under a concurrent fixed-ratio/ continuous schedule of reinforcement. This schedule was used to determine BSR **threshold** according to the methods similar to Huston and Mills (1969). After reliable BSR performance was established, all rats were subjected to 3 hrs of 22°C(control) and then either 30°C or 40°C heat in an insulated temperature controlled chamber. Rats were immediately removed at the end of the period of heat application and BSR threshold, rate of response and brain impedance were determined in an operant chamber. Heat stress of 40°C, but not 30°C, lowered BSR threshold levels and increased brain impedance over control values. No change in overall response rate for the sessions was observed. Other rats subjected to the 40°C heat stress showed a decrease in food and, unexpectedly, water intake during a 40 minute period after the heat stress. The effects of acute heat stress on BSR are discussed in terms of known effects of acute heat stress on brain monoamine systems.

19.3 BEHAVIORAL AND HISTOLOGICAL ANALYSIS OF PSYCHOSOCIALLY STRESSED MICE. W.P. Meehan* and J.N. Naranjo.(SPON: J.C. Shih). Department of Physiology,University of Southern California School of Medicine,Los Angeles, CA 90033 and Department of Anatomy,Harvard Medical School,Boston,MA 02178

The highly accellerated rate of neuron loss in stressed animals may be related to increased levels of corticosteroids. The adrenal glands of psychosocially stressed CBA/USC male mice are enlarged as compared to aged-matched controls, indicative of increased corticosteroid synthesis and release. In addition, stressed male mice have been shown to have increased plasma levels of corticosterone. Recent evidence suggests that high levels of corticosteroids lead to pathologic changes in the brain including neuron loss.

The brains of stressed and non-stressed same age control mice were compared histologically using a silver degeneration stain (Naranjo and Greene,1977).Numerous degenerating fiber tracts were noted in the stressed animals while minimal degeneration was found in the non-stressed animals.

To test the behavioral ramifications of the neuronal loss, especially loss in the fornix and hippocampus, two additional groups of animals were compared in their ability to learn a delayed alternation task. The stressed animals displayed a significant deficit ($p<.01$) in spatial learning ability, and were significantly ($p<.01$) slower than the controls.

After behavioral testing, the brains of the animals were removed, stained, and examined in a blind fashion by three trained observers. The hippocampus of each stressed animal as well as the fiber tracts communicating hippocampal afferent and efferent imput (fornix, fimbria, and mammillothalamic tract) contained degenerating neuronal material. Examination of the non-stressed animals revealed only occassional degenerating fibers.

The histopathology of the stressed animals' hippocampus and fiber tracts strongly supports the possibility that memory impairment in these animals was a result of stress related degenerative changes in the central nervous system.

19.4 CORRESPONDENCE OF BEHAVIORAL THERMAL SELECTION PREFERENCES WITH AUTONOMIC THERMONEUTRAL ZONE. M.L. Laudenslager, D. Tomback*, University of California at Santa Barbara, 93106.

Previous studies of Chukar partridges suggested that the preferred ambient temperature (PAT) defined within a lab environment overlapped the autonomic thermoneutral zone (TNZ) of that species. The present study determined the PAT in three additional species (mourning doves, domestic pigeons, and Clark's nutcracker) and compared these with the TNZ for these species. PAT was determined in a two-compartment environmental chamber. One chamber was maintained at 0°C; the other could be varied between 20 and 55°C. The bird could move between the two chambers at any time. For any test, only one warm chamber temperature was presented. PAT was determined from the warm chamber temperature at which the bird would not escape into the cold. Two domestic pigeons demonstrated PATs of 32.1 and 32.3°C. A single mourning dove selected a PAT of 34.5°C. Two nutcrackers showed PATs of 21.5°C and 28.7°C. The PATs demonstrated for columbiformes fell within TNZs previously reported in the literature. TNZ for the nutcrackers was found by measuring rates of oxygen consumption ($\dot{V}O_2$) over an ambient temperature range of -5 to 44°C. Minimum $\dot{V}O_2$ was observed between 25 and 30°C for winter-adapted birds and between 20 and 30°C for summer-adapted birds. The lack of perfect correspondence between the PATs and TNZs for the nutcracker may be related to the fact that the behavioral tests were made in laboratory-acclimated birds. In general, these additional tests further support the common sense notion that when a choice is possible, birds will select ambient temperatures at which metabolic rate is minimized. (Supported by University of California, Santa Barbara Faculty Grant #412 and National Science Foundation Grant #PCM-7825238.)

19.5 SYMPATHO-ADRENAL AND CARDIOVASCULAR CORRELATES OF AGGRESSIVE BEHAVIOR IN THE AWAKE CAT. S.L. Stoddard-Apter, A. Siegel, C.H. Block* and B.E. Levin. Dept. of Neurosciences, College of Medicine & Dentistry of New Jersey, New Jersey Medical School, Newark, N.J. 07103, and Dept. of Neurology, V.A. Medical Center, East Orange, N.J. 07019.

The hypothalamus of the awake, intact cat was stimulated at multiple sites to determine those regions which could elicit integrated behavioral responses and/or activation of the cardiovascular (CV) and sympatho-adrenal (SA) systems. Cats were restrained in a headholder, and CV parameters (blood pressure and heart rate) were monitored continuously from an intra-arterial cannula. Activation of the sympathetic nervous system and adrenal medulla were determined simultaneously by radioenzymatic assay of plasma norepinephrine (NE) and epinephrine (E), respectively. Blood samples were withdrawn from an indwelling venous cannula prior to stimulation of the hypothalamus at 0.4 mA for 5 sec, and immediately, at 30 sec, and at 1, 2, 3, 4, 5, 10, and 15 min after stimulation (30 min intertrial interval). Preliminary trials showed that the method of restraint used produced plasma catecholamine levels intermediate between those in the unrestrained and those in the anesthetized cat. Sites which elicited maximum CV and SA activation were generally located along a continuum throughout the hypothalamus, extending from the perifornical area rostrally, through the dorsolateral hypothalamus, to the mammillary bodies caudally. The CV and SA activation sites were, for the most part, identical; they differed only at the level of the ventromedial nucleus, where the effective CV sites were situated more dorsally than the effective SA sites, and at the level of the caudal extent of the mammillary bodies, where the effective CV sites were located lateral to the effective SA sites. Inasmuch as these responses could be elicited throughout the rostro-caudal extent of the hypothalamus, these data suggest that hypothalamic sites which activated the CV and SA systems represented stimulation of descending fiber bundles originating at more rostral levels. Those sites which elicited integrated behavioral responses, however, were localized in more circumscribed regions, which were not necessarily contiguous with the descending CV and SA pathways. Escape behavior was generally associated with the greatest CV and SA activation; a smaller response was elicited from stimulation of sites producing affective defense behavior. Predatory attack sites tended either to inhibit the sympathetic system (NE), or to activate it only after an initial delay.

19.6 INFLUENCE ON CARDIOVASCULAR FUNCTION BY PREFRONTAL CORTEX AND ITS THALAMIC RELAY NUCLEUS. Charles H.K. West and Robert M. Benjamin. Dept. of Neurophysiology, Univ. of Wisconsin Medical School, Madison, Wisconsin 53706.

Influence of prefrontal cortex on emotions and autonomic functions has long been known. Prefrontal cortical modulation of autonomic parameters was re-emphasized by the report that electrical stimulation of orbitofrontal cortex in awake rhesus monkeys evoked cardiovascular changes (Hall and Cornish, Exp. Neurol. 56: 289-297, 1977). One dramatic finding of this study was the occurrence of severe multifocal cardiac necrosis in most of the stimulated animals, implying a relationship between prefrontal cortex and emotionally induced cardiopathy. We decided to investigate the neural pathways that might mediate this phenomenon in the rabbit, where much of the neuroanatomy of the prefrontal cortex system has been studied by our laboratory. Only small (<5%) changes in heart rate to stimulation of sulcal prefrontal cortex were observed in anesthetized animals. In contrast, electrical stimulation (20-300 μA, 60 Hz sine wave, 3 sec duration) of the thalamic mediodorsal nucleus (MD), the primary relay nucleus for prefrontal cortex, elicited highly significant decreases in heart rate proportional to the stimulating current. At the higher current intensities used (100-300 μA), heart rates were reduced by as much as 75-85% from pre-stimulus levels. This stimulus-produced bradycardia appeared quickly after stimulus onset (delay < 1 sec, peak within 5 sec), and the heart rate usually returned to baseline within 30 sec after stimulation. The cholinergic innervation of the heart by the vagus was implicated in the generation of the response since either administration of atropine (sulfate or methyl nitrate, 0.15 mg/kg iv) or bilateral vagotomy abolished the majority of the response. Administration of a β-adrenergic receptor blocker (propranolol, 3 mg/kg iv) did not affect the heart rate response. The effective area for evoking a response within the medial thalamus was localized to MD, the midline nuclei between both MD's, and a region posterior to MD (e.g., parafascicular nucleus). The descending effector pathway from MD to autonomic centers may involve these neighboring midline areas since a knife cut along the medial border of MD blocked the responses elicited from areas farther lateral in M.D. Furthermore, complete bilateral ablation of prefrontal cortex did not diminish the stimulus - produced bradycardia evoked from MD. Previous work on the rabbit has shown that the midline nuclei medial to MD (but not MD itself) project to various subcortical regions including the medial (periventricular) portion of the hypothalamus (West, et al., Neuroscience, 4: 1977-1988, 1979), thus suggesting a potential output pathway for autonomic responses.

19.7 BRAIN AREAS IMPLICATED IN CHOLINERGIC MEDIATION OF SEXUAL BEHAVIOR. G. P. Dohanich* and L. G. Clemens. Department of Zoology, Michigan State University, East Lansing, MI 48824.

Sexual behavior in female rats was measured following stimulation of cholinergic receptors in several brain areas. Ovariectomized female rats were pretreated with .13 μg estradiol benzoate 72, 48, and 24 hr before behavioral testing. This estrogen regimen does not induce sexual behavior in female rats. However, carbamylcholine chloride (carbachol), a muscarinic receptor agonist, significantly increased sexual behavior, as indicated by the incidence of lordosis, in these estrogen-primed females within 15 min after bilateral infusion (.5 μg/cannula) into the medial preoptic area (POA) or ventromedial hypothalamus (VMH). Carbachol failed to induce sexual behavior at this dose of estrogen priming following infusion into the mesencephalic reticular formation (MRF) or frontal cortex. Infusion of the artifical cerebrospinal fluid vehicle (aCSF) was ineffective in all sites.

			MEAN LORDOSIS QUOTIENT ± SEM			
SITE	TREATMENT	RESPONDING	Pretest	15 min	45 min	90 min
POA	aCSF	0/12	2 ± 1	3 ± 3	1 ± 1	2 ± 1
	Carbachol	9/12	4 ± 3	58 ± 9	37 ± 8	7 ± 3
VMH	aCSF	0/12	8 ± 4	5 ± 4	4 ± 3	6 ± 4
	Carbachol	10/12	2 ± 1	58 ± 8	38 ± 9	26 ± 9
MRF	aCSF	1/9	2 ± 2	8 ± 8	9 ± 9	12 ± 9
	Carbachol	1/9	0 ± 0	8 ± 5	6 ± 6	11 ± 8
Cortex	aCSF	1/11	4 ± 2	8 ± 5	13 ± 7	11 ± 5
	Carbachol	4/11	5 ± 3	21 ± 8	18 ± 8	17 ± 8

Results indicate an estrogen-dependent cholinergic mechanism in the POA and VMH which facilitates the occurrence of sexual behavior in female rats. In addition, the rapid but transient nature of the behavioral response suggests that carbachol induced sexual behavior by directly stimulating postsynaptic cholinergic receptors, rather than by a secondary action.

19.8 EFFECTS OF TESTOSTERONE ON BODY WEIGHT AND PROTEIN INTAKE. L. I. Siegel*, A. A. Nunez* and G. N. Wade*. (SPON: J. Meyer). Dept. Psychology, Univ. Massachusetts, Amherst, MA 01003.

Previous work from this laboratory has shown that testosterone propionate (TP), administered peripherally or centrally, affects both food intake (FI) and body weight (BW) in gonadectomized (GX) male rats. To determine the influence of TP on intake of dietary components, GX male rats, each receiving a daily injection of either 0.2 mg TP, 2.0 mg TP or the injection vehicle, were given access to one of two pairs of diets. One set of diets was isocaloric and equal in fat content, varying only in percent compo- of carbohydrate and protein; in the other pair both diets had equal percentages of protein and of fat but varied in carbohydrate and caloric content. Injections of the low dose of TP resulted in increased caloric intake and rate of weight gain in GX males compared to control rats. The increase in FI was due to increased consumption of all dietary components. Males given long-term treatment with the high dose of TP, however, ate fewer calories and had lower body weights than did rats given 0.2 mg TP. Although FI was decreased in rats receiving the 2.0 mg TP dose, protein intake was selectively increased such that it did not differ significantly from that of the low TP-treated males.

We have previously shown that the lowered BW of males given high TP doses may be due, in part, to metabolic effects of estrogenic metabolites of the hormone, although at lower doses the estrogenic effects may be masked by anabolic actions of TP. The results of the present study show that TP stimulates protein consumption whether or not it is given in amounts sufficient to be converted to estrogens. In addition, the decrease in FI and BW in rats receiving the high dose of TP is similar to that observed in intact, sexually active male rats who show a rise in circulating testosterone titers and a concomitant decrease in FI and BW.

19.9 VASOPRESSIN-DEFICIENT RATS (BRATTLEBORO STRAIN) ARE IMPAIRED IN ADAPTATION AND POSITIVELY REWARDED DISCRIMINATION LEARNING. S. I. Gingold*, G.N.O. Brito, G. J. Thomas and D. M. Gash*. Center for Brain Research, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Vasopressin has recently been implicated in memory processes. However, most studies which have suggested a role of vasopressin in memory processes have used negatively reinforced behavioral tasks (i.e., shock). It is unclear then whether the effects observed are due to associative (memory) or nonassociative (performance) factors. If vasopressin is really a "memory molecule" then it should also be involved in positively reinforced behavioral tasks.

Six Brattleboro rats from our colony and six normal rats (Long-Evans) obtained commercially were used in this study. The Brattleboro animals were characterized as homozygous diabetes insipidus (DI) by water intake (24 hr.) and osmolarity of urine. The animals were housed in individual wire-mesh cages and given food and water ad lib. After 7 days they were started on a reduced food-regimen that lasted for the duration of the experiment. Seven days later maze adaptation began. The animals were given eight daily sessions (12T/day) of adaptation in the T-maze. On each trial, only the door to one of the two arms was raised (Fellows' schedule) 2 sec after raising the start-box door. After the animals were running fast, visual brightness discrimination was begun. The rats were given 15 daily sessions (12T/day) and the position of the positive stimulus (a 7.5W light bulb) was located in either arm according to a Fellows' schedule.

DI rats were significantly slower than normals in the maze adaptation sessions, although by the 8th session they were running as fast as normals. DI animals made significantly more errors than normals in the visual discrimination task. Only one of the six DI animals reached criterion (92% correct for two consecutive sessions) within 15 sessions whereas every normal animal reached criterion within that time.

The data suggest that vasopressin-deficient rats differ from controls in adapting to a new environment and in the performance of a positively rewarded visual discrimination task. Whether this represents a defect in associative mechanisms or a performance defect at the sensory level (visual) remains to be determined.

19.10 ESTRADIOL IMPLANTS IN THE AMYGDALA FACILITATE MATERNAL BEHAVIOR IN THE FEMALE RAT. A.S. Fleming*, G. Orpen* and C. Luebke.* (SPON: E. Dudek). Psychology, Univ. of Toronto, Mississauga, Ontario.

Five groups of day 18 pregnant, ovariectomized Caesarian-delivered Wistar female rats were tested for maternal behavio to four 5-10 day old foster pups proffered 48 hours after pregnancy termination and daily until animals became maternal, or for 10 days. Four groups sustained intracerebral implants of estradiol 17-β in 1) the amygdala, 2) the lateral hypothalamus, and 3) other control sites. Two groups received implants of cholesterol in 4) the amygdala and 5) other control sites. Implants were inserted through chronically implanted cannulae at the time of pregnancy-termination and were removed 48 hours later on the day of the first test.

Animals with estradiol implants in the amygdala (Group 1) became maternal more rapidly than did groups sustaining estradiol implants in other brain areas (Groups 2 and 3) and Groups 2 and 3 became maternal more rapidly than did Groups 4 and 5 who received cholesterol implants.

This study suggests that the high levels of endogenous estradiol found at parturition may promote the rapid onset of maternal behavior at this time by acting on estrogen receptors in the amygdala (Fleming, Vaccarino and Luebke, Physiol. and Behav., in press) as well as by acting on the medial preoptic area (Numan, 1974).

19.11 CENTRAL EFFECTS OF ESTRADIOL ON FOOD INTAKE IN FEMALE RATS. A. A. Nunez*, J. M. Gray* and G. N. Wade* (SPON: R. M. Gold). Department of Psychology, Univ. Mass., Amherst MA 01003

Implants of estradiol benzoate (EB) in the ventromedial hypothalamus (VMH) reduce food intake in ovariectomized rats. Recent findings indicate that in addition to possible central effects, estrogens may modulate food intake by acting directly on peripheral sites to alter metabolism (Phys. Behav. 1979, 22:583-593). In this experiment, we investigated the effects of VMH implants of EB on food intake in ovariectomized rats. After 24 hrs of intrahypothalamic hormone stimulation, vaginal smears were obtained and adipose tissue lipoprotein lipase (LPL) activity and cytoplasmic progestin receptors were measured.

The hormonal treatment resulted in a significant reduction in food intake without cornification of the vaginal epithelium. Furthermore, the reduction in food intake was observed in the absence of changes in adipose tissue LPL activity or progestin receptors. Systemic administration of EB reduces LPL activity and induces the appearance of progestin receptors in adipose tissue. These data suggest that estrogenic stimulation of the VMH may be sufficient to produce the changes in food intake seen after systemic administration of EB to ovariectomized rats.

(Supported by Grants NS 10873, NS 05854-01 and NS 00090 from the NINCDS, by Grant AM 20785 from the NIAMDD and by Training Grant MH 11823 from the NIMH)

20.1 CHRONIC LITHIUM ADMINISTRATION IN RATS: PHARMACOKINETICS, DISTRIBUTION AND EFFECTS ON DOPAMINE RECEPTORS. W.J. Shoemaker, D.A. Staunton, P.J. Magistretti, F.B. McCoy and F.E. Bloom. Arthur V. Davis Ctr. for Behav. Neurobiol., The Salk Inst., La Jolla, CA 92037.

Most published procedures for chronic lithium dosing yield highly variable food and water intake with corresponding variations in blood and brain Li^+ values, weight gain and state of hydration. We have devised a diet containing 40 mmoles/Kg Li^+ that allows weight gain without evidence of toxic symptoms when ingested over several weeks. The diet is formulated into a pellet form containing 1.696 g/Kg LiCl, 210 g/Kg protein, 690 g/Kg carbohydrate sources, 50 g/Kg lipid; rats are allowed to eat ad libitum and have access to water at all times. The lithium dose per day during the first week on the diet ranges from 86-96 mg/L; during the second week the range is 92-136 mg/L. The animals require 5-6 days to reach a steady-state level of brain and blood Li^+. Blood levels in a series of 75 rats ranged from 0.5 to 0.7 mEq/L, although the average brain levels were always higher (range 0.6 to 0.8 mEq/L). However, Li^+ does not accumulate evenly throughout the brain. When specific brain regions were analyzed, the corpus striatum accumulated Li^+ to the greatest extent (1.15 mEq/L) compared to cerebellum (.69 mEq/L) and pons medulla (.632 mEq/L). The great accumulation of Li^+ in the corpus striatum led us to study the binding properties of dopamine receptors in rats maintained on the lithium diet. Antagonist binding to dopamine receptors in crude, resuspended membranes prepared from the corpus striatum was determined with ^{3}H-spiroperidol in a group of animals fed the lithium diet (brain levels = 1.08 mEq/L) for 3 weeks. Consistent with previous reports, Scatchard analysis revealed no alteration in the affinity (K_D: 84.6 ± 18 pM, treated; 81.0 ± 19 pM, control) of ^{3}H-spiroperidol for the receptors or the density (B_{max}: 577 ± 38 fmoles/mg protein, treated; 590 ± 35 fmoles/mg, control) of dopamine receptors. The ability of the dopamine agonists, apomorphine and ADTN, to compete for ^{3}H-spiroperidol binding was also determined in striatal membranes prepared from these animals. The K_is for both apomorphine ($p < 0.01$) and ADTN ($p < 0.05$) were elevated in lithium-fed animals. These preliminary results suggest that lithium selectively reduces the affinity of dopamine agonists, but not antagonists, for dopamine receptor sites in the neostriatum. Further studies may reveal the behavioral and therapeutic relevance of this action of lithium. Supported by NIMH grants MH 29466; MH 08080 for D.A.S. P.J.M. is a recipient of a Swiss National Sciences Foundation Fellowship.

20.2 BEHAVIORAL EFFECTS OF EARLY POSTNATAL LEAD EXPOSURE IN THE RHESUS MONKEY: FIXED INTERVAL RESPONDING AND INTERACTIONS WITH DRUGS. P.J. Bushnell, P. Mele and R.E. Bowman. Dept. Biochemistry and Dept. Psychology Primate Laboratory, Univ. of Wisconsin, Madison, WI 53706.

Operant behavior was studied in a group of adolescent monkeys as a part of a test battery designed to assess the behavioral sequelae of early postnatal Pb intoxication. During the first year of life, a high-Pb group (n=4) received Pb in milk at 0.88 mg/kg·day, a low-Pb group (n=4) at 0.29 mg/kg·day, and a control group (n=4) received no added dietary Pb. Pb levels in whole blood, obtained biweekly from each animal throughout treatment, averaged 65, 32, and 4 ug/dl for the high-Pb, low-Pb, and control groups, respectively, over the year of treatment. Blood Pb levels in experimental animals fell after Pb ingestion stopped, and were all less than 10 ug/dl by 33 months of age, when operant testing began (Bushnell & Bowman, Pharm. Biochem. Behav. 10:733, 1979). One monkey in each experimental group responded at very low rates throughout these tests; their data were excluded from analysis. Otherwise, the performance of the experimental animals did not differ from control on measures of barpress response acquisition, response characteristics on FR schedules, or on resistance to extinction. However, the performance of the experimental groups on an FI60" schedule showed a flatter scallop in cumulative records and significantly smaller indices of curvature, compared to controls. In challenges with pentobarbital (0 - 20 mg/kg, sc) and scopolamine (0 - 40 ug/kg, sc)during FI responding, the FI scallop flattened at lower doses of both drugs for controls than for experimental animals. Thus a small but persistent behavioral deficit, resulting from early postnatal exposure to Pb, was observed in an operant paradigm, complementing results in the same animals on a reversal learning task (Bushnell & Bowman, J. Toxicol. Envir. Health 5:1015, 1979). Supported by NIEHS grant 2-R01-ES01062 and funds from the Food Research Institute, Univ. of Wisconsin.

20.3 INTRAVENOUS SELF-ADMINISTRATION OF ETHANOL MAINTAINS PHYSICAL DEPENDENCE IN RATS. R. Numan. Psych., U. Santa Clara, CA 95053

In a previous report (Numan & Gilroy, Pharmac. Biochem. Behav. 9:279, 1978) it was shown that the intravenous (IV) method is a rapid and reliable model for the induction of physical dependence upon ethanol in rats. The present research now reports that rats will also self-administer (IV) ethanol, and that these self-infusions maintain previously induced physical dependence.

In Exp.1, male hooded rats (N=10) were implanted with jugular cannulae and housed in sound attenuated operant chambers with food and water freely available. They were maintained under these conditions 24h/day. Following habituation, the rats were exposed to periodic cycles of forced ethanol infusions that induced physical dependence. Each of these induction cycles was administered as previously described (ibid). Briefly, ethanol (30% V/V) was administered over a 5-day period at a dose of 10-16g/kg/day. Following each cycle, forced infusions were discontinued, but the rats were allowed access to a lever for self-administration of ethanol (CRF). Each lever press infused 0.2ml of ethanol (20% V/V). The rats were maintained on self-administration for at least 24h. If a rat did not develop self-administration behavior (SAB) within 24h, the next forced induction cycle was initiated.

Of the 10 rats tested, 2 failed to show any signs of SAB, even after 5 cycles of forced dependence. In contrast, 8 rats did develop SAB on CRF after a mean of 4 (S.E. 0.38) forced dependence cycles. These rats were maintained on CRF for a mean of 6.4 days (S.E. 0.75) and self-infused a mean of 11.3g/kg/day (S. E. 0.87). These rats were then advanced to Fixed Ratio (FR) schedules of reinforcement (FR2-FR5). Results on FR were more variable; 5 of the rats increased lever presses and maintained daily ethanol intake comparable to CRF. The other 3 rats also increased lever presses, but did not maintain ethanol doses comparable to CRF.

Following extended testing under the various schedules, the rats were placed on withdrawal. All rats that maintained high rates of SAB showed mild to severe withdrawal symptoms, suggesting that the self-infusions maintained physical dependence.

In Exp.2, rats (N=6/group) were allowed to self-infuse either saline or ethanol (20% V/V). These rats had no prior exposure to either saline or ethanol, and forced infusions were never administered. The rats remained in their operant chambers for 21 days under CRF. Each lever press led to a 0.2ml infusion. None of the rats developed SAB, but the saline controls made more self-infusions than the ethanol rats ($P<.05$). These results suggest that the ethanol paramaters yielding significant self-administration in Exp.1 are neutral or even aversive to ethanol naive rats. (supported by Grant AA 03451)

20.4 THE EFFECT OF ORAL ALCOHOL ADMINISTRATION ON BRAIN γ-GLUTAMYL TRANSPEPTIDASE. E. Reyes*, J. M. Rivera and L. J. Lewis. Dept. Pharmacology, Sch. of Medicine, University of New Mexico, Albuquerque, N.M. 87131

The effect of oral alcohol administration on γ-glutamyl transpeptidase (γGTP) was studied. Wistar rats were pair-fed nutritionally adequate liquid diets containing either alcohol (36% of total calories) or isocaloric carbohydrates (dextrin) for 6 weeks as described by Teschke et al (1977). Blood samples were obtained from the tail vein of each animal to monitor blood alcohol levels throughout the experiment. Blood alcohol levels were determined by measuring the increase in NADH according to the method described by Lundquist (1959). Weights of the animals were also determined daily. At the end of the 6 week experimental period, the animals were found to have an average blood alcohol level of 765 mg/dl. The animals were decapitated and the brains dissected according to the method described by Glowinski and Iverson (1966). Each brain region was homogenized in Tris buffered saline and assayed for protein and γGTP activity. γGTP activity was increased significantly in the cerebellum, pons-medulla and striatum. Serum samples were applied to a concanavalin A column and eluted as described by Reyes and Barela (1980). Serum γGTP activity was found to be increased in the alcohol treated animals. This work was supported by MBS program grant 081-39.

20.5 CHRONIC ETHANOL EFFECTS ON SYNAPTIC FUNCTION AND DISTRIBUTION IN THE CA1 FIELD OF RAT HIPPOCAMPUS. W.C. ABRAHAM, B.E. HUNTER, P.B. MANIS, S.F.ZORNETZER and D.W. WALKER. Dept. Neuroscience, Univ. Florida Coll. Med. and VA Med. Ctr., Gainesville, FL 32610.

This study explored the neurotoxic effects of chronic ethanol exposure through electrophysiological analyses of the Schaffer collateral-commissural (SC-COM) input to CA1 stratum radiatum in the rat hippocampus.

Long-Evan rats were maintained on an ethanol-containing liquid diet (35-39% ethanol-derived calories; 8.1-9.4% v/v ethanol) for 20 weeks. Control groups were pair-fed a liquid diet with sucrose isocalorically substituted for ethanol or given free access to standard laboratory chow and water. Two to four months following removal from the special diets, the animals were prepared for acute electrophysiological study. Concentric bipolar electrodes were placed in stratum radiatum of anterodorsal CA1 to stimulate the Schaffer collateral and commissural fibers coursing through this region. Extracellular field potentials were recorded with micropipettes (1-2μm tip) placed in field CA1 1mm posterior to the stimulating electrode.

Laminar profiles were conducted in 25μm steps perpendicular to the pyramidal cell layer. Analysis of the field potentials by current-source density (CSD) techniques revealed a statistically significant shrinkage (45μm) of the SC-COM synaptic field in the stratum radiatum of ethanol-exposed rats. The CSD also unexpectedly revealed the apparent existence of two overlapping but spatially distinct synaptic fields (current sinks) in the stratum radiatum of control animals. Chronic ethanol treatment led to a significant reduction in the spatial extent of the synaptic field proximal to stratum pyramidale with a corresponding expansion of the more distal synaptic field. The anatomical basis of these two synaptic fields is currently under investigation.

The ethanol treatment had little effect on population EPSP or population spike (PS) responses to single or multiple shocks of the SC-COM fibers. The treatment groups had virtually identical input-output curves. Furthermore no differences between groups were found in the post-tetanic effects of 1, 5, 10 or 100Hz stimulus trains. However during paired-pulse stimulation stimulation, the ethanol group exhibited greater facilitation of the test pulse PS. In addition the ethanol group showed a trend toward greater facilitation of the PS during 5 and 10Hz tetani. The overall pattern of results suggests that although chronic ethanol treatment reduces the extent of the SC-COM terminal zone in stratum radiatum, there are no dramatic changes in the normal physiology of this pathway. However ethanol treatment may produce a reduction of recurrent inhibitory processes, thus leading to greater responses during repetitive stimulation.

20.6 CONTINGENT TOLERANCE TO AMPHETAMINE ANOREXIA IS DIET SPECIFIC. David L. Wolgin. Dept. Psychol., Florida Atlantic University, Boca Raton, Fla. 33431.

When rats are injected with amphetamine and given sweetened milk on a repeated basis, they gradually recover from the initial drug-induced anorexia and ingest more and more each day. However, if the drug is injected after the rats have had access to milk, a similar loss of sensitivity to amphetamine is not observed; i.e., there is no attenuation of anorexia when the drug is subsequently given prior to the milk (Carlton & Wolgin, Physiol. Behav. 7:221, 1971). It is generally assumed that such "contingent tolerance" is mediated by some form of learning. To help specify more clearly what, precisely, is learned, amphetamine tolerant rats were given transfer tests in which they were offered substances different from the ones they had ingested while becoming tolerant.

In the first experiment, rats made tolerant to amphetamine with sweetened milk as the diet showed no tolerance when subsequently offered a variety of other foods (sucrose, Nutrament, Noyes pellets, Purina pellets) or water. In the second experiment, rats were made tolerant to amphetamine with either sweetened milk or milk adulterated with a small amount (.06 mg/cc) of quinine as the diet. Control groups treated identically but injected with saline did not differ in the amount of diet ingested during this phase of the experiment, demonstrating that the diets were equally palatable to undrugged animals. Following the development of tolerance, each of the groups was switched to the other diet for six additional tests. Tolerant rats switched from milk to quinine-adulterated milk reverted to anorexia throughout the six trials. The corresponding control group drank less of the adulterated diet for 1-2 days but then recovered to the previous level of milk consumption. Conversely, tolerant rats switched from adulterated to unadulterated milk showed an immediate and sustained increase in consumption. The corresponding control group showed no change, maintaining the same high level of intake it had previously shown with the adulterated milk.

These results demonstrate that tolerance is not due to adaptation to drug-induced cues within a specific behavioral task. They are also inconsistent with a conditioning theory of tolerance. Such a theory would predict a loss of tolerance whenever the conditional stimuli associated with the test differ from those present during the acquisition of tolerance. Switching rats from quinine-adulterated to unadulterated milk, however, did not result in a loss of tolerance.

20.7 MOUSE STRAIN DIFFERENCES IN THE RESPONSE TO CHRONIC BROMOCRIPTINE TREATMENT. P.K. Randall*and J.F. Stern* (SPON: J.E. Holmes). Andrus Gerontology Center, USC, Los Angeles, CA. 90007.

Chronic treatment with the dopamine agonist, bromocriptine results in diminution of striatal DA receptor number and DA-activated adenyl cyclase in striatal slices(Quik, M. and Iverson,L. L., Naunyn-Schmiedeberg's Arch. Pharmacol., 304: 141,1978). Following a 7 day (15mg/kg/day,subcutaneous) regime of bromocriptine stereotypic behavior resulting from 2.0 mg/kg apomorphine was significantly reduced in the C57BL/6J mouse, paralleling a 15% reduction in ^{3}H-spiroperidol binding in the striatum. These data suggest that bromocriptine produces a functionally significant reduction in the sensitivity of striatal DA receptors in this strain.

In BALB/cJ mice,on the other hand the classic stereotypic behavior pattern totally disappeared as a coherent behavioral syndrome. Instead, these mice showed increased motility and an oro-buccal abnormality consisting of repeated and extreme tongue protrusion when tested with apomorphine. Since this behavior was blocked by the DA receptor blocker, haloperidol, it is likely that it results from DA receptor activation.

Additional experiments confirmed that acute combinations of bromocriptine and apomorphine do not elicit the oro-buccal behavior in any strain tested and the the dose response curve with respect to the chronic bromocriptine in the BALB/cJ mice is biphasic. Increases in the incidence of the behavior were observed between 3.75 and 15 mg/kg/day with a subsequent decline to 30mg/kg/day.

These data suggest that DA-related oro-buccal abnormalities may be potentiated by chronic drug treatment with the induction of receptor supersensitivity in some strains of mice. Further, chronic bromocriptine treatment may produce a relatively greater subsensitivity of the DA "auto-receptor" than of the striatal post-synaptic receptor in the BALB/cJ mouse. The disappearance of the normal decrease in locomotor activity following apomorphine treatment in this strain is consistent with this interpretation.

20.8 DEVELOPMENT OF TOLERANCE TO PHENCYCLIDINE (PCP)-INDUCED STEREOTYPED BEHAVIOR AND ATAXIA. R. G. Fessler, R. D. Sturgeon*, S. F. London*, and H. Y. Meltzer. Lab. of Biological Psychiatry, Illinois St. Psychiatric Inst., Chicago, IL 60612.

The development of tolerance to chronic, once daily administration of PCP (5 or 10 mg/kg ip) was quantified in male rats on independent scales designed to assess locomotor activity, stereotyped behavior and ataxia. Blind ratings of these PCP-induced behaviors were compared on days 1, 3, 5 and 10 of the experiment. Tolerance to the stereotypy-inducing effect of PCP was apparent by the third day of administration (5 mg/kg, $p < .05$; 10 mg/kg, $p < .01$). By day 5 the stereotypy-inducing effects of PCP were reduced by approximately 30% at either dose. Tolerance to PCP-induced ataxia was also apparent by day 3 for the 5 mg/kg dose of PCP ($p < .02$), but was not significant until day 5 for 10 mg/kg of PCP ($p < .01$). By day 5 PCP-induced ataxia was reduced by 31% and 37% for the 5 and 10 mg/kg doses of PCP, respectively. Although not statistically significant, locomotor activity was observed to increase during chronic PCP (10 mg/kg) administration as ataxia decreased. This observation agrees with previous reports of an inverse relationship between PCP-induced locomotor activity and ataxia. At 5 mg/kg, PCP-induced locomotion increased on day 3 compared to day 1 in a manner similar to that found for 10 mg/kg PCP, but then decreased at days 5 and 10. This subsequent decrease in locomotor activity may represent the development of tolerance to the locomotor activating effects of PCP. This research was supported by USPHS DA 02081.

20.9 BEHAVIORAL AND PHYSIOLOGICAL RESPONSES TO CONCURRENT FOOD-DEPRIVATION AND ETHANOL CHALLENGES. James L. Tramill* and Andrea L. Wesley, Univ. of Southern Mississippi, Hattiesburg, MS 39401.

Studies of the behavioral and physiological responses to ethanol administration may present differences which hold in common some causative factors. Facilitation of aggressive responding has been reported by some studies, while others report inhibition after ethanol exposure. Significant reductions in aggressive responding have been observed in fasted rats, but not in nonfasted controls. Homeostatic factors regulating the organism's nutritional state could influence aggressive responses to ethanol administration as well as physiological responses. Some findings indicate that fasted humans, rats, and dogs exhibit ethanol-induced hypoglycemia. Other findings indicate ethanol-induced hyperglycemia in both fasting and nonfasting states. These studies propose that a fasting period is necessary, but not sufficient to produce the effect. Repeated differences in findings may reflect species and/or methodological variables and, thus, emphasize the need for clarification of the possible interactions of nutritional state and ethanol exposure. Female, Sprague-Dawley rats were maintained on a 12:12 LD cycle at 80% of free-feeding body weight. Intraperitoneal injections of either saline or 50% ethanol were administered for 14 days. Ethanol injections resulted in a significant decrease in blood glucose levels (t (10) = 2.29, $p < .05$). Aggression as the behavioral measure was then tested in a single-restrained animal, shock-elicited aggression apparatus (Azrin, et al., 1968). There was a significant reduction in the shock-elicited biting response for the ethanol group (t (10) = 3.65, $p < .01$). Results support the need to study nutritional state as a factor in developing an animal model for chronic alcoholism.

20.10 EFFECTS OF NALOXONE ON DEVELOPMENT OF ETHANOL DEPENDENCE IN RATS. Robert F. Berman, Julia A. Lee*, Karen L. Olson*, and Mark S. Goldman*. Dept. of Psychology, Wayne State University, Detroit, Michigan 48202.

A link between ethanol dependence and opiate addiction is suggested by several lines of evidence, including a cross-tolerance between ethanol and morphine and alleviation of ethanol withdrawal by morphine. Recently, Ho and Ho (Pharm. Biochem. Behav., 11:111, 1979) reported reduced ethanol narcosis by the opiate antagonist naloxone; and Blum, et al (Nature, 265:49, 1977) reported reduced withdrawal symptoms in naloxone-treated mice made ethanol-dependent by exposure to ethanol vapor. In the present study the effects of naloxone on the development of ethanol dependence were further examined in rats, using an ethanol-containing liquid diet previously shown to produce ethanol dependency (Baker, Cannon, Berman, Atkinson, Addict. Behav., 2:35, 1977). Thirty adult male Long Evans rats were reduced to 75% of their free-feeding body weight and made ethanol-dependent by maintenance on a liquid diet consisting of Sustacal (Mead Johnson & Co.) and ethanol. The percentage of total calories derived from ethanol in the diet was increased daily by 1%, from 35% to 40%, where it remained for the duration of the 21 day addiction phase. Half of the animals (Groups NS and NN) were injected with 2 mg/kg naloxone (ip) daily, and the remaining animals (Groups SS and SN) were injected with saline. After 21 days on the ethanol diet, all animals were withdrawn from ethanol, injected (ip) with either naloxone (10 mg/kg, Groups SN and NN) or saline (Groups SS and NS), and observed for the occurrence of withdrawal symptoms. Withdrawal symptoms were rated using a scale developed by Hunter, et al (Pharm. Biochem. Behav., 3:619, 1975). Rats that received daily injections of naloxone during the addiction phase consumed significantly more of the ethanol diet than did saline-injected rats. As a consequence, naloxone-injected rats showed significantly greater weight gains on the diet compared to the controls. During acute withdrawal (1st 24 hours), rats injected with naloxone both during addiction and during withdrawal (NN) showed significantly fewer withdrawal symptoms when compared to all other groups. However, audiogenic seizures were reliably elicited from almost all animals, regardless of naloxone treatment history. In addition, animals treated with naloxone during addiction (Groups NS and NN) showed greatly attenuated postwithdrawal hyper-excitability and hyper-irritability compared to animals injected with saline during the addiction phase (Groups SS and SN). These results indicate that naloxone can modify alcohol intake and withdrawal symptomatology. The exact mechanism remains to be determined.

20.11 NEURONAL LOSS IN HIPPOCAMPUS INDUCED BY PROLONGED ETHANOL INGESTION IN RATS. David E. Barnes and Don W. Walker. VA Medical Center and Dept. of Neuroscience, Univ. of FL College of Medicine, Gainesville, FL 32610.

Ninety male Long-Evans hooded rats (Charles River) were used. At 75 days of age, they were weighed and divided into weight-matched groups (N=10). One group received unrestricted access to the ethanol-containing diet. A second group was pair fed an identical diet except that sucrose was substituted isocalorically for ethanol. A third group received unrestricted access to standard pelleted laboratory food. The liquid diets contained 35-39 percent of the total caloric content as ethanol or sucrose-derived calories. The ethanol containing diet was 8.1 to 9.4 percent ethanol (by volume). Groups were maintained on the diets for 10, 20, or 30 weeks. After the liquid diets were discontinued, all animals were on Lab Chow for at least two months before sacrifice. Following intracardiac perfusion with 10% neutral buffered formulin and post-fixation in Bouin's solution, the brains were coded and embedded in Paraplast. Both sagittal and coronal 4 µm sections (1 in 10) were saved and stained with either cresyl violet or hematoxylin-acid fuschin. Quantitative determination of the total number of hippocampal pyramidal cells per section were made by counting at a magnification of 675X each soma containing a clearly defined nucleolus throughout the entire stratum pyramidale from CA1 through CA4.

Ethanol exposure resulted in a 16-28% loss in hippocampal pyramidal cells with the 10 week group being least affected and the 30-week animals most severely affected (-28%, $P < .001$). In addition, the majority of neuronal loss was in region CA1 suggesting a preferential susceptibility of these cells to ethanol exposure. Qualitative observations suggest that the dendritic field of remaining CA1 pyramidal cells may be attenuated by ethanol exposure. (Supported by the Veterans Administration and NIAAA Grants AA-00200 and AA-03965).

20.12 POTENTIATION OF THE STIMULANT EFFECTS OF D-AMPHETAMINE AFTER CHRONIC DESIPRAMINE TREATMENT. C. Spyraki and H.C. Fibiger, Div. Neurol. Sci., Univ. British Columbia, Vancouver, B.C. Canada.

A characteristic feature of tricyclic antidepressants (TCA) is their ability to potentiate various central effects elicited by amphetamine-like drugs. However, this effect has only been observed after acute administration whereas the clinical efficacy of TCA's are observed after chronic (10-20 days) administration. The present study examined the effect of chronic administration of desmethylimipramine (DMI) on amphetamine-induced motor stimulation, a constellation of dopamine-mediated behaviors (Brain Res. 1975, 93, 441).

Male Woodlyn rats were injected intraperitoneally twice daily, for 14 days with 5 mg/kg of DMI per injection. Control rats received injections of an equivalent volume of vehicle. Twenty-four hours after the last injection the rats were placed individually in the photoactometers and their activity recorded for one hour. They were then injected with vehicle or d-amphetamine sulphate (0.5 or 1.5 mg/kg) i.p. and immediately replaced in the activity cages for another three-hour period.

Chronic DMI treatment did not alter spontaneous locomotor activity during the one hr habituation phase. However, the motor stimulation produced by 1.5 mg/kg d-amphetamine was greatly enhanced in the chronic DMI treated group ($P < .01$). No differences were observed between the DMI and vehicle groups after 0.5 mg/kg d-amphetamine. In another experiment, DMI pretreatment for 2 days did not affect the amphetamine-induced motor behavior. The potentiation of the stimulant effect of amphetamine after two weeks of DMI treatment was not due to any anticholinergic effects of DMI because this regimen did not affect either hypothermia or other effects of oxotremorine.

These results demonstrate that 14-day but not 2-day chronic pretreatment of DMI potentiates the stimulant effects of d-amphetamine. Inasmuch as this is a dopamine-mediated phenomenon, these results point to an influence of chronic DMI treatment on central dopaminergic mechanisms. The results are consistent with a growing body of evidence implicating dopamine in the mechanism of action of TCA's, and indirectly, in the pathogenesis of depression.

21.1 THE EFFECTS OF PONTINE TEGMENTAL LESIONS ON NUCHAL MUSCLE ACTIVITY IN THE RABBIT: A QUANTITATIVE STUDY. C. Bratin*, and R.T. Pivik. Lab. Neurophysiology, School of Psychology and Department of Psychiatry, Faculty of Health Sciences, University of Ottawa, Ottawa K1N 5C8, Canada.

Lesions in the region of the pontine tegmental nucleus locus coeruleus (LC) are reported to eliminate tonic EMG inhibition which normally accompanies paradoxical sleep (PS) and increase activity during wakefulness. In a previous communication (Bratin, C. and Pivik, R.T., 20th Annual Meeting of the Association for the Psychophysiological Study of Sleep, Abstract, 1980) we reported the absence of PS and the presence of agitated behavior sequences following slow wave (SW) sleep in rabbits with bilateral LC lesions $\geq$ 80%. The present analyses of quantified nuchal EMG activity were undertaken in these animals and a second group with partial, primarily posterior, LC lesions (<50%) to assess possible changes in EMG activity subsequent to these brainstem lesions.

Adult male New Zealand White rabbits (n=13) were implanted for chronic recording of EEG, EOG and nuchal EMG activity, and bilateral guide tubes were stereotaxically aimed at the medial pontine tegmental and central regions of the brainstem. Recordings (9:00-15:00 hrs) were taken one week after implantation (baseline) and at weekly intervals for at least two weeks post-lesion. Lesions, effected via a temperature controlled radio-frequency probe inserted through the guide tubes, were histologically verified (28µ serial sections). Data reported are based on initial analyses comparing baseline and two week post-lesion periods. EMG activity was quantified using resetting integrator techniques. Frequency counts of quantified EMG activity corrected for system noise were correlated with independently scored state determinations (1 minute samples).

For the LC group a slight increase in post-lesion EMG activity occurred during SW and pre-PS periods, with significant ($p<.01$) increases post-lesion for active wakefulness (AW) and PS. Post-lesion PS data consisted primarily of phasic motor activation whereas pre-lesion PS data included both tonic and phasic PS episodes. Pre-post lesion comparisons for the partial LC group showed, for every comparison, i.e., AW ($p<.01$), QW ($p<.01$), SW ($p<.05$), pre-PS ($p<.05$) and PS ($p<.05$), significant post-lesion decreases. The total LC lesion data do not indicate a tonic post-lesion increase in EMG activity across states. The partial LC lesion data are more difficult to interpret. The post LC has been implicated in suppression of motor behavior during PS in the cat. The present data may reflect a species difference in this phenomenon, but are also consonant with the suggestion that neurons other than noradrenergic, e.g., cholinergic, located in the LC region may mediate motor phenomena during PS and related states.

21.2 ASYMPTOMATIC ALPHA-DELTA SLEEP. Carl P. Browman and James K. Walsh. Department of Psychiatry, State University of New York at Stony Brook, Stony Brook, NY 11794 and Sleep Disorder Center, University of Cincinnati Medical Center, Cincinnati, OH 45267.

The intrusion of alpha activity during slow-wave sleep (SWS) had been described as a characteristic waveform associated with certain behavioral, psychological and physiological disorders. However, we observed alpha-delta sleep in two asymptomatic young adults, a male rotating shift worker (age 32) and a female college student (age 22). Medical histories were unremarkable, as was a cardiovascular examination for the female. Personality test results were within normal limits; projective techniques failed to reveal any affective disorder. Both were socially well adjusted. Polysomnograms were obtained for three to four consecutive, drug-free nights. The EEG was recorded from standard C3-A2 or C4-A1 placements. All polysomnographic results exclude first-night data and are based on five nights. The mean sleep latency was 13.2 min. The average amount of REM sleep was 21.2% and the mean SWS was 15.1%. The sleep efficiency index was .951 for the male and .988 for the female. Alpha-delta sleep was evident to varying degrees on all nights for each person. The alpha frequency during SWS was slightly slower than that observed during wakefulness. Postsleep questionnaires and subjective evaluations of typical sleep were comparable to normal controls without alpha-delta sleep. Neither subject reported symptoms of any sleep-wake pathology.

We conclude that the superimposition of alpha and delta frequencies in the sleep EEG is not necessarily an indicant of pathology. The significance of this waveform and the etiologic basis, in either asymptomatic subjects or patients with concomitant disorders, are yet to be determined.

21.3 TONIC AND PHASIC INFLUENCES DURING REM SLEEP UPON UNIT ACTIVITY OF DORSAL LATERAL GENICULATE NUCLEUS IN THE RAT. G.A.Marks*, J. Farber*, J.K.Chapin, H.P.Roffwarg. Sleep Neurophysiology Lab, Department of Psychiatry, University of Texas Health Science Center, Dallas, Texas 75235.

Evidence derived mainly from the cat indicates that there is a central phasic event system operating during REM sleep. One measure of its output is the Ponto-Geniculo-Occipital (PGO) wave. We have recently reported on a REM sleep associated waveform, recorded from the dorsal pontine tegmentum of the rat, that shares many of the properties of PGO waves (Farber et.al. Science, in Press, Marks et. al. Exp. Neurol., in Press) The failure of studies to reveal the presence of PGO waves at the level of the thalamus in the rat raises the question as to whether the rat pontine waves are isolated local events or components of a system of propagated phasic influences.

In the present investigation, etched tungsten microelectrodes were used to record the activity of single cells extracellularly in unanesthetized freely moving rats. The presence of both tonic and phasic REM sleep influences were examined in 27 identified dorsal lateral geniculate (dlgn) units during at least one entire sleep-wake cycle. In all units spontaneous discharge rates were increased in REM sleep (median increase=150%) as compared to slow wave sleep (SWS). During SWS, units exhibited a characteristic burst-pause pattern. With the transition to REM sleep, the units assumed a more continuous high frequency pattern at or above waking levels. Visual inspection of the recordings did not reveal an obvious temporal relationship between dlgn unit discharge and the occurrence of REM sleep pontine waves. However, perievent time histograms, averaged over at least 15 waves, revealed three distinct populations of dlgn units with: 1) no relationship to pontine waves (30%); 2) a significant increase in discharge rate within 250 msec after the peak of pontine waves (48%) and, 3) a decrease preceding a significant increase at approximately 600 msec after the pontine waves (22%).

These data support the conclusion that there are both tonic and phasic influences upon the dlgn during REM sleep. Tonic influence is evidenced by a sustained increase in unit discharge rate and phasic influence is evidenced by the more subtle changes in discharge rate temporally associated with a pontine central phasic event. The latter further supports the presence of a REM sleep phasic event system in the rat.

21.4 DIFFERENTIAL RESPONSIVITY OF RATS TO A CONDITIONED AVERSIVE STIMULUS DURING REM AND SLOW WAVE SLEEP. J.M. Halperin, D. Miller* and L.C. Iorio*. Schering-Plough Corp., Bloomfield, N.J. 07003.

This study investigated whether conditioned aversive and neutral stimuli differentially affect arousal from rapid eye movement (REM) and slow wave sleep (SWS) by measuring the incidence of arousal from each state in response to a tone prior to and following conditioning.

Eight rats, chronically implanted with electrodes for recording EEG and EMG, were housed individually in soundproof chambers throughout the experiment. After 24 hr adaptation to the recording leads, a 2-sec tone was played into the chamber 14-20 times within an 8-hr period while the rat was in either REM or SWS for a minimum of 30 sec. The number of times that the rat awakened within 5 sec of the tone was determined using standard EEG and EMG criteria. During each of the next 5 days, 4 rats received a delayed conditioning paradigm in which a 5-sec., 0.5 ma, electric shock was delivered through the floor grid of the chamber 1 sec after the termination of the tone; the others received backwards conditioning, during which the shock preceded the onset of the tone. During both procedures there were 40 trials with a 60-sec intertrial interval. Rats received the same exposure to the two stimuli with both conditioning paradigms, however, the tone should have become associated with the shock only as a result of delayed conditioning. The day after the fifth conditioning session consisted of presentation of the tone alone, as was done prior to conditioning.

Prior to conditioning the tone awakened the rats significantly ($p<.001$) more from SWS than REM. Delayed conditioning significantly increased the incidence of arousal following the tone during SWS ($p<.05$), while there was a small, non-significant, reduction of arousal from REM ($p>.10$). Backwards conditioning resulted in small, non-significant, reductions in arousal following the tone from both states of sleep ($p>.05$). No significant differences occurred in SWS or REM time between pre- and post- conditioning arousal sessions.

The addition of an aversive component to the tone, through conditioning, increased its awakening potency during SWS, but not during REM. This suggests that REM may be a period that maintains sleep even in the presence of environmental duress.

21.5 INCREASED ^{3}H-LYSINE INCORPORATION IN DIFFERENT FRACTIONS OF BRAIN DURING SLEEP. G. Chakraborty* and A. K. Sinha. Dept. Physiol. & Biophys. College of Medicine & Dentistry of NJ-Rutgers Medical School, Piscataway, NJ 08854.

A number of indirect observations and some experimental evidence suggest that sleep may be a period of increased protein synthesis in brain. We are investigating to determine what area of brain and which subcellular fractions are related to this increased synthesis. We have used an experimental protocol that produces uninterrupted non-rapid eye movement sleep (no rapid eye movement sleep during this time) in hamsters (40 gm) for about an hour (Macho and Sinha, Life Sc. 26:291, *1980*). Ten min after an animal fell asleep, we injected 0.5 mCi (in 0.5 ml saline) of ^{3}H-lysine (sp. activity 80.5 Ci/mmol) through a chronically implanted femoral venous catheter. Fifty min after that injection we killed it by decapitation. Same amount (mCi/gm bd wt) of ^{3}H-lysine was injected in awake animals that were kept awake till decapitation (50 min after injection). The presence of incorporated ^{3}H-lysine was determined in the protein powder prepared from liver and mitochondrial, synaptosomal, microsomal and soluble supernatant fractions of cerebral cortex and brain stem. In 6 awake and 6 sleeping hamsters no difference in ^{3}H-lysine incorporation was detected in any fraction of liver and in the mitochondrial and microsomal fractions of cerebral cortex and brain stem. The synaptosomal fraction prepared from cerebral cortex and brain stem, showed respectively 30% and 37% increased incorporation during sleep. The soluble supernatant from cerebral cortex showed 26% increased incorporation during sleep. Currently we are electrophoretically fractionating the proteins to determine if the increased incorporation is taking place in all proteins or in some specific groups of proteins. [This project was supported by grants from NIH (NS 13118) and Air Force Office of Scientific Research (78-3532A)].

21.6 ^{14}C-DEOXYGLUCOSE AUTORADIOGRAPHY OF THE RAPHE NUCLEI DURING SLEEP-WAKE ACTIVITY IN THE RAT. P.Ramm* and B.J. Frost (Spon: M.W. Donald). Dept. of Psychology, Queen's University, Kingston, Ontario. Canada K7L 3N6.

Investigations of the role played by the raphe nuclei in sleep-wake activity have involved lesions, pharmacological treatments or electrophysiological recordings. As an adjunct to these methods, and to direct subsequent electrode penetrations in the diffuse raphe system, we report state-dependent variation in functional activity revealed by ^{14}C-2-deoxyglucose (^{14}C-2DG) autoradiography.

^{14}C-2DG was injected into waking (n=4) or sleeping (n=4) rats via a chronic in-dwelling jugular cannula. During the following 45 min, EEG and EMG records were obtained. Autoradiographs were analyzed using a computerized image analysis system to read optic densities within the films. Optic densities of the dorsal raphe (dr), nucleus centralis superior, and raphe magnus, obscurus, pallidus and pontis were compared to surrounding areas of the ponto-mesencephaic reticular formation. A significant relative difference in optic density was observed in an area app. 1 mm posterior to the interaural line, comprising part of the dr and extending laterally into the periaqueductal central gray (SG). The ratio of density in this area/density in the reticular surround was 0.84 in sleeping animals, and 0.77 in waking animals. The area exhibits relatively increased regional metabolic activity in the waking state. These findings support a recent report that lesions involving the dr and lateral SG are among the only raphe lesions which are followed by long-lasting and specific slow wave sleep deficits. We are presently placing lesions within the area delineated by the autoradiographs, to further examine its relation to sleep-wake activity.

21.7 FENFLURAMINE, FLUOXETINE AND QUIPAZINE SUPPRESS SLEEP IN RATS. C. Fornal* and M. Radulovacki (SPON: E.M. Burns). Dept. of Pharmacology, Univ. of Ill. Med. Ctr., Chicago, IL 60612.

The aim of the present study was to investigate the effects of pharmacological agents which increase serotonin (5-HT) receptor activity by various mechanisms on the sleeping behavior in rats. For this purpose we administered fenfluramine (FEN) (1, 5, 10 mg/kg, i.p.), which releases 5-HT from the nerve terminal, fluoxetine (FLU) (5, 10 mg/kg, i.p.), which inhibits reuptake of 5-HT into the nerve terminal, and quipazine (QUIP) (1, 3, 5, 10 mg/kg, i.p.) which directly stimulates post-synaptic 5-HT receptors, to rats previously implanted with EEG and EMG electrodes for a 12-hr recording session.

Our results show that all agents significantly altered sleep-wake patterns in a dose related manner, suppressing sleep and prolonging wakefulness. Slow wave sleep (SWS) and rapid eye movement (REM) sleep latencies were greatly increased. The suppressant effect on SWS seen with the 5 mg/kg dose of FEN was effectively blocked by pretreatment with a serotonergic receptor antagonist, methergoline (MET) (2.5, 5.0 mg/kg, i.p.) 1 hr prior to FEN administration. In contrast, pretreatment with a dopaminergic receptor antagonist, α-flupenthixol (.2 mg/kg, i.p.) had no effect on the action of FEN. Pretreatment with FLU (5, 10 mg/kg, i.p.) 24 and 1 hr, to prevent FEN from entering the serotonergic nerve terminal and releasing 5-HT, did not counteract the effects of FEN. These results suggest that FEN may effect sleep through direct 5-HT receptor stimulation. Similarly, the suppressant effects on SWS induced with the 5 mg/kg dose of QUIP was reversed by pretreatment with MET (2.5 mg/kg, i.p.) 1 hr prior to QUIP administration.

We conclude that increased availability of 5-HT at post-synaptic receptors or direct 5-HT receptor stimulation suppresses sleep and increases wakefulness.

21.8 ATROPINE ABOLISHES REM SLEEP REBOUND AND INCREASES WAKEFULNESS IN RATS. W.C. McDaniel* and M. Radulovacki (SPON: K.R. Unna). Dept. of Pharmacol., Univ. of Il. at the Med. Ctr, Chicago, Illinois 60680.

Laboratory studies of animals and studies of humans suggest cholinergic modulation of rapid eye movement (REM) sleep. The anticholinergic agent atropine delays the onset and decreases the amount of REM sleep while physostigmine, which enhances cholinergic activity, when injected during slow wave sleep (SWS), induces REM sleep. The purpose of this work was to determine whether the decrease of REM sleep caused by atropine represents a suppression of REM sleep followed by REM rebound or reduction of REM sleep without subsequent REM sleep rebound.

Adult male rats were implanted with EEG and EMG electrodes and were deprived of REM sleep by a flower pot method for 24hrs. After REM sleep deprivation animals were given saline (control group), atropine sulfate (50mg/kg. i.p.) or atropine methyl nitrate (53mg/kg. i.p.). Atropine methyl nitrate was given in order to differentiate between the central and peripheral anticholinergic effects on REM sleep rebound since the drug is a cholinergic antagonist with predominant peripheral effects.

TABLE I

	HOURS	CONTROL	ATROPINE SULFATE	ATROPINE METHYL NITRATE

REM	12-42	174 ± 25	156 ± 31	172 ± 8
	0-42	269 ± 34	178 ± 31*	271 ± 32

The results are means SD (minutes) for 4 animals in each group. *$p<0.025$

From the Table 1 it can be seen that administration of atropine sulfate significantly increased wakefulness during 0-12h period which remained increased during the entire 42h recording period. The results also show significant reduction of REM sleep during the initial 0-12h which was not followed by REM sleep rebound during the next 12-42h period. Administration of atropine sulfate did not significantly affect SWS.

Our data show that unlike caffeine, which is a suppressant of REM sleep (see Yanik, Walovitch and Radulovacki, this meeting) atropine reduces REM sleep without subsequent appearance of REM sleep rebound. According to the postulate of Stern and Morgane (Behav. Biol. 11: 1, 1974) elimination of REM sleep rebound by atropine may be indicative of the drug's role in fulfulling the REM "need".

21.9 α-FLUPENTHIXOL ABOLISHES THE EFFECTS OF d-AMPHETAMINE AND CAFFEINE ON WAKEFULNESS AND SLOW-WAVE SLEEP BUT NOT ON REM SLEEP IN RATS. R. Walovitch*, G. Yanik*, W. J. Wojcik, C. Fornal* and M. Radulovacki. University of Illinois at the Medical Center, Dept. of Pharmacology, Chicago, Illinois 60680.

CNS stimulant effects of amphetamine and caffeine have been attributed to their action on brain catecholamines. Since brain dopamine (DA) has been proposed in the regulation of wakefulness and brain norepinephrine (NE) in the regulation of rapid eye movement sleep (REM), we decided to use in rats a DA receptor blocker, α-flupenthixol (α-Flu), in order to investigate the contribution of dopaminergic system in the effects of amphetamine and caffeine on wakefulness slow-wave sleep (SWS) and REM sleep.

Adult male rats were implanted with the EEG and EMG electrodes and selectively deprived of REM sleep by a flower pot method for 24h. One hour before termination of REM sleep deprivation animals were pretreated with either the drug vehicle (propylene glycol, i.p.) or α-Flu (0.2 mg/kg or 0.4 mg/kg i.p.). Upon termination of REM sleep deprivation both propylene glycol and α-Flu pretreated rats received saline (i.p.), d-amphetamine (1 mg/kg, i.p.) or caffeine (25 mg/kg i.p.). The results show that administration of amphetamine and caffeine alone significantly increased wakefulness and reduced SWS and REM sleep during the first 3h of EEG recording. They also indicate that administration of 0.2 mg/kg α-Flu had no effect on wakefulness or sleep while administration of 0.4 mg/kg α-Flu significantly reduced wakefulness and increased SWS. Pretreatment of animals with 0.2 mg/kg α-Flu did not affect amphetamine's action on wakefulness or sleep. In contrast, pretreatment with 0.4 mg/kg α-Flu abolished amphetamine's effect both on wakefulness and SWS but not on REM sleep. However, pretreatment of animals with either 0.2 mg/kg or 0.4 mg/kg α-Flu abolished effects of caffeine on wakefulness and SWS. Unexpectedly, 0.2 mg/kg but not 0.4 mg/kg α-Flu antagonized caffeine's effect on REM sleep, although the mean REM sleep minutes between the two groups differed by only 2 minutes during the 3h recording period.

In conclusion, our findings show that the actions of amphetamine and caffeine on wakefulness and SWS can be abolished by blocking DA receptors. This indicates that stimulation of DA receptors is directly related to increase in wakefulness and decrease in SWS. However, DA blockade did not antagonize amphetamine and caffeine reduction of REM sleep suggesting that these agents do not affect REM sleep by a dopaminergic mechanism.

21.10 SPECIFIC INCREASE IN BRAIN DOPAMINE, BUT NOT NOREPINEPHRINE OR SEROTONIN, TURNOVER DURING REM SLEEP REBOUND IN RATS. W.J. Wojcik and M. Radulovacki. Dept of Pharmacol., Univ. of Il. Med. Ctr., Chicago, Il. 60612

Increased brain norepinephrine (NE) turnover has been reported during rebound of REM sleep in rats which were deprived of REM sleep by a flower pot method (Pujol et al Sci.159:112,'68). Since the method, using small platforms on inverted flower pots, cannot discriminate between the effect of stress and REM sleep loss, modification was made by introducing larger platforms on which animals can have REM sleep but are still subjected to immobilization stress as on small platforms. We have implanted rats with electrodes for EEG and EMG recording and deprived them of REM sleep for either 24 or 96 hrs by placing them on small (8 cm. dia./400g rat) or large (17 cm. dia./400g rat) platforms. The results showed that only the 96 hr protocol produced a selective REM rebound in the rats placed on small platforms. Both the small and large platform rats lost 18% of their initial body weight in 96 hrs.

Turnover of brain monoamines, DA, NE and serotonin (5HT) was determined by measuring the brain content of monoamine metabolites using the flurometric method of Meek and Neff (Br. J. Pharm 45:435,'72) for the NE metabolite, MOPEG-SO_4, and the HPLC method using reverse phase chromotography with electrochemical detection for the DA metabolites, DOPAC and HVA, and the 5HT metabolite, 5HIAA. Probenecid (50mg/kg), a dose which blocks the egress of these metabolites from the brain without suppressing REM rebound, was administered to all groups 4 hrs after termination of the 96 hr deprivation and all rats were decapitated 2 hrs later.

	CONTROL	SMALL PLATFORM	LARGE PLATFORM
MOPEG-SO_4	528 ± 30(6)	708 ± 27(8)*	693 ± 35(7)*
5HIAA	2181 ± 143(6)	2966 ± 200(6)	3123 ± 278(6)*
DOPAC	808 ± 47(6)	1081 ± 42(6)*	931 ± 51(6)
HVA	378 ± 12(6)	539 ± 59(6)*	421 ± 25(6)

*$p<0.05$, means ± SE (pmole/g tissue), () indicate the number of animals.

The data show that brain MOPEG-SO_4 and 5HIAA levels were elevated in rats on both small and large platforms and could not be correlated to REM rebound which appears only in rats on small platforms. However, DOPAC and HVA levels were selectely elevated only in the REM rebounding rats indicating an increase in DA turnover during REM sleep rebound.

21.11 BROMOCRIPTINE REDUCES SLEEP IN RATS. M. S. Brodie*, R. Walovitch*, G. Yanik* and M. Radulovacki (Spon: H. L. Jackman), Dept. of Pharmacology, Univ. of Ill. at the Medical Center, Chicago, IL. 60680.

The aim of the study was to test the hypothesis that repeated administration of bromocriptine, a dopamine receptor stimulant, to rats would reduce sleep in these animals. The hypothesis was based on our previous findings that administration of bromocriptine (5 mg/kg, i.p.) to rapid eye movement (REM) sleep deprived rats increased wakefulness and abolished REM sleep rebound (Radulovacki et al, Life Sci., 24, 18, 1705, 1979).

Bromocriptine (7.5 mg/kg, i.p.) was administered at 9h intervals 4 times within 27h to adult male rats implanted with EEG and EMG electrodes which were polygraphically recorded for 84h. The results show that slow wave sleep (SWS) was most significantly affected by the administration of the drug. From Table 1 it can be seen that there was a significant reduction of SWS during the entire 0-84h polygraphically recorded period. However, the effects of bromocriptine administration were more pronounced on wakefulness and REM sleep than on SWS during 0-36h period.

Table 1

	N	Time period (Hours)	Wakefulness	% Change SWS	REM
Bromocriptine 7.5 mg/kg	8	0-36	+43^C	-35^B	-57^C
	8	37-84	+ 4	- 7	+14
	8	0-84	+21	-21^A	-25

N-number of animals. A($P<0.05$), B($P<0.001$), C($P<0.0005$), by one-way ANOVA with multiple comparisons performed by Scheffe' Test.

It is of interest to note that the reduction of SWS or REM sleep during 0-36h period was not followed by a rebound of SWS or REM sleep during the next 36-84h period. The question that our data raise is the nature of bromocriptine's effect on sleep. According to Stern and Morgane (Behav. Biol. 11, 1, 1974) absence of REM sleep rebound (in this case also SWS rebound) upon withdrawal of a drug treatment which decreases REM sleep could be interpreted as a fulfillment of a possible neurochemical function of REM sleep. In agreement with that postulate, it appears that the effects of repeated administration of bromocriptine on wakefulness and sleep in rats may be indicative of fulfillment of sleep "need" in the animals.

21.12 REM SLEEP DEPRIVATION DOES NOT AFFECT B-ADRENERGIC RECEPTOR SENSITIVITY IN RAT BRAIN. N. Micovic* and M. Radulovacki (Spon: C. Anderson). Dept. of Pharmacol., Univ. of Ill. at the Medical Center, Chicago, Illinois 60680.

Repeated administration of electroconvulsive shock (ECS) or chronic administration of tricyclic antidepressants has been accepted to be an effective therapy for patients with depression. Both treatments probably augment the postsynaptic availability of norepinephrine (NE) and were reported to decrease the density of B-adrenergic receptor binding sites in rat brain.

Recently, REM sleep deprivation has been suggested as a successful treatment for patients with endogenous depression (Vogel et al. Arch. Gen. Psychiat. 37, 247, 1980). In order to evaluate the effect of REM sleep derprivation on B-adrenorectors, we decided to compare the effects of REM deprivation with those of desipramine (DI), a tricyclic antidepressant, on the density of B-adrenoreceptors in the brains of rats.

Adult male rats were subjected to REM deprivation by flower pot technique for 7 days, while the other group of animals received DI (10mg/kg, i.p.) once a day for 7 days. Animals in the control group were kept in their individual cages and were administered with saline (i.p.) once a day during 7 days. We have used the radiolabelled ligand ^{3}H-dihydroalprenolol (^{3}H-DHA) for identification and characterization of B-adrenergic receptors in the brain and measured the binding of ^{3}H-DHA to particulate fractions prepared from rat cerebral cortex. The method used was that of Bylund and Snyder (Molec. Pharmac. 12, 568, 1976). The effects of DI and REM deprivation treatments on B-adrenergic receptor sensitivity (Table 1) were assesed by determining the maximum number of ^{3}H-DHA binding sites by Scatchard analyses. The results show that DI caused a 25% reduction in receptor density ($p<0.05$), while REM deprivation treatment showed only a tendency for the receptor density to decrease.

Table 1

Treatment	Maximum binding (pmol/gm tissue)
Control	7.88 ± 0.25
REM Deprivation	6.98 ± 0.25
Desipramine (10mg/kg)	5.90 ± 0.67*

*$p<0.05$. Results are represented as means ± s.e.m.

In conclusion, our data indicate that REM sleep deprivation did not significantly affect the sensitivity of B-adrenergic receptors in rat brain. If changes in B-adrenergiv receptor sensitivity could be taken as an indicator of successful antidepressant therapy, then REM sleep deprivation method compares less favorably than chronic ECS or chronic administration of tricyclic

21.13 CAFFEINE PRODUCES REM SLEEP REBOUND IN RATS. G. Yanik*, R. Walovitch* and M. Radulovacki (Spon: M. Buschman). Dept. of Pharmacology, Univ. of IL. at the Medical Center, Chicago, IL. 60680.

Caffeine, a CNS stimulant, produced a dose-related decrease in total sleep time in humans without evidence to indicate the presence of carry-over or rebound effects from one night to the next (Karacan et al. in Sleep Res., Eds. Chase, Stern and Walter, BIS/BRI, 3, 56, 1974). In view of the findings that administration of bromocriptine (Radulovacki et al. Life Sci., 24, 18, 1705, 1979), α-adrenoreceptor blockers phenoxybenzamine and phentolamine (Radulovacki et al. Pharmacol. Physiol. Behav. in press), or atropine (McDaniel and Radulovacki, this meeting) abolishes REM sleep rebound in rats, we administered caffeine (25 mg/kg, i.p.) to adult male rats deprived of REM sleep for 24h to investigate its effect on REM sleep rebound. The animals were implanted with EEG and EMG electrodes and were continuously monitored by the EFG for 36h immediately following REM sleep deprivation (RD) and administration of caffeine. The results show significant increase in wakefulness and decrease in slow wave sleep (SWS) during the first 12h following administration of caffeine. In agreement with the above mentioned human study, there was no SWS rebound effect during the entire recording period. However, there was a significant REM sleep rebound during the 12-18h period after initial suppression of REM sleep during the first 6h following RD and caffeine administration.

	Hours after RD	RD Control	Caffeine (25 mg/kg)	Diff. from control (min)
	0- 6	69 ± 8	10 ± 3	-59^{X}
	6-12	64 ± 3	56 ± 7	- 8
REM	12-18	42 ± 4	66 ± 6	+24^{X}
Sleep	18-24	42 ± 4	53 ± 3	+11
	24-30	36 ± 4	43 ± 4	+ 7
	30-36	37 ± 3	40 ± 3	+3

The results are means ± S.E. (minutes), for 8 rats in each group. *P<0.01

These data show that caffeine produces a significant suppression of REM sleep which is followed by REM sleep rebound. The effect is at variance with those of bromocriptine, α-adrenoreceptor blockers or atropine on REM sleep rebound and indicates that caffeine is a mere suppressant of REM sleep.

22.1 GABA UPTAKE BY ISOLATED CELLS OF THE GOLDFISH RETINA.
George S. Ayoub and Dominic Man-Kit Lam. Program in Neuroscience and Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030.

In the goldfish retina, H1 horizontal cells, which receive input predominantly from red-sensitive cones, possess a high-affinity uptake mechanism for the neurotransmitter γ-aminobutyric acid (GABA). Additionally, GABA accumulation into these neurons is enhanced by light stimulation of the retina (Lam and Steinman, PNAS 68:2777; Marc et al., J. Comp. Neurol. 182:221). To examine the cellular mechanisms regulating this stimulation-dependent process, isolated cells enriched with horizontal cells that contain few or no synaptic endings were prepared from goldfish retinas using a procedure described previously (Lam, Nature 254:345). These cells were placed on a transparent Nucleopore filter (5 μm pore size) which allows visualization of cellular morphology by interference optics as well an incubation and perfusion of the cells with different media. When isolated cells were incubated with isotonic Ringer's solutions containing 1 to 60 mM K^+ and 1 μM ^{3}H-GABA, H1 horizontal cells still retained a Na^+- and temperature-dependent mechanism for ^{3}H-GABA accumulation which was inhibited by 100 μM nipecotic acid, indicating that somas of these cells possess high-affinity uptake sites for GABA. The ^{3}H-GABA accumulated was not significantly degraded during a 10 minute incubation and was not released by increasing the K^+ concentration in the medium. Thus, ^{3}H-GABA accumulation under our experimental conditions is predominantly due to uptake rather than release of GABA. Under these conditions, ^{3}H-GABA uptake is maximal at about 6 mM extracellular K^+ and decreases to less than 15% of the maximum at 60 mM extracellular K^+. Kinetic analyses of both initial and steady rates of GABA uptake indicate that our findings are consistent with the hypothesis that GABA uptake into somas of H1 horizontal cells increases with hyperpolarization and decreases with depolarization.

22.2 IN VITRO ASSESSMENT OF NOREPINEPHRINE (NE) UPTAKE IN RAT CORTICAL-HIPPOCAMPAL SYNAPTOSOMES FOLLOWING DEPOLARIZATION.
R. G. Thompson* and F. H. Gage (SPON: M. W. Emmett-Oglesby). Chem. of Behavior Program, Texas Christian Univ., Fort Worth, Texas 76129.

A number of investigators have reported that the rate of choline (CH) uptake is directly related to the level of nerve impulse activity and release of acetylcholine (ACh). In contrast to these data are several reports of a decreased uptake of norepinephrine (NE) following treatments which increase the activity of catecholamine neurons. The implication that the uptake mechanism of NE nerve terminals may be subject to qualitatively different regulatory influences than the mechanism for CH uptake was investigated in the present study by comparing the effects of K^+ depolarization on the in vitro uptake of NE and CH into synaptosomes isolated from rat hippocampus and cortex.

Synaptosomes were initially incubated in a buffered media containing 4.7mM K^+-no Ca^{++}, 55mM K^+-no Ca^{++} or 55mM K^+-1.8mM Ca^{++}. Duplicate aliquots of each condition were subsequently incubated in the presence of 10^{-8}M tritiated CH and NE. Preincubation of synaptosomes in 55mM K^+ alone resulted in a 37% increase in the uptake of CH but did not affect the uptake of NE. When Ca^{++} was present in the incubation media, depolarization with elevated K^+ levels produced a 107% increase in CH uptake and an 18% increase in the uptake of NE. When rats were anesthetized 30 min prior to sacrifice, CH and NE uptake were decreased by 35 and 15 per cent respectively. We interpret these data to indicate that the uptake of NE is not regulated to the same extent as CH by changes in neural activity. This difference may be accounted for by the differences between the means available to the nerve terminal for maintaing releasable pools of neurotransmitter. While replenishment of ACh pools relies predominantly on the uptake and conversion of choline into ACh, maintenance of NE stores occurs as the result of both the re-uptake of released transmitter and the synthesis of new NE from tyrosine. The absence of marked changes in NE uptake following depolarization is thus suggested to reflect the ability of the nerve terminal to either maintain or increase its rate of NE synthesis as necessary to compensate for the loss due to release.

22.3 INHIBITION OF CATECHOLAMINE TRANSPORT INTO CHROMAFFIN GRANULES BY PHENYTOIN.
Jean D. Deupree, David A. Downs*, Carl F. Gessert*, and James A. Weaver*. Dept. of Pharmacology, University of Nebraska College of Medicine, Omaha, NE 68105.

The anticonvulsant drug, phenytoin, has been reported to inhibit the transport of norepinephrine into synaptosomes, but the effects of this drug on the transport of catecholamines into storage granules has not been studied. In order to determine whether phenytoin would alter the storage of catecholamines, we examined the effects of phenytoin on the uptake of catecholamines into bovine chromaffin granules.

Relatively pure chromaffin granule ghosts were isolated from bovine adrenal glands. The ghosts contained less than 10 nmoles of epinephrine per mg of protein and less than 0.5 nmoles/mg/min of monoamine oxidase activity. Uptake of catecholamines was measured by incubating the granules for 10 min with 1 μM [^{3}H](-) norepinephrine in 50 mM Hepes buffer, pH 7.5, 4 mM ATP, 4 mM $MgCl_2$, and 0.1 mM EDTA. The transport process was terminated by adding 1 μM reserpine. The granules were isolated by centrifugation, solubilized with Protosol and counted for radioactivity. Nonspecific binding of [^{3}H](-)norepinephrine was eliminated by conducting control assays in the presence of 1 μM reserpine.

Phenytoin (0.4 mM) inhibited [^{3}H](-)norepinephrine transport by 47% whereas 1 mM phenobarbital inhibited transport less than 10%. Maximal inhibition of uptake appeared to occur at 0.4 mM, although it was not possible to test higher concentrations of the drug due to its limited aqueous solubility at this pH. The concentration of phenytoin required to produce 50% of this maximal inhibition was 50 μM, which is within the anticonvulsant range of the drug in blood plasma. The inhibition by phenytoin appeared to be noncompetitive with respect to norepinephrine since phenytoin reduced the Vmax but not the Km for norepinephrine. Catecholamines are transported into chromaffin granules by a carrier-mediated transport mechanism which utilizes a Mg ATPase as the driving force. Phenytoin (0.1 mM) did not inhibit the Mg ATPase activity in the chromaffin granules, suggesting that the inhibition of transport was not due to an inhibition of the driving force for the transport process.

These results indicate that phenytoin inhibits the transport of catecholamines into chromaffin granules. This action of phenytoin was not shared by phenobarbital, but it may be related to the anticonvulsant properties of the drug since it occurred at therapeutic doses of the drug.
(Supported by NIH grant NS15187)

22.4 MEASUREMENT OF UPTAKE SITES FOR GLUTAMATE AND OTHER NEUROTRANSMITTERS IN PREVIOUSLY FROZEN RAT AND HUMAN BRAIN TISSUE.
Robert Schwarcz and William O. Whetsell Jr.*. Maryland Psychiatric Research Center, Baltimore, Md. 21228 and Division of Neuropathology, Univ. of Tennessee, Memphis, Tenn. 38163

Glutamate uptake appeared to be stable when measured in striatal synaptosomes from rat brains stored for up to 4 hours postmortem at 25°C. Uptake decreased sharply between 4 and 8 hours at room temperature. Freezing of tissue on dry ice, storage at 4°C for up to 7 days and at -80°C for 5 days resulted in 20-25% residual glutamate uptake. Quantitatively similar data were obtained in eight extrastriatal brain areas.

Kinetic analysis of glutamate uptake sites in stored + frozen tissue revealed the loss of the majority of both sodium-dependent high-affinity- and temperature-sensitive low-affinity sites (V_{max} values) while the respective K_m values were not altered. Pharmacological properties of the high-affinity site versus a number of specific and unspecific uptake inhibitors remained unchanged by the storage- and freezing procedure.

The striatal reuptake systems for GABA, choline, serotonin and dopamine were differentially labile to storage and freezing: whereas 39% of the GABA-sites were still measurable, choline- and monoamine uptake processes decreased to 12% or less as compared to control values. Experiments using fresh and frozen kainic acid lesioned striata (Schwarcz and Coyle, Brain Res., 127,235,1977) showed that this differential vulnerability to freezing of the various neurotransmitter uptake sites was not due to differential localization on surviving non-neuronal elements.

The tissue treatment chosen for parts of the present study roughly corresponds with the preparation of human post-mortem brain tissue for enzyme-, neurotransmitter- or receptor binding assays. Our animal data suggested that uptake could be demonstrated in human autopsy material, thus adding an important parameter to the battery of neurochemical markers already available for post-mortem in vitro examination; and studies on rapidly processed human tissue showed that sodium-dependent glutamate uptake could indeed be measured in various brain regions including caudate nucleus, putamen, pallidum, cerebellum, thalamus, hypothalamus and cortical areas.

This study was performed largely to test the feasibility of a direct experimental approach to the glutamate uptake hypothesis of the human neurodegenerative disorder, Huntington's disease (Coyle et al., Prog. Neuro-Psychopharmacol., 1,13,1977). Our present data suggest that such an undertaking may be more realistic and meaningful than hitherto assumed.

This work was supported by a grant from the Wills Foundation.

22.5 INHIBITION OF NOREPINEPHRINE UPTAKE IN RAT SUPERIOR CERVICAL GANGLIA BY XYLAMINE. J.B. Fischer*, A.K. Cho* (SPON: B. Howard). Brain Research Institute and Pharmacology Department, UCLA, Los Angeles, CA 90024

Xylamine, (N-2'-chloroethyl-N-ethyl-2-methylbenzylamine)(XYL), an alkylating analog of bretylium synthesized in this laboratory, is an irreversible inhibitor of cortical norepinephrine (NE) uptake at concentrations that hardly affect striatal dopamine uptake in studies with rat brain synaptosomes. When administered to rats in vivo XYL produced an inhibition of cortical NE uptake and a depletion of cortical NE content that persisted for several days. Rat superior cervical ganglia (SCG) maintained in organ culture in a chemically defined medium (BGJ_b, with penicillin and streptomycin) have been used to examine the actions of this compound on adrenergic neurons. The ability of SCG to take up NE by a cocaine sensitive and Na^+ dependent mechanism increases about sixfold after 2 days in culture. This increased uptake capacity is maintained through 6 days of culture, so that the preparation is exceedingly stable. SCG were preincubated in Kreb's Ringer bicarbonate solution (KRBS) for 1 hr with different concentrations of XYL, placed in fresh KRBS for 30 min to wash away unbound drug, and then in fresh KRBS containing 0.2 µM [^{3}H]NE for 30 min. [^{3}H]NE in the SCG was extracted with 15% 1 N formic acid in acetone, and the protein content of each ganglion was determined. NE uptake was calculated as pmol NE taken up per mg of protein per 30 min. XYL inhibited NE uptake in cultured SCG with an IC_{50} of about 0.1 µM, a value similar to that found in rat brain synaptosomes and rabbit aorta, and inhibited NE uptake into freshly removed, uncultured SCG with an IC_{50} near 0.3 µM. XYL, at 1 and 10 µM, inhibited NE uptake into cultured SCG by 62 and 89%, respectively. Cultured SCG recovered their NE uptake ability, so that with 2 days of culture following 1 and 10 µM XYL treatment, the SCG showed only 12 and 21% inhibition of NE uptake, respectively. The protein content of the SCG did not decrease significantly during 2 days of culture after 10 µM XYL treatment, having 63 $\pm$ 3 and 56 $\pm$ 4 µM per ganglion for control and XYL treated SCG. Fresh SCG treated with 1 µM XYL and then cultured for 2 or 4 days showed no decrease in NE uptake ability or in protein content. As XYL is thought to act by covalently binding to a site or sites involved in NE uptake, the reversal of its inhibition of NE uptake in the SCG after culture may be due to the synthesis of new sites. Therefore the recovery of SCG but not cortical uptake may reflect the proximity of the noradrenergic cell bodies. The fact that 10 µM XYL does not decrease the protein content of the SCG indicates that this compound is not acting in a non-specific, cytotoxic manner. Thus XYL shows potential as a useful tool for studying noradrenergic systems.

23.1 EFFECTS OF VALPROIC ACID AND γ-ACETYLENIC GABA ON METABOLIC ENZYMES IN PRIMARY DISSOCIATED CELL CULTURE OF MOUSE FOREBRAIN. R.C. Frere*, A.B. Young, and R.L. Macdonald. Neurosciences Program and Dept. of Neurology, University of Michigan, Ann Arbor, MI 48109.

The enzymes glutamic acid decarboxylase (GAD), γ-aminobutyric-α-oxoglutarate transaminase (GABA-T) and succinic semialdehyde dehydrogenase (SSADH) regulate the levels of γ-aminobutyric acid (GABA) in mammalian brain. Alteration of GABA-mediated inhibition has been implicated in the action of many convulsants and anticonvulsants and some of these drugs have been shown to have effects on the GABA regulating enzymes. We have investigated the actions of the anticonvulsant valproic acid (VPA) and γ-acetylenic GABA (GAG) on GABA metabolic enzymes in primary dissociated cell (PDC) culture of mouse forebrain.

We have found that these cultures show measurable enzymatic activity for GAD, GABA-T and SSADH. The respective activities of these GABA regulators are as follows: 16 nmole CO_2/mg/hr protein, 81 nmole/mg/hr, and 265 nmole/mg/hr.

The effects of VPA and GAG on these enzymes were measured following a 20 minute preincubation. Different drug doses were used with a minimal concentration of substrate necessary to produce activity. VPA (10-40 mM) reduced GAD activity with an IC_{50} of 22 mM in forebrain cultures, but did not affect GABA-T or SSADH. Using the same methods with extracts of adult rat brain, we found that VPA had an IC_{50} of 25mM for GAD and an IC_{50} of 6mM for SSADH. GAG (1 μM-10 mM) had an IC_{50} of 200 μM for GAD, 30 μM for GABA-T and no effect on SSADH in forebrain cultures.

These studies have demonstrated the presence of the primary GABA metabolic enzymes in PDC cultures of forebrain. Previous work has shown that VPA has an inhibitory effect on SSADH and GABA-T, but this was not found in our in vitro preparation. The inhibition of GABA-T and GAD by GAG correlates with findings in other preparations. The effect of VPA and GAG on convulsant-induced paroxysmal activity will be correlated with these neurochemical results. The culture model lends well to simultaneous biochemical and neurophysiologic studies of drug action and permits direct correlation of physiological data with pharmacological effect. Supported by The United Cerebral Palsy Foundation and NIH grants NS 15140-02, NS 00420-01, NS 15225-01 and RCDA NS 00408.

23.2 ERYTHROSIN B: SPECIFIC INHIBITOR OF HIGH AFFINITY [^{3}H]-OUABAIN BINDING AND ION TRANSPORT IN RAT BRAIN. E.K. Silbergeld and S.M. Anderson*. Section on Neurotoxicology, NINCDS, NIH, Bethesda, MD 20205.

The U.S.F.D.& C. dye Red No. 3 (erythrosin B (EB), tetraiodofluorescein) has been recently investigated for possible neurotoxic properties (c.f. Science (1980) 207: 1485, 1497, 1489). EB appears to affect sodium-sensitive processes, such as neurotransmitter uptake by synaptosomes. Its inhibition of high affinity dopamine uptake by rat caudate synaptosomes is restricted to sodium-dependent uptake. An important regulator of sodium metabolism in neurons, and other cells, is provided by Na, K-ATPase. The effects of EB on Na, K-ATPase were studied in rat cortical tissue by using three approaches: (1) displacement of specific [^{3}H]-ouabain binding to synaptic membranes; (2) inhibition of ^{86}Rb transport into intact synaptosomes; and (3) enzyme activity (catalysis of ATP) in synaptosomes. Two binding sites for [^{3}H]-ouabain were observed under conditions of 135 mM NaCl, 1 mM $MgCl_2$, and 1 mM Na_2ATP in a 50 mM Tris-HCl buffer. The two sites had Kd values of 1-2 nM and 80-100 nM, and Bmax values of 50 and 110 fmol/mg protein respectively. EB, in concentrations as low as 100 pM, significantly inhibited binding of [^{3}H]-ouabain to the high affinity site; at 100 nM, EB completely inhibited binding to this site. Concentrations of EB as high as 100 μM did not inhibit [^{3}H]-ouabain binding to the low affinity site. In submicromolar concentrations, EB also inhibited synaptosomal uptake of ^{86}Rb and activity of ATPase. EB was inactive in inhibiting ATPase activity in red blood cell ghosts. In a structure-activity study (binding and enzyme activity) of ten other fluorescein analogs, only rose bengal (tetrachloro-tetraiodofluorescein), eosin Y (tetrabromofluorescein) and diiodofluorescein possessed any activity in brain tissue. The base compounds fluorescein and xanthene were inactive in concentrations as high as 100 μM.

As recently proposed on the basis of binding studies and electrophoretic separation, two Na, K-ATPases appear to exist in mammalian brain. One enzyme may be associated with those neural functions involving rapid ion fluxes. These experiments suggest that EB is a specific probe for one ouabain binding site (or one Na, K-ATPase), in brain. This hypothesis is supported by the lack of activity of EB or its congeners in red blood cells. The results may be of interest in investigating possible neurotoxic effects of fluorescein-based food and cosmetic dyes. However, there is at present no information on penetrability of these compounds into brain after peripheral administration or ingestion.

23.3 INACTIVATION OF GLUTAMATE DECARBOXYLASE. Mary P. Meeley* and David L. Martin. Department of Chemistry, University of Maryland, College Park, MD 20742.

Glutamate promoted dissociation of pyridoxal-P from glutamate decarboxylase (GAD), which results in inactive apoenzyme, has been implicated in the regulation of the enzyme. Previous studies also suggest that inorganic phosphate and adenine nucleotides may be involved in GAD regulation. We have examined the roles of glutamate, ATP and Pi in the inactivation process using partially purified GAD from hog brain. The time course of apoenzyme formation was measured by preincubating holoenzyme with unlabelled glutamate for various times at 30°C, followed by a 5 min assay with labelled substrate to determine the activity remaining. An initially rapid inactivation was observed which was still ongoing even after 90 min of incubation with 10 mM glutamate. The overall rate of apoenzyme formation was dependent on the glutamate concentration. α-Methyl glutamate promoted inactivation of holoenzyme at least twice as effectively as glutamate. The inactivation was not first order but appeared to be the sum of two exponential decay processes. With 10 mM glutamate, the half-lives were approximately 6 min for the first component and greater than 50 min for the second. The potent inhibition of GAD exhibited by ATP can be relieved by Pi, but only in the presence of the cofactor, pyridoxal-P. 500 μM ATP accelerated glutamate-promoted inactivation more than two-fold, but had little or no effect on GAD in the absence of substrate. The ATP stimulation of inactivation by glutamate was unaffected by Pi, which was consistent with the finding that Pi only relieves inhibition by ATP when pyridoxal-P is present. This result indicated that Pi and ATP are not merely directly competitive. GAD regulation may involve a balanced cycle of apoenzyme formation and its reactivation to holoenzyme by pyridoxal-P. Reactivation by pyridoxal-P is stimulated by Pi, whereas the opposing inactivation with glutamate is enhanced by ATP.

23.4 CYSTEINE SULFINIC ACID DECARBOXYLASE ISOENZYMES IN RAT BRAIN - COMPARISON WITH LIVER CYSTEINE SULFINIC ACID DECARBOXYLASE D.H. Ransom*, W.H.Oertel, V.K.Weise*, D.E.Schmechel*, H.Krutzsch* and I.J. Kopin. Laboratory of Clinical Science,NIMH, Bethesda, MD 20205

The biosynthetic enzyme for taurine is considered to be cysteine sulfinic acid decarboxylase [CSD(CSAD/CAD)4.1.1.29]. Recent work has demonstrated the presence of two CSD-enzymes in bovine brain (Wu et al., 1978; Heinämäki and Piha, 1979) one of which seems identical to glutamic acid decarboxylase (GAD). As CSD-activity is also present in non-neuronal systems, we compared the two brain enzyme activities with liver CSD activity in rat. Brain- and liver-CSD were partially purified by homogenization, centrifugation and ammonium sulfate precipitation (27%-68%) and subsequently chromatographed in parallel on amino-ethyl-Sepharose. Brain CSD was separated into two peaks, termed CSD I and CSD II. Brain CSD I eluted exactly in the same fraction as liver CSD at a potassium phosphate (KP)(pH = 6.9) concentration of 15-20 mM, CSD II coeluted with GAD at 50 mM KP. Using cysteine sulfinate as substrate, the apparent Kms of the partially purified preparations were 6 mM for brain CSD II, 55-100 μM for brain CSD I and 50 μM for liver CSD. pH-dependency for brain CSD I and liver CSD was virtually identical with an activity maximum between pH 7.4 to 7.8, however, brain CSD II exhibited a distinct pH-maximum at 7.4 to7.5.

Liver CSD and brain CSD I were not effected, whereas, brain CSD II was inhibited to 75% by 8mM glutamic acid. Liver CSD and brain CSD I were not effected by a specific anti-rat GAD-antiserum No. 1440, which precipitates GAD and brain CSD II.

The evidence obtained suggests the existence of two CSD isoenzymes in brain: CSD I appears to be very similar or identical to liver CSD and CSD II is indistinguishable from GAD.

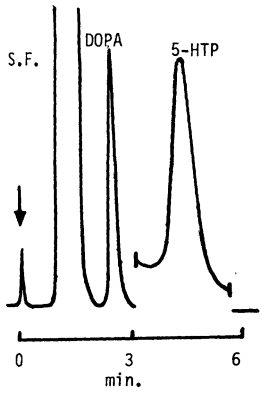
23.5 SIMULTANEOUS DOPA AND 5-HTP ANALYSIS FROM RAT BRAIN UTILIZING HPLC WITH ELECTROCHEMICAL DETECTION. S. P. Arneric*, D. B. Goodale, J. R. Flynn*, and J. P. Long* (SPON: W. W. Kaelber). Dept. of Pharmacology, Univ. of Iowa, Iowa City, IA 52242.

We have developed a rapid one step assay for simultaneous measurement of picogram amounts of 5-hydroxytryptophan (5-HTP) and nanogram amounts of dihydroxyphenylalanine (DOPA) by high performance liquid chromatography with electrochemical detection (HPLC-EC). Methodology, importance of sample storage and applications to pharmacologic alteration of DOPA and 5-HTP synthesis in rat brain is presented.

Tissue (~10 mg) from olfactory tubercle and caudate nucleus was homogenized in 0.1 N $HClO_4$ containing 0.02% ascorbic acid. Suspensions were incubated on ice for 30 min, centrifuged at low speed, and 30 µls of supernatant assayed. Samples were injected onto strong cationic exchange resin (Bondapak, CX/Corasil, Waters Associates Inc.) in a 750 mm x 2 mm i.d., microbore glass column. A Bioanalytical Systems, Inc. electrochemical detector was used. Sensitivities of 15 ng/ml for DOPA and 3 ng/ml for 5-HTP were obtained. Extraction efficiency of DOPA and 5-HTP from tissue was 95% ± 7%. Time and temperature dependent storage experiments suggest that 5-HTP samples may be stored a maximum of 24 hours at 4°C. Freezing (-10°C) is detrimental to 5-HTP samples. DOPA may be stored at 4°C or -10°C for at least 96 hours. Pharmacologic alteration of DOPA and 5-HTP synthesis was measured following para-chlorophenylalanine (PCPA, 100 mg/kg, i.p.) or apomorphine (APO, 1 mg/kg, s.c.); gamma-butyrolactone (GBL, 750 mg/kg, i.p.); and an aromatic L-amino acid decarboxylase inhibitor (NSD 1015, 100 mg/kg, i.p.). APO and PCPA selectively decreased DOPA and 5-HTP, respectively, in striatal brain as expected. Rapid and easy sample preparation, excellent tissue recoveries, and low equipment cost make this method suitable for routine measurement of DOPA and 5-HTP. (Supported by NIH Grant NS-4431.)



23.6 INFLUENCE OF DEVELOPMENT AND RESERPINE ON CATECHOLAMINE BIOSYNTHETIC ENZYMES IN BRAIN AND ADRENALS OF SPONTANEOUSLY HYPERTENSIVE RATS (SHR). Ranbir K. Bhatnagar, M. Squillante*, M. O'Neil*, S. Kasik* and G. Rios*. Dept. of Pharmacol., Univ. of Iowa, Iowa City, IA 52242.

Catecholamines in the adrenal glands and hind brain, and elevated sympathetic activity have been implicated in the ontogenesis and maintenance of hypertension. This study was undertaken to assess the developmental pattern of phenylethanolamine-N-methyltransferase (PNMT) in the adrenals and pons-medulla of SHR and normotensive Wistar-Kyoto rats (WKYR). In addition, the effects of reserpine induced increase in sympathetic activity on PNMT and other biosynthetic enzymes was determined in adult rats. In young rats whole adrenals and medulla oblongata were removed at 3, 10, 15, 21 and 37 days of age. Adult rats were treated with reserpine for 4 days and adrenals, pons + medulla and blood samples were removed for study.

In young rats, PNMT activity/per pair of adrenals was significantly lower at all ages in SHR except 3 days. In contrast PNMT activity was significantly higher in the medulla of SHR at 15 and 21 days of age. The activities of tyrosine hydroxylase (TH), dopamine-β-hydroxylase (DβH) and PNMT (per pair of adrenals) were not different between adult SHR and WKYR whereas PNMT activity of pons + medulla was significantly higher (44%) in SHR. Norepinephrine (NE)/Epinephrine (E) ratio was significantly higher in the adrenals of SHR at 3, 10, 15, 21 and 37 days of age but not in adults (300-350 gm).

After reserpine, NE and E were reduced by 57 and 82% respectively in the adrenals of SHR and WKYR. Adrenal TH and DβH activities increased by 160% and 110% respectively in both SHR and WKYR whereas PNMT activity remained unaltered. In pons + medulla, TH activity increased by 79 to 86% in both SHR and WKYR and again PNMT activity remained unaltered. The increase (100-150%) in serum DβH activity was similar in both strains of rats. The adrenal weight of adult SHR (45.9 mg/pair) was significantly greater than that of WKYR (36.4 mg/pair). Reserpine produced a further significant increase in the adrenal weight of both SHR (54.8 mg/pair) and WKYR (47.9 mg/pair).

In conclusion: (1) the epinephrine system in the pons-medulla but not the adrenal glands may be involved in the ontogenesis and maintenance of hypertension in SHR, (2) based on adrenal TH and DβH and plasma DβH activities the sympathoadrenal activity does not appear to be elevated in adult SHR and (3) PNMT, inducible by glucocorticoids, is not activated by stimuli which increase sympathetic outflow as measured by enhanced activity of TH and DβH. Supported in part by Grants HLB-14388 and NS-12121.

24.1 DEMONSTRATION OF MOTOR CIRCUITS WITH CORTICAL STIMULATION AND 14-C-DEOXYGLUCOSE AUTORADIOGRAPHY. R.C. Collins, T. Der*, E.W. Lothman, and E.F. Vastola*, Neurology, Wash. Univ., St. Louis, MO 63110

In order to learn which neuroanatomic structures are active during a particular movement we have used the method of 14-C-deoxyglucose autoradiography (DG) in combination with intracortical bipolar stimulation of motor cortex. 300 g rats were anesthetized with halothane for insertion of vascular catheters for later infusion of DG. A side by side or concentric bipolar electrode (0.2 mm diameter; 0.5 mm tip separation) was inserted into forelimb motor cortex 2 mm anterior and 3 mm lateral to bregma and cemented to the skull. Stimulation was begun 1 to 4 hours after halothane, or after several days recovery. Stimulation parameters were varied in order to determine the necessary and best conditions for autoradiographic labeling. In each case DG (60 μCi/kg) was given intravenously during steady stimulation and animals killed at 45 min for processing. Brains were perfused-fixed, frozen, cut serially at 20 μm and exposed to SB-5 film for autoradiographic development. Single shocks (.25 msec, 0.5/sec, 40V) which caused a barely detectable movement caused no consistent increment in DG uptake. Train stimuli (0.25 msec, 250 hz, 40 msec, 0.5/sec, at 5 to 15V) caused discrete contralateral forelimb movements and DG uptake in ipsilateral subcortical structures: caudate/putamen, GP, N. reticularis, VA-VL, VL, VM, CL, Pf, STN, and SN. Metabolism was also increased in ipsilateral and transcallosal cortical columns. Train stimuli caused a local evoked potential but no seizure. The stimulus site was characterized by 1.5 to 3 fold increment in DG uptake. The lateral borders of the stimulus site were sharpley defined by a *surrounding field* where DG metabolism was slightly depressed. "Metaboic" columns appeared beyond this. Barbiturate raised the voltage threshold for stimulation induced movement 5 to 10 fold, but resulted in a generally similar pattern of metabolic activation.

24.2 TURNING BEHAVIOUR AND 2-DEOXYGLUCOSE AUTORADIOGRAPHY FOLLOWING UNILATERAL KAINIC ACID LESIONS OF THE GLOBUS PALLIDUS IN RAT.
J. S. Yeomans and D. van der Kooy. Depts. of Anatomy and Psychology, U. Toronto, Toronto, Ontario, M5S 1A1, Canada.

Unilateral injection of 1.5 n moles of kainic acid into the rat globus pallidus produces intense turning to the contralateral side for several hours post injection, weaker ipsilateral turning for about 2 more days, followed by no apparent turning bias. To determine the neural correlates of these turning biases, ^{14}C-2-deoxy-D-glucose was injected at the peaks of the turning (3 hr., 20 hr. post injection) and 7 days post injection, and Sokoloff's autoradiographic procedures were applied. At the injection site a region of relatively little label was seen within about 1 mm of the cannula tip 3-4 hr. post injection. Patches up uptake were found 20-22 hr. and 7 days post injection in loci which correlated with concentrations of glial cells in Nissl stained sections.

Farther away from the injection site intense consistent increases in ipsilateral vs. contralateral ^{14}C-2DG uptake were seen in caudate-putamen and substantia nigra. Dramatic, but inconsistent changes were found in many other brain structures.

24.3 PRESYNAPTIC INPUT FROM THE VENTRAL TEGMENTAL AREA OF TSAI TO HYPOTHALAMIC NEURONS. F. C. Barone, M. J. Wayner, W. H. Tsai, S. L. Scharoun*, H. U. Aguilar-Baturoni and R. Guevara-Aguilar. Brain Research Lab, Syracuse Univ, 601 Univ Ave, Syracuse, NY 13210 and Depto de Fisiologia, Facultad de Medicina, U.N.A.M., Mexico.

Electrical recordings from single neurons were made in the hypothalamus of urethane anesthetized male hooded rats. A concentric bipolar stimulating electrode was placed in the ventral tegmental area of Tsai (VTA) and the effects of electrical stimulation, 0.5 msec single rectangular pulses of 0-500 μA, on ipsilateral lateral preoptic and lateral hypothalamic (LPA-LH) neural activity were determined. Reliable current dependent increases and decreases in neural activity were observed. An analysis of response latencies indicated that the effects were mediated mono and polysynaptically. Significant effects occurred with relatively short latencies and at low current intensities. Antidromic invasion was also observed in some cells indicating interconnections between the VTA and LPA-LH. In addition, horseradish peroxidase (HRP, Sigma Type VI, 25%) was applied microiontophoretically in the LPA-LH. Alternate brain sections were processed with DAB and BDH for the brown and blue reactions. Labeled neurons were identified in the VTA utilizing light and dark field microscopic examination of sequential sections. Therefore, shorter latency effects of electrical stimulation are monosynaptic and are probably not due to stimulation of fibers of passage in the VTA. These results, in terms of neurophysiological and neuroanatomical data, demonstrate unequivocally significant direct and indirect presynaptic inputs to neurons in the LPA-LH area mediated by neurons in the VTA. (Supported by NIH Grant NINCDS USPHS No. 13543)

24.4 MESENCEPHALIC CENTRAL GRAY PRESYNAPTIC INPUTS TO HYPOTHALAMIC NEURONS. W. H. Tsai, F. C. Barone, M. J. Wayner, S. L. Scharoun*, R. Guevara-Aguilar and H. U. Aguilar-Baturoni. Brain Research Lab, Syracuse Univ, 601 Univ Ave, Syracuse, NY 13210 and Depto de Fisiologia, Facultad de Medicina, U.N.A.M., Mexico.

Single unit electrical recordings were made from central neurons in urethane anesthetized male hooded rats. The central gray area in the mesencephalon (MCG) was stimulated by applying 0.5 msec single rectangular pulses of 0-500 μA through a concentric bipolar stimulating electrode and the effects on ipsilateral lateral preoptic and lateral hypothalamic (LPA-LH) neural activity were determined. Reliable current dependent responses were observed. An analysis of response latencies indicated that effects were mediated mono and polysynaptically. Significant responses occurred with relatively short latencies and at low current intensities. In addition, horseradish peroxidase (HRP, Sigma Type VI, 25%) was applied microiontophoretically in the LPA-LH. Alternate brain sections were processed with DAB and BDH for the brown and blue reactions. A light and dark field examination of sequential sections revealed positively labeled neurons in the MCG area. These results, in terms of neurophysiological and neuroanatomical data, unequivocally demonstrate a significant input from neurons in the MCG to neurons in the LPA-LH. The shorter latency LPA-LH neuronal effects of MCG electrical stimulation must be due to monosynaptic connections and apparently are not due to the stimulation of fibers of passage. (Supported by NIH Grant NINCDS USPHS No. 13543)

24.5 THE TECTORETICULOSPINAL PATHWAY IN THE GOLDEN HAMSTER. J. A. Muntz, R. C. Shults, and J. D. Rose. Dept. of Psychol., Univ. of Wyoming, Laramie, WY 82071.

The behavioral functions of the deep tectum have become of increasing interest recently. Previous work in this laboratory has demonstrated a role for this region of the dorsal midbrain in the lordosis response of female golden hamsters. The present investigation demonstrates the organization of descending projections from the deep tectum to pontomedullary reticulospinal neurons by means of neuroanatomical and electrophysiological methods. In the anatomical studies 50% horseradish peroxidase (HRP) and 2% dimethyl sulfoxide in normal saline was injected through a micropipette into caudal pontine and anterior medullary gigantocellular nuclear regions. The cerebellum was ablated prior to injection to prevent spread of the enzyme. After a 3-day survival period brains were processed using the technique of Mesulam (1978) employing tetramethyl benzidine as a chromogen. The injections resulted in retrograde labeling of neurons at all rostro-caudal levels of the deep superior colliculus. The labeled cells lay principally in a lateral position in the stratum profundum and almost exclusively contralateral to the injection site. Microelectrode recordings were performed in urethane-anesthetized hamsters. Tectoreticular neurons identified by antidromic response to stimulation of the contralateral ponto-medullary gigantocellular nuclei were found to lie in the same deep tectal region as cells retrogradely-labeled with HRP. Electrophysiologically identified tectospinal neurons were located in the anterior deep tectum exclusively, in accord with previous neuroanatomical findings (Shults and Rose, 1979). Single neurons comprising the reticular portion of the tectoreticulospinal system were identified in the medullary gigantocellular nucleus by orthodromic response to contralateral deep tectal stimulation and antidromic response to ipsilateral cervical spinal cord stimulation. The properties of tectoreticular, tectospinal and tectoreticulospinal neurons were relatively uniform in that these cells showed little or no spontaneous activity and were largely unresponsive to somatosensory stimulation. The inactivity and unresponsiveness of these caudally-projecting neurons stood in marked contrast to the presence of active, highly responsive neurons lying around them, and may reflect the close association between tectoreticulospinal and tectospinal neurons and motor function. The tectoreticular neuronal population was clearly larger and more spatially extensive than the tectospinal one in neuroanatomical as well as electrophysiological experiments.

24.6 PROJECTIONS FROM THE PONTINE GIGANTOCELLULAR TEGMENTAL FIELD IN THE RAT. B.E. Jones, Neuroanatomy Lab., Montreal Neurological Inst., McGill University, Montreal, Quebec, Canada H3A 2B4.

The pontine gigantocellular tegmental field (FTG) has been shown to be important in the control of eye movements (Bender and Shanzer, 1964), head movements (Peterson et al, 1978), posture (Kuypers, 1964), locomotion (Mori et al, 1977) and paradoxical sleep (McCarley and Hobson, 1971; Jones, 1979). Early anatomical studies demonstrated diffuse projections from this area of the reticular formation ascending into the diencephalon and descending the full length of the spinal cord, whereas more recent experiments have emphasized local projections onto bulbar oculomotor neurons (Grayfield, 1977) and heavy spinal projections onto the ventral horn (Holstege et al, 1977; Martin et al, 1979).

To investigate the entire projection from the pontine FTG in the rat, small localized injections of radiolabelled amino acids were performed with a pressure micro-injection system. Amounts ranging from 10-250 nl of ^{3}H-leucine or proline (100nCi per nl) were delivered through glass micropipettes with 1-5 micron tips. Animals were sacrificed by perfusion 24-48 hours after injections for autoradiographic processing of the tissue that involved 14-90 day exposures (NTB-2 emulsion).

Large injections (∿250 nl) labelled the small celled fields in the more lateral reticular formation and the more rostral central tegmental field in addition to the giant cell field (FTG) of the pons and they resulted in a pattern of projections which could be described as diffuse, that is including local propriobulbar projections (onto 6th and 7th n. nuc., vestibular nuc., and brainstem RF), long ascending projections into the zona incerta and thalamic intralaminar nuc., and long descending projections along ipsi- and contralateral ventral funiculi to ventral horn and the contralateral dorsolateral funiculi to the dorsal horn.

In contrast very small and restricted injections (10-100 nl) into the pontine FTG produced a limited and fairly specific pattern of largely ipsilateral projections. Reticulo-reticular projections extended ipsi- and contralaterally into the paramedial regions through the brainstem, but were especially heavy into the bulbar giant cell field and magnocellular region (FTM). Cranial nerve nuc. were not directly innervated nor was the lateral reticular formation. Long projections were evident only down into the spinal cord passing through the ventral funiculus into the intermediate zone (lamina 7 and 8) on the ipsilateral side.

In summary the major projections of the pontine FTG are bilateral reticulo-reticular into the paramedial zone of the brainstem and unilateral reticulo-spinal into the intermediate zone of the ventral horn. This area probably functions in the control of postural mechanisms during waking and sleep.

24.7 LOCUS COERULEUS NEURONS HAVE AXONS THAT BRANCH TO BOTH THE CEREBRUM AND CEREBELLUM: AN HRP AND IRON DEXTRAN DOUBLE-LABELLING STUDY IN THE MOUSE. D.A. Steindler* (SPON: E. Eisenstein). Dept. of Anatomy, Michigan State University, East Lansing, Mi. 48824.

Particular monoaminergic neurons within the brainstem (i.e. nucleus locus coeruleus (LC) and raphe nuclei) have been described as giving rise to extremely divergent axonal projections to numerous CNS areas (Ungerstedt, Acta Physiol. Scand. Suppl., 367: 1971; Nakamura and Iwama, Brain Res., 99: 1975). Collateral axonal branching represents one way in which divergent projections may be achieved by meager numbers of neurons and at the same time allow these neurons to affect and possibly interrelate the ontogeny, maturation, and adult patterns of activity of various CNS neurons.

The present double-labelling study utilizes the retrograde axonal transport of horseradish peroxidase (HRP) and iron dextran (ID) in order to identify LC neurons that are involved in a branched innervation of the cerebrum and cerebellum. One group of adult white mice received HRP injections within the prefrontal, frontal, or somatosensory cerebral cortices as well as injections of an iron dextran complex (Anchor Laboratories, concentrated to approximately 200mg/ml in 0.9% NaCl containing 0.03% poly-L-ornithine or DDH_2O) within portions of the ipsilateral cerebellum (particularly the crus II and neighboring hemispheric lobules). In a second group these injections were reversed. After survival times of up to 8 days, and HRP histochemistry (using DAB/glucose oxidase) followed by the Prussian blue reaction on 50µm sections (Cesaro et.al., Neurosci. Lett., 15: 1979), retrograde labelling was assessed in the thalamus, locus coeruleus, and pre-cerebellar nuclei.

Populations of single-labelled neurons were found in the ventral tier, mediodorsal and intralaminar thalamic nuclei, pons, inferior olive, principal sensory, oralis and interpolaris divisions of the trigeminus, locus coeruleus, as well as other areas. Neurons within these nuclei displayed varied degrees of retrograde ID-labelling. In many situations, analysis was carried out at high magnification in order to discern weak labelling in neurons containing as little as 3-10 blue granules per cell. Other times, the ID-labelling can be quite pronounced with neurons containing several blue granules that appear to coalesce resulting in intensely labelled portions of somata and dendrites. The uptake and detection of both tracers can be manipulated in order to achieve distinct poplations of brown and blue granules within single branched neurons. In addition to HRP or ID-labelled cells, many double-labelled neurons have also been observed in LC, and it is possible that particular portions of the nucleus may be involved in interrelating portions of the fore- and hindbrain cortices.

Supported by NIH Grant BRSG RR0572-04.

24.8 TERMINAL DENDRITIC STRUCTURE AND DENDRITIC APPENDAGES OF NECK MUSCLE MOTONEURONS IN THE ADULT CAT. P. K. Rose, S. Keirstead* and S. Vanner*. Dept. of Physiology, Queen's University, Kingston, Canada K7L 3N6.

Most descriptions of motoneuron morphology have been concerned with the size and distribution of their dendritic trees. However except for several reports, published in the late 19th century, little is known about dendritic appendages and terminal dendritic structure of motoneurons. Consequently we have re-examined the fine structural characteristics of motoneurons in the adult cat. All motoneurons examined were intracellularly stained with horseradish peroxidase and electrophysiologically identified as neck muscle motoneurons.

Distal dendrites often followed a tortuous course and frequently were varicose or appeared as a string of beads joined by narrow processes. This was in contrast to proximal dendrites which were smooth and cylindrical and followed a straight path. The structure of the dendritic terminal itself was variable. Some dendrites ended as a swelling whereas others had a single fine spike-like process originating from a pre-terminal swelling. Occasionally a distal dendrite divided into two or more short branches, forming a tufted or claw-like ending.

Spines were a common occurrence on all motoneurons examined. They were most frequently located on proximal dendrites. Most spines were either short (2-3 µm) and stubby or long (5-8 µm) and narrow. Another kind of dendritic appendage was also characteristic of all motoneurons. Unlike spines, these appendages were long (50-250 µm) and usually emerged from the apex of a cone-shaped protrusion. The origin of each appendage was narrow (less than 0.5 µm) and cylindrical in contrast to the central and distal parts which were 1-2 µm in diameter and varicose. Most of these processes were found on proximal dendrites but they were also common on the central part of the dendritic tree of biventer cervicis and complexus motoneurons.

The functional significance of the unusual terminal dendritic structure is not clear. However, the long dendritic appendages are strikingly similar to descriptions of presynaptic dendrites. Neck muscle motoneurons may consequently influence neighbouring neurons via two routes: 1) axon collaterals or 2) dendrodendritic contacts. The significance of this arrangement may be related to the fact that unlike the output mediated by axon collaterals, the output of presynaptic dendrites would be dictated by synaptic inputs distributed to only a fraction of the total dendritic tree.

24.9 POSTERIOR TIBIAL-TO-PERONEAL NERVE CROSSOVER: AN ELECTROMYOGRAPHIC STUDY. R. R. Weisz, R. J. Cox*. Electromyographic Lab., *Department of Neurology, Indiana University Medical Center*, Indianapolis, Indiana 46202.

A Posterior Tibial-to-Peroneal nerve anastomosis was found as an incidental finding in a patient studied electromyographically. In contrast with the well described and recognized Peroneal-to-Posterior Tibial nerve crossover, the reverse anastomosis has hitherto not been documented. It is important to recognize the anastomosis because it can be a source of error when one evaluates the results of an electromyographic study. The main difficulty in identifying the anastomosis is differentiating it from an Accessory Deep Peroneal Nerve. The technique of proving the anastomosis will be presented, and methodology employed to avoid pitfalls will be discussed. The signficance of the anastomosis in terms of electrodiagnostic studies and functional human neuroanatomy will be discussed.

24.10 NEUROMUSCULAR ORGANIZATION IN THE HINDLIMB OF THE OPOSSUM, DIDELPHIS VIRGINIANA. D. A. Thomas* (SPON: J. A. Kugel). *Department of Anatomy, West Virginia University, Medical Center*, Morgantown, West Virginia 26506

Numerous studies of neural organization in the opossum, a metatherian mammal, have generally revealed systems which are qualitatively, typically mammalian in arrangement. Yet the total size of opossum central nervous system is extremely small when compared to body size or to the CNS in comparably sized placental mammals. This study is a preliminary examination of neuromuscular innervation in two antagonistic hindlimb muscles, the medial gastrocnemius (MG) and the tibialis anterior (TA). It is intended to quantitate directly the innervation, motor unit size and fiber types of these muscles in the opossum for comparison to other mammals. Detailed dissection of the lumbosacral plexus revealed that both of these muscles are supplied by branches of the sciatic nerve (origin from L5, L6, S1, S2). One or two descending sciatic branches reach the head of MG; multiple branches enter the head of TA just below the popliteal fossa. Nerves to these fibers were osmium stained, Epon embedded, sectioned, and fibers were counted and measured. Mean nerve fiber count for MG is 255 and for TA is 347. All sizes were charted on histograms. The muscles were also removed, frozen sectioned and reacted with alkaline ATPase. Paraffin embedded tissue from adjacent areas was used for total fiber counts. MG (from a small sample) has a range of 11,202 - 16,718 muscle fibers; the ratio of fast to slow muscle fibers is 1:1. TA has from 8,265 - 14,766 muscle fibers. The ratio of fast to slow muscle fibers in TA is 3:1. Cross sectional areas of muscle fiber types (slow or fast) were similar within each muscle. Until deafferentation studies are completed, estimation of motor unit size is tentative. Assuming that the percentage of afferent nerve fibers is the same as reported in the cat (40 - 55 %), motor unit size for these muscles would fall into the typical mammalian range.

(Supported in part by NSF Grant BNS-7924172).

24.11 DISTRIBUTION OF FIBER TYPES IN MONKEY FOREARM MUSCLES. J.S. McIntosh, M. Ringqvist*, E.M. Schmidt. Lab of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Histochemical staining methods were applied to the following forearm muscles from one Macaca mulatta and two Macaca fascicularis monkeys: ext. carpi ulnaris, ext. carpi radialis longus, ext. carpi radialis brevis, ext. digitorum, ext. digiti 4th and 5th proprius, flex. carpi radialis, flex. carpi ulnaris (FCU) and brachioradialis (BR).

In all the muscles studied we found a mosaic of type I and type II fibers and in all but FCU, the histochemical mosaic was essentially the same throughout the muscle cross section. FCU is a bipennate muscle with distinctly different proportions of type I and II fibers on either side of a central tendon (see Table). BR in M. Mulatta had very low percentages of type I and IIA fibers as compared to the other monkeys studied (see Table).

Monkey forearm muscles except FCU appear to be similar to human in that they have a mosaic pattern of fiber types, fairly uniformly distributed throughout the muscle.

Mean values and S.D. for percentage distribution of fiber types in the forearm muscles of one Macaca mulatta and two Macaca fascicularis monkeys.

24.12 ORIGINS OF CARDIAC PREGANGLIONIC NEURONS IN THE RAT; A COMPARISON OF ATRIAL AND VENTRICULAR INNERVATION. S. L. Stuesse. With the technical assistance of K. S. Stockton.* Neurobiology Program. N. E. Ohio Univ. Col. of Med., Rootstown, Ohio 44272

A retrograde cell labeling technique was used to compare origins of preganglionic neurons in the sinoatrial and mid-ventricular regions in adult rats. Animals were anesthesized with halothane, thoracotomized, and 2-5μl of 30% horseradish peroxidase (Sigma, type VI) was injected into the myocardial wall in either an atrial or mid-ventricular location. After a 24-48 hr. survival time, the animals were reanesthesized, perfused, and their brains removed. 40μm sections were made from the brainstems and upper spinal cords, and the sections were then reacted with tetramethyl benzidine (TMB). Sections were lightly counterstained with Neutral Red to visualized cellular anatomy. Whole hearts were also reacted with TMB to confirm injection sites.

The majority of labeled cells were found in the nucleus ambiguus (NA) about 1mm rostral to the level of the obex; fewer cells were found in the dorsal motor nucleus (DMN); no labeled cells were found in the nucleus tractus solitarius. In the NA, labeled cells were also found in the most caudal part of the medulla. At this level, a few periambigual cells were labeled. Slightly caudal to the obex, 2-4 labeled cells were found in some sections in an intermediate zone between the NA and DMN.

The same nuclei were labeled with atrial and ventricular injections but fewer cells were labeled with the latter. Labeling was bilateral in both cases. In rats in which either right or left vagotomies were performed several days prior to the HRP injections, the labeling was ipsilateral to the intact vagus.

Supported by NIH grant HL 23964 and the American Heart Association, Akron District Chapter.

24.13 ORIGINS OF SUPRASPINAL PROJECTIONS TO THE SPINAL CORD IN THE TEGU LIZARD. W.L.R. Cruce, D.B. Newman*, and J.A. Finkelstein, With the technical assistance of D.F. Ayers.* Neurobiology Department N.E. Ohio University College of Medicine, Rootstown, OH 44272 and Anatomy Department, Uniformed Services University of the Health Sciences School of Medicine, Bethesda, MD 20014

Cells of origin for pathways from the brain to the spinal cord were localized in the Tegu lizard, Tupinambus nigropunctatus, by making spinal injections of horseradish peroxidase (HRP), 30%-40%, or Bisbenzimide (BIS), 10%. Small and large injections were made unilaterally and bilaterally at cervical, thoracic, and lumbar levels. Survival times ranged from 2 to 11 days. Frozen sections were cut at 40 micra thickness and reacted with tetramethyl benzidine (TMB) for HRP or immediately mounted for BIS. Alternate sections were counterstained with Neutral Red for cytoarchitectonic localization. Sections were viewed with brightfield or darkfield transmitted light for HRP or with incident fluorescent light methods for BIS.

Labelled cells were found on the ipsilateral side in the interstitial nucleus and the superior, middle and inferior reticular fields. The raphe nucleus was labeled in the midline. Contralateral labeling was found in nucleus ruber. Bilateral labeling was found in the nucleus of the solitary tract, the dorsal motor nucleus of the vagus, the ventrolateral vestibular nucleus (Deiter's), and locus coeruleus. Within the hypothalamus a few labeled cells were observed in the periventricular region. Our previously described subdivisions of the lateral portion of the superior reticular field were identified: the dorsolateral (MDL) and ventrolateral (MVL) metencephalic nuclei. Ipsilateral labeling was seen in MDL and bilateral labeling was found in MVL. Our previously described subdivisions of the inferior reticular field were also identified: the dorsal (RID) and ventral (RIV) medial parts and the ventral lateral (RVL) part. Labeling in these cells was ipsilateral except for RID which was bilateral. Further studies are under way to determine if any of the bilateral labeling is due to spread of the injected label across the midline.

Comparison of injections at different levels of the cord suggested that there may be a somatotopic orginazation within the ventrolateral vestibular nucleus such that thoracic and lumbar projecting neurons are located caudally and ventrally to cervical projecting cells.

25.1 LAMINAR DIFFERENCES IN THE SIZE AND SHAPE OF RECEPTIVE FIELDS IN RAT SOMATOSENORY (SI) CORTEX. John K. Chapin, Chia-Sheng Lin, and Donald J. Woodward, U. of Tx. Hlth. Sci. Cntr., Dallas,Tx. 75235

This study was conducted to quantitatively describe the differences in the spatial configurations of somatic receptive fields (RF's) of cells in different layers of the primary somatosensory (SI) cortex. Post-stimulus time histograms of single unit responses in nembutal anesthetized rats were generated by delivering standardized punctate mechanical stimuli to each of 25 to 40 closely spaced points on the skin of the contralateral forepaw or hindpaw, or of 26 adjacent whiskers on the face. Computer techniques were used to calculate the magnitudes of the excitatory peaks in each histogram within such a series. These were used to plot a two-dimensional "response contour map (RCM)" showing the exact spatial configuration and point-to-point topography of the receptive fields of cells in various cortical laminae.

The RCM's of all cortical cells studied here exhibited central regions of high sensitivity surrounded by less responsive zones. In neurons encountered within single vertical penetrations through cortex such foci generally represented the same peripheral cutaneous location. No clear inhibitory surrounds were ever observed. The overall sizes of the RF's (defined here as the total area of the active zones seen within the response contour maps) were always larger than could be detected by aural monitoring. The RF's in layer IV and deeper layer III were quite small and exhibited steep slopes rising sharply to clearly defined central peaks. In the paw areas they were generally elongated in shape and were oriented proximo-distally along limb, paw or digit surfaces. In the vibrissa field they were more circular in shape and encompassed only 2-5 whiskers. The RF's were slightly larger in the more superficial parts of layer III and layer II. In the vibrissa areas they tended to be elongated rather than circular in shape and were oriented vertically across the rows of whiskers. By contrast, most cells in layer V exhibited very large RF's, often covering the whole paw surface or vibrissa field. Localized foci existed in the same location as in the overlying layer IV cells, but one or two additional foci were often clearly distinguishable in locations elsewhere within the RF.

In conclusion, the organization of the SI cortex appears to be somewhat similar to that of the visual cortex in that layer IV contained small, circular RF's while in deeper and more superficial layers they were larger and had more complex shapes. Despite these differences, the concept of a vertical "columnar" organization remains intact since RF's in all layers contained central foci corresponding to the same cutaneous area.

25.2 CHRONIC CHANGES IN CAT SOMATIC SENSORY-MOTOR CORTEX (Sml) FOLLOWING SELECTIVE DORSAL-ROOT SECTION. Joel I. Franck*[1], Jacqueline Metzler, and Philip S. Marks* (SPON: Franklin C. Wagner, Jr.). Sect. of Neurosurg., Yale Univ. Sch. of Med., New Haven, CT 06510.

Several recent studies have reported both acute and chronic changes in the somatotopic map in spinal cord (Dostrovsky et al., 1976), DCN (Millar et al., 1976) and Sml (Metzler & Marks, 1979; Franck, 1980) following selective blocking of ascending spinal pathways. In order to examine further the long-term effects of selective deafferentation on the body surface projection to Sml, extracellular responses of single units were studied from 12-40 weeks following the sectioning of all dorsal roots caudal to L3 with the exception of L7.

Response and receptive-field (RF) properties of 451 units were studied in 3 awake, paralyzed, adult cats under N_2O analgesia and compared to both the control recordings and the recordings taken 8 to 55 days following deafferentation in the same animals, and the results obtained during acute blocking of the L4-L5 dorsal roots in another population. In all cats, the somatotopic map in Sml continued to change 12-20 weeks after deafferentation, with a progressive increase in the area representing the trunk and abdomen in the more medial, partially deafferented region which had responded to hind-limb stimulation in control preparations. While nearly 60% of the 212 cells examined during this period had highly specific response properties, the remaining 40% were classified as nonspecific, as compared to 33% in these same animals 8-55 days post-rhizotomy, and to 7% in control preparations. These cells had multiple, bilateral or uncharacteristically large RFs which often responded to multiple subclasses of stimulation. There was also an increase in the percentage of cells with higher thresholds of stimulation. During the 20-40 weeks post-rhizotomy, 239 units were examined and few additional changes in Sml somatotopy were observed. There was, however, a progressive decrease in the percentage of units with nonspecific response and RF characteristics such that, by 30 weeks after dorsal-root section, the percentage of nonspecific cells had decreased to nearly 18%. This proportion remained relatively constant through the 40 weeks of observation.

These findings support previous reports of the presence of widespread afferent connections throughout the somatosensory systems of intact animals which are usually ineffective. They suggest, further, that the increased effectiveness of afferents from the intact body segments in activating cells in the deafferented region may be essentially complete by 30 weeks following deafferentation.

Supported by NIH Grant 2P50 NS10174.

25.3 THE CORTICO-CORTICAL CONNECTIONS OF DIFFERENT BODY REPRESENTATIONS FROM SI IN THE RAT. C.S. Lin, S.E. Knowles, J.K. Chapin and D.J. Woodward. Department of Cell Biology, The Univ. Tx. Health Sci. Ctr., Dallas, Texas 75235

The aim of this study was to determine the cortical afferents converging upon electrophysiologically identified zones of body representation in SI cortex. Electrophysiological maps of body parts in SI were obtained prior to iontophoretic HRP injections (2-3 μ Amp for 15-20 min) which were made from electrodes (tip size 20-30 μM) containing a mixture of L-lysophosphatidyl choline in 20-30% HRP (Sigma VI). Brain sections were preheated with $CoCl_2$ and then reacted with DAB. These enhanced methods allowed visualization of dendritic morphology of cells projecting to the injection site as well as axonal arborizations of cell bodies whose axons left the injection site. Major findings were: a) The glabrous skin of the finger digits and the forepaw is represented twice in SI with the finger digits in between the rostral and caudo-medially located forepaw areas. A zone in which cells were unresponsive (UZ) to light cutaneous stimuli was found between the forepaw and vibrissae. Cytoarchitectonically, this zone lacked the thick layer IV, a characteristic of the other SI cortical areas. b) Afferents to forepaw, hindpaw and vibrissae areas of SI were found primarily from cells located ipsilaterally in layers III and V of both SII and MI. Anterogradely filled SI axons to the SII cortex arborized and formed terminals mainly in layers V and III. Only a few cells projecting to SI were found in layers III and V of the contralateral homotopic zones of SI. c) The callosal connections of the UZ were much denser than from any other part of SI. The labeled cells arose mainly from the contralateral homotopic UZ in layers II, III and V. A few retrogradely labeled cells were found in ipsilateral SII and MI in layers III and V. d) Reciprocal connections between SI and MI were identified by injecting HRP in MI and Fast green in SI after electrophysiological identification of similar body parts. e) Cortico-cortical connections between the representations of different body parts in the SI cortex originated from densely filled pyramidal cells located in the lower border of layer III and middle of layer V adjacent to the injection sites.

In summary, the present results indicate that SI predominantly communicates with other cortical areas (MI, SII, contralateral SI) via connections between areas of homotopic body representations. Corito-cortical connections between heterotopic body areas are most strong from adjacent regions within SI.

25.4 COMPARISON OF THE RESPONSES OF NUCLEI RAPHE DORSALIS, MAGNUS, AND OBSCURUS TO SOMATOSENSORY STIMULI. S. Springfield* and G-M Moolenaar, Physiology Dept., Howard Univ. Med. Schl., Washington, DC 20059.

Experiments were done on chloralose-anesthetized cats to 1) discern the differences, if any, in the responses of cells in the rostral raphe (R) nucleus R. dorsalis and the more caudal nuclei, R. magnus and R. obscurus to somatosensory stimuli and 2) to compare their responses to those of reticular formation (RF) neurons. The responses of 230 cells were recorded extracellularly using glass micropipettes filled with 3M NaCl. Stimuli included brief tap, deep muscle pressure, an 80 db click, noxious pinch, cold (ethyl chloride) spray, and heat (test tubes of water heated to 47°C). Brief tap was the most effective stimulus in activating cells in all three nuclei. Like reticular neurons, raphe units had extensive receptive domains which often included both fore-and hindlimbs. Tap applied to the distal forelimb was particularly effective. Furthermore, the responses of R cells became attenuated with increasing stimulus frequency, a second feature in common with RF neurons. Among the nuclei, two major differences were observed. First, while cells which responded to noxious input could be located throughout the R, the majority were observed in R. magnus. These units were often multi-modal, responding to a variety of inputs. Preliminary data suggest a second difference which is related to the rate of spontaneous discharge and responsiveness to sensory input. Slowly firing neurons (<1 Hz), when responsive to stimuli, discharged with one or two spikes. Most of these slowly firing units were found in R. dorsalis. More rapidly firing cells (>10 Hz) were commonly inhibited by the natural stimuli. Duration of inhibition was related to the intensity of the stimulus. Such cells were found throughout R. However, the majority of cells which were excited by sensory input had spontaneous discharge rates between 1-10Hz. These cells responded with a burst whose duration was related to stimulus intensity. Excitation was followed by an intensity-related period of inhibition. Cyclic bursts of activity was seen primarily in R. obscurus. These cells fired in doublets or bursts of 4-6 spikes and could not be driven by somatosensory stimuli. These results suggest strong similarity to RF neurons and suggest, furthermore, a correlation between rate of R unit spontaneous discharge and characteristics of the response to somatosensory stimuli.

25.5 PROJECTIONS OF PERIPHERAL NERVES TO THE CUNEATE NUCLEI OF RATS. C. H. M. Beck, Psychology, University of Alberta, Edmonton, Alberta, Canada, T6G 2E9.

Preliminary to electrophysiological single cell recording from the cuneate nuclei, anatomical maps were constructed of peripheral nerve projections to those nuclei in rats. Horseradish peroxidase (Sigma VI, 30% in Ringer's solution) was injected (.2µl) into the stumps of peripheral nerves distal to the brachial plexus. Survival times ranging from 40 to 48 hours were followed by sectioning of the brainstem, cord and nerves at 33µ and reacting chemically with tetramethylbenzidine.

Injections into median, radial and ulnar nerves cut 1 cm above the elbow revealed that each nerve had a distinct projection zone in the cuneate nuclei. The radial nerve projected quite heavily to the external cuneate and to a narrow band along the dorsal edge of the internal cuneate. The ulnar and median nerves projected mainly to the medial and lateral portions of the internal cuneate ventral to the projection of the radial nerve. Injection into the deep radial and the superficial radial nerves just below the elbow revealed that they contributed to the external and internal cuneate projections respectively of the radial nerve. Reacted ventral horn cells in the most dorso lateral portion of the ventral horn of the spinal cord were apparent after all injections except those of the superficial radial nerve. Reaction particles were visible in the nerve stumps and in the dorsal root ganglia cells of the affected nerves.

25.6 FUNCTIONAL PROPERTIES OF RACCOON CUNEATE NEURONS RESPONDING TO TACTILE STIMULATION OF GLABROUS SKIN. Mark J. Rowinski, John H. Haring*, Susan Warren*, Christine H. Maliniak*, and Benjamin H. Pubols Jr. Department of Anatomy, College of Medicine, Pennsylvania State University, Hershey, PA. 17033.

The functional properties and dorsal column projection of mechanoreceptive afferent fibers innervating the glabrous skin of the raccoon's forepaw have been extensively characterized (Pubols, Pubols & Munger, Exp. Neurol., 1971; Pubols & Pubols, J. Neurophysiol., 1973). The present investigation was undertaken to gain insight into transformations of tactile information occurring in the cuneate nucleus. Unit activity was recorded in 77 neurons in 17 methoxyflurane-anesthetized raccoons. Recording loci were between 1.5 mm rostral and 5.5 mm caudal to the obex, and peripheral receptive fields were located entirely on glabrous skin.

Units were classified according to their response to mechanical stimuli as rapidly adapting (RA), slowly adapting (SA), or Pacinian (Pc). Of those neurons antidromically activated by electrical stimulation of the forepaw region of the contralateral thalamic ventrobasal complex (47% of sample), 19 were RA, 7 were SA, and 10 were Pc. Of those not antidromically activated (53% of sample), 33 were RA, 3 were SA, and 5 were Pc. One unit classed as SA also gave an "off" response, suggesting convergence from primary SA and RA fibers. Still other cuneate units (not included in the above tabulations) had receptive fields spanning both hairy and glabrous skin, indicative of another type of modality convergence.

Receptive field (RF) areas are larger on palmar (range = 11.0-99.2 mm^2) than on digital (range = 1.2-62.2 mm^2) surfaces ($P < .0001$). The median digital RF area (= 7.4 mm^2) is > 40 X that for primary afferents ($P < .0001$), and the palmar median RF area (= 30.3 mm^2) is > 100 X that for primary afferents ($P < .0001$); however, primary afferent RF areas do not differ significantly for those located on digits versus palm ($P = .20$). There is no systematic relationship between RF area and anteroposterior recording locus within the cuneate nucleus ($r = .194$; $P > .20$).

Most cuneate neurons display a resting discharge, typically in the form of bursts of 2-5 spikes, and the major effect of mechanical stimulation is to decrease the interburst interval. The range of absolute displacement thresholds is ≈ 5-250 µm, similar to that for primary afferents. The range of power function exponents relating instantaneous burst frequency to skin displacement velocity = .50-.86 (encompassed by the range of exponents for primary afferent instantaneous spike frequency). Evidence was obtained that repeated mechanical stimulations lead to a decrease in post-stimulus inhibition of resting discharge. (Supported in part by research grant NS-13418, USPHS.)

25.7 CUNEATE NUCLEAR PROJECTIONS TO THE CEREBELLUM AND OTHER REGIONS IN THE RACCOON. Susan Warren*, Mark J. Rowinski, Christine H. Maliniak*, John H. Haring*, and Benjamin H. Pubols Jr. Department of Anatomy, College of Medicine, Pennsylvania State University, Hershey, PA 17033.

Experiments were designed to study the projection of cuneate nucleus neurons to the cerebellum in the raccoon, and to compare this projection with cuneate projections to other regions as previously described by others. The direct axonal trajectories and corresponding terminal fields of cuneate neurons were demonstrated by ^{3}H-leucine autoradiography in four raccoons (4.54-7.10 kg). The subjects were anesthetized with halothane, surgically prepared under sterile conditions, and injected with 0.05-0.20µl of ^{3}H-leucine (50µCi/µl)-saline solution in the rostral or middle region of the main cuneate nucleus. Injection was unilateral in one raccoon and bilateral but asymmetric in the other subjects. Survival periods (2 days or 1 week) and tissue processing followed conventional methods for tritiated amino acid autoradiography.

Neurons of the main cuneate nucleus project to the ipsilateral cerebellum by way of the restiform body. The axons of these neurons follow a trajectory which is predominantly anterior and lateral to the deep cerebellar nuclei, arching dorsomedially toward the medial regions of the anterior lobe. The projection apparently diverges over a wide extent of cortical volume. The primary target areas of the cuneocerebellar axons are lobules III, IV, and V of the anterior lobe. Both superficial and deep cerebellar folia exhibit cuneocerebellar terminations. Evidence was also obtained for termination of fibers in the ipsilateral interposed and lateral nuclei.

Cuneate neurons projecting to the cerebellum in the raccoon are intermingled with neurons which project to brain stem and diencephalic structures such as the inferior olivary complex, red nucleus, zona incerta, and thalamic ventrobasal, posterior, and magnocellular medial geniculate cellular aggregates. Injections which moderately label the cuneocerebellar projection result in a very strong projection to the contralateral thalamus, moderate projection to the ipsilateral inferior olive, and weak projection to the contralateral red nucleus. The cuneate nucleus rostral to the obex appears to be the most potent source of cuneocerebellar axons since minimal injections in this region produce labelling comparable to that seen in cases of maximal injection in the middle region (obex to 3 mm caudal). This finding is consistent with physiological studies of the incidence of antidromically activated cuneocerebellar neurons throughout the rostral and middle nuclear regions in the raccoon. (Supported in part by research grant NS 13418, USPHS.)

25.8 MECHANOSENSORY PROJECTIONS TO DORSAL COLUMN NUCLEI IN A TREE SQUIRREL (FOX SQUIRREL, SCIURUS NIGER). E. M. Ostapoff* and J. I. Johnson. Neuroscience Program and Psychology, Biophysics and Zoology Depts., Michigan State Univ., East Lansing, MI 48824.

Our purpose is to compare the distribution and organization of mechanosensory projections to three pairs of dorsal column nuclei (cuneate, gracile and external cuneate) in an arboreal jumping rodent, with those previously determined for an arboreal marsupial (American opossum) and an arboreal carnivore (raccoon). Micromapping procedures were used to record unit and unit cluster activity with tungsten microelectrodes in squirrels anesthetized by means of ketamine followed by equithesin. Electrode penetrations were spaced at intervals of 200-500 µm forming mediolateral rows traversing all three nuclei in transverse planes. Rows were placed to sample rostral, caudal, and central (near the obex) regions of the nuclei. The locations of rows and penetrations were verified in Nissl-stained sections of the experimental brains. These preliminary conclusions are based on 130 responsive loci in 63 penetrations in four wild-caught squirrels.

In fox squirrels the three nuclei appear to be about the same size, with the gracile and external cuneate slightly smaller than the cuneate nucleus in cross-sectional extent and total volume. Most responses in the external cuneate were evoked by stimulation of deep-lying tissues or moving joints in the hand or forelimb, although a few responses were found to cutaneous or hair stimulation. Most responses in the gracile nucleus were to hair and cutaneous stimulation of the tail, hind foot and leg, and trunk, in that order going dorsoventrally in the nucleus, but some responses were to deep or movement stimulation. A similar distribution of responses was found in the cuneate to stimulation of hand, forelimb and neck. The pattern of projections in fox squirrels differed most strikingly from that seen in raccoons and opossums, in the relatively small extent and number of projections from the glabrous skin on the volar and plantar surfaces of the hands and feet. These surfaces provide a majority of projections to these nuclear regions in opossums and raccoons, but their representation is small in our squirrels: 10 of the total of 25 activating loci on the hand from a total of 72 on the forelimb; and 3 from a total of 15 from the hindlimb. In squirrels projections from hairy receptive fields were especially frequent: 33 on the forelimb including 9 on the hand of a total of 72; 9 of 15 on the hindlimb, and 11 of 18 on the trunk. (Supported by NSF grant BNS-7903421).

25.9 QUANTITATIVE EM ANALYSIS OF THE NORMAL SYNAPTIC ORGANIZATION OF THE RACCOON CUNEATE NUCLEUS. B.C. Albright. Dept. of Anatomy, Med. Sch., Univ. of North Dakota, Grand Forks, N.D. 58202.

The synaptic organization of the cuneate nucleus was studied in the cell nest or column region in a 2 mm area immediately caudal to the obex. Tissue blocks were not oriented in any particular plane and sections were collected from a variety of levels throughout the blocks. A random sampling procedure was used in the selection of grids, sections and micrographs. Quantitative methods involved the computer assisted direct measurement of the area, perimetry and length of identified neuronal profiles from micrographs. Only those profiles that were observed to related synaptically to one another by the presence of a distinct synaptic site were studied. Eighty-five percent of all measured axon terminals were axodendritic, 13% were axoaxonic and 2% axosomatic. Sixty-five percent of the axodendritic terminals synapsed on a single dendritic profile. These terminals contained either spherical, flat or pleomorphic vesicles and averaged 1.64 μm^2 in area. The associated dendritic profiles averaged 3.1 μm^2 in area. A one to one relationship between axon and dendritic profiles existed in 34% of the cases. Another major category of axodendritic terminals included those which were presynaptic to two or more dendritic elements. These averaged 4.3 μm^2 in area and were often postsynaptic (48%) to a smaller axon profile. They were presynaptic to an average of 4 dendritic profiles which had a mean area of 2.57 μm^2. More than half of these dendritic profiles were also related synaptically to other axon terminals. The axoaxonic terminals involved in these complexes averaged .8 μm^2 in area and primarily contained either flat or pleomorphic vesicles. One-third of these axoaxonic profiles were also in an axodendritic position. Some of the dendritic profiles of these terminals received synaptic input from the larger axonal postsynaptic component of the axoaxonic complex. These terminals therefore possess both axonic and dendritic terminations and may modulate dendritic activity either directly or indirectly in a preinhibitory manner. Axon terminals on dendritic spines accounted for 2% of the axodendritic terminals and averaged .8 μm^2 in area. Associated dendritic spines averaged 2.3 μm in length. Axosomatic profiles accounted for 2% of all terminals studied. They averaged 1.27 μm^2 in area and contained either spherical, flat or pleomorphic vesicles. The results of this study will be discussed relative to other cytoarchitectural and degeneration studies in the raccoon dorsal column nuclei.

Supported by NSF Grant BNS-7903421.

25.10 PROJECTIONS FROM DENTAL STRUCTURES TO THE BRAIN STEM TRIGEMINAL COMPLEX: TRANSGANGLIONIC HRP TRANSPORT. L. E. Westrum, R. C. Canfield* and T.A. O'Connor*. Departments of Neurological Surgery and Biological Structure and Department of Restorative Dentistry, University of Washington, Seattle, WA 98195.

There has been a recent increased interest in the trigeminal primary afferents from teeth and periodontal structures to the brain stem. The precise CNS representation for these structures, however, continues to be controversial. We are using transganglionic neuronal transport methods in an attempt to delineate these various pathways and to test our previous observations using degeneration techniques following pulpectomies or tooth extractions. Horseradish peroxidase (HRP), both crystals and a 30% solution in 2% DMSO, was deposited in pulpal chambers of 10 adult cats, either as single or repeated applications. Thus far emphasis has been directed towards projections from single maxillary canines, but additional experiments are underway or planned for other teeth. Following survival times of 2-5 days the animals are reanesthetized, perfused and the tissues processed by the TMB method of Mesulam or with diamino benzidine. HRP-positive fibers enter the ipsilateral ganglion, where numerous cells are labeled, then fibers pass through the central root, enter the spinal tract and are distributed variably to each of the ipsilateral subnuclei. For maxillary canines the terminal distribution is greatest to the dorsal division of the main sensory nucleus, adjacent pars oralis, to pars interpolaris near obex and diminishes in pars caudalis. The pattern is variable but is rather extensive in the dorsoventral and mediolateral distributions. Fibers and terminal granules are distributed through broad regions of each nucleus, except for pars caudalis, with clusters of granules ventrally, medially and especially in the dorsal 1/3 of the nucleus. In pars caudalis, there is a distribution to the middorsal superficial layers, including substantia gelatinosa. A few fibers are also seen passing medially beyond the nucleus into the reticular formation, but no obvious crossing fibers could be identified. The results suggest a more extensive ipsilateral CNS representation for some dental structures than previously indicated corresponding well with certain physiological studies, but the reduced termination in pars caudalis and apparent absence of contralateral pathways are at variance with other studies. Supported by NIH grants DE-04942, NS-09678 and NS-04053. Dr. Westrum is an Affiliate of the CDMRC at the University of Washington.

25.11 CENTRAL PROJECTIONS OF PRIMARY AFFERENT BRANCHES OF THE OPHTHALMIC DIVISION OF TRIGEMINAL NERVE IN THE CAT. W.M. Panneton and H. Burton. Dept. Anat/Neurobiol., Wash. Univ. School of Med., St. Louis, MO 63110

The transganglionic transport of horseradish peroxidase (HRP) was utilized to investigate the central projections of branches of the ophthalmic division of the trigeminal nerve (V_1), including the innervation of the cornea. The frontal, lacrimal, and infratrochlear nerves were isolated, transected and soaked in a 50% HRP solution. Corneal experiments involved injection of the HRP solution into the corneal stroma. After 48-72 hours, the animals were sacrificed and serial sections through the brainstem were processed using tetramethylbenzidine as the chromagen.

Results show that all branches of V_1 distribute processes throughout the longitudinal extent of the ipsilateral trigeminal sensory complex, including the principle nucleus and subnuclei of the spinal nucleus. The centripetal transport of HRP within all branches of V_1, including those that innervate the cornea, was confined primarily to the most ventral parts of the principle nucleus and subnucleus oralis except at levels of the trigeminal motor nucleus where label extended along the lateral border of the principle nucleus. HRP also was transported to ventral parts of subnucleus interpolaris where a topography was apparent, e.g., peripheral fields innervated by the lacrimal, frontal and infratrochlear nerves were represented in lateral, intermediate, and medial positions, respectively, while the cornea was represented most ventrally. A topography of V_1 was especially evident within the intermediate laminae of subnucleus caudalis. In the rostral to caudal direction our results show that the nerve innervating the most anterior receptive fields, the infratrochlear, distributes to laminae II-IV approximately 1.5-3.2 mm caudal to the obex while progressively more posterior fields are represented more caudally (e.g., cornea, 2.2-4.2 mm; frontal, 2.4-6.3 mm; and lacrimal 3.7-8.0 mm). Where the respective distributions of the V_1 branches overlap in the rostro-caudal dimension, topographical segregation is maintained about the medial-lateral radius of the nucleus. In contrast, cases indicated considerable overlap in the distribution of HRP to laminae I and V and label could be found from levels near the obex through at least the first cervical segment.

The central processes of the nerves studied were distributed to all laminae of subnucleus caudalis. However, the infratrochlear had a denser projection to lamina I when compared to the frontal and lacrimal nerves. Corneal cases also resulted in intense staining of lamina I but showed a preferential distribution of label to lamina II. (Supported by NINCDS grants NS09809 and T32-NS07071.

25.12 CENTRAL CONNECTIONS OF THE INFERIOR ALVEOLAR NERVE IN THE CAT AS DETERMINED BY THE HORSERADISH PEROXIDASE (HRP) TECHNIQUE. Carl Marfurt* and Jan Arvidsson* (SPON: J. Way). Department of Anatomy, Hershey Medical Center, Hershey, PA 17033, and Department of Anatomy Karolinska Institutet, S-10401 Stockholm, Sweden.

Previous horseradish peroxidase and transganglionic degeneration studies in our laboratories have demonstrated a somatotopical projection of cutaneous primary trigeminal sensory neurons onto the trigeminal brain stem sensory complex in cats and rats. The current investigation was undertaken to extend these observations by identifying the pattern of central termination of primary trigeminal afferent neurons whose peripheral processes distribute through the inferior alveolar nerve.

In 6 adult cats, the inferior alveolar nerve was transected and anchored in microtubing filled with a 50% solution of HRP in saline. Forty-eight to ninety-six hours postoperatively, the brain stem and trigeminal ganglia were perfusion fixed, sectioned, and reacted with tetramethyl benzidine. HRP labeled neuronal cell bodies, 15 to 85 microns in diameter, were observed throughout the posterolateral region of the ipsilateral trigeminal ganglion. Labeled central processes of these neurons terminated in the dorsal 1/4 to 2/5 of the ipsilateral trigeminal brain stem sensory complex. Terminals were most numerous in the trigeminal main sensory nucleus (MSN) and appeared to decrease slightly in caudal direction through the spinal nucleus of V. Heavy labeling extended into the most rostral and dorsomedial pole of MSN. Occasional fibers approached, but did not enter the solitary nucleus. Labeling was heavy in all laminae of pars caudalis and extended well into the subjacent reticular formation (lamina V). Terminals were somatotopically localized in the dorsomedial region of caudalis, with the exception of a prominent plexus of lamina I fibers which arched laterally into maxillary and even ophthalmic division territory. Fibers which descended into the upper cervical spinal cord terminated only in laminae I and V. Occassional fibers passed through the dorsal commisure at the levels of C1 and C2 to terminate in the contralateral dorsal horn.

Numerous large-diameter fibers, presumably conducting proprioceptive information from the periodontal ligaments, entered the mesencephalic tract of V. Labeled cell bodies of origin were distributed throughout the rostrocaudal extent of the ipsilateral mesencephalic nucleus. Labeled central processes of these cells projected to the cerebellum by way of the superior cerebellar peduncle and to the inferior and superior colliculi. No fibers were seen to project to the thalamus or the motor nucleus of V.

25.13 AN HRP STUDY OF THE COURSE AND TERMINATION OF THE SPINAL TRIGEMINAL TRACT AND CONVERGENCE WITH CERVICAL PRIMARY AFFERENTS IN RAT. R. W. Pacholka*, R. M. Beecher*, C. H. Phelps, B. A. Fisher*, and J. C. Pearson* (SPON: G. Crampton). Dept. of Anatomy, Wright State Univ. Sch. of Med., Dayton, Ohio 45435.

Myofacial pain dysfunction, in humans, involves perception of pain at several points in the face and neck, although pain typically originates in the muscles overlying the temporomandibular joint (TMJ). The neuroanatomical basis for this referred pain has not been previously described. The purpose of this study was to trace primary afferents in rat from sites known to be involved in the pain syndrome; i.e., masseter superficial to the TMJ and the sternocleidomastoid. Projections from these areas were traced using horseradish peroxidase (Sigma VI, 16% solution) dissolved in a dimethylsulfoxide/physiological saline solution with tetramethylbenzidine utilized as a chromagen. Following a survival time of 24 hours the animals were perfused and the tissues prepared for light microscopy. Retrograde transport from the masseteric injection site resulted in densely labeled cell bodies in the ipsilateral Gasserian ganglion. Anterograde transport to the ipsilateral brain stem and spinal cord resulted in dense labeling of the spinal trigeminal tract (STT) which was shown to extend caudally to the C-3 level. Projections from the sternocleidomastoid were visualized entering the cord at the C-2 level, bifurcating into ascending and descending branches and becoming coincident with the STT. Fibers from this tract were observed to terminate in the nucleus caudalis and substantia gelatinosa at the C-3 level.

25.14 GOLGI STUDIES OF INTERNEURONS AND INTERNUCLEAR PROJECTION NEURONS IN THE VENTROLATERAL SUBDIVISION OF TRIGEMINAL NUCLEUS ORALIS. W.M. Falls and J. King*. Dept. of Anatomy, Michigan State Univ., East Lansing, MI. 48824.

Trigeminal nucleus oralis (TNO) at the upper end of the spinal trigeminal nucleus (SVN) can be divided into dorsomedial, intermediate and ventrolateral (VL) subdivisions in the adult rat. These three subdivisions extend the entire length of TNO and are distinguished by morphological differences in the texture of their neuropil, as revealed in 1µm sections and electron micrographs and by the morphology and distribution of the axons and dendrites of their neurons as seen in Golgi preparations. The VL neuropil consists of multiple neuronal cell types squeezed between numerous tightly packed deep axon bundles which run longitudinally through the entire SVN. Among these cell types are Golgi type II interneurons, i.e. neurons whose unmyelinated axons arborize within or near their dendritic arbors and internuclear projection neurons whose axons via the deep bundles link up different levels of SVN.

Golgi type II interneurons are found in small clusters throughout VL. Their cell bodies (9 - 14µm in diameter) give rise to dendritic arbors which extend 300-500µm in the rostrocaudal axis and are generally confined to the subdivision. The unmyelinated axons generate highly branched axonal arbors which more or less overlap the dendritic arbors. Some axonal branches extend at least 150µm beyond the dendritic arbors in the rostrocaudal axis. These neurons are similar to islet cells in the substantia gelatinosa (Gobel, S., J. Comp. Neur., 162:397, 1974) and are considered to be inhibitory interneurons interposed between primary trigeminal axons which arborize in VL and second order projection neurons.

Small internuclear projection neurons with cell bodies ranging from 8-10µm in diameter, are found in large numbers throughout VL. Their dendritic trees occupy spherical or elliptical domains up to 300µm in diameter and are usually confined to VL. The unmyelinated axons of many of these cells arise either directly from the cell body or from a primary dendrite and give rise to a single collateral 15-30µm from their site of origin. This collateral generates a fine axonal plexus within the dendritic arbor of the parent cell while the parent axon, without branching further, travels a short distance in VL and enters a deep axon bundle. On the basis of axonal morphology these neurons are thought to function not only as internuclear projection neurons, modifying the output of neurons at other levels of SVN, but also as intranuclear interneurons involved in local circuits in VL. Supported by General Research Support Grant to the College of Osteopathic Medicine, M.S.U.

25.15 FURTHER OBSERVATIONS ON STIMULUS-RESPONSE RELATIONSHIPS OF VIBRISSA-ACTIVATED NEURONS IN NUCLEI ORALIS AND INTERPOLARIS IN THE RAT. John M. Gibson and Wally I. Welker, Department of Neurophysiology, University of Wisconsin, Madison, Wisconsin, 53706, USA.

We have demonstrated significant quantitative differences in stimulus-response relationships of neurons of the oral and interpolar divisions of the spinal trigeminal nucleus (Gibson, et al., Neurosci. Abstr. 5:707, 1979). In this report, we will present additional evidence for differential specialization of these trigeminal nuclei.

Single-unit action potentials were recorded extracellularly with tungsten microelectrodes in the trigeminal complex of barbiturate-anesthetized albino rats. Stimuli consisted of quantitatively-controlled deflections of single mystacial vibrissae in the unit's "preferred" (maximally activating) direction. Data were recorded digitally as spike discharge times with a resolution of 0.1 msec. These data were subjected to a variety of quantitative analytic procedures.

In both oralis and interpolaris, about half the more slowly adapting units were capable of discharging 10 seconds or more in response to a 7-degree step deflection. The regularity of discharge of these units was not significantly different for the two samples, nor was there evidence for two distinct subpopulations in either sample.

The "average" neuron of oralis responds to a given stimulus with significantly more spikes than the "average" neuron of interpolaris. This is true for static deflection (step function), constant angular velocity deflection (ramp) and for impulsive deflection (pulse).

Intensity functions (spikes per trial as a function of stimulus amplitude) for all first order neurons were monotonically increasing, and generally had a a "staircase" shape. In contrast, about one-fourth of the neurons recorded from oralis and interpolaris had nonmonotonic pulse intensity functions. In the extreme case, a few neurons of interpolaris were found to cease firing completely at some suprathreshold amplitude. These nonmonotonic units had an interesting cluster of properties, generally being more rapidly adapting, having low thresholds, and having multiple-vibrissa receptive fields. However, population intensity functions (total spikes in all units as a function of stimulus amplitude) were all smooth and monotonic. The curve for oralis lies above that for interpolaris, which lies, in turn, above that for the first-order units.

25.16 Electrophysiological Studies on the Spinothalamic Tract of the Cat.
J. R. Maddox* and J. A. Holloway. Dept. of Physiol. Biophys., Coll. Med., Howard Univ., Wash., D. C. 20059

Microelectrode recordings were obtained from spinothalamic tract (STT) neurons in the lumbosacral spinal cord of adult cats anesthetized with chloralose, paralyzed with gallamine triethiodide, and artificially ventilated. Recording electrodes contained 3M KCl saturated with fast green dye. Units were identified as cells of origin of the STT if they could be activated antidromically by thalamic stimulation, responding with fixed latencies to paired stimuli (2 msec separation) and short trains (< 200 uA, 0.2 msec duration) of high frequency stimuli (200-500Hz). Collision of antidromic and orthodromic action potentials was used as final confirmation of STT recording. Recording sites were verified histologically in 30um frozen formalin-fixed cord sections. STT neurons were excited by mechanical stimulation of one or more hind limbs. Sixty percent were activated by light tactile stimuli; forty percent were activated by firm manipulation of deep tissue within the thigh region. The peripheral receptive fields (RF) of the units were fully analyzed. Forty percent of the units responding to light touch of the hind paw possessed contralateral RFs. Twenty percent of the units had ipsilateral cutaneous fields which were excited by light tactile stimuli of the entire hind limb. Also, twenty percent of units in this study possessed bilateral RFs. The vast majority of STT neurons recorded were located in Rexed's lamina VII of the spinal cord gray matter. The estimated mean conduction velocity was 12 m. sec^{-1} (range 5-20 m. sec^{-1}). None of the units were excited by noxious mechanical or noxious thermal stimulation of the skin. These preliminary results suggest that the majority of spinothalamic tract neurons respond primarily to mechanical stimuli, and that some of these neurons may project to the thalamus ipsilaterally.

25.17 RESPONSE PROFILES OF INTERPOLARIS NEURONS PROJECTING TO THE CEREBELLUM AND THE VENTROBASAL THALAMUS IN THE RAT. D. C. Woolston☆, J. M. Gibson and W. I. Welker. Dept. of Neurophysiology, University of Wisconsin, Madison, WI 53706.

Horseradish peroxidase studies have shown that the interpolaris (IP) region of the medullary trigeminal complex projects heavily to both the cerebellum (C) and the ventrobasal thalamus (VB) (Watson, C. and Switzer, R., Neurosci. Let., 10:77, 1978; Fukishima, T. and Kerr, F., J. comp. Neur. 183:169,1979). We are determining, using a battery of precisely-controlled quantitative tactile stimuli, the response profiles of vibrissae-activated single neurons in IP that are driven antidromically by electrical stimulation of either VB or the uvular (folium 9A) tactile area of the cerebellum. Female Holtzman rats anesthetized with sodium pentobarbital served as subjects.

Major results of our study to date include:

1) No neurons were activated antidromically from both C and VB.
2) Although half the sampled neurons had single vibrissa receptive fields (RF'S), as was the case in a previous sample of IP neurons (Gibson, J. et al., Neurosci. Abst. 5:707, 1979), none of these neurons with punctate receptive fields were found to project to C or VB. C- and VB-projecting neurons had larger RF's (5 vibrissae median).
3) Median amplitude thresholds were very low for both C-projecting (0.07°) and VB-projecting neurons (0.06°), compared to the median for Gibson's sample of all IP neurons (0.37°).
4) C-projecting neurons had a somewhat lower median velocity threshold (2.86°/sec) than VB-projecting neurons (10.02°/sec). The median velocity threshold for Gibson's sample of all IP neurons was higher (22.0°/sec).
5) Most C- and VB-projecting neurons had nonmonotonically increasing responses to increasing deflection amplitudes.
6) Nearly all C-projecting and VB-projecting neurons adapted rapidly (within 100 msec) to a sustained deflection of 7.2°.

In summary, little difference between C-projecting and VB-projecting neurons has been found to date. However, the sample of projection neurons differs in several respects from Gibson's sample of all IP neurons, which we assume included interneurons and neurons which projected to CNS loci other than C and VB. The projection neurons' large RF's and nonmonotonic responses to increasing amplitudes suggest that extensive intranuclear processing occurs in IP.

25.18 ORIGIN, COURSE, AND TERMINATION OF TRIGEMINOTHALAMIC PROJECTIONS IN THE OPOSSUM. Ross J. Kosinski* and James C. Hazlett (SPON: A. Castro). Dept. of Anatomy, Loyola Univ. Stritch Sch. of Med., Maywood, Il 60153.

Trigeminothalamic connections were studied utilizing orthograde and retrograde axon transport techniques. HRP injections centered in the ventral basal complex resulted in dense retrograde neuronal labelling in both subdivisions of the contralateral chief sensory nucleus with intermittent labelling throughout all levels of the corresponding spinal trigeminal nucleus. In the subnucleus caudalis, labelled cells were located predominately in the marginal and magnocellular layers and to a lesser extent in the substantia gelatinosa and paratrigeminal nucleus. These results are in essential agreement with a recent report by Stritzel et al.,'80. Interestingly, a few reactive neurons were observed throughout the trigeminal complex ipsilateral to the injection. With a few notable exceptions, similar results were obtained following HRP injections centered in the parafascicular complex. The major differences are:1.the apparent absence of retrograde labelling in the ventral subdivision of the contralateral chief sensory nucleus;2.a marked reduction of reactive neurons in the marginal layer of the subnucleus caudalis and 3.an overall decrease in the number of retrogradely labelled neurons in those areas giving rise to thalamic afferents. The course and termination of the trigeminothalamic projections emanating from both the chief sensory nucleus and the subnucleus caudalis were studied utilizing the orthograde transport of ^{3}H-leucine. In both series of injections, the main bundle of labelled axons coursed rostrally through the brainstem in association with the contralateral medial lemniscus. From this location, fibers were observed to distribute to various brainstem centers. The ultimate target of these ascending projections was identified as the dorsal portion of the contralateral ventral basal complex. As expected, the orthograde labelling was always more extensive in this nucleus after the chief sensory nucleus injections. Additional sites of termination included the contralateral parafascicular complex and zona incerta.

(Supported by National Science Foundation NO.BNS 79-14072).

25.19 TRIGEMINOTECTAL PROJECTIONS IN THE RAT. R.S. Erzurumlu* and H.P. Killackey. (SPON: J.E. Swett). Dept. of Psychobiology, Univ. of Calif., Irvine 92717.

The projections from the brainstem trigeminal complex to the superior colliculus were studied using anterograde degeneration and horseradish peroxidase (HRP) retrograde labeling techniques.

Tectal projections from the brainstem trigeminal complex arise from the contralateral principal sensory nucleus and the subnuclei oralis and interpolaris of the spinal trigeminal nucleus. Tectal fibers from all three nuclei collect in the trigeminal lemniscus after crossing the midline at successive levels of the brainstem. In the rostral pons, these fibers leave the trigeminal lemniscus and ascend towards the superior colliculus which they reach inferolaterally. The terminal fields of trigeminal projections, originating from different portions of the brainstem trigeminal complex overlap in the superior colliculus. In most cases the terminal fields are confined to the stratum griseum profundum and the stratum album intermediale. The exception is the interpolaris projections, which are the heaviest and often extend into the deep portions of the stratum griseum intermediale. In general, the trigeminotectal terminal fields occupy the entire lateral portion of the superior colliculus along its rostrocaudal extent.

Following an injection of HRP into the superior colliculus, cells of origin of the trigeminotectal projections can be identified. In the principal nucleus and the subnucleus oralis they are confined to the ventral portions of these cell groups. Labeled cells in the principal nucleus, while few in number, are the largest cells in this nucleus and are easily distinguished from the thalamic projection cells. The labeled cells in oralis are polygonal in shape and are the largest in the entire trigeminal complex. After superior colliculus injections of HRP, the majority of labeled cells are found in the subnucleus interpolaris. These cells are dispersed throughout the nucleus. At the caudal and rostral poles of the nucleus the labeled cells are small and medium in size, but the majority of labeled cells which lie between the two poles of interpolaris are large in size and polygonal in shape. Further, these labeled cells look similar to the thalamic projection cells of this nucleus.

Based on this similarity and the finding of anterograde label in the ventrobasal complex after collicular HRP injections, we conclude that the same cell of interpolaris projects to both thalamus and superior colliculus, whereas different cells project to these two targets from the principal nucleus.

(Research supported by NSF Grant #BNS74-00626.)

25.20 CORTICAL PROJECTIONS TO THE SPINAL TRIGEMINAL NUCLEUS IN THE ADULT CAT. Dunn, R.C., Jr., Tolbert, D.L. Departments of Neurosurgery and Anatomy, St. Louis University School of Medicine, St. Louis, MO 63104.

As background for a developmental study of the corticotrigeminal projection in kittens, a correlative light and electron microscopic analysis of this pathway has been undertaken in adult cats. In some animals unilateral cortical ablations of the coronal and/or proreate gyri were performed. After survival periods of 3-21 days, sections through the spinal trigeminal complex from 3 mm caudal to 6 mm rostral to the obex were examined using silver impregnation techniques and electron microscopy. In other animals combined ^{3}H-leucine and proline injections were made into the same cortical areas. Following survival periods of 5-7 days, tissue from the spinal trigeminal complex was processed for autoradiography.

Data from the light microscopic studies indicate that corticotrigeminal fibers exit dorsally from the ipsilateral pyramid, cross the midline and enter the spinal nucleus of V from its ventromedial aspect. The degeneration and orthograde labeling techniques demonstrate similar terminal fields which are mainly within the contralateral spinal trigeminal nucleus. In subnucleus caudalis these afferents are localized primarily in the ventral magnocellular layer and in the inner zone of the substantia gelatinosa. In subnuclei interpolaris and oralis these cortical projections occupy a lateral position immediately adjacent to the spinal trigeminal tract.

The electron microscopic data confirm the light microscopic impression that the corticotrigeminal fibers are small axons. These axons are thinly myelinated and measure 0.8-1.6 μm in diameter. Corticotrigeminal terminals appear widely dispersed within the spinal trigeminal nucleus. They are small boutons containing round vesicles that form asymmetric synaptic contacts onto small dendritic profiles. Both electron-dense and vesicle depleted electron-lucent terminals have been identified.

Previous studies by Wold and Brodal (Neurobiol. 3:353, 1973; Brain Res., 65:381, 1974) described substantial differences in the spinal trigeminal projections arising from the proreate and coronal gyri. In contrast to the coronal projection, that from the proreate was characterized as sparse, purely contralateral and entering the nucleus through the spinal trigeminal tract. Our data, however, indicate: (1) the proreate and coronal spinal trigeminal projections appear similar in density and distribution; (2) both projections gain access to the spinal nucleus from the contralateral pyramid; (3) both are predominantly contralateral.

Supported by USPHS grant no. 1 R01 NS 15622-01.

25.21 CORRESPONDENCE BETWEEN PATTERNS OF SOMATOSENSORY RECEPTIVE FIELD (RF) PROJECTIONS AND MUSCLE-MOVEMENT FIELDS (MMF's) EVOKED FROM WITHIN THE TRIGEMINAL (Tr) NUCLEAR COMPLEX. G.M. Shambes and Wally Welker. Department of Neurophysiology, University of Wisconsin, Madison, WI 53706.

The trigeminal nuclear complex (Tr) is a major mediator of exteroceptive reflexes associated with head, face and perioral structures. It is also a mediator of head, oral and facial movements initiated from central motor circuits. Peripheral tactile projections to Tr are organized somatotopically within all its subnuclei. This study was designed to determine whether (a) the motor projections (via motor V and VII) are also organized somatotopically and (b) the motor output patterns are topographically related to the tactile input patterns. Nine albino rats were anesthetized with either pentobarbital or ketamine hydrochloride. Patterns of projection of tactile RF's to Principalis (P), Oralis (O), Interpolaris (I), and Caudalis (C) subnuclei of Tr were determined by using systematic micromapping sampling methods and threshold natural stimulation of oral, facial and head structures. Tungsten ball microelectrodes were used to record single-unit or multiple-unit responses. After defining the RF for each recording location, the electrode was switched to stimulus mode to electrically stimulate the same locus, and the muscle-movement field (MMF - the muscle or body structure moved) was determined. This paired recording-stimulating procedure was carried out for every electrode locus. Electrical stimulus parameters: 100 μsec pulses (biphasic, balanced polarity, 2/sec). RF's, puncture depths, threshold stimulus voltages and MMF's were recorded for each puncture site. Results: (1) Threshold oral-facial tactile projections to P,O,I,C were somatotopically organized; (2)Threshold electrical stimulation (10-50 μA) of these same oral-facial projection sites evoked ipsilateral vibrissal movements, jaw opening and closing, ear protraction, eye opening and closing, dilation of the nares, and retraction of upper and lower lips; (3) There was partial or complete correspondence of RF's and MMF's for 74% of the 200 recording-stimulating loci studied, e.g. when a vibrissal RF projection site in P,O,I,C was stimulated, a movement of the same peripheral vibrissal region was elicited; (4) Although RF's and MMF's were different in 26% of the loci, they seem related in some adaptive way, e.g. stimulation of an upper incisor site in Tr elicited jaw opening movements. The sensorimotor correspondences and organizational specificity discovered in Tr suggests that it is a basic integrating component for simple local reflexes as well as for more complex specialized facial behaviors involving cerebral, brainstem and cerebellar circuits connected to it. (Supported by NSF Grant BNS-16230)

25.22 SOMATIC PROJECTIONS TO SUPERIOR AND INFERIOR COLLICULUS: AN HYPOTHESIS CONCERNING SENSORIMOTOR INTEGRATION. Martine RoBards, Mark Stritzel*, and Richard T. Robertson, Department of Anatomy, College of Medicine, University of California, Irvine, 92717.

Investigations of the somatic-recipient part of the superior colliculus have shown that the trigeminal representation in the deep layers is somatotopic and comprises a facial "hemisphere" which lies in dramatic correspondence with the hemisphere of visual receptive fields of cells in the overlying visual stratum. This laminar assembly of visual and somatic afferents serves to anchor the visual world to "head space."

In apparent contrast with the somatic projection to superior colliculus, the somatic-recipient inferior colliculus (external and intercollicular nuclei) shows a mosaic of spinal and dorsal column-mediated somatic afferents which defy description along traditional somatotopic lines. Acoustically sensitive cells in these nuclei have also been difficult to understand, since they show little resemblance to the frequency-specific, tightly tuned cells characteristic of the central nucleus.

Our analysis of the afferent and efferent organization of the somatic-recipient midbrain of opossum and rat, using HRP and fluorescent retrograde methods, and degeneration and autoradiographic anterograde techniques, has shown: (1) almost all hindbrain somatic cells projecting to superior colliculus arise from the trigeminal complex and the dorsal forepaw and preaxial forelimb portion of the cuneate nucleus--the frontal 180° of personal space for a four-legged animal--while dorsal column nuclei efferents representing the caudal 180° account for most somatic projections to the inferior colliculus; (2) some somatic cells projecting to midbrain also project to thalamus; (3) dorsal column nucleus cells projecting to midbrain both resemble and lie among muscle afferent-activated cells and cells projecting to cerebellum; (4) the rostral cuneo-trigeminal confluence projects widely to midbrain, as well as to thalamus and cerebellum, and may represent a special nucleus controlling neck movements; and (5) the external nucleus projects to somatic-recipient superior colliculus, providing auditory information and somatic information from spinal levels to the tectal motor cells (where other auditory and direct spinal projections also converge).

The apparent lack of somatotopy and frequency specificity in external nucleus cells may reflect an economical collapsing of sensory information--orthogonal to frequency, only roughly correlated with somatotopy--onto a map of personal space which makes most sense from the motor perspective. Thus, in turning to orient to an event behind him, an animal's initial trunk and neck movements require only crude information about the locus of the stimulus. Final orientation, in frontal body space, requires increasingly more precise sensory information and refined movements. NSF#BNS7825744

25.23 EVIDENCE FOR TWO TYPES OF THALAMOCORTICAL RELAY CELLS IN THE VENTRAL POSTERIOR LATERAL NUCLEUS (VPL) OF THE OPOSSUM (DIDELPHIS VIRGIANA). John C. Pearson* and Maria Regina Coccia* (SPON: H. Davis). Dept. of Anatomy, Wright State University, School of Medicine, Dayton, OH 45435.

Golgi analyses of the lateral geniculate nucleus (LGN) in rat, cat, and primate have described two kinds of geniculocortical relay cells (classes 1 and 2) distinguished primarily by the presence or absence of appendage clusters located at primary dendritic branch points. Primary branch points of class 1 cells are free of appendages; whereas, those of class 2 cells contain clusters of small excresences. EM and physiological studies indicate that the synaptology associated with the clusters of appendages may provide for a functional difference between these two relay cell types in cat LGN. Golgi analyses of the ventral posterior lateral nucleus (VPL) are mostly limited to rat, cat, mouse and rabbit, and describe only one class of thalamocortical relay neuron (the bush cell) which contains neurons similar in morphology to class 1 cells in LGN. However, a recent study of VPL in a prosimian primate (Galago) described two types of relay cells which are similar to the two classes described in LGN. In view of the functional importance recently associated with class 2 cell appendage clusters and evidence that relay cells containing these clusters are present in VPL of a primate, a reinvestigation of cell types in VPL of non-primate mammals was initiated. In the present study, the zinc chromate and Kopsch modifications of the Golgi technique were utilized to study the morphology of cells in the VPL of five adult opossoms. Two types of relay neurons are described (type 1 and type 2 cells). Type 1 neurons have multiangular somata and primary dendritic branch points which are free of appendage clusters of any kind; whereas, type 2 neurons have more rounded cell bodies and many appendages of various shapes and sizes located at or near the point at which the primary dendrites branch in a tufted fashion. The distal dendrites of both cell types contain numerous, small appendages which are either "bump-like" in nature, contain small spherical terminals, or appear as inverted drumsticks.

26.1 CHOLINERGIC SLOW POTENTIALS INFLUENCE PARASYMPATHETIC GANGLIONIC TRANSMISSION. William H. Griffith, III, Joel P. Gallagher and Patricia Shinnick-Gallagher. Dept. of Pharmacol. and Toxicol., Univ. of Texas Med. Br., Galveston, TX 77550.

We have previously reported the existence of slow synaptic potentials in mammalian parasympathetic neurons. These potentials occur after nicotinic receptor blockade (hexamethonium, $5x10^{-4}$M) and repetitive preganglionic nerve stimulation (30-40 Hz for 1 sec). We now demonstrate how these slow potentials can alter ganglionic transmission.

Cat vesical pelvic ganglia (VPG) and conventional intracellular techniques were used for in vitro recording.

The nerve evoked slow potentials consisted of only a slow inhibitory post synaptic potential (S-IPSP) in 48% of the cells (N=145). Both a S-IPSP and a slow excitatory post synaptic potential (S-EPSP) occurred in 31% of the neurons. Only a S-EPSP was recorded in 13% of the cells. No slow potentials were found in the remaining 8% of the cells. All of these slow potentials could be mimicked by either iontophoretic application of acetylcholine or superfusion of the ganglion with muscarinic agonists, bethanechol or methacholine. Iontophoretic responses occurred after synaptic transmission was blocked with a zero Ca^{++}/high Mg^{++} EGTA (1 mM) solution. All slow potentials were blocked with atropine (10^{-7}M).

Concentrations of muscarinic agonists that elicited membrane polarizations varied among cells. Most responses required between 1-100μM of agonist. The hyperpolarizing response was always seen at lower concentrations and always occurred before the depolarizing response.

Since the ionic mechanisms for the two responses appear to be different and the hyperpolarizing response is more sensitive to muscarinic agonists, a differential sensitivity may exist for the muscarinic receptors on these ganglion cells.

During the S-IPSP a decrease (15±2%, N=12) in membrane resistance was observed; whereas an increase (5±1%, N=9) in resistance occurred during the S-EPSP. The reversal potential for the S-IPSP, determined with double barrel electrodes, was 104.1±4.6 mV (N=6). This value is close to the equilibrium potential of potassium. During the increase in membrane conductance induced by the S-IPSP, ganglionic transmission was depressed in three ways: 1) spontaneous action potentials were inhibited, 2) direct action potentials were depressed, and 3) iontophoretically induced ACh potentials were depressed. Frequently, spikes were generated during the S-EPSP. These data suggest that in parasympathetic neurons slow synaptic potentials can alter ganglionic transmission. (Supported in part by USPHS Grant #NS 16228.)

26.2 **THYROTROPIN-RELEASING HORMONE ACTIVATES CNS PARASYMPATHETIC OUTFLOW TO THE EYE.** Michael C. Koss. Dept. of Pharmacology, Univ. of Oklahoma Health Sciences Center and Dean A. McGee Eye Institute, Oklahoma City, Oklahoma 73190.

Thyrotropin-releasing hormone (TRH) is found in many central nervous system (CNS) regions other than the hypothalamus and exerts potent effects on the CNS which are independent of its release of thyrotropin and prolactin from the pituitary. TRH has been shown to act on the spinal cord to stimulate efferent motor activity to the skeletal musculature and to activate the extrinsic neural input to the gastrointestinal tract. The present series of experiments were undertaken in order to determine if TRH would produce a similar activation of the parasympathetic motor input to the eye. Toward this end, the effect of TRH on ciliary nerve activity was monitored in anesthetized cats.

Intravenous administration of TRH (0.03-5.0 mg/kg) caused a dose-dependent stimulation of tonic ciliary nerve activity which appeared to be independent of the excitatory light reflex. As shown by the example below, TRH produced a rapid increase in integrated nerve activity which was sustained for the period of observation. TRH (1 mg/kg) was administered in preparations in which the nerve fibers were crushed proximal to the ciliary ganglion. In these cases there was no activation of firing in the short ciliary nerve in response to TRH. TRH also produced a dose-dependent pressor effect which was not associated with a consistent alteration of heart rate.

These results demonstrate that TRH acts in the CNS to stimulate parasympathetic outflow to the eye, and suggest that it may play a neurotransmitter or neuromodulator role with regard to this autonomic system.

26.3 A CENTRALLY MEDIATED MECHANISM FOR CONTROL OF OCULAR BLOOD FLOW. C. R. Auker, L. M. Parver* and D. O. Carpenter. Armed Forces Radiobiology Research Institute, Bethesda, MD 20014 and Georgetown University, Washington, D.C.

In a previous report (Soc. Neurosci. Abstr. 5:802, 1979) we showed that choroidal blood flow in the cynomolgus monkey eye serves an apparently homeostatic function in maintaining macular temperature at a relatively constant level.

We now report the existence of a centrally mediated reflex that elevates choroidal blood flow in response to light stimulation. We believe this is a protective mechanism that aids in removing excess heat generated by focusing of light on the macula.

Cynomolgus monkeys were anesthetized with Nembutal (30 mg/kg, i.v.) and placed in a stereotaxic head holder. A thermistor probe (YSI 524) was inserted through the pars plana and the probe tip lodged in the macular region. Intraocular pressure was maintained at a constant 18-20 mmHg by a lactated Ringer's reservoir connected to a needle inserted into the anterior chamber. In other experiments, scleral surface temperature was measured by a disc-shaped thermistor (YSI 409 or 427) inserted behind the eye through a slit in the conjunctiva.

When a 7.5-V light was shone into the contralateral eye, the macular and scleral temperature in the instrumented eye (which was shielded from the light) rose 0.10-0.17°C. Femoral arterial pressure and rectal temperature were constant throughout this maneuver. Closing the lid over the light-stimulated eye eliminated the response. Application of topical Proparacaine anesthetic to the cornea of the stimulated eye did not block the response.

These results suggest that blood flow was reflexly elevated in the instrumented eye when light was shone into the fellow eye. It is not yet clear whether the adequate stimulus is light or heat, but the receptors are apparently not located in the skin surrounding the eye nor in the cornea. The fact that blood pressure and rectal temperature were not changed suggests that this was not a generalized response to a noxious stimulus.

Additional work is under way in our lab to further characterize this reflex.

26.4 EFFECTS OF CHEMICAL SYMPATHECTOMY UPON THYMUS DEPENDENT IMMUNE RESPONSES. Nicholas R. Hall, John E. McClure*, Shu-Kuang Hu*, Nadine T. Tick*, Cary M. Seals*, and Allan L. Goldstein*. Department of Biochemistry, George Washington University School of Medicine, Washington, D.C. 20037.

Several immunologic parameters were measured in C57Bl/6J male mice following treatment with 100 mg/kg ip of 6-hydroxydopamine (6-OHDA). Twenty-four hours after drug treatment, a single ip injection of sheep red blood cells (SRBC) was given to the primary (1°) immune response subjects (n=8). Secondary (2°) immune response animals (n=8) received a second SRBC injection 21 days after the first sensitization. The immune system was evaluated 5 days after the final antigen injection. A single cell suspension of spleen cells was dispensed in triplicate onto agarose-coated slides for the plaque forming cell assay (PFC). An enzymatic assay was used to measure thymocyte levels of terminal deoxynucleotidyl transferase (TdT) and a radioimmunoassay was used to measure serum levels of thymosin α_1.

No significant differences between body, thymus and spleen weights were measured between the 6-OHDA versus the saline treated control group in either the 1° or 2° immune response. Antibody production as measured by PFC and hemagglutination assays was significantly reduced in the drug treated animals after 1° and 2° exposure to the SRBCs. The response to LPS was also reduced, but 6-OHDA increased the spleen cell response to Con-A, PHA-P and PWM. These increased measures were observed only in the 1° immune response group. Thymocyte TdT levels were significantly elevated by 6-OHDA treatment in the 1° response group but were not different from control values in the 2° response mice. Preliminary measurement of thymosin α_1 revealed a significant increase in levels of this peptide hormone in the serum of drug treated animals in both the 1° and 2° response groups.

These data suggest involvement of the autonomic nervous system in modulating the immune response to thymus dependent antigens. The possibility that the endocrine thymus performs an important function in a central nervous system-immune system axis is currently being investigated.

26.5 THE DEVELOPMENT AND CHARACTERIZATION OF AUTONOMIC INNERVATION OF THE THYMUS IN STAGGERER AND NORMAL MICE: AN INDICATION OF CNS REGULATION OF THE NEUROENDOCRINE-IMMUNE NETWORK. K. Bulloch and R. Loy. Dept. Neurosciences, UC San Diego, La Jolla, CA 92093

Recently the hypothesis has been put forth that many human as well as murine autosomal recessive diseases expressing multiple defects in the nervous, endocrine and immune systems have their etiology in a disruption of the neuroendocrine-immune network (Bulloch and Moore, 1980). It is now apparent that the functional integrity of the thymus gland during the perinatal period is crucial to the formation of this network. To determine if innervation is an integral part of the regulation of the neuroendocrine-immune network, we have undertaken a developmental study of autonomic nervous system mapping to the thymus of one such mutant, the staggerer and its normal counterpart. Parasympathetic innervation was studied using horseradish peroxidase (HRP) histochemistry with benzidine dihydrochloride as the chromagen. Acetylcholinesterase (AChE) staining was employed as an approximate determination of the localization of the parasympathetic terminals in the thymus. Sympathetic innervation was characterized utilizing a cryostat glyoxylic acid fluorescent histochemical technique for the demonstration of catecholamines. Our findings indicate that parasympathetic projections to the thymus are intact in the adult staggerer. There are no outstanding differences between the staggerer and normal animals in the topographical distribution of HRP-labeled cells in either the nucleus ambiguus or cervical spinal cord. Terminal distribution or acetylcholinesterase activity may be aberrant in the staggerer's thymus. Normal animals displayed light, consistent staining around medullary areas and little to no staining in the cortex and capsule. Staggerer, on the other hand, demonstrated very heavy AChE activity in the capsule and cortex and irregular, sporadic staining around the medulla. Sympathetic innervation also appears to be altered in staggerer mice. Catecholamine fibers did not follow the normal developmental or topographical patterns of normal mice. Some fibers were observed associated with the vasculature and capsule, but generally demonstrated erratic patterns in their cortical and medullary distribution. In addition, a delicate system of cortical thymic cells normally associated with catecholamine fibers were found irregular in both their organization and autofluorescent granule content. In view of the crucial role the thymus plays in the development of the neuroendocrine-immune network, such irregularities in thymic cell populations and innervation patterns may well be responsible in part for the phenotypes expressed in the staggerer mouse.

26.6 RECEPTIVE RELAXATION AND INTRAGASTRIC PRESSURE IN THE INTACT RAT AND IN THE ISOLATED STOMACH. C. Takata*, W.G. Young and J.A. Deutsch*. (SPON: E. R. Marchand) Depts. of Psychology and Neurosciences, UC San Diego, La Jolla, CA 92093.

3 rats, Sprague-Dawley males (400-500 g), were infused with a liquid diet (Carnation Evaporated Milk, diluted 1:1 with water) at a rate of 2 ml/min into the lumen of their stomachs via an indwelling catheter (Dow Corning Silastic tubing #602-305)(Deutsch, J. A. and H. S. Koopsman. Science, 179:1242, 1973). Egress from the stomach was prevented with an inflatable cuff that occluded the pylorus (Deutsch, J. A. Prog. in Neurobiol. 10:135, 1978). A total of 20 ml was infused. The intragastric pressure (GP) rose linearly from the outset of infusion to 27 cm $\pm$ 4 cm (SEM) of water pressure. This is normally not the case with rats voluntarily drinking. 4 rats tested drank an average of 9.4 ml $\pm$ 0.9 ml (SEM) and GP rose only to 4.3 cm $\pm$ 2.3 cm (SEM) of water at the end of intake. However, pentobarbital-anesthetized rats (n = 2) displayed linear rises in GP to 52 cm $\pm$ 2 cm (SEM) of water. GP measured in isolated stomachs (n = 4) rose only to 12 cm $\pm$ 8 cm (SEM) of water pressure.

It appears that in the intact rat, receptive relaxation (RR) is necessary to cause gastric muscular relaxation so that increasing gastric volumes may be accomodated without substantial rises in GP. Such is the case in rats indulging in deglutition. Rats, both awake and anesthetized, that are not indulging in deglutition demonstrate very high GP. There may be an intrinsic reflex present within the gastric musculature allowing for accomodation. Since RR is dependent on external vagal innervation (Martinson, J. Acta. Physiol. Scand. 64:453, 1965;(Jansson, G. Acta. Physiol. Scand. 75:245, 1969), it appears that the nature of such signals may be inhibitory (i.e., vagal inhibition of an intrinsic accomodation reflex) when the rat is not swallowing. However, when it is swallowing, these vagal inhibitory signals are lifted and this permits gastric relaxation (i.e., normal drinking pressures).

This research was funded by NSF grant BNS 78-01605 awarded to J. A. Deutsch, Dept. of Psychology, UCSD, La Jolla, CA.

26.7 AN ELECTROPHYSIOLOGICAL STUDY OF THE MICTURITION REFLEX PATHWAY IN NEONATAL KITTENS. G. Mawe* and W. C. de Groat, Dept. of Pharmacology, Medical School, Univ. of Pittsburgh, Pittsburgh, PA 15261

Previous studies showed that micturition in neonatal kittens could be induced by tactile stimulation of the perigenital region. This somatovesical reflex which is mediated by a spinal pathway disappeared in most animals by the age of 7-8 weeks but reappeared in chronic spinal adult cats and older kittens 3-12 days after transection of the spinal cord. The present study was undertaken to determine whether micturition reflexes induced by stimulation of bladder afferents undergo similar changes during development and after spinal injury.

Experiments were performed on kittens 5-67 days of age anesthetized with chloralose. Reflexes were recorded from postganglionic fibers on the surface of the bladder in response to distension of the bladder or electrical stimulation of afferents in the pelvic nerve. Bladder activity was recorded via a urethral cannula. In kittens 5-24 days of age reflexes occurred at very long latencies (mean 360 msec; range, 325-430 msec) in comparison to reflex latencies in older kittens (28-34 days, 150-275 msec; 56-67 days, 125-150 msec) and adult cats (95-140 msec). Recordings of axonal volleys on dorsal and ventral roots indicated that the peripheral afferent and efferent limbs of the reflex pathway in 5-24 day kittens were composed of slow conducting fibers (0.6-2 m/sec). The estimated central delay for the reflex ranged from 225 to 325 msec. Transection of the cervical spinal cord initially abolished spontaneous bladder contractions and pelvic nerve evoked reflexes but did not block responses evoked by perigenital stimulation. However, in chronic spinal kittens (8-21 days of age) examined 3 to 14 days after spinal transection, spontaneous bladder contractions had returned and pelvic nerve-evoked reflexes occurred with a latency (mean 135 msec; range, 90-200 msec) that was considerably shorter than the latency in intact animals.

We conclude that in neonatal kittens micturition induced by stimulation of bladder afferents is normally mediated by a spinobulbospinal pathway (SBS), whereas micturition induced by perigenital stimulation is mediated by spinal reflex mechanisms. The decrease in the latency of the SBS reflex during postnatal development is attributed to progressive myelinization of the peripheral and central axons. The maturation of the SBS pathway seems to correlate with the disappearance of the perigenital-bladder reflex. Recovery of bladder function in chronic spinal neonatal animals is associated with the emergence of a bladder to bladder spinal reflex that was undetectable in kittens with an intact neuraxis. (Supported by NSF Grant 79-06093).

26.8 REFLEX MICTURITION INDUCED IN CHRONIC SPINAL DOGS WITH "VOLUME CONDUCTION" STIMULATION OF SACRAL NERVE ROOTS. Pei Chin Tang. Chicago Medical School, Chicago, Il. 60612.

As reported previously, the "volume conduction" method consists of inserting 3 platinum electrodes near the sacral nerve roots through holes drilled in the sacrum. Stimulation via these electrodes with 60 Hz AC resulted in vigorous contraction of the bladder with pressures ranging from 50 to 100 mmHg in anesthetized spinal dogs. By studying the distribution of fatty tissues and locations of the sacral roots, we designed a 6-pronged stimulating electrode with which we routinely generated bladder pressures of 80 mmHg or higher. As the method stimulates all sacral roots, it caused contraction of bladder as well as its sphincter. In chronic spinal dogs we applied alternate 1/2 sec. on and 3½ sec. off stimulation to induce post-stimulation micturition. Urine flow occurred only after cessation of stimulation when the skeletal muscles of the external sphincter had relaxed while the smooth muscles of the bladder were still contracting. We were able to maintain spinal dogs, both male and female, in healthy condition by emptying their bladders twice daily with this method. Here the 6-pronged electrode was also superior to the 3-pronged one. Immediately following the spinal transection, each stimulation induced a small amount (around 10 ml.) of urine output, presumably due to stimulation of the bladder efferent fibers in the sacral roots. Soon afterward, the output following each stimulation became larger, sometimes over 100 ml. Duration of urine flow often lasted over 10 sec. This prolonged urine flow could be due to reflex micturition induced by simultaneous stimulation of the bladder afferents and efferents. Thus, the "volume conduction" method can induce brief micturition during spinal shock by stimulating the bladder efferents and reflex micturition after the shock by stimulating both bladder afferents and efferents in the sacral roots.

In several dogs, the soldered joint between the lead wire and the electrode was broken within the electrode holder which was anchored to the sacrum. We had no difficulty in replacing the entire electrode assembly under local anesthesia as the holder was on the surface of the sacrum and the solid mass of fibrous tissue encapsulating the holder could be cut off without touching the contents of the sacral canal. Re-inserting the electrodes into the existing holes in the sacrum and re-anchoring the holder could be done in a few minutes. We have replaced the electrode assembly in 5 dogs and every one was successful. The ease of electrode replacement extends further the longevity of this method. (Supported by NINCDS Grant #NS15353-02).

26.9 LESIONS OF THE SUBSTANTIA NIGRA PRODUCE ALTERATIONS OF PANCREATIC ISLET SIZE. B.J. Davis*, R.J. Carey, J.R. Sladek, Jr. and P.H. Smith* (SPON: N.R. West). Dept. of Anatomy, SUNY Upstate Med. Ctr Dept. of Psychiatry, Vet. Admin. Hosp., Syracuse, NY; and Dept. of Anatomy, Univ. of Rochester School of Medicine, Rochester, NY. Lesions of the ventrolateral hypothalamus (VLH) have been shown to reduce food intake (FI) and body weight (BWT) and also to alter pancreatic islet function (Smith, et al. 1979). Recently, it has been reported that lesions of the substantia nigra (SN) produce a syndrome of aphagia and adipsia similar to that observed following VLH lesions. Thus it seems likely that interruption of dopaminergic fibers from the SN that project through the hypothalamus in the medial forebrain bundle may contribute to the reductions of FI and BWT that follow VLH lesions. The focus of the present investigation was to determine whether alterations of the endocrine pancreas occur after lesions of the SN. Adult male rats were given bilateral injections of 6-hydroxydopamine (3.0µl in 1.5µl ascorbic acid soln.) into the SN following pretreatment with des-methylimipramine (25mg/kg). Sham and unoperated rats served as controls. After lesions, rats were given high fat diets and FI and BWT were recorded throughout the experiment. Ten weeks after lesion placement animals were killed by decapitation. Lesion sites were verified using Falck-Hillarp fluorescence histochemistry. Samples of the head, body and tail of the pancreas from each animal were fixed in Bouin's fluid, dehydrated and embedded in a single paraffin block. Serial sections (4µm) were processed for the immunocytochemical localization of insulin-, glucagon-, and somatostatin-containing cells. Islet sizes were measured by a point-counting technique and size-class distributions were constructed as follows: small=625-7500µm^2; medium=7625-17500µm^2; large=18125-37100µm^2. The results of this study show that when the endocrine pancreas of SN lesioned rats is compared to that of weight-matched controls there is a significant reduction of total islet area. Moreover, in the pancreas of lesioned rats, there is a shift of islet size distribution with a marked increase of total islet area represented by the smaller islets, and a reduction of total area contributed by the larger islets.

	Islet Area	% of Total Area		
		Small	Medium	Large
Controls (n=3)	$10.7 \times 10^5 \mu m^2$	18	26	56
Lesioned (n=3)	$6.9 \times 10^5 \mu m^2$*	36	27	37

*p<0.001

These findings indicate that alterations of endocrine pancreatic function known to occur following VLH lesions may be related to destruction of dopaminergic fibers originating within the SN. (Supported in part by NIH Grant AM-25325.)

26.10 EFFECTS OF LESIONS IN LOWER BRAIN STEM AND CEREBELLAR VERMIS ON MOTION SICKNESS-INDUCED EMESIS IN THE SQUIRREL MONKEY. K. R. Brizzee, J. M. Ordy and W. R. Mehler, Delta Regional Primate Research Center, Covington, LA 70433 and NASA-Ames Research Center, Moffett Field, CA 94035.

Twenty-one young adult female squirrel monkeys of the Bolivian subspecies were subjected to continuous, counter-clockwise horizontal rotary motion at 25 rpm, together with a sinusoidal vertical excursion of 6 inches every 2 seconds (0.5 Hz). Each animal was exposed to this motion regimen for a period of 60 minutes once each week for 3 consecutive weeks, and each exhibited from 1 to 5 emetic responses within the test period. Following the third weekly motion test bilateral electrolytic lesions were made in the lower portion of the nucleus of the tractus solitarius (NTS) in 3 animals, and in the nodule and uvula of the cerebellar vermis in 4 animals. In 8 animals bilateral ablation of area postrema (AP) was performed by thermal cautery. Three control animals were sham-operated after the third motion test while 3 additional controls were given the motion tests as noted above but were not operated. After a recovery period of 30 to 40 days in all operated animals and at a comparable interval in the nonoperated controls, each animal was again tested for motion sensitivity for 3 consecutive weeks. The brains of all of the animals were then fixed by left ventricular cardiac perfusion with Bouin's fluid and processed for histological evaluation of the lesions. One of the animals with NTS lesions was refractory to the motion test postoperatively while two exhibited about the same number of emetic responses postoperatively as preoperatively. One of the animals with cerebellar lesions failed to respond to the motion regimen while two others exhibited about the same number of emetic responses postoperatively as preoperatively. The fourth animal in the cerebellar group exhibited two emetic responses on the first weekly postoperative test as compared with 4 responses preoperatively. On the subsequent weekly postoperative tests, however, no further emetic responses were observed. Five of the AP-ablated animals were completely refractory to the motion regimen postoperatively, 2 exhibited a decreased number of emetic responses, and one exhibited the same number of responses before and after the AP lesions. The AP-operated animals which exhibited emetic responses to motion in the postoperative tests were found to have an appreciable amount of AP tissue remaining while those which were refractory had little or no AP tissue remaining. The controls exhibited no significant difference in emetic sensitivity on the second series of three weekly tests than on the first series. (Supported by NASA-Ames Grant NSG-2139 and NIH Grant RR00164-18.)

26.11 THE EFFECT OF PASSIVE LIMB MOVEMENT ON HYPOTHALAMIC-EVOKED THERMOREGULATORY RESPONSES IN RABBITS. I.M. Scott,* M.M. Toner* and J.A. Boulant. Department of Physiology, Ohio State Univ. Sch. of Med., Columbus, Ohio 43210.

A controversy exists over the role of proprioceptive limb afferents that may modify the hypothalamic control of thermoregulation during exercise. While some studies indicate no "exercise factor"; other studies suggest that exercise may lower the hypothalamic set-point temperature for heat-loss responses. This apparent set-point lowering was observed for salivation in the exercising dog (Sharp and Hammel, 1972) and for sweating in exercising man (Tam, Darling, Cheh and Downey, 1978). Two important questions still remain:

1) Since body temperature rises during exercise, is this modification of hypothalamic responses due to: a) extrahypothalamic, deep-body thermoreceptor afferents or b) proprioceptive afferents from the moving limbs? The proprioceptive role was tested in the present study by comparing hypothalamic-evoked thermoregulatory responses in the rabbit during rest and during passive limb movement (which did not increase core temperature).
2) In addition to heat-loss responses, does passive movement modify the hypothalamic control of heat-retention and heat-production responses? This was tested in the present study by determining the effect of limb movement on the hypothalamic control of panting or breathing frequency (Bf); relative skin blood flow (SBF)(or ear thermal conductance); and metabolic heat production (MR) due primarily to shivering.

In unanesthetized rabbits, preoptic-anterior hypothalamic temperature (T_{po}) was manipulated and measured using previously-implanted hypothalamic thermodes. The rabbits were supported in a sling so that their legs could be attached to movable rails. A motor connected to the rails produced the passive limb movements. Characteristically, decreasing T_{po} produced a proportional increase in MR, while increasing T_{po} produced proportional increases in SBF and Bf. During passive limb movement, MR was significantly reduced at T_{po}'s below 35°C; while Bf was higher at T_{po}'s between 37° and 39°C. Also the hypothalamic thermosensitivity for both responses was reduced. Finally, during movement, SBF was significantly increased at T_{po}'s above 40°C. The results indicate that proprioceptive afferents may reduce the hypothalamic thermoregulatory set-point by decreasing heat-production and increasing heat-loss responses during changes in T_{po}.

26.12 FEVER IN THE DEVELOPING KITTEN. Ch.E. Olmstead and J.R. Villablanca. Depts. of Psychiat. and Anat. and the Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

In normal kittens thermoregulation as measured by the ability to maintain an adult rectal temperature (T_B) of 38.2±2°C, either in a normal ambient (T_A) of 23 to 25°C or in response to hot or cold challenges, develops over the first 45 days of life (Physiol. Behav. 23: 489, 1979). As part of our continuing investigation of the behavioral and physiological development of normal and brain-damaged kittens we now report the ontogeny of the febrile response to intravenous injections of an exogenous pyrogen, salmonella typhosa, in intact kittens (107 observations in 63 kittens from 16 litters).

The results are shown in Table I where a Friedman 2-way ANOVA showed significant group effects (X^2=121.8, df = 7, p< .001).

TABLE I

Age	N	Pre T_B°C	Peak ΔT_B°C	Hrs to Peak
0-5	12	37.6	.5	2.0
11-15	11	37.5	.6	1.5
21-30	14	37.5	.5	2.0
31-40	10	37.7	.6	0.5
41-50	7	38.3	.8	2.5
50-90	9	38.6	.9	1.0
Adults	5	38.6	1.4 - 1.5	2.0 - 4.0

In general there was an increase in both the magnitude and the duration of fever as a function of age, with the greatest change occurring between 41 and 50 days of age. There was an obvious relationship between the ability of the kitten to maintain its T_B at an ambient of 23-25°C as indicated by the baseline T_B and the magnitude of the fever. The dose necessary to elicit a fever in the very young kitten (0-20 days of age) was considerably higher (5.0-7.0 ml/kg standard dose) than that in the adult (0.5-1.0 ml/kg standard dose). Normal adult cats show a distinctive, bimodal response to the IV injection of exogenous pyrogen (Am. J. Physiol. 208:703, 1965) which, in the present study, was characterized by peak fevers of 1.4°C and 1.5°C at 2.0 and 4.0 hours, respectively, post-injection. No such bimodal response was seen in any of the kitten groups. Even in the 50-90 day animals the fever was transient and there was rapid return to the baseline. In summary, the febrile response to exogenous pyrogen develops over at least the first 7 weeks of life. The data will be discussed in relation to other physical parameters of development, to the animals behavior, and to the immunological status of the mother. (Supported by USPHS HD 05958 and HD 94612).

26.13 THERMOREGULATORY RESPONSES OF CHRONIC DECEREBRATE KITTENS. J.R. Villablanca and Ch.E. Olmstead. Mental Retardation Research Center and Depts. of Psychiat. and Anat., UCLA, Los Angeles CA 90024

We report here preliminary results showing that kittens (N=4) transected above the midcollicular level in the first month of life and followed chronically (survival 13-135 days) do not develop normal thermoregulation. Due to this impairment they must be maintained in an incubator. However, their body weight develops in parallel with that of intact littermates until about 90 days of age.

In intact kittens the ability to regulate rectal temperature (T_B) matures over the first 45 days of life (Physiol. Behav. 23: 489, 1979). This maturational sequence goes from a mean T_B of 37.5°C at 5 days of age to adult levels (38.2±2°C) at about 7 weeks of age. Up until 14 days of age the predominant response to being removed from the nesting box to an ambient temperature (T_A) of 23 to 25°C is a decrease of the T_B of about .02°C/min. For the chronically decerebrate kittens removal from the incubator to a similar T_A resulted in a drop of 0.07-0.10°C/min.

In response to stronger thermal challenges (T_A's of -15°C or +60°C) all of the intact kittens showed, from the first day of life, the ability to detect and move along a thermal gradient as reflected in the approach to warmth and the avoidance of coolth. Nothing resembling behavioral thermoregulation has been seen in the decerebrate. At -15°C normal kittens showed a decrease in the T_B of about .2°C/min at 10 days decreasing to about .1°/min at 40 days of age accompanied by shivering and piloerection which appeared immediately with cold onset. Although there appeared to be some non-specific motor activity, we saw no shivering or piloerection in the decerebrate kitten and it has been possible to regularly and easily decrease the T_B to 30°C at a rate of about .2°/min, regardless of age. In response to heating the intact kitten shows an increase of 0.05°/min at 10 days and 0.02°/min at 40 days of age. Panting was of very short latency as were other behavioral responses. In no case has it been possible to elevate the temperature of an intact kitten above 42°C in the T_A of +60°C. In contrast, the increase in the T_B of the decerebrate animal ranges from 0.08 to 0.20°/min and extreme care was necessary to avoid elevating the temperature into the lethal zone above 42°C, a condition which resulted in the death of our 13 day animal. We have not seen decerebrate kittens pant while being heated.

Contrary to the report (Exp. Neurol. 42: 519, 1974) that kittens decerebrated above the midcollicular level develop near normal thermoregulation, the present data demonstrate that body temperature regulation, which in intact kittens develops over the first seven weeks of life, is dramatically and permanently disrupted by an early high decerebration. (Supported by USPHS HD 05958 and HD 094612.

26.14 MEDULLARY THERMOSENSITIVE UNITS--THE EFFECT OF Δ^9-TETRAHYDROCANNABINAL. W.T. Schmeling* and M.J. Hosko (SPON: A.S. Bloom). Department of Pharmacology and Toxicology, Medical College of Wisconsin, Milwaukee, WI 53226.

Recent studies have demonstrated that many sites in the CNS may play a role in thermoregulation. Previous evidence from our laboratory has demonstrated that thermosensitive neurons (TS) in both the hypothalamic preoptic region (POR) and mesencephalic areas may function in mediating the degree of hypothermia produced by administration of the primary psychoactive component of marihuana, Δ^9-tetrahydrocannabinol (THC). This laboratory has also demonstrated a functional role for the spinal cord (SC) in THC induced hypothermia. In order to further identify those CNS sites which play a role in the modulation of THC induced hypothermia, as well as to investigate the physiological role of such thermoregulatory sites, medullary (MED) TS neurons were studied using extracellular electrodes. Cats were anesthetized with urethane. Double-wall stainless steel thermodes were implanted in POR and MED. Epidural flexible thermodes were inserted into the spinal canal to provide SC thermal challenge. Thermocouples or thermistors were utilized to monitor POR, SC, MED and deep rectal temperature. Tungsten microelectrodes were used to isolate and record single unit activity. A high percentage (70%) of the units we have isolated in the medulla exhibited some TS to local thermal challenge. Of the medullary units exhibiting some TS, 47% demonstrated thermosensitive convergence to heating and/or cooling of SC and/or POR. The firing rate response to such convergent driving varied from neuron to neuron. Selected, stable TS units were challenged by systemic administration of small doses (0.5-2.0 mg/kg) of THC. Typically, THC decreased the spontaneous firing rate while the TS was differentially altered. Non-TS neurons (controls), exhibited little or no change in firing patterns after THC. These studies document the presence of TS neurons in the medulla. Many of these TS units receive convergent information from other known TS sites. The action of THC on these neurons may contribute to the hypothermic action of this agent. (Supported by PHS Grant #DA-00124).

26.15 SYMPATHETIC RHYTHMS IN SPINAL CATS. P.M. Gootman and M.I. Cohen. Depts. of Physiol. Downstate Med. Ctr., Bklyn., 11203 and Albert Einstein Col. Med., Bx., N.Y., 10461.

Simultaneous recordings from preganglionic sympathetic nerves at different levels, cervical sympathetic (CS) and greater splanchnic (SPL), reveal the presence of common periodicities as shown in crosscorrelation histograms (CCH). The major types of periodicities were cardiac, respiratory and 10/sec (Cohen & Gootman, Am. J. Physiol. 218:1092, 1970). The CCHs revealed that peak SPL activity lagged peak CS activity.

These common periodicities can be explained in two ways: (1) there are common periodic inputs to the two types of preganglionic neurons; (2) there are feedback connections in the spinal cord between the two groups of neurons. To distinguish between these two possibilities, spinal cord transections (at C-1) were performed on decerebrate cats with neuromuscular blockade (gallamine or decamethonium), vagotomy, pneumothorax, and artificial ventilation with 100% O_2. SPL and left and/or right CS discharge were monophasically recorded. The central respiratory cycle was monitored by recording phrenic (PHR) discharge. The EKG and systemic arterial pressure were also simultaneously recorded.

After spinal cord section, recordings were taken at hourly intervals for up to 12 hours. Throughout this period activity gradually increased but still remained small compared to presection levels. This low level activity showed no sign of periodicity. Asphyxia of sufficient duration produced increased activity in sympathetic nerves. SPL activity during asphyxia had 2-3/sec oscillations; but the CCHs of CS and SPL activity were almost flat.

Strychnine stimulated neurons in the spinal cord more effectively than asphyxia or doxapram: it produced markedly increased activity with bursting patterns in CS, SPL and PHR. Power spectra of the recordings showed a dispersed range of frequencies (2-10 Hz) without markedly distinct peaks such as were present in the intact animal. The CCHs showed locking of activity in PHR, CS and SPL nerves on a slow time scale (1-5 sec) but no appreciable locking of CS and SPL activity on a faster time scale (2-10 Hz) such as occurs in the intact animal.

These results indicate that, while there can be oscillation of activity at the spinal cord level, the normally occurring synchrony of sympathetic discharges at different segmental levels is dependent on inputs from the brain stem. (Supported by NIH Grants HL-20864 and HL-20800.)

26.16 PREDICTABILITY: A PSYCHOLOGIC/BEHAVIORAL VARIABLE AFFECTING STRESS-INDUCED MYOCARDIAL PATHOLOGY IN THE RAT. W. H. Bailey, D. R. Alonso*, J. M. Weiss*, and S. Chin*. Rockefeller Univ. and Dept. of Pathology, Cornell Univ. Med. Coll.,New York, NY 10021.

In studies with humans there is increasing evidence that psychological and behavioral aspects of stressful situations affect the functioning of the heart and the likelihood of later cardiovascular disease. The evaluation of such factors and their physiological consequences in animals is difficult, however, because of the confounding of psychological factors with potent physical characteristics of stressor stimuli. To avoid this problem, we exposed rats in pairs to the same stressor (3.5 mA inescapable shocks of 2 sec duration on a VI 1 min schedule through tail electrodes wired in series in which one of the rats received a tone 4 sec before each shock (predictable shock condition) . The other rat received a tone bearing no relationship to the shock (unpredictable shock). Since exactly the same physical stimuli (shock, tones) were given to both rats, differences between these two animals would have to relate to their ability to predict the occurrence of shock. To assess the effect of the shock stressor as a separate variable, the experimental design also included a third animal which was presented tones but not shock. Hearts were removed from 23 such triplets 48 hr after a single 24-hr stress session, and multiple sections at four different levels were prepared and stained with hematoxylin-eosin. Focal areas of myocardial necrosis were identified by the degeneration of myocardial cells and their replacement by leucocytes, macrophages, and fibroblasts in a majority of rats given unpredictable shock. Significantly fewer such lesions were found in the hearts of rats given predictable shocks. Indeed, the incidence of myocardial damage observed in rats given predictable shock was hardly greater than that found in a few control rats. Such a result indicates that a psychological variable, predictability, can almost completely counteract the adverse effects of stressful physical stimulation per se. The size and prominent distribution of these focal lesions in subendocardial regions is consistent with the hypothesis that the release of endogenous catecholamines may be directly or indirectly responsible. Histochemical procedures based on fuchsinophilia or fuchsinorrhagia were found to be completely unreliable indicators of stress-induced myocardial pathology in rats. (Supported by NIH grant HL 19974.)

26.17 CARDIOVASCULAR AND CATECHOLAMINE RESPONSES IN INDIVIDUALS DIFFERING IN REACTIVITY. R.H. Cox,* J.E. Lawler,* K.A. Lawler,* and E.T. Howley* (Spon: K. Kant). Depts. of Psychology and Physical Education, Univ. of Tenn., Knoxville, TN 37916.

The difficulty encountered in attempts to induce a permanent hypertension in animals with psychologically stressful paradigms has contributed to doubts about the importance of this factor among some investigators. However, recent evidence suggests that selective breeding can produce an animal with a predisposition to develop hypertension. This fact has contributed to a renewed interest in individual differences which might produce a vulnerability to hypertension. A cardiovascular (CV) system which is reactive to stress may be one manifestation of such a vulnerability. However, for such a characteristic to have significance it must be demonstrable in a variety of situations. This study was undertaken in an effort to demonstrate the generality of CV reactivity and to define its relationship to the sympathetic nervous system and to obtain basic information about the CV and oxygen uptake capacities of individuals who differ in reactivity to stress.

Thirty-four male undergraduate volunteers were exposed to three forms of psychological challenge: 1) a reaction time-shock avoidance (RT-AV); 2) a reaction time-money reward (appetitive or RT-AP); and 3) a mental arithmetic stress (MA). Heart rate, systolic and diastolic blood pressure and urinary excretion of epinephrine and norepinephrine were measured. The primary focus of the study was on those 14 individuals showing extremes in CV reactivity. Eight subjects showing a heart rate increase of over 30 bpm were compared to six subjects who responded with less than 10 bpm increase to the RT-AV task. The reactive group displayed a greater change in heart rate to the RT-AP task but not the MA condition. Their systolic blood pressures, while no different at rest, were higher during the RT-AV, RT-AP and MA conditions. No difference in urinary excretion of catecholamines between the two groups was detected but significant positive correlations between baseline epinephrine values and resting heart rate and mean heart rate change in all psychological conditions were found. A significant relationship between CV reactivity and familial hypertension was also found.

The reactive and non-reactive groups did not differ in aerobic capacity or maximum heart rate and both met the metabolic demands of exercise with similar rises in CV parameters. There was evidence however that as a group the reactive subjects show higher heart rates and systolic blood pressures than the non-reactive group to the same relative and absolute workloads.

26.18 AUTONOMIC RESPONSES AS MEASURES OF LEARNING IN PREWEANLING RATS. Louise T. Martin and Jeffrey R. Alberts*, Dept. Psychology, Indiana Univ., Bloomington IN 47405

The purpose of the present study was to investigate ontogenetic differences in the effectiveness of various autonomic and behavioral response systems as measures of learning. Preweanling rat pups were trained in 1 of 2 classical conditioning paradigms: odor-illness and odor-temperature conditioning. During a 24-hr retention test, both autonomic (heart rate, respiration) and behavioral (ultrasounds, gross motor activity) responses were simultaneously monitored at 4 different ages (5, 10, 15, and 20 days). Pups were restrained in a wire mesh cage, which was placed in a wind tunnel that received the effluent airstream of an olfactometer. Test trials consisted of 30-sec presentations of the conditioned odor and a novel odor; responses were monitored for 1 min prior to and following each odor presentation.

Only the cardiac measure proved to be a sensitive index of learned associations throughout the preweanling period. However, the direction of the cardiac response appears to undergo a major developmental shift around Day 20. At 5, 10, or 15 days of age, aversive associations lead to large and sustained accelerations in heart rate; by Day 20 the cardiac response is primarily deceleration. Younger Ss that have acquired specific olfactory aversions decelerate in response to novel odors, whereas 20-day-olds show cardiac acceleration. Unpaired aversive experiences are also reflected in the cardiac response patterns. Younger Ss show acceleration following offset of a novel odor and sustained deceleration to a familiar-safe odor. Again, by Day 20 these directional differences in heart rate are reversed.

These results demonstrate that in a restrained testing situation, cardiac responses can provide an effective measure of learning at young ages. Changes in heart rate do not appear to be coupled with changes in respiratory rate or motor activity until around Day 20, the age at which tonic parasympathetic restraint on the heart becomes established. We have interpreted these distinctive cardiac response patterns as orienting and defensive reflexes to sensory stimulation. The observed shift in the organization of these responses at Day 20 may correspond to a shift in the organization of behavior -- from stimulus-bound, reflexive responses to behaviors that are more instrumental and voluntary in nature.

We are currently monitoring these same response systems during a spatial orientation test. Under this less restrained condition we hope to determine the age at which behavioral measures surpass a cardiac measure as indices of learning in preweanling rat pups.

26.19 INTERACTION BETWEEN BRAIN DEGENERATION AND PSYCHOSOCIAL STRESS. J.N. Naranjo*. (SPON: C.A. Marotta). Department of Anatomy, Harvard Medical School, Boston, MA 02115 and McLean Hospital, Belmont, MA 02178.

A considerable body of data indicates that mice that are psychosocially stressed in free wheeler and Reimer-Petras colonies consistently exhibit a chronic elevation in blood pressure. The present study examines the effects of psychosocial stress on the central nervous system. The C57/USC mice that were placed in the stress colonies had a significant increase in blood pressure ($p < .001$) in relation to the age matched controls. The brains of both groups were analyzed using a reduced silver stain (Naranjo and Greene, 1977) and electron microscopy. Using coded slides, the light microscopy was analyzed by four trained observers; a consensus indicated that there was a significant amount of widespread neural atrophy ($p < .004$) in all stressed animals and a virtual lack of degeneration in the same age controls.

An analysis of the tissue not only confirmed that there were differences in the amount of neuronal degeneration between the stress colonies (probably due to the level of stress in each colony) but also there were individual differences in the amount of degeneration among the mice in each stress colony. Axonal degeneration was observed in the optic tract, corpus callosum, fimbria, fornix, internal capsule, neocortex, hypothalamus and hippocampus. Neural damage in fiber tracts was noted as black coarse fragmented fibers, fiber debris, numerous small impregnated spheroidal or slightly irregular structures, argyrophilic material and a proliferation of oligodendroglia. Damage to cellular areas consisted of small circumscribed regions of retrograde dust, fragmented dendritic processes and silver impregnated soma. The silver staining results were confirmed by electron microscopy, and the ultrastructural changes in neurons and glia will be presented.

Supported by a grant from the June Rockwell Levy Foundation and the Alfred P. Sloan Foundation.

26.20 NERVE GROWTH FACTOR-LIKE ACTIVITY IN SERUM SAMPLES FROM PATIENTS WITH PERIPHERAL AND DIABETIC NEUROPATHY. D. J. Wells* and B. L. Strehlo* (SPON: J. Krier). Section of Cardiovascular Research, Mayo Clinic and Foundation, Rochester, MN 55901.

Nerve growth factor-like proteins (nerve growth stimulating activity, NGSA) are likely to be involved in the normal and pathological development of the human sympathetic and sensory nervous systems. Development of a radioligand assay for measuring serum and tissue levels of NGSA has been hampered by the lack of proven cross-reactivity of antibodies developed against mouse nerve growth factor (NGF) with a purified sample of human protein and by the presence of NGF binding proteins in serum which compete for labeled NGF.

The well-established chick embryo dorsal root ganglion biological assay for NGSA has been utilized in this laboratory to measure the levels of NGF-like material in male and female subjects of varying age. Serum samples were obtained from laboratory normal value study subjects or from pediatric patients undergoing routine physical examinations. Samples were diluted with isotonic saline and incubated with 8 day-old chick embryo dorsal root ganglia at 37°C for 24 hours. NGF activity was determined by comparing the amount of neurite outgrowth obtained with the patient sample dilutions with the outgrowth produced by a series of dilutions of purified mouse NGF protein. Subjects ranging in age from 6 months to 75 years gave no significant sex or age difference (females: $N = 37$, $\bar{x} = 11.3 \pm 10.5$ B.U./ml; males: $N = 33$, $\bar{x} = 15.5 \pm 15.4$ B.U./ml).

Patients diagnosed with peripheral neuropathies did not show significant differences in levels of NGF-like activity from controls although individual exceptions were observed (females: $N = 9$, $\bar{x} = 18.8 \pm 22.3$ B.U./ml; males: $N = 6$, $\bar{x} = 9.5 \pm 9.7$ B.U./ml). Samples of cerebral spinal fluid from these patients showed no NGF-like activity. In contrast to the results obtained with the control subjects, serum samples from patients with either diabetes mellitus ($N = 6$) or diabetic neuropathy ($N = 6$) gave no detectable NGF-like activity. The amount of mouse NGF protein which gave maximal biological activity did not vary when the assay dilutions were done with isotonic saline or pooled serum samples, indicating that serum did not exert an inhibitory effect on the assay. Continued efforts will be made to assess the relevance of these results to development of diabetic and peripheral neuropathies.

All experiments reported here were approved by the Human Studies Committee, Mayo Clinic. This research was supported by the Mayo Foundation.

26.21 RESPONSES OF DENTAL-PHOBIC AND NON-DENTAL-PHOBIC CHILDREN TO DENTAL TREATMENT: COMPARISON OF FOUR AUTONOMIC MEASURES. G. A. West and K. H. Reid. Dept. Physiology & Biophysics, Health Sci. Ctr., Univ. of Louisville, Louisville, Ky. 40292.

Seventeen children, ages 6-12, were monitored during routine dental restorations in the Pedodontic Clinic at the U of L Dental School. Continuous recordings were made of red light transmission through the distal phalanx of the left little finger, and of the voltage developed between two 1 cm^2 electrodes placed on the palm and dorsum of the left hand during passage of a 8 microampere constant current between them. Pulse rate (PR) and finger pulse volume (FPV) values were derived from the light transmission signal, while absolute skin conductance (ASC) and skin conductance response (SCR) values were derived from the voltage signal. Both signals were recorded on chart paper for monitoring and on FM magnetic tape for later processing.

PR and FPV values were obtained by graphic averaging over 3 second epochs, followed by averaging these numberical values over the time devoted to each dental procedure. In 7 children PR and FPV records were incomplete due to movement artifact. SCR values were obtained by summing SC amplitude changes over the time of each dental procedure. ASC values were obtained by calculating a mean baseline value over the time devoted to each procedure. The separation of children into phobic and non-dental-phobic groups was done by asking mothers to fill out a questionnaire which indicated how they felt their children would react to dental treatment. This assessment was supplemented by observation of each child's reaction to the restoration procedure itself.

Each of the 4 autonomic measures was evaluated using analysis of variance, repeated measures, with procedures and subjects as main effects. The group of 4 measures was tested by discriminant analysis for ability to separate groups. Salient results were:

1. ASC best separated dental-phobic from non-dental-phobic children ($N=10$, 5/group, $p < .05$)
2. SCR most consistently separated dental procedures ($F=8.35$, $p < .01$)
3. PR showed the largest inter-subject variability.
4. Using SCR, PR, or FPV as measures, we found no significant difference between dental-phobic and non-dental-phobic children.
5. For all 4 measures, the largest effect was seen during the injection of the local anesthetic. We interpret this as indicating that this was the most stressful of the routine dental procedures.

27.1 [^{3}H]-2-DEOXYGLUCOSE UPTAKE IN THE MOLLUSCAN CENTRAL NERVOUS SYSTEM. Stephen C. Reingold & Terrence J. Sejnowski+. Department of Biology, Princeton University, Princeton, New Jersey 08544.

We have used [^{3}H]-2-Deoxyglucose ([^{3}H]-2-DG) to localize metabolically active neurons within the buccal ganglion of the mollusk Limax maximus. Autoradiographic analysis gives a resolution of 0.5 um, with label concentrated in cell somata and neuropil processes. Within somata, nuclei appear less heavily labelled than cytoplasm. Labelling of neurons may be correlated with intracellular stimulation and spontaneous activity within the ganglion.

Individual buccal ganglia were dissected and incubated in high Mg^{++}, low Ca^{++} saline to reduce transmission at chemical synapses. Peripheral nerve roots were recorded with suction electrodes. Glass microelectrodes were used to impale individual neurons within the ganglion. Upon impaling a neuron, the bath solution was replaced by 100-200 uCi [^{3}H]-2-DG/ml high Mg^{++} low Ca^{++} saline. The cell was depolarized with intracellular current pulses to fire at a rate of 1-2 spikes/second, while monitoring peripheral nervous system activity. After 30-60 minutes of intracellular stimulation, the microelectrode was removed and the ganglion washed in 5 changes of non-radioactive saline over 30 minutes. Individual ganglia were freeze-substituted in acetone at -70°C or dehydrated in dry acetone at 4°C. Ganglia were embedded in Araldite or Spurr's Medium and serially sectioned at 3-5 um. Sections on slides were dipped in Kodak Nuclear Emulsion (NTB-2), exposed for 2-4 weeks, and subsequently developed and counterstained.

In control experiments in which a neuron is impaled but not driven and peripheral activity is absent, several somata are often labelled. Rarely, a single cell was activated with current injection in the absence of spontaneous activity, and a single cell soma was labelled with [^{3}H]-2-DG. In most experiments, several cells were labelled, even though only a single cell was experimentally activated. Such multiple cell labelling may result from spontaneous firing of normal or autoactive neurons; from activation of follower cells by the impaled neuron through electrical or still-functioning chemical synapses; or from subthreshold activity or non-electrical metabolic activity.

27.2 ORTHOPTERAN JUMPING MOTOR NEURONS: A COMPARISON. John A. Wilson, Christine E. Phillips, DeForest Mellon, Jr., and M. E. Adams*. Dept. of Biol., Univ. of Virginia, Charlottesville, VA 22901 and Max Planck Inst. V., Abt. Huber, Seewiesen D-8131, Fed. Rep. Germany.

The extensor tibiae muscle provides the propulsive force for jumping in locusts, grasshoppers, and crickets. In the locust Schistocerca gregaria and grasshopper Gomphocerippus rufus the hind legs are much larger than the front and middle legs, but in the cricket Gryllus bimaculatus the difference is not nearly as pronounced. This difference is highlighted by the roles of the hind legs in walking. Locusts and grasshoppers use them occasionally, but the cricket uses them in every step. We wanted to know if these behavioral and structural differences would be reflected in the anatomy of the fast extensor tibiae motor neurons.

Fast extensor tibiae motor neurons from the 3 species were physiologically identified and iontophoretically injected with cobalt. Neurons were then fixed for examination in the light and electron microscope. To date, we have found no significant differences in the morphology of the locust and grasshopper fast extensors. The cricket fast extensor is significantly different at the level of the light microscope. Whereas the locust and grasshopper fast extensors have primarily small diameter (less than 2μM) processes leaving their primary neurites, more than 5 processes with 3μM or greater diameter leave the cricket fast extensor primary neurite. Also, only very few small branches are seen to leave the primary neurite of locust and grasshopper between the cell body and the "turn" but the cricket has at least 2 branches of greater than 3μM diameter leaving the neurite in this region. When the structure of these neurons are compared with the serial homologues of the locust fast extensor, the slow extensor of the front and middle legs, the greatest similarity is seen between the cricket fast extensor and the locust slow extensors. The changes in structure from the front and middle leg's slow extensors to the cricket fast extensor and finally to the locust and grasshopper fast extensors closely parallels the presumptive evolution of jumping abilities.

This work was supported by the Max Planck Gesellschaft. Additional support was from the USPHS grant #15006 to DeF. Mellon (JAW), Dept. of Biol., U. Va. (C.E.P.) and the D.F.G. (M.E.A.).

27.3 SEGMENTAL VARIATIONS IN MGF-MEDIATED ESCAPE BEHAVIOR IN INTACT EARTHWORMS. C. D. Drewes* and S. L. Pallas* (Spon: D. E. Emery) Department of Zoology, Iowa State University, Ames, Iowa 50011.

Non-invasive electrophysiological recording methods were used to study segmental variations in the functional properties of MGF (medial giant fiber) efferent pathways in the earthworm, Lumbricus terrestris. In each segment of the animal MGF spikes are followed in one-to-one fashion by spikes in the serially arranged giant motor neurons, termed GMN1. A single GMN1 spike evokes a small longitudinal muscle potential but no visible shortening. When two GMN1 spikes occur (due to firing of two MGF spikes) there is a marked facilitation of the second GMN1-mediated longitudinal muscle potential. Such facilitation is more pronounced in anterior than in middle or posterior segments. This marked anterior-to-posterior gradient in facilitation of muscle potentials correlates well with the observations that GMN1-mediated shortening in anterior segments is greater, occurs earlier, and requires fewer antecedent spikes than does shortening in middle segments. In the most posterior segments of the animal the MGF mediates a dorsoventral flattening of the tail, rather than a longitudinal shortening. Such tail flattening responses usually precede shortening in anterior segments by several milliseconds, even though the MGF activity is initiated in anterior segments.

The observed segmental gradient in longitudinal shortening appears to represent a mechanism for focussing rapid escape withdrawal into anterior segments which are most vulnerable to attack when the animal is extended from its burrow. The early onset of MGF-mediated tail flattening would ensure that the animal's tail is securely anchored within the burrow before shortening begins.

27.4 EFFECTS OF CINGULATE AND FORNIX LESIONS ON CONTACT DEFENSIVE IMMOBILITY IN THE RABBIT. M. L. Woodruff and R. H. Baisden. Department of Anatomy, College of Medicine, East Tennessee State University, Johnson City, Tn. 37601.

Contact defensive immobility (CDI) is a name suggested by Woodruff (Psychol. Rec., 27: 161, 1977) for a behavior also called animal hypnosis, death feigning, tonic immobility, and the immobility reflex. CDI is an ethologically significant response emitted by a prey after other behaviors have failed to allow escape from a predator. For example, Sargeant and Eberhardt (Am. Midl. Nat., 94: 108, 1975) observed that assumption of CDI by ducks significantly enhanced the chances of survival of an encounter with foxes. Evidence reviewed by Gallup (Psychol. Bull., 81: 836, 1974) also supports the contention that CDI has survival value for prey animals and, additionally, the hypothesis that fear is an important variable influencing CDI. Because CDI is a form of species typical behavior and is influenced by the emotional state of the animal, it is reasonable to expect that lesions of limbic structures would influence it. Therefore, the cingulate cortex and the fornix were chosen for destruction. Two separate behavioral experiments were conducted. Each group contained 12 rabbits. Postoperative recovery time was 35 days for both experiments. The procedure for inducing CDI has been described in detail (Woodruff & Lippincott, Brain Behav. Evol., 13: 22, 1976). In the first experiment rabbits with fornix lesions remained in CDI significantly longer than sham-operated or unoperated controls [$F(2,33)=5.99, p<.01$]. In the second experiment lesions of the cingulate cortex in the region approximately overlying the fornix produced significantly shorter durations of CDI than the durations of the control groups [$F(2,33)=8.38, p<.01$]. Other rabbits were given either unilateral fornix or cingulate lesions and their brains were processed using the Fink-Heimer technique. In addition to projections unique to each lesion, degenerating terminals after either lesion were observed in the anterior thalamic nuclear complex, the midline thalamic nuclei, the midbrain tegmentum, and the presubicular region. The observation of opposite effects on CDI duration produced by these lesions is congruent with previous experiments in which such lesions produced opposite effects on avoidance behaviors (McCleary, Prog. Physiol. Psychol., V.1, 1966). The presence of overlapping terminals in thalamus and mesencephalon suggests possible anatomical sites where efforts might first be made to determine how the cingulate cortex and hippocampus exert reciprocal effects on behavior. CDI is a good behavior to use for such an endeavor because it is relatively simple. The sensory systems which initiate it and the areas in the brainstem involved in its production have been delineated (Klemm, Psychol. Rec., 27: 145, 1977). (Supported by Biomedical Research Development Grant 1-S08-RR 09171.)

27.5 NEUROETHOLOGY OF PREY CAPTURE BY LARVAL FIREFLIES: INHIBITORY EFFECTS OF FIREFLY EXTRACTS ON CARDIAC FUNCTION IN TERRESTRIAL MOLLUSKS. Jonathan Copeland. Department of Zoology, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin 53201.

The larval form of Photuris lucicrescens, a North American firefly of the beetle family Lampyridae, is predatory upon soft-bodied terrestrial annelids and mollusks, including the slugs Limax maximus and Agriolimax reticulatus. Larval Photuris lucicrescens attacked and consumed small (less than 1.2 g) Limax and Agriolimax when confined overnight in a test chamber. Slugs, when observed after attack, were flaccid and areflexive.

Because European Lampyridae have been reported to inject their prey with a paralyzing toxin, I examined the mandibles of Photuris lucicrescens for morphological evidence of toxin injection capabilities. Using SEM I have found a rectangular (40 µM long x 10 µM wide) pit less than 100 µM from the tip of each fang-like mandible. The pit is the external opening of a duct which runs through each mandible. The duct opening is ideally suited for the injection of a toxin into a prey organism.

The relative toxicity of a number of body compartments of the firefly was tested by utilizing the in vitro cardiac preparation of Limax maximus (MacKay and Gelperin, Comp. Biochem. Physiol. 43A, 877-896, 1972). Slug heartbeat was recorded with extracellular electrodes from either auricle or ventricle. Extracts of larval firefly mandibles, head, thorax-abdomen, or hemolymph were prepared and added at full or reduced concentration for 30 - 180 seconds. Extracts prepared from larval Tenebrio molitor served as a control. Larval firefly extract produced either a complete cessation of heartbeat or a reduction in beat frequency. Inhibition was usually complete, although occasionally cardiac escape occurred. Cardiac inhibition was sometimes preceeded by a transient increase in beat frequency and a decrease in beat amplitude. All effects were completely reversible. The order of potency was hemolymph>thorax-abdomen>head>mandibles.

Future experiments will test the hypothesis that the hemolymph, or some derivative of the hemolymph, contains an active agent or agents which are injected into prey during capture by firefly larvae.

27.6 VISUAL PREY ACQUISITION BEHAVIOR IN THE FROG: EFFECTS OF VARIOUS UNILATERAL LESIONS. S.K. Kostyk and P. Grobstein. Dept. of Pharmacol. Physiol. Sci., Univ. of Chicago, Chicago, IL, 60637.

We compared the effects on visual prey acquisition behavior in Rana pipiens of three lesions: a) unilateral optic nerve section, b) unilateral tectal ablation, c) hemisection at a level between tectum and cerebellum. Tectal ablation and midbrain hemisection were done by aspiration and subsequently verified histologically. Visual behavior was tested by observing responses to live mealworms presented at a series of positions at eye level around the frog.

Frogs with one optic nerve sectioned oriented with reasonable accuracy to stimuli in a region of visual space on the side of the intact eye and extending about 45° across the midline in front; they failed to respond to stimuli outside this region. Thus either eye alone is sufficient for orientation toward stimuli within the central 90° of visual field which is normally seen by both eyes. Frogs with unilateral tectal ablation oriented with comparable accuracy in a region on the side ipsilateral to the lesion and again extending about 45° across the sagittal plane; they failed to respond to stimuli outside this region. This indicates that the effects of unilateral tectal removal are laregely equivalent to the effects of unilateral optic nerve section. Either tectal lobe alone is sufficient to produce orienting toward stimuli within the central 90° of visual field.

Frogs with hemisections responded to stimuli at any position around the animal. The nature of the response, however, depended on the stimulus position with respect to the sagittal plane. For positions contralateral to the lesion, frogs oriented with accuracy comparable to that of normals. For any position ipsilateral to the lesion, frogs responded as if the stimuli were directly in front of them. The results indicate that at the level of the lesion there are no tracts or structures essential either for detection of stimuli at any position or for production of accurate turns toward stimuli located contralaterally. They suggest that tracts or structures on one side of the brain may be essential for turns toward stimuli ipsilateral of the sagittal plane.

The behavioral deficits of hemisected frogs differed from those of the first two groups in that: 1) there was no stimulus position at which frogs failed to respond, and 2) the region of normal orienting was bordered by the sagittal plane instead of extending 45° across the midline. The former indicates that lesions at this level dissociate turn production from other aspects of prey acquisition behavior. The latter suggests that the bilaterally redundant representation of spatial information evident at retinal and tectal levels may be lost at subsequent levels of the neuronal circuitry underlying this behavior.

27.7 MOTOR CONTROL OF VOCAL BEHAVIOR IN RING DOVES (Streptopelia risoria). Jeffrey Cohen and Mei-Fang Cheng. Inst. Anim. Behav., Rutgers Univ., Newark, NJ 07102.

In recent years data have been gathered on the neural control of vocalizations of songbirds. One of the most intriguing findings is the phenomenon of left hypoglossal dominance (Nottebohm, J. Exp. Zool. 177: 229, 1971). Except for the chicken, few comparable data exist for birds with relatively simple vocal repetoires, such as the ring dove. For this reason, and because the ring dove has been the subject of extensive brain and behavior analysis, we decided to investigate the motor control of its vocalizations.

In the first study, the question of whether the ring dove exhibits left hypoglossal dominance was examined. Recordings of the male's bow-coos and nest-coos were made on a Uher Report L tape recorder (7 1/2 cps) and analyzed on a Kay sonagraph model 7029A. Following preoperative recordings males received either left or right hypoglossal nerve sections (HNS), bilateral HNS or a sham operation. Only minor changes occurred following left HNS or sham operation. Structural changes in coos were more noticeable after right HNS, but the most dramatic changes in coo structure followed bilateral HNS.

Because of the greater changes in cooing after right HNS, we wondered whether this would be reflected anatomically by an increase in size of the syringeal musculature on that side (as is true for left hypoglossal dominance and the left tracheolateralis muscle (TLM) in songbirds). In the second experiment, syrinxes from intact doves were processed using paraffin sectioning and the sections were traced. The relative volumes of the TLM's were calculated with the aid of a polar planimeter. In 75% of the animals, the right TLM had a larger volume than did the left TLM (mean % increase = 33%). Thus the relatively greater deficits induced by right HNS are reflected by a greater volume of the ipsilateral TLM.

In the third study we sought to determine the site of origin of the hypoglossal nerves. Unilateral HNS was performed, and after varying survival times, birds were sacrificed. The brains were cut and stained with cresyl violet, and examined for retrograde degeneration. Following unilateral HNS, there was a reduction in the number of cells in the n. hypoglossus tracheosyringealis (formerly called n. intermedius) of the ipsilateral side, but no changes in other nuclei on that level. It thus appears, that although the ring dove does not have left hypoglossal dominance, its hypoglossal nerves have the same CNS site of origin as do songbirds.

27.8 NEURAL CONTROL OF HATCHING IN THE CHICK. A. Bekoff and J. Kauer*. Dept. EPO Biology, Univ. of Colorado, Boulder, CO 80309.

Hatching normally occurs only once in the chicken, during an interval of about 45 to 90 minutes, at the end of the 21-day incubation period (Hamburger and Oppenheim, J. Exp. Zool., 166: 171, 1967). In the present study the leg motor output typical of normal hatching was first characterized using electromyographic (EMG) and videotape recordings. Then the following questions were examined: 1)is the pattern generator for the leg hatching movements retained in the post-hatching chick? and 2)under what conditions can it be turned on?

We found that the leg motor output typical of hatching could be re-elicited in post-hatching chicks at least up to 4 weeks of age by folding them into the hatching position and placing them into artificial eggs of the appropriate sizes. Therefore the pattern generator for hatching leg movements is present and remains functional long after the occurrence of normal hatching. By selective manipulation of the position of various body parts we determined that only bending the neck to one side was both necessary and sufficient to turn on leg motor output with characteristics typical of hatching.

27.9 FACILITATION OF SPONTANEOUS MOUSE-KILLING IN THE RAT BY CHOLINERGIC STIMULATION OF THE LATERAL HYPOTHALAMUS. B.C. Yoburn* and M. Glusman (SPON. M. Potegal). Dept. of Psychiatry, Columbia Univ., and N.Y. State Psychiatric Institute, New York, NY 10032.

Lateral hypothalamic cholinergic systems have been implicated in the mediation of interspecific aggression in the rat (Bandler, R.J., Brain Research, 20:409, 1970; Bandler, R.J., Nature, 224:1035, 1969). In these studies the application of the cholinergic agonist carbachol reduced the latency to kill prey in spontaneously aggressive rats. However, the actual dose of the drug delivered to the brain could vary between 3 and 10µg and only one dose level was presented. Therefore, the present study examined the effects of three precisely controlled doses of carbachol injected into the lateral hypothalamus on spontaneous mouse-killing in rats.

Eight male rats which spontaneously killed mice were implanted with a 22ga guide cannula aimed at the right lateral hypothalamus. Following postoperative recovery, each animal was injected using a 28ga internal cannula connected to a microsyringe mounted on a microdrive with .5µl of buffer, and .5µl of 5, 12.5 and 20µg of carbachol dissolved in buffer. The order of presentation was counterbalanced and a minimum of 48 hrs elapsed between injections. Ten minutes following the injection, subjects were exposed to five aggression tests spaced ten minutes apart in which a white mouse was introduced into the homecage and the latency to killing was recorded. If the rat failed to kill in two successive tests or if seizure activity was apparent, the session was terminated. Sessions with seizures were excluded from the data analysis.

The latency to kill was decreased in seven of the eight animals by at least one dose of carbachol and in four animals by at least two different doses relative to the buffer injection. In general, aggression was facilitated by the lowest dose and this facilitation was decreased as the dose was increased. For five animals the 5µg dose was the most effective in facilitating aggression, while the 12.5µg dose was maximally effective for only two animals, and the 20µg dose was not maximally effective for any animals and actually suppressed aggression for three animals. The 5µg dose was not observed to induce seizures in any animals, although the 12.5 and 20µg doses did so for one and two animals, respectively.

These results are consistent with suggestions that interspecific aggression in the rat is controlled by cholinergic systems in the lateral hypothalamus. However, the specific effectiveness of carbachol in this study varied with dose and the individual animal studied. The interaction of these two variables indicates the importance of accurately controlling drug dose and evaluating several doses in each subject. (Supported by NIH Grant MH 15174.)

28.1 BEHAVIORAL CHANGES IN AGING APLYSIA. C. Bailey,* V. Castellucci, J. Koester, M. Chen, and U. T. Koch.* Div. of Neurobiol. and Behavior. Depts. of Anatomy, Physiology and Psychiatry, Columbia Univ., P & S, New York, N.Y. 10032, and The NYS Psychiatric Institute.

We have used Aplysia californica to explore the effect of age on two simple forms of learning and memory; sensitization and the retention of habituation in the siphon-withdrawal reflex. Changes in arousal as reflected by changes in heart rate were also examined. Since weight is correlated with age we have, in initial experiments, used this parameter to separate animals. The mean weights of the animals used in these studies were 1291g ± 41 (S.E.M.), N=60 for large, presumably old animals; and 136g ± 6, N=53 for small, presumably young animals.

For the sensitization studies all animals received five blocks of habituation training sessions (Carew et al., 1973). Each block consisted of ten tactile stimuli to the siphon and was separated by 1.5 hrs. Experimental animals received an electrical shock (200 mA, 60 Hz for 2 sec) as a sensitizing stimulus between block 4 and 5. The shocked young animals (N=14) had a significant increase in their response (duration of siphon withdrawal) when block 5 was compared to block 4 (Wilcoxon, $p < 0.01$, 2-tailed). By contrast, experimental old animals (N=19) showed no significant increase. The sensitization scores of young animals were significantly higher than the scores in old animals (Mann-Whitney U-Test $p < 0.002$). These results suggest that the ability to undergo sensitization in old animals is impaired.

To examine the retention of habituation, animals received 4 blocks of training on the first day. Retention was tested by giving a single block 24 hours and 1 week later. Young animals (N=12) exhibited significant retention of habituation at 24 hrs (Wilcoxon, $p < 0.01$) and 1 week ($p < 0.05$). In old animals (N=15) significant habituation of the response was present at 24 hrs (Wilcoxon, $p < 0.01$) but not 1 week after training. Therefore the retention of habituation in older animals is of shorter duration.

We have also examined the effects of age on food arousal. Presentation of seaweed to Aplysia produces a state of arousal that results in an increase in biting rate with a concomitant increase in heart rate. This change in behavioral state was compared in young (N=5) and in old (N=5) animals. The change in biting rate during food arousal was the same in both groups but the change in heart rate was significantly greater (5-fold) in young animals than in older ones.

Our results suggest that aging in Aplysia may lead to specific learning and memory impairments as well as altered states of arousal. We are currently investigating the cellular basis of these age-related changes in behavior. (Supported by NSF grant BNS 7824476, NIH grant NS 14385 and an Irma T. Hirschl Career Scientist Award.)

28.2 AGE-IMPAIRED FUNCTION OF CENTRAL NEURON L_7 IN APLYSIA. B. Peretz, G. Ringham and R. Wilson. Depts. of Physiology and Biophysics and Pharmacy, Univ. of Ky. Med. Ctr., Lexington, KY 40536.

Three functions have been ascribed to L_7, a central neuron in the abdominal ganglion: i) motorneuronal, in gill pinnules (Kupfermann and Kandel, 1969; Peretz, 1969; Kupfermann et al, 1971; Jacklet and Rine, 1977); ii) dishabituatory of the gill withdrawal reflex (Peretz and Lukowiak, 1975; Lukowiak and Peretz, 1977); iii) modulatory of central rhythmicity mediating periodic respiratory movements of the gill (GPM, Sinback, 1975). These functions were observed in young, ca. 60 days old, and in sexually mature animals, ca. 120 days old. Recently, it was reported that in old animals, 200 days and older, L_7 lost the capability of dishabituating the gill withdrawal reflex (Peretz, et al, 1979). We report here a comparison of L_7's motor neuronal function in mature and old Aplysia.

In the preparation used the innervation between the abdominal ganglion and the gill was intact. Intracellular stimulation of L_7 at low spike rates, 1-2/sec, reliably resulted in one-for-one evoked potentials in the ctenidio-genital nerve and in the pinnules, as recorded with suction electrodes, in both mature and old animals. With the force of gill contraction generated during periodic GPM's being approximately 50 mg/g of gill wt for the two age groups, the maximum force elicited by L_7 stimulation in mature animals was ca 45% of the GPM, whereas that elicited in old animals was only 12% of the GPM, at the same spike rates. The latency of onset of pinnule contractions was longer in old than in mature animals, 660 ms vs 325 ms. The difference in latencies was longer than can be accounted for by the difference in conduction time between L_7 and its terminations in the pinnule, 250 ms in old vs 100 ms in mature animals.

Possible age-dependent changes of contractile properties of gill musculature do not explain the differences between L_7 elicited pinnule contractions in the two age groups since the force generated during GPM's was comparable. In old animals impaired function of L_7 does not appear to be the result of conduction block between L_7 and the pinnule as demonstrated by one-for-one following in the nerve and in the pinnule. L_7's age-impaired motor neuronal function may result from changes in L_7's terminations in the gill pinnule. (This research supported by a grant from the National Institute of Health, MH18611.)

28.3 RETENTION DIFFERENCES IN YOUNG, MID-AGED AND SENESCENT MICE. S.M. Fraley* and A.D. Springer, (Spon: R. Browner). Dept. of Anatomy, New York Medical College, Valhalla, N.Y. 10595

Distinguishing between performance and learning deficits in old animals is often problematic since sensory systems are impaired during aging. Therefore, we chose to study age-related retention changes using a simple situation in which learning did not depend on the use of specified sensory systems. Young (2 month), mid-aged (12 month) and senescent (24 month) male C57/B16 mice were given nine 3 minute exposures to a novel environment in which activity was measured. In this paradigm decrements in activity reflected adaptation resulting from learning the stimulus characteristics of the environment. Conversely, between-session increments in activity reflected forgetting. Within the first 4 days, all age groups showed a progressive decline in activity, and baseline levels were maintained for the duration of testing. However, throughout the entire testing period, the activity levels of the mid-aged and senescent animals were higher than that of the young mice. This age difference was related to the older animals showing appreciable forgetting during the 24 hr interval between sessions.

Attempts were made to attenuate the between-session forgetting in the older animals by providing them with longer daily exposures to the environment. Eighteen days after the end of the 3 minute sessions, the same animals were given daily sessions of 12 minutes in duration. Results indicated that prolonged exposure to the environment improved retention in the mid-aged and senescent mice. Aged animals, therefore, appear to require a longer time to process information concerning stimuli in their environment.

In other experiments, 2, 12 and 24 month old mice were given a 3 minute exposure to the novel environment and retested 4 and 8 days later. At both time points, total activity of the mid-aged and senescent mice was higher than that of young animals. These results corroborated those of the previous experiment in showing that aged animals demonstrate greater forgetting of a simple learning situation. Other groups of 2, 12 and 24 month old mice were tested only 8 days after a 3 minute exposure to the novel environment. In this instance, forgetting was evident in all age groups. Other experiments attempted to determine the effect of neuropeptides on retention in aging mice.

28.4 EFFECTS OF DRUGS ON MEMORY PERFORMANCE IN AGED NON-HUMAN PRIMATES AND RODENTS. R.L. Dean and R.T. Bartus, Dept. CNS Research, Med. Res. Div. of American Cyanamid, Pearl River, NY.

Serious impairments on memory and related cognitive tasks occur with age, in both humans and other animal species. Because it is commonly assumed that functional changes in the CNS contribute to these behavioral impairments, many clinical trials have attempted to alleviate the neurobehavioral disturbances by giving elderly humans various drugs. However, no single drug has yet achieved universal acceptance as being efficacious. For this reason, a clear need exists to develop animal test procedures to measure these deficits in animals and assess the ability of drugs to reduce them.

Two such procedures have been used in our laboratory for these purposes. One, a variation of the delayed alternation procedure, uses aged F344 rats. The other, a variation of the delayed response task, uses aged Cebus monkeys. Both procedures allow extensive drug testing to be performed on individual subjects, allowing each subject to serve as its own control, facilitating direct comparisons between doses and drugs.

A number of drugs currently on the international market for geriatric indications (piracetam, naftidrofuryl, centrophenoxine, and dihydrergotoxine) were tested in each procedure. Further, various cholinergic agents (choline, physostigmine and arecoline) were also evaluated, due to the current interest in the cholinergic hypothesis of impaired geriatric memory.

The results of these tests revealed that many of these drugs can, in fact, reduce the memory impairments observed in aged animals. However, in certain cases, substantial differences in individual responses to particular doses of drug minimize the group effects. Further, although the test procedures were not able to differentiate between aged subjects within each species, some animals failed to exhibit facilitative effects at any dose, whereas, others exhibited marked improvement. These results demonstrate that: 1) animal procedures can be developed to evaluate the effects of drugs intended to improve geriatric cognition; 2) statistical proof of efficacy is possible with many agents available in Europe, even within the strict confines of a laboratory setting; and, 3) unless individual differences in response to dose and drug are taken into account, subtle facilitative effects may be obscured.

28.5 CHANGES IN ^{3}H-NALOXONE BINDING IN THE BRAINS OF SENESCENT RATS. J. N. McDougal*, N. W. Pedigo, P. R. Marques*, H. I. Yamamura and T. F. Burks. Department of Pharmacology, Arizona Health Sciences Center, Tucson, AZ 85724.

Investigations of the changes in pharmacologic response due to the aging processes are becoming increasingly important because of the growing size of the elderly population. Aged laboratory animals respond differently than young animals to morphine. Thermic effects of morphine in senescent rats are more pronounced at low doses and are attenuated at high doses in comparison with young rats (McDougal, Marques and Burks, Proc. West. Pharmacol. Soc. 23: in press). In addition, senescent rats acquire tolerance to the thermic effects of morphine less readily than young rats. When a low dose of morphine (5 mg/kg s.c.) was readministered three days after the same initial dose, 27 month old rats responded the same to both doses, but the 3 month old rats responded with increased hyperthermia to the second dose. When a higher dose of morphine (25 mg/kg s.c.) was injected and then readministered three days later, 3 month old rats had a decreased hypothermic response, but the 27 month old rats responded the same as with the initial dose. However, upon morphine pellet implantation, all groups showed a decreased hypothermic response to morphine (25 mg/kg s.c.). These age-related changes in hypothermic response were not present with the administration of two doses of ethanol (1.5 and 3 mg/kg i.p.).

To determine if changes in opiate receptor binding are responsible for these altered pharmacological responses to morphine, we assayed opiate receptors in the corpus striatum, frontal cortex, hippocampus, nucleus accumbens and olfactory tubercle, hypothalamus, and brain stem of 3, 10 and 27 month old Fischer 344 rats from the colony supported by the National Institute on Aging. Specific ^{3}H-naloxone binding (1 nM in Tris buffer) was defined as the difference between binding in the presence and absence of 1 μM naltrexone. Preliminary results show a significant decrease (33%) in the specific ^{3}H-naloxone binding in the hypothalamus of senescent rats when compared with 3 month old rats. Binding in the 10 month old animals was intermediate between 3 and 27 month old rats. No significant age-related changes were noted in the other brain regions examined. The decrease in hypothalamic opiate receptors with aging may explain the observed age-related differences in the thermic effects of acutely administered morphine as well as the differences in acquisition of tolerance. (Supported by USPHS Grants AG01289, NS15420, NS06217 and RSDA to H.I.Y. MH00095.)

28.6 MORPHINE EFFECTS ON PAIN THRESHOLDS AND OPEN FIELD ACTIVITY IN YOUNG AND OLD RATS. B.J. Vasquez, R.B. Messing, R.A. Jensen, V.R. Spiehler, T.J. Hannan*, J.L. Martinez, Jr. and J.L. McGaugh. Department of Psychobiology, University of California at Irvine, Irvine, CA 92717.

Previously, we have reported alterations in forebrain dihydromorphine binding in old (24-26 month) as compared to young (3-5 month) male F344 rats.

We now report that morphine effects on nociception and locomotor activity are altered in these animals.

Flinch and jump thresholds to electric shock were unchanged in young rats when measured immediately following i.p. administration of 2.5 or 5.0 mg/kg of morphine. However, jump thresholds of old rats were significantly elevated immediately after injection of these doses of morphine. Pain thresholds of old and young rats given saline injections were not different from each other.

In contrast to these data, open field activity was higher in old as compared to young rats when rats were exposed to an open field for the first time. In this experiment rats were placed in an open field with a floor divided into 16 squares (25 x 25 cm). Activity was measured for 5 min by counting the number of squares crossed. When rats were injected i.p. with saline immediately following the initial 5-min testing period, and placed in the open field one hr later, activity levels of young rats were unchanged, but there was a decline in the open field activity of old rats. Morphine (1.0 mg/kg immediately following initial testing) increased the locomotor activity of young rats one hr later. In old rats given morphine (1.0 or 3.0 mg/kg) however, activity levels did not change upon subsequent exposure to the open field.

Taken together, these results indicate that differential effects of morphine in young and old rats probably depend on age-related changes in the neurochemical substrates on which the drug is acting, as well as on alterations in drug metabolism in old animals.

28.7 FUNCTIONAL ASPECTS OF THE NIGRO-STRIATAL DOPAMINERGIC SYSTEM IN SENESCENT RATS. M. Roffman, F. Cordasco* and A. Kling. CMDNJ-Rutgers Medical School, Piscataway, New Jersey 08854.

Chronic administration of neuroleptics to mature rats have been shown behaviorally to produce changes in the dopaminergic receptors of the striatum indicative of hypersensitivity. However, there is a paucity of data on the effects of such treatment in senescent rats. The present experiments sought to determine the effects of chronic haloperidol treatment on the functional integrity of the nigro-striatal dopaminergic system as determined by apomorphine-induced stereotypy. Stereotypy was determined according to Costall and Naylor (EUR. J. Pharmacol. 21:350, 1973). With no prior treatment the senescent rats were less sensitive to the effects of apomorphine (0.25 mg/kg) with respect to the number of subjects exhibiting stereotypy (0.08%) and intensity of the behavior (1.1) than mature rats (67% and 0.083, respectively).

After chronic treatment with haloperidol both the senescent rats and the mature rats exhibited significantly ($P<.01$) more stereotypy than corresponding rats that had been chronically treated with saline. Seven days after cessation of chronic haloperidol treatment, a threshold dose (0.25 mg/kg) of apomorphine caused the senescent rats to emit a degree of stereotypy (1.25) that was similar to that elicited by the mature rats (1.86). However, by 14 and 21 days after chronic treatment no such behavior was detected in the senescent rats whereas the mature rats continued to emit the stereotypy (1.5 at both 14 and 21 days). On the other hand, after administration of 0.75 mg/kg of apomorphine the senescent rats exhibited similar stereotypic scores (1.5) at 7, 14 and 21 days after cessation of chronic drug treatment whereas the behavior of the mature rats was more intense than that of the senescent rats at 7 and 14 days (3.0 and 2.9 respectively) but not at 21 days (1.8) after chronic haloperidol treatment. These data indicate that the number of dopaminergic receptors in the nigro-striatal pathway are decreased in the untreated senescent rat. However, after chronic antipsychotic treatment these receptors appear to remain capable of becoming supersensitive and that this sensitivity may be more persistent than that occurring in mature rats.

Changes in the functional capabilities of the dopaminergic receptors within the nigro-striatal system of senescent rats may explain the clinical observation that geriatric patients are, in general, more prone to some of the neurological side effects, especially extrapyramidal symptoms, of the antipsychotic medication than are younger patients.

28.8 SODIUM PENTOBARBITAL IMPAIRS DELAYED-RESPONSE PERFORMANCE IN AGED RHESUS MONKEYS. J. S. Abelson and J. G. Marriott. Pharmacology Dept., Warner-Lambert Research Labs, Ann Arbor, MI 48105.

Barbiturates are commonly prescribed to geriatric patients for anxiety, pain, and insomnia. However, these drugs are often contraindicated in the elderly, for they may produce motor and cognitive side effects such as ataxia, forgetfulness, and confusion. The nature of the cognitive impairments produced in the elderly by these drugs has not been studied in laboratory models. The bulk of research on the effects of barbiturates upon cognition in young animals has attributed poor performance on cognitive tasks to depressed sensory and motor activity and not to specific memory impairments. We examined the effects of sodium pentobarbital (SP) on delayed-response (DR) performance of aged rhesus monkeys to determine the activity of barbiturates in an animal model of cognition in old subjects.

Ten test- and drug-sophisticated aged rhesus monkeys (18 + years) were tested on an indirect DR task. Subjects were presented with a visual stimulus on one of nine panels in a 3 x 3 matrix. Recall of the spatial position of the stimulus was tested following retention intervals of various durations. Both 0 sec (control) and non-zero (memory) intervals were tested. Duration of the non-zero retention intervals was established by a titration procedure, allowing the interval length to be adjusted dynamically by each subject's performance. SP (1.0, 2.0, 4.0, 8.0, and 16.0 mg/kg) was administered PO 30 min prior to behavioral testing twice a week. In general, higher doses of the drug led to increased variability in DR performance. The highest dose, 16.0 mg/kg, impaired performance in all animals. Statistical analysis revealed that overall DR performance with 1.0-8.0 mg/kg SP was not different from non-drug control, whereas 16.0 mg/kg significantly impaired both 0 sec and non-zero performance of the task ($p<0.5$). Further, there was a significant interaction of dose and retention interval; the difference between 0 sec control and non-zero performance increased as SP dose increased ($p<.01$), yielding greater effects of non-zero delay intervals with increasing dose.

These results clearly indicate that barbiturates have specific effects on short-term memory (STM) in aged subjects. The debilitating effects of SP are not simply due to impairments in motor activity, for DR performance at non-zero delays was more severely disrupted than 0 sec control responding. In this respect the present results in aged subjects are different from the young animal studies which have generally not noted specific STM impairments with barbiturates, demonstrating that aged subjects are more sensitive to these drugs than are young ones. Thus, the present results substantiate the view that barbiturates are contraindicated in geriatric patients.

28.9 BRAIN DAMAGE, STRESS, AND LONGEVITY: AN EXPERIMENTAL STUDY.
D. Wozniak*, S. Finger, H. Blumenthal*, and R. Poland*. Dep't of Psychology, Washington Univ., St. Louis, Mo., 63130, and U.C.L.A., Dep't of Psychiatry, Harbor General Hospital, Torrance, Ca. 90509.

Our principal objectives were to investigate whether (a) brain damage, (b) environmental stressors, or (c) the interaction of these factors would affect lifespan or susceptability to disease. To examine these questions, over 300 C57 BL/6J mice underwent bilateral frontal lobotomies or sham operations at sexual maturity. Approximately every 4 months, half of the animals were subjected to stress sessions involving cold-restraint or cold alone while other animals remained in their home cages. Following each stress session a small number of animals was sacrificed from each experimental condition to assess gastric lesions and serum corticosteroid levels (immediate effects of the stressors), and to provide well-preserved animals for pathological study. The remaining mice were allowed to die from "natural causes", and attempts were made to retrieve and autopsy each body.

The mean life span of the mice was about 28 months, although certain animals lived beyond 36 months. However, neither the lesion, nor the stress, nor the interaction of these variables was found to affect longevity.

The stress procedures were observed to elevate circulating corticosteroid levels and on occasion to produce a significant incidence of gastric lesions. The lesion variable, by itself or interacting with stress, was never found to produce significant effects with regard to gastric erosions or corticosteroid levels. Prevalent causes of death included leukemia, lymphosarcoma, metastatic pulmonary tumors, pulmonary adenomas, and pneumonias. Analyses assessing the potential relationships between the lesion and stress variables and the cause of death are currently being conducted.

It may be concluded that brain damage need not necessarily affect life span or alter an animal's resistance to stress-related pathophysiological changes. Conclusions as to whether brain lesions and/or stress will affect susceptability to different diseases will also be presented.

29.1 ALTERATIONS IN REGIONAL CEREBRAL BLOOD FLOW IN THE BRAIN-INJURED CAT WITH MORPHOLOGICAL CORRELATES. E. L. Auen, A. B. Malik, L. R. Nelson, K. D. Barron, and R. S. Bourke. Div. of Neurological Surgery and Depts. of Neurology and Physiology, Albany Medical College, Albany, N.Y. 12208.

Using the radioactive microsphere (15micron) reference blood flow technique, we injected 3 differently labelled microspheres (^{141}Ce, ^{113}Sn, & ^{46}Sc) at 3 different times into the left heart of brain injured and control cats to determine regional cerebral blood flow (rCBF). The brain injury model utilizes repetetive translation plus rotation acceleration impulses applied to the skull encased brain of the anesthetized cat (Nelson, L.R., et. al. Neurosci. Abs. 5:516 1979). Microsphere injections were made before, during, and 40 min. after the injury. Parallel experiments were done in control cats. In another set of experiments, control and brain injured cats were perfused for electron microscopy at times corresponding to the microsphere injections. Mean arterial blood pressure, intracranial pressure, EKG, EEG, and arterial blood gases were monitored throughout the experiment. The rCBF data for 19 different brain regions, and cervical and lumbar spinal cord were normalized based on tissue dry weight determinations.

There was a decrease in blood flow of 27.8%±1.9% in the cerebral hemispheres of the brain injured cats at 40 min. after the brain injury compared to controls. There was a decrease in blood flow in the cerebellar hemispheres of 14.3%±0.8% at the same time but blood flow in the brain stem, cervical, and lumbar spinal cord did not change significantly. The reduction in blood flow to the supratentorial regions was not associated with significant alterations in mean arterial blood pressure, intracranial pressure, electroencephalogram, or blood gases. Electron microscopy of supratentorial sites 40 minutes post injury demonstrated scattered focal perivascular astroglial swelling. These electron lucent perivascular foot plates often completely surrounded the capillary endothelium. The capillary endothelium of the brain injured animals often displayed luminal villous "finger like" projections. The relatively greater flow reduction observed in supratentorial regions 40 min. after trauma may be due in part to the perivascular astroglial process edema and endothelial alterations observed electron microscopically at that time.
Supported by NIH grants NS 13042, GM15426, and RCDA HL00363 to A.B.M.

29.2 EVALUATION OF TREATMENT MODALITIES USING AN ANIMAL MODEL OF SEVERE HEAD INJURY. L. R. Nelson, E. L. Auen, & R. S. Bourke. Div. of Neurological Surgery, Albany Medical College, Albany, NY 12208.

We previously have reported the development of an animal model of severe head injury (Nelson, L.R. etal Neural Trauma, pg.297-311, ed. Popp, A.J., Raven Press N.Y. 1979). The model utilizes a repetetive acceleration injury to the skull encased brain of the anesthetized cat followed by a 1 hour period of hypoxia induced by mechanically ventilating the paralyzed cat with 6% O_2 in N_2. This paradigm results in a 51% delayed mortality rate (control group) with an impaired rate of neurological recovery in survivors.

We have used this model to evaluate the relative effectiveness of 6 drugs in reducing both mortality and morbidity in head injury. Animals were randomly assigned to treat or control groups. Following the trauma each treat animal received a single dose of either Edecrin, DCPI, DCPHI, DCPIB, Acetazolamide (1to5mg/kg IV) or Methylprednisolone (30mg/kg IV q6h).

RESULTS

GROUP	MORTALITY RATE	P VALUE
Control	38/75=51%	
Edecrin*	14/39=36%	NS
DCPI*	11/42=26%	< .01
DCPHI*	8/22=36%	NS
DCPIB*	9/32=26%	< .025
Acetazolamide	8/16=50%	NS
Methylprednisolone	9/18=50%	NS

When all acylaryloxyacetic compounds (*) are grouped together the mortality rate is 42/135=31% P<.005. With a translational only mode of injury, the Edecrin and DCPI groups also showed a significantly improved rate of neurological recovery as measured by our numerically quantifiable neurologic examination. The other groups have not been tested with this mode of injury. With a translational plus rotational mode of injury none of the groups showed a significantly improved rate of neurological recovery. This data suggests that the translational only mode of injury is a superior model for drug testing since with this mode of injury one can assess the effectiveness of a drug both in terms of reducing mortality and morbidity.
Supported by NIH grant NS13042.

29.3 VASCULAR ENDOTHELIAL RESPONSES TO ACUTE HYPERTENSIVE INSULT: A SCANNING AND TRANSMISSION ELECTRON MICROSCOPIC STUDY. D.S. DeWitt*, J.T. Povlishock, R.L. Hayes, D.P. Becker. Departments of Neurosurgery and Anatomy, Medical College of Virginia, Richmond, Virginia 23298

Hypertension has been reported to cause balloon- or crater-like lesions in vascular endothelium. The temporal sequence of the genesis and resolution of these lesions has not been investigated and, to this end, the present investigation was undertaken.

Cats were anesthetized and infused with norepinephrine bitartrate (Levophed) to produce a rapid elevation in arterial pressure ($\bar{x}$=173 mm Hg). In two animals, perfusion was initiated two minutes after the onset of the hypertensive episode, while in all other animals, the hypertensive insult was sustained for approximately eight minutes. The animals were perfused with 2% paraformaldehyde and 2.5% glutaraldehyde at two minute, ten minute, thirty minute, and four and eight hour intervals following the onset of the hypertensive insult. The brains were removed and samples were taken from the cerebral cortex, diencephalon, the brain stem and pial arterioles. The brain parenchymal samples were then sectioned on a vibratome and together with the bisected pial vessels they were osmicated and processed for scanning electron microscopy. Selected samples were also processed and embedded in Epon 812 for transmission electron microscopy. The luminal surfaces of intraparenchymal vessels contained within these tissue samples as well as the luminal surfaces of the pial arterioles were viewed with a Hitachi S-500 scanning electron microscope. On the basis of randomized selection micrographs were taken at a constant magnification (1500X) of the luminal surfaces of the pial and intraparenchymal vessels. Endothelial lesions were characterized and quantified from these micrographs.

Through such a regimen, endothelial balloons and craters were recognized within two minutes of the onset of the hypertensive episode. Lesions were observed in the vessels of the brain parenchyma as well as in pial arterioles, and in both cases,they occurred predominantly along the marginal lines. With increasing survival times, more lesions were recognized with the maximum number occurring at thirty minutes. By the fourth hour after the insult, the number of endothelial lesions was significantly decreased. At eight hours, although there was no significant decrease in the number of endothelial lesions, the lesions appeared to be resolving as they were less conspicuous.

The results of the present investigation suggest that an acute hypertensive insult may initiate immediate endothelial damage which, with time, progresses and ultimately begins to resolve.

29.4 PROLIFERATION AND IMMUNOFLUORESCENT STAINING OF GLIAL CELLS WITH MULTIPLE SCLEROSIS SERUM. V.K. Singh, D.A. Thomas* and R.D. Mashal*. Div. of Immunology, Dept. of Pathology, University of British Columbia, Vancouver, Canada, V6T 1W5.

The proliferation of rat brain glial cells in tissue culture supplemented with normal human or multiple sclerosis (MS) patient serum was studied. The proliferative response (PR) was measured by the incorporation of ^{3}H-thymidine into DNA. The PR with MS patient sera as compared to normal human sera was found to be very diffused. Only 2 patient sera caused about 50% inhibition; 4 patient sera had no effect, and the remaining 9 patient sera enhanced the PR by 30-90% over the control values. Increased PR corroborated with morphological differentiation whereas the suppressed PR was recorded with the degeneration of glial cells in cultures. Simultaneous detection, by means of indirect immunofluorescent (IF) technique,of glial cell antibodies in MS patient serum revealed that 5 out of 15 MS sera were strongly positive. Two sera were equivocal whereas the remaining 8 sera were completely negative. None of the 7 control sera exhibited any positive staining. The antibody staining with positive sera was localized with the cell surface membranes and the antibodies appear to be of IgG class. Those sera which caused inhibition of PR also displayed positive IF-staining whereas the sera which had no effect on PR exhibited equivocal IF-staining. The remaining patient sera with enhancing effect on PR were generally IF-negative. These observations indicate that glia proliferation in tissue culture with MS patient's serum correlates significantly with the antibody staining of glial cells by MS serum.

29.5 FURTHER ULTRASTRUCTURAL EVIDENCE TO SUPPORT THE PRESENCE OF A PROGRESSIVE AXOPLASMIC DEGENERATIVE PROCESS IN CASES OF JAKOB-CREUTZFELDT DISEASE. J.P. MACHADO-SALAS. Laboratorio de Neuromorfología Experimental y Aplicada.Depto.Anatomía.Facultad de Medicina, UNAM. México, 20.D.F. MEXICO.

Jakob-Creutzfeldt disease (J-C D) and Kuru are fatal neurological diseases in which a long-latency viral process appears to trigger some unknown mechanisms that end up with a severe destruction of neuropiles. For a long time it has been recognized that these alterations are characterized by the presence of vacuoles throughout the cortical gray matter.

Most of the ultrastructural studies that have been done in cases of J-C D., have localised these vacuoles at the level of nerve- or glial-cells bodies or their shorter branches.Few reports have mentioned that this alteration can also be observed in axons. Whatever the final localisation of these vacuoles, there still it remains to uncover the etiology and/or mechanisms that are involved in their production.

We have studied the ultrastructural features shown by the cerebral biopsy obtained from a young subject, who had shown a dementia of rapid evolution and myoclonic jerks.A sequence of changes can be identified as the putative degenerative process that ends up with axonal vacuolization, which, by the way, it was rather outstanding in the present case.

First, it appears to occur a darkening of the axoplasm and/or the development of osmiophilic bodies, and distortion of mitochondria. In a later stage, a centrifugal displacement of the axoplasm, progressively takes place, until it becomes attached to the myelin sheath.Finally, a distended, flattened and empty myelin sheath stands out as the remaining structure.Ocassionally, some distortion of myelin may parallel these changes.

Some probable mechanisms involved shall be discussed.

29.6 INDUCTION OF MYOTONIA IN UTERO BY 20, 25-DIAZOCHOLESTEROL TREATMENT. S. K. Mishra, M. Hobson*, S. H. Subramony and D. Desaiah. Neurology and Research Service, VA Medical Center, Department of Neurology, University Mississippi Center, Jackson, Mississippi 39216.

Myotonia is characterized by the continuous active contractions of muscles which persists after the cessation of voluntary efforts or stimulation (a slowness in the relaxation of muscles). The purpose of this study was to develop an animal model which mimics the genetically determined human myotonic muscular dystrophy. Myotonia was produced in offsprings of 20, 25-diazocholesterol (DAC) induced myotonic female rats which were mated either with normal or DAC-treated males. The rats were administered with DAC by gastric intubation of 80 mg/kg b.w. at weekly intervals. Myotonia was confirmed in adults by electromyography (EMG) preceeded by breeding (5 successive treatments). DAC treatment was continued in adult females thru 21 days post partum. After weaning offsprings were treated as adults. Myotonia was confirmed in the offsprings at 28 days of age (3^+ on a scale of 1-5) by routine EMG examination. At the age of six weeks biopsies of plantaris quadriceps and soleus muscles were taken for histopathological analysis. Frozen sections were cut and stained with various histological and histochemical stains and the following changes were noted: 1. Variability of fiber size, 2. internal nuclei, 3. decreased PAS positive fibers, 4. moth eaten fibers, 5. dark angulated fibers, 6. decrease and absence of type 2-B fibers (most effect seen in quadriceps muscle), 7. fiber splitting and 8. spindle abnormalities. The onset of myotonia in the offsprings was seen at 28 days as compared to 42 days in adults. Similarly, early histological and histochemical changes were seen in the myotonic offsprings (after 6 weeks) as compared to adults (after 16 weeks). The present data demonstrate for the first time that the myotonia is produced in utero by DAC treatment in rats. These results also suggests that the observed abnormalities are compatible with the genetically determined disorders seen in human myotonic muscular dystrophy. (Supported by Medical Research Service of Veterans Administration.

29.7 CELL LOSS IN DIENCEPHALIC NUCLEI OF PURKINJE CELL DEGENERATION (pcd) MUTANT MICE. S.V. O'Gorman and R.L. Sidman*. Dept. of Neuropathology, Harvard Medical School & Dept. of Neuroscience, Children's Hospital Medical Center, Boston, MA 02115.

Previous studies of mice homozygous for this autosomal recessive mutation have demonstrated a rapid degeneration of nearly all cerebellar Purkinje cells during the second and third postnatal weeks, and more slowly developing, progressive losses of retinal photoreceptors and olfactory bulb mitral cells (Mullen et al., 1975, PNAS 73: 208). We have found that additional cell losses occur between 50 and 60 days of age (P50-P60), when discrete neuronal subpopulations of the mediodorsal, submedial, ventrolateral, reticular and posterior thalamic nuclei, and all neurons of the ventral medial geniculate nucleus (vMG) degenerate. The ventrobasal, ventromedial, intralaminar, lateral geniculate, and anterior thalamic nuclei suffer no obvious neuronal loss between P24 and P180. The timing and morphological features of degeneration appear to be similar in each affected thalamic nucleus. vMG neurons, for example, are morphologically normal at P40 when examined in one micron sections of Epon embedded material stained with toluidine blue. By P50, many somatic profiles contain large areas of homogeneous, lightly-stained material, and a few frankly pyknotic neurons are present. Very few vMG neurons survive at P60. Examination of P50 material by electron microscopy shows that lysosomal number and size are increased in most vMG neurons, and many cells contain one or a few small, spherical (0.2-0.6μm diameter) aggregates of fine (8nm) particles, commonly apposed to the convexity of cresentic or cup-shaped cisternae of endoplasmic reticulum. Cytoplasmic organelles are reduced in number and curiously distributed in more severely affected P50 vMG neurons. Large areas of perinuclear cytoplasm are occupied exclusively by polyribosomes, while the remaining organelles are often clustered at the base of a primary dendrite. Collicular and cortical afferent terminals form morphologically normal synapses on vMG dendrites at P40, and intact boutons are often apposed to degenerating dendrites at P50. At P60, but not at P50, vMG axons in the thalamic radiations and their terminals in auditory cortex are intensely argyrophilic in Fink-Heimer preparations. The pcd locus affects an apparently disparate assortment of neuronal classes at different chronological ages, with the presumed common denominator yet to be established. We have no evidence to suggest that thalamic cell loss is a consequence of synaptic agenesis or dysgenesis, and doubt that it is related by transneuronal mechanisms to previously described cerebellar, retinal or olfactory bulb pathology.

29.8 AXONAL NEUROFILAMENTS AND NEUROFILAMENT AGGREGATES EXPERIMENTALLY INDUCED IN THE RABBIT BY ALUMINUM AND MITOTIC SPINDLE INHIBITORS ARE IMMUNOHISTOCHEMICALLY DIFFERENT. A. Bignami, D. Dahl, N. Chi* AND N. Bich*. Spinal Cord Injury Research Laboratory, Harvard Medical School and West Roxbury VA Medical Center, Boston, MA. 02132.

Based on indirect evidence it is now believed that the mammalian neurofilament is formed by a triplet of polypeptides at approximately 200K, 150K and 70K daltons (Lazarides, E., Nature 283:249, 1980). We have previously shown that the 70K and 150K proteins are biochemically and immunologically not related (Dahl, D., FEBS Lett. 103:144, 1979; ibid. 111:152, 1980). We now report that the localization of the two proteins are different. Aggregates of neurofilaments in the spinal cord neurons of the rabbit were experimentally induced by the intrathecal injection of aluminum and mitotic spindle inhibitors (colchicine, vinblastine and vincristine). As previously reported (Dahl, D. and Bignami, A., Exp. Neurol. 58:74, 1978; Dahl, D. et al., Acta Neuropath., in press), neurofibrillary tangles stained intensely by immunofluorescence and the PAP procedure with neurofilament antisera raised to degraded chicken antigen (Dahl, D. and Bignami, A., J. Comp. Neurol. 176:645, 1977). These antisera strongly reacted with the 70K polypeptide in brain filament preparations as indicated by immunoaffinity chromatography (Dahl, D., BBA 622:9, 1980). Neurofibrillary tangles were not stained with antisera to antigen extracted from the 150K band in SDS gel electrophoretograms of brain filament preparations. Both antisera (anti-150K and anti-chicken antigen) demonstrated the same structures in cryostat sections of cerebellum, that is, Purkinje cell baskets, a fine mesh of fibers in the lower half of the molecular layer and granular layer, and myelinated axons in white matter. Large motor axons adjacent to neurofibrillary tangles in the anterior horns were equally well stained with both antisera. The findings may suggest that neurons contain a distinct class of filaments sharing with other classes of intermediate filaments the property of colchicine-induced aggregation. An alternative explanation is that the 150K polypeptide is not a "core" neurofilament protein but a neurofilament associated protein involved in axonal transport. 30.1 EVIDENCE FOR SORTING OF PROTEINS DURING THE INITIATION OF RAPID AXONAL TRANSPORT. G.C. Stone and R. Hammerschlag. Div. of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

During the initiation of fast axonal transport, newly synthesized proteins destined for transport may be routed through neuronal somata in a manner similar to that of secretory proteins and integral membrane proteins in non-neuronal cells (Droz, in The Nervous System 1:111, 1975; Hammerschlag, & Lavoie, Neurosci., 4: 1195, 1979). This analogy predicts that fast transported proteins (FTPs) are synthesized in the endoplasmic reticulum and pass through the Golgi apparatus prior to reaching the transport system proper. To further investigate this possibility we have examined the synthesis and turnover of microsomal proteins in bullfrog dorsal root ganglia (DRG) and compared these membrane proteins to identified FTP species. In vitro fast axonal transport was performed as described previously (Stone et al., Brain Res. 144:287, 1978) in which ^{35}S-met FTPs accumulate proximal to ligatures of spinal nerves. In separate preparations DRG were pulse-labeled with ^{35}S-met and fractionated. Proteins present in crude microsomal fractions (100,000 x g pellet) as well as FTPs in 4 mm nerve segments proximal to ligatures were separated via two-dimensional gel electrophoresis (m.w. ~20 K - 200 K daltons; pI ~ 4.5 - 8.0). Gel fluorographic patterns of microsomal and FTPs were compared using comigration analyses. Qualitative results demonstrate that nearly all of 47 FTP gel spots could be identified in the microsomal fraction. However, of the 12 most abundant FTPs, 10 were present at barely detectable levels in the DRG sub-fraction. Despite varying the pulse period from 15 min to 4 h and allowing up to 10 h of chase, this population of FTPs still did not appear in the microsomal fraction in appreciable amount. Thus, it is unlikely that differential rates of incorporation could explain our basic observation. Since most of the population of proteins that were not readily detected in the DRG fraction are of lower m.w. (~20 K - 35 K daltons) it is possible that their more abundant appearance at the ligature is due to proteolytic processing of higher m.w. precursors during translocation. This explanation is weakened since no higher m.w. species show obvious decreases at the ligature relative to the DRG. Another possibility is that proteins of this sub-group do not accumulate in the cell bodies because they experience a markedly shorter transit time from soma to axon. Added evidence to support this explanation is that cobalt, an agent known to interfere with somal events of fast transport, depresses the amount of the low m.w. FTPs arriving at the ligature to a lesser extent than the higher m.w. species (Stone & Hammerschlag, Trans Am. Soc. Neurochem., 11:143, 1980). (Supported by a MDA fellowship and by NSF grant BNS 79-24125.)

30.2 MILD CNS ISCHEMIA ACCELERATES FAST AXONAL TRANSPORT. M. Jacewicz* and D.E. Levy. Lab. of Cerebral Metabolism, Dept. of Neurology, Cornell Univ. Med. College, New York, NY 10021.

We recently reported (Neurology, 30:376, 1980) the effects of transient central nervous system (CNS) ischemia on fast axonal transport. Employing a radiotracer technique in a rat model of unilateral optic nerve ischemia, we found that ischemia blocked transport. With reperfusion, however, some proteins remained blocked, but others showed accelerated movement down the axon. We now report that a similar surge of radioactive material may occur with persistent, but relatively mild ischemia.

In a double-label experiment, we first injected both eyes of awake rats with 30 μCi of ^{3}H-leucine, allowed 1 hour for protein synthesis and transport, and then induced unilateral eye and optic nerve ischemia. Ischemia was achieved by occluding the right external carotid and pterygopalatine arteries with clasps placed the previous day. The left side served as a control. Following 1 hour of ischemia, animals were injected intravenously with the blood flow marker, ^{14}C-iodoantipyrine, and were decapitated 6 seconds later. Optic nerves and tracts were rapidly removed and frozen; 1 mm segments were prepared for double-label liquid scintillation counting.

Radioactivity of both labels was measured for each optic nerve and tract and was expressed as a function of distance from the eye. Most animals showed marked blanching of the right eye; ipsilateral blood flow was reduced to 30% of control in the proximal optic nerve and rose to 80% of control near the chiasm. All such animals demonstrated blocked fast axonal transport during ischemia. A few animals, however, showed minimal or no blanching, and blood flow in this group fell to only 60% of control proximally and was 100% of control distally. This group showed increased levels of incorporated leucine (TCA-precipitable) along the entire length of optic nerve and tract (3-4 times the control side).

We conclude that fast axonal transport in the CNS is very sensitive to the level of blood flow. Severe ischemia blocks the appearance of radioactive protein down the axon, but mild ischemia accelerates this process. Prolonged, mild ischemia and brief, severe ischemia followed by reperfusion may have similar effects on fast axonal transport.

30.3 BIOCHEMICAL AND RADIOAUTOGRAPHIC STUDY OF THE CALCIUM REQUIREMENT FOR FAST AXONAL TRANSPORT OF PROTEINS. P.-A. Lavoie and G. Bennett*. Dépt. de pharmacologie, Université de Montréal, and Dept. of Anatomy, McGill University, Montreal, Canada.

Many fast transported proteins are glycoproteins. Dorsal root ganglia (DRG) from bullfrogs were exposed to [^{3}H]fucose in vitro, and the fate of the [^{3}H]glycoproteins was followed during a subsequent incubation period where the ganglia and spinal nerves from one side of the animal served as control preparations and those from the other side served as experimental preparations. The DRG of the experimental preparations were incubated in a medium which either lacked Ca^{2+} or was supplemented with Co^{2+} (a Ca^{2+} antagonist). Two parallel studies were done: in one, the effect of the modified medium on fast axonal transport of [^{3}H]glycoproteins was quantitated by liquid scintillation counting of the TCA-insoluble radioactivity in nerve segments; in the other, the effect of the modified medium on the distribution of label in the DRG was assessed by light microscopic radioautography.

With either calcium-free medium + 1 mM EGTA or normal medium + 0.18 mM $CoCl_2$, the biochemical analysis showed that the quantity of [^{3}H]glycoproteins carried by the fast transport system was greatly reduced as compared to the contralateral control. However, the incorporation of [^{3}H]fucose into glycoproteins, which occurs mostly during the incubation period (Hammerschlag & Lavoie; Neuroscience 4: 1195, 1979), was normal. This would indicate that proteins destined for transport had migrated normally to the Golgi apparatus. In radioautographs of control ganglia, reaction in most neurons was diffusely scattered over the cytoplasm of the cell body; in instances where the beginning (unmyelinated) portions of axons were seen in continuity with neuronal cell bodies, the axoplasm exhibited a diffuse reaction of the same intensity as that of the cell body. After longer exposure times, diffuse reaction also appeared over the axoplasm of myelinated axons. In experimental ganglia, reaction in most neuronal cell bodies was concentrated in the paranuclear Golgi region and less diffuse reaction was present; in instances where the beginning portions of axons were observed, the axoplasm was usually unlabeled. Similarly, even after long exposure times, the axoplasm of myelinated axons remained relatively free of label. These results provide further support for the concept that glycoproteins destined for fast axonal transport pass through the Golgi apparatus, and suggest that Ca^{2+} is necessary for the glycoproteins to leave the Golgi apparatus.
Supported by MRC of Canada grants to G. Bennett and P.-A. Lavoie, and a CRSQ Establishment Grant to P.-A. Lavoie.

30.4 SEQUENTIAL DAMMING ANALYSIS OF GLYCOPROTEIN AXOPLASMIC TRANSPORT. Johnson* J.L. & J.-H. Kim, Div. of Biochem., Physiol. & Pharmacol., USD School of Medicine, Vermillion, S.D. 57069

The precise nature of the distribution of most highly mobile glycoproteins in the axonal advancing wave has not yet been precisely defined. The purpose of this study therefore is to use a sequential damming technique in order to define this distribution. Following dorsal root ganglionic injection of ^{3}H-fucose an *in vivo* flow time of 4 hrs, 10 hrs or 24 hrs was allowed after which the cat was sacrificed and the sciatic nerves separated from the ganglion, cleared of excess material and crushed at 30mm, 60mm, 90mm and 120mm distances from the most proximal site. The nerves were then placed in an oxygenated Ringer's solution (37°C) for 4 hrs of *in vitro* damming (4+4, 10+4 and 24+4 hrs). At 4+4 hrs, damming was only seen at 30+60mm sites, while at 10+4 hrs damming was seen at all sites (transport rate = 360mm per day). In all cases, the damming level decreased exponentially when passing towards the ganglion side from the 120mm site. For the 10+4 hr, the equation for this was $\ln Y = 0.0125X + 4.556$ (Y=% damming, X=distance in mm, correlation coefficient = 0.998, N=4). This may reflect an exponentially decreasing output of the pulse injected fucose label, and predicts, when extrapolated back to the ganglion, that at 10 hrs there was no more output of this labeled fraction. Consistent with this was the observation that by 24+4 hrs the damming amount was much less than that seen at 4+4 or 10+4 hrs. The slope of this trailing edge was 26% steeper at 10 hrs than at 4 hrs. Consistent with this was the observation that the distal damming was greater at 10 hrs than at 4 hrs. This suggests an enrichment of the fast transported material with passage away from the ganglion. Assuming a constant output of these fast transported proteins, it was calculated that over the entire distribution at 10 hrs, 40% was labeled protein and 60% was newly formed and unlabeled. Analysis of the damming site using SDS-acrylamide gel electrophoresis showed that although several molecular weight ranges were involved in this damming, glycoprotein in the range of 36-58,000 are the most enriched. This is consistent with data (Brain Res., 121, 1977, 215) suggesting that glycoproteins in this range contain components that are rapidly conveyed to the synapse as well as deposited in the axon.

30.5 BATRACHOTOXIN BLOCKS SALTATORY ORGANELLE MOVEMENTS IN ELECTRICALLY EXCITABLE NEUROBLASTOMA CELLS. D. S. Forman and W. G. Shain, Jr. Naval Medical Research Institute and Armed Forces Radiobiology Research Institute,NNMC,Bethesda,MD 20014.

The fast axonal transport of intra-axonal organelles that can be visualized by light microscopy proceeds by a series of saltatory movements, similar to those seen in other types of cells (Forman et al., Brain Res. 136:197, 1977). Saltatory organelle movement in neurites of neuroblastoma cells is a convenient model for studying this process in a cell with neural properties. Batrachotoxin inhibits fast axonal transport of labeled materials, and there is evidence suggesting that this effect may be independent of the well-established action of batrachotoxin in opening action potential Na^+ channels (Ochs and Worth, Science 187:1087, 1975; Kumara-Siri, J. Neurobiol. 10:509, 1979). It was therefore of interest to determine whether batrachotoxin would inhibit saltatory organelle movements. N115 neuroblastoma cells were grown on glass coverslips, and were observed in a continuously perfused chamber using phase optics and time-lapse Video Intensification Microscopy (Willingham and Pastan, Cell 13:501, 1978). Batrachotoxin inhibited saltatory movement in a time- and concentration-dependent manner. In 0.5 µM batrachotoxin saltatory movement stopped in most cells within 1 hr. In 1.0 µM batrachotoxin this time was reduced to 30 minutes, while in 0.1-0.2 µM more than an hour was required, and little or no effect was seen after 3 hours in 0.01 µM. This dose-response curve is consistent with that for the activation of action potential Na^+ channels in neuroblastoma cells by batrachotoxin (Catterall, J. Biol. Chem. 250:4053, 1975). The inhibition of saltatory movements by 0.5 µM batrachotoxin was reversible. Batrachotoxin also produced other changes, including neurite retraction and organelle clumping, but membrane ruffling movements were not inhibited. 1 µM tetrodotoxin, which blocks the Na^+ channels opened by batrachotoxin, completely prevented the effects of 0.5 µM batrachotoxin. Batrachotoxin (1.0 µM) had no effect on a number of cells that are not electrically excitable: 3T3 fibroblasts, and N103 and LB4 neuroblastoma cells. Replacing Na^+ in the medium with choline partially prevented the effects of 0.5 µM batrachotoxin, although morphological changes such as neurite retraction occurred in many cells. This evidence is all consistent with the hypothesis that the primary action of batrachotoxin is the activation of the action potential Na^+ channels, and that the inhibition of saltatory organelle movements (and by inference, fast axonal transport) may be a consequence of the disruption of normal internal ionic concentrations following depolarization of the cells.

30.6 4S RNA IS AXONALLY TRANSPORTED IN INTACT AND REGENERATING SCIATIC NERVES OF RATS. T.D. Lindquist*, N.A. Ingoglia, and R.M. Gould. (SPONS: F.P.J. Diecke) CMDNJ-New Jersey Med. Sch., Newark, NJ 07103 and New York State Inst. for Basic Res. Ment. Retard., Staten Island, NY 10314.

Experiments were designed: (1) to determine if following application of ^{3}H-uridine to ventral horn cells of the rat spinal cord ^{3}H-RNA could be demonstrated within intact and/or regenerating axons of the sciatic nerve, and (2) to test the hypothesis that only 4S RNA is transported axonally in this system.

In the first set of experiments the left sciatic nerve of rats was crushed. Two days later 170 µCi of ^{3}H-uridine was injected into the vicinity of the ventral horn cells giving rise to the sciatic nerve, thus labeling the nerve by axonal transport. Ten days after injection, rats were sacrificed and sciatic nerves were prepared for light and EM autoradiography. Photomicrographs were taken of randomly labeled areas of intact and regenerating nerves and grains were counted over Schwann cells, myelin, axons and other unspecified areas. Approx. 22% of the grains were associated with axons, 43% with Schwann cell cytoplasm, with the remainder either over myelin or other non-neural structures. Thus >20% of the ^{3}H-RNA in the nerve is present in axons.

In the second series of experiments the left sciatic nerve was crushed and 10 days later (^{3}H)-uridine was bilaterally injected intraspinally into 6 rats. Four control rats were sacrificed at 14 or 20 ds after injection. In the remaining 2 rats the sciatic nerve was cut 14 ds after injection and the distal part of the nerve was allowed to degenerate for 6 ds before sacrificing the rat. Thus, the distal portion of the nerve contained Schwann cells labeled by axonal transport but lacked intact axons. RNA was isolated from experimental and control nerve segments by hot phenol extraction and ethanol precipitation. RNA species (28S,18S and 4S) were separated by polyacrylamide gel electrophoresis and radioactivity was measured in a liquid scintillation counter. Control groups had RNA profiles similar to those already described, with approx. 40% of the radioactivity present as 4S RNA. The proximal portions of nerve taken from the group in which nerves were cut, also had approx. 40% of the radioactivity present as 4S RNA. However, in the distal segments of these nerves (in which the axons had degenerated thus creating an "axon-less" nerve) the amount of radioactivity in the 4S peak decreased to approx. 15% of the total RNA, suggesting that 4S RNA is the predominant if not the only RNA present in these axons. These results strongly indicate that both intact and regenerating axons in the sciatic nerves of rats selectively transport 4S RNA along their axons.

Supported by EI-02887 from NIH.

30.7 POSTNATAL CHANGES IN AXONALLY TRANSPORTED ^{3}H-FUCOSYL MEMBRANE PROTEINS AND GLYCOLIPIDS OF HAMSTER OPTIC NERVE SYNAPTOSOMES. Susan Corey Specht and Teresa Candelas*. Dept. of Pharmacology, Univ. Puerto Rico Sch. Med., San Juan, PR 00936.

The glycoconjugates axonally transported to optic nerve endings of neonatal and adult hamsters were studied following intraocular injection of ^{3}H-fucose. Subsynaptosomal fractions were isolated by the method of Cohen et al. (J. Cell Biol., 74, 181, 1977), and precipitated with 5% TCA for analysis of incorporated ^{3}H-fucose. One day post-injection labeling was predominately in the external membrane fraction of adults with only 9% in the "vesicle" fraction, whereas approximately 35% was in the "vesicle" fraction of 12 and 16 day neonates. Nonetheless, in adults sacrificed 3 h post-injection, 35% of the ^{3}H-fucose was present in the "vesicle" fraction, suggesting rapid turnover in adults.

A Folch-Suzuki procedure was used to extract and partition glycolipids. Although the "vesicle" fraction contained only 8-14% of total synaptosomal protein, at least 80% of the label was in CM-insoluble or CM-extracted glycoprotein; a maximum of 15% was found in the ganglioside phase of both adults and neonates. Hence, "vesicle" fraction glycoprotein has the highest specific activity (dpm/mg protein) of subsynaptosomal components.

Synaptosomal membranes isolated by the flotation gradient method of Jones and Matus (Biochim. Biophys. Acta, 356, 276, 1974) were subjected to SDS-polyacrylamide slab gel electrophoresis 24 h following intraocular injection of ^{3}H-fucose. Protein bands comigrating with α-tubulin, β-tubulin, actin and at 55K were noted at all ages in addition to 48-52K bands. The most heavily labeled band in adults and 16 day hamster optic nerve membrane had an apparent molecular weight of 48-52K. This band did not contain detectable ^{3}H-fucose at 5 days postnatal (major labeling was in bands of more than 100K), and was a minor labeled band at 12 days postnatal. Hence, fucosylation of a major synaptic membrane protein demonstrates a developmental pattern. (Supported in part by USPHS grant EY 02334.)

30.8 SLOW AXONAL TRANSPORT IN GOLDFISH OPTIC AXONS. Roberta M. Alpert*, Bernice Grafstein, and D. Louise Edwards. (SPON: T.J.Cunningham). Dept. Physiology, Cornell Univ. Med. Coll., New York, NY 10021.

Axonal transport of proteins in the optic axons of goldfish can be studied by injecting a radioactively labeled amino acid into the eye and then determining the rate of displacement of radioactively labeled protein along the optic nerve. Slow axonal transport manifests itself in the appearance of a gradient of radioactivity extending along the nerve for several mm behind the eye. A semi-logarithmic plot of the distribution of radioactivity gives a straight line, the slope of which changes with time after the injection as the slow transport advances (B. Grafstein and M. Murray, Exp. Neurol. 25, 494, 1969).

In the present study, measurements of the change in slope were made to determine whether the rate of advance of slow transport was affected by various experimental conditions. The experiments were carried out on fish in which the optic tract had been cut 6-8 days earlier, in order to accelerate the rate of change of slope. After the injection of 4 µCi of ^{3}H-leucine into the eye, 2 days were allowed to elapse to permit the slowly transported protein to emerge from the eye into the nerve, and then one of the following procedures was carried out on the experimental group of animals: a) block of retinal protein synthesis by intraocular injection of cycloheximide or actinomycin-D; b) removal of the retina; c) block of physiological activity in the retina by intraocular injection of tetrodotoxin; d) lowering the temperature. In each case the experimental conditions were maintained for 24 or 48 hours, while the control animals remained under normal conditions for the same period of time. The optic nerves were then fixed in Bouin's solution and divided into 250 µ segments, which were assayed by liquid scintillation counting.

These experiments have led to the following conclusions: slow transport is immediately arrested when retinal protein synthesis is blocked; the transport continues for 24 hours in axons that have been separated from their cell bodies; abolition of action potentials by tetrodotoxin does not affect the transport velocity; the transport velocity does not change with lowering of the temperature, but transport is blocked at a temperature of about 10° C. The arrest of slow transport upon inhibition of cell body protein synthesis and the insensitivity of the transport velocity to low temperature are features that distinguish this mode of transport from fast axonal transport.

30.9 DIRECT VISUALIZATION OF THE CYTOSKELETAL NATURE OF AXOPLASM. Thomas J. Deerinck* and Mark H. Ellisman Dept. of Neuroscience, U. Calif. at San Diego, La Jolla, CA 92093

It has been suggested that the electron scattering properties of epoxy resins hinder the full visualization of the finer components within the matrix of axoplasm. To circumvent this potential problem, we have adapted a technique that allows the direct visualization of axoplasm in thin sections with transmission EM (TEM) or with scanning EM (SEM) without an embedding matrix.

The technique involves fixing rat spinal roots in glutaraldehyde, paraformaldehyde, and tannic acid, post-fixing in osmium tetroxide and infiltrating with a water soluble polyethylene glycol (PEG) compound. Sections are cut on a special glass knife into water and mounted underwater on polybutene-coated grids. The PEG is further washed out with water and the sections are dehydrated and critical point dried.

Earlier, in standard epoxy preparations we noted that the so-called wispy fragments projecting from microtubules and neurofilaments within axoplasm are part of a three-dimensional lattice. This lattice or microtrabecular matrix of axoplasm was found to consist of an organized system of crossbridges between microtubules, neurofilaments (100Å filaments), cisternae of the smooth endoplasmic reticulum and the plasma membrane. Unlike conventional epoxy sections where the microtrabecular lattice of axoplasm appears as wispy, discontinuous fragments, these "tissue only" PEG sections show an axoplasm rich with a continuous crossbridging lattice.

Preparations derived from PEG embedded tissue may be examined in the SEM after removal of the embedding matrix. For these purposes we have found it most useful to cut a large block face, then save, not the sections, but the block face, removing the PEG and further processing the tissue as mentioned above. Where axons have been sectioned open, the fibrous nature of the axoplasm may be readily appreciated. At high magnifications neurofilaments and microtubules may be recognized as well as fine lateral projections corresponding to the trabecular elements described in our PEG thin sections. The preparation of PEG embedded blocks of tissue for SEM is far less difficult and more rapid than preparing sections of PEG embedded material for TEM.

Using a periodate-lysine-paraformaldehyde fixative (McLean & Nakane, 1974) that preserves antigenicity, we have shown that the lattice structure is maintained long enough to permit immunocytochemical localizations. Either sections or block faces from these preparations may be suitable for immunoelectron microscopy and may help circumvent antibody accessability problems.

30.10 THE ULTRASTRUCTURAL SITE OF FAST AXONAL TRANSPORT INITIATION: ROLE OF THE GOLGI APPARATUS AND SMOOTH ENDOPLASMIC RETICULUM. James D. Lindsey and Mark H. Ellisman, Department of Neurosciences, University of California at San Diego, La Jolla, CA 92093.

Recent studies have shown that the initiation of fast axonal transport requires the presence of calcium and is selectively poisoned in the presence of 0.18 mM cobalt (Hammerschlag et al., 1977). To identify the cellular systems that might play important roles in transport initiation, frog spinal ganglia were incubated for 24 hrs. in media known to inhibit the export of glycoproteins from the soma to the axon, and then examined electron microscopically. When compared with incubation in normal frog Ringer's medium (NM), incubations in calcium free media (CFM), NM supplemented with 0.18mM cobalt (NM-Co), and CFM supplemental with 0.18mM cobalt (CFM-Co) had little effect on the morphology of most somal organelles. Striking changes, however, were seen in the smooth endoplasmic reticulum (smooth ER) and the Golgi apparatus.

Quantitative analysis showed that in order of effect, CFM, NM-Co, and CFM-Co produced increasing amounts of smooth ER coupled with decreasing densities of identifiable Golgi apparatus stacks. In the extreme case CFM-Co incubation resulted in a nearly 10-fold increase in the smooth ER volume as well as a virtually complete depletion of Golgi apparatus stacks. The accumulated smooth ER often appeared as clumps of rounded profiles and was strongly associated with rough ER. After NM-Co incubation, the remaining GA stacks usually exhibited swollen cis pole elements. Disruption at the cis pole was also noted after CFM incubation, however, it was much less pronounced than after NM-Co incubation.

Incubations in CFM-Co for 12 hr. produced results similar to the longer incubation except that some Golgi apparatus stacks remained. After processing 12 hr. CFM-Co preparations for the demonstration of thiamine pyrophosphatase, the trans elements of these Golgi apparatus stacks stained similarly to those of control ganglia. The accumulated smooth ER profiles, however, were not stained by this technique.

Axons originating within the ganglia were also examined. CFM and NM-Co incubation resulted in moderate vesiculation of the axonal smooth ER. CFM-Co incubation resulted in moderate swelling of the SER profiles. Otherwise, the incubations had little effect on axonal ultrastructure.

30.11 HORSERADISH PEROXIDASE DETERMINATION OF BRAIN STEM AND DIENCEPHALIC INNERVATION OF THE LUMBAR AREA OF THE SPINAL CORD. S. L. Scharoun*, F. C. Barone and M. J. Wayner. Brain Research Lab, Syracuse Univ, 601 Univ Ave, Syracuse, NY 13210.

Horseradish peroxidase (HRP, Sigma Type VI, 50%) was injected into the second lumbar segment of the spinal cord of male hooded rats. After 36-48 hr the animals were perfused intracardially with a phosphate buffer plus a sucrose wash followed by glutaraldehyde and paraformaldehyde fixative. The whole brain and the injected portion of the spinal cord were removed and sectioned. Alternate sections were processed with DAB and counterstained with cresyl violet, and with BDH and counterstained with neutral red for the brown and blue reactions respectively. Sequential sections were examined and positively labeled neurons were identified and photographed by a microscope with both light and dark fields. Labeled neurons were identified in the lateral hypothalamic and ventromedial hypothalamic regions of the diencephalon. In addition, labeled neurons and axons were also observed in the brain stem. These results, based on the retrograde movement of HRP, indicate that direct innervation of spinal motor neurons occurs from some neurons in the ventral diencephalon and that these direct connections, together with polysynaptic connections through the descending reticular formation and other mesencephalic regions, are involved in the motor control functions of the hypothalamus. 31.1 HIPPOCAMPAL POLYMORPHE NEURONS PROJECT TO THE "COMMISSURAL" DENDRITIC ZONE OF THE DENTATE GYRUS. S. L. Semple-Rowland*, J.L. Bassett* and T. W. Berger (SPON: A. Mallinger). Psychobiology Program, Dept. Psych., Univ. of Pittsburgh, Pittsburgh, PA 15260.

A longitudinal association system in the dentate gyrus has been anatomically identified by Zimmer (J. Comp. Neurol., 142:393 1971). This projection terminates within the inner one-third of the dentate dendritic region, the same zone which receives commissural hippocampal input (Gottlieb, D.I. and Cowan, W.M., J. Comp. Neurol., 149:393, 1973). While Zimmer's evidence implicated the CA3c/CA4 pyramidal neurons as the cells of origin for this projection, hilar polymorphic neurons could not be ruled out (Lorente de No, R., J. Psychol. Neurol., Lpz., 46:113, 1934). We have begun analysis of the system using axonal transport techniques, and here report the conclusive identification of polymorphe neurons of the hippocampal hilus as the cells of origin for afferents to the inner one-third of the dentate stratum moleculare.

All studies were conducted in male, New Zealand white rabbits. Horseradish peroxidase (HRP-Sigma, type VI, concentration of 33%) in volumes of 0.02-0.10 ul was injected into various septo-temporal regions of the hippocampus proper. Tissue was prepared according to Mesulum (J. Histochem. Cytochem., 24:1273, 1976; ibid., 26: 106, 1978). For autoradiographic experiments, volumes of 0.1-0.2 ul of ^{3}H proline (New England Nuclear) in 50 uCi/ul concentration were injected into the hilar region of the temporal hippocampus, and material was prepared with established procedures (Cowan, W.M. et al., Brain Res., 37:21, 1972).

Examination of temporal hippocampal regions following septal hippocampal HRP injections revealed retrograde cell labeling of polymorphic neurons within the temporal dentate hilar area. In almost all cases, HRP-containing neurons were easily discriminated as lying directly beneath the dentate granule cell layer and regionally separate from CA4 hilar neurons. Only neurons in this location were ever observed as labeled, and these were seen only after injections involved the dorsal hippocampal dentate gyrus. Labeled polymorphe neurons were seen both ipsilaterally and contralaterally to the injection site.

When either HRP or tritiated amino acids were injected into the dentate/hilar region of the temporal hippocampus, dense terminal labeling was visible in the inner one-third of the molecular layer of the dentate gyrus, in a laminated pattern identical to that described by Zimmer. No other region of the hippocampus was seen to contain anterogradely transported product. We feel this evidence conclusively identifies hippocampal hilar polymorphe neurons as the cells of origin for afferents to the "commissural" zone of the dentate gyrus.

31.2 ASSOCIATION CONNECTIONS BETWEEN POSTERIOR AND ANTERIOR LIMBIC CORTICES IN THE RABBIT. J. L. Bassett* and T. W. Berger (SPON: R. Jennings). Psychobiology Program, Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15260

Association connections between subdivisions of cingulate cortex have been difficult to evaluate with degeneration anatomical methods (Domesick, V.B., Brain Res., 12:296, 1979). We have recently begun an examination of limbic cortical connectivity with axonal transport techniques, and here report the existence of reciprocal associational pathways between posterior cingulate/retrosplenial and anterior limbic cortical regions in the rabbit brain.

Terminology for limbic cortical regions refers to that of Rose and Woolsey (J. Comp. Neurol., 89:279, 1949) for the rabbit. That is, posterior limbic cortex is assumed to include granular cingulate and retrosplenial components; rostral agranular limbic areas of interest here are the anterior limbic and infralimbic cortical subdivisions. HRP (Sigma, type VI, concentration 33%) in volumes of 0.02-0.05 ul was injected into cingulate, retrosplenial, or anterior limbic cortical zones. Following a survival time of 24-48 hours, tissue was prepared according to Mesulum (J. Histochem., 24:1273, 1976; ibid., 26:106, 1978). For autoradiographic experiments, ^{3}H proline in 50uCi/ul concentration was injected into the above cortical regions and material was prepared with established procedures (Cowan, W.M. et al., Brain Res., 37:21, 1972).

After HRP injections into posterior limbic cortex, retrogradely labeled neurons were consistently seen within what Rose and Woolsey have termed the anterior limbic cortical region (i.e. ventral to the precentral agranular area). HRP-positive neurons were occasionally found within the infralimbic area as well. Injections producing this retrograde pattern typically involved the cingulate and dorsal retrosplenial cortical regions. Anterogradely transported product from these anterior limbic regions was concentrated in layer I of both cingulate and retrosplenial cortex.

Injections of HRP in anterior limbic cortex resulted in heavy retrograde labeling of posterior retrosplenial cortical cells of lamina V. Injections did not infringe on the cingulum, so the latter labeling should not have resulted from uptake and transport by ruptured corticofugal fibers of unknown termination, or from corticothalamic projections which arise from layer VI (Berger, T. W. et al., Neurosci. Abstr., 5:270, 1979). To insure this was not the case, however, tritiated amino acids were injected into posterior cingulate/retrosplenial cortex. Silver grains were visible in the anterior cingulum, as expected, but were also evenly distributed over lamina in the anterior limbic cortex.

In total, these results demonstrate reciprocal associational connections between major subdivisions of limbic cortex in the rabbit.

31.3 DEVELOPMENT OF CA1 NEURONS IN RABBIT HIPPOCAMPUS. P. A. Schwartzkroin, L. H. Mathers, D. D. Kunkel, Dept. Neurological Surgery, Univ. Washington, Seattle, WA 98195 and Dept. Biological Structure, Stanford Univ., Stanford, CA 94305.

The development of hippocampal neurons in the CA1 region of rabbit has been studied using electrophysiological and neuroanatomical techniques. Intracellular recordings were obtained from cells in animals from fetal stage to the adult using an in vitro hippocampal slice preparation. At comparable ages, hippocampal tissue was taken for light and electronmicroscopic investigation.

Recordings from young rabbits revealed spiking activity and functional synaptic contacts. Healthy impalements were difficult to obtain, presumably due to the small cell size. Resting potential in good penetrations, however, was similar in mature and immature rabbits. Action potentials were somewhat broader in young animals than in the adult (> 2.0 msec at birth vs. 1.4 msec in adults), and cell input resistance was considerably higher (50-60 MΩ in newborn vs. 25 MΩ in adults). These differences were undetectable by the second to third weeks of age. Calcium spikes were seen in very young rabbits (4 days, probably younger), but in no case were calcium spikes seen before sodium spikes. Onset of spiking activity appeared to be 7-10 days before birth.

Synaptic events were first observed 2-5 days before birth, and events were almost always long duration depolarizations. These EPSPs were elicited by stimulation in strata radiatum and oriens, could trigger action potentials, and were associated with conductance increases. Repetitive stimulation at 3-10 Hz produced EPSP potentiation and in some cases led to seizure after-discharge. Animals 1-2 weeks old were particularly seizure-prone. IPSPs were rarely seen in animals less than 2 weeks old; IPSPs were apparent after this time, as were cell types tentatively identified as interneurons.

Anatomical studies provided parallel data. Light microscopic analysis indicated that the dendritic regions of CA1 undergo the greatest expansion during development. Dendritic length, number of branches, and spine density all increase to near adult levels at 3 to 4 weeks of age. Synapse number and location were analyzed in EM photomicrographs from CA1 pyramidale and radiatum regions, using both osmicated and E-PTA stained material. In both regions there was a monotonic increase in number of synapses in animals up to 1 month of age. Synapses in stratum pyramidale were rare in young animals, the earliest synapses being concentrated in dendritic regions. Symmetrical synapses first appeared in countable numbers in animals 5-10 days old, just prior to onset of physiologically-recorded IPSP activity.

31.4 NEUROGENESIS IN THE RAT AMYGDALA. S. A. Bayer. Dept. of Biol. Sci., Purdue Univ., W. Lafayette, IN 47907.

Neurogenesis in the rat amygdala was examined with ^{3}H-thymidine radiography. The animals were the offspring of pregnant females given two injections of ^{3}H-thymidine on consecutive days in an overlapping series: Embryonic day (E) 12+E13, E13+E14, ... E21+E22. On 60 days of age, the percentage of labelled cells and the proportion of cells added during each day of formation were determined at several anatomical levels within the amygdala.

All large and many small neurons originate in most nuclei between E13-E17, those in the intercalated masses between E15-E19, those in the amygdalo-hippocampal area between E16-E19. The anterior amygdaloid area, intercalated masses, central, medial, posterolateral cortical, posteromedial cortical, basomedial, basolateral and lateral nuclei have strong rostral to caudal intranuclear gradients. There are five additional intranuclear gradients: 1) medial to lateral in the central nucleus, anterior amygdaloid area, and anterior intercalated masses; 2) lateral to medial in the bed nucleus of the lateral olfactory tract and basolateral nucleus; 3) superficial to deep in the amygdalo-hippocampal area, posterolateral and posteromedial cortical nuclei; 4) ventral to dorsal in the medial nucleus; 5) dorsal to ventral between the small and large-celled parts of the lateral nucleus. Only the bed nucleus of the accessory olfactory tract and the anterior cortical nucleus do not have intranuclear gradients. Between 10-15% of the total cell population in most nuclei are very small neurons and/or glia which originate simultaneously between E18-E20. This population is absent in the ventral part of the medial, anterior cortical, and anterior basomedial nuclei; these contiguous areas may form a distinct subunit in the amygdala.

In contrast to the pronounced intranuclear gradient, internuclear gradients are weak. There are groups of early-originating neurons in the central, medial and basolateral nuclei located near the periphery of the amygdala. Each of these groups is surrounded by younger neurons farther within the interior. The youngest cells are in the centrally-placed intercalated masses. These settling patterns suggest that cells in the amygdala arise simultaneously from more than one neuroepithelial source during morphogenesis. The chronology of neurogenesis in the amygdala may be related to some of its anatomical connections; for example, rostral to caudal gradients in the corticomedial complex may be timed to coincide with early vs. late arrival of olfactory fibers.

Supported by the National Science Foundation (BNS 79-21303).

31.5 FURTHER OBSERVATIONS ON THE DEVELOPMENT OF THE CONNECTIONS OF THE HIPPOCAMPAL FORMATION. D.G. Amaral, B.B. Stanfield and W.M. Cowan. Dept. of Anatomy and Neurobiology, Wash. Univ. Sch. of Med., St. Louis, MO 63110.

The development of certain of the afferent and efferent connections of the hippocampal formation of the rat has been examined by making relatively small injections of ^{3}H-proline or horseradish peroxidase (HRP) into either the hippocampal region itself or the diencephalon, on the day of birth (day 0) or on postnatal day 1,2,3,5,7 or 9; in each case the post-injection survival time was 6 hours.

Following injections of HRP into the hippocampus on day 0, retrogradely labeled pyramidal and hilar cells were seen in the contralateral hippocampus in those areas which, in mature animals, are known to contribute to the commissural projection. Comparable injections of ^{3}H-proline at this stage resulted in substantial labeling in both the *stratum oriens* and the *stratum radiatum* of the contralateral *regio superior* and *regio inferior* of the hippocampus but failed to give rise to label in the contralateral dentate gyrus. However, both the ipsilateral associational and the entorhinal projections to the dentate gyrus were labeled by ^{3}H-proline injections on day 0.

On day 1, diencephalic afferents to the hippocampus (but not to the dentate gyrus) could be seen after ^{3}H-proline injections. The commissural fibers may have reached the septal pole of the dentate gyrus by day 1 but this projection was not clearly labeled until day 2. Hypothalamic injections on day 3 gave rise to labeled fibers within the developing *stratum moleculare* of the supra-pyramidal blade of the dentate gyrus.

Some observations were also made on the development of hippocampal efferents. The projections from the subicular complex to the thalamus and hypothalamus could be seen as early as day 0, as could the projection from the hippocampus to the lateral septum. The hippocampal and subicular projections to the entorhinal cortex (especially layer 4) were labeled on postnatal day 1.

These results demonstrate that the various hippocampal afferents investigated reach their sites of termination somewhat earlier than has previously been shown and, when taken together with developmental ultrastructual studies, indicate (at least for the dentate gyrus) the major afferent fiber systems are present and topographically arranged in a manner characteristic of their eventual lamination several days before significant numbers of morphologically-identifiable synapses can be seen in their zones of termination. Although the different fiber systems appear to be topographically segregated from the time of their arrival, we cannot exclude the possibility of some degree of overlap between them, when they first reach their target regions.

Supported in part by grants NS 10943 and F32-NSO-5765.

31.6 NEURONS OF ORIGIN OF THE PERFORANT PATH. P.D. Coleman and S.P. Schwartz* (SPON: J. Ison). Dept. of Anatomy, Univ. of Rochester Sch. of Med. and Dent., Rochester, NY 14642.

The perforant path projection from entorhinal cortex to the hippocampal formation was first described over 70 years ago by Cajal. Yet, the identity of the neurons of origin of this pathway remains uncertain. Recent investigations utilizing the horseradish peroxidase (HRP) retrograde transport method have provided evidence that these neurons are in layers II and III of the entorhinal cortex. However, the unequivocal identification of these cells in terms of the cell types seen in Golgi-stained material could not be accomplished in these retrograde transport studies.

Diffuse filling of injured axons with HRP has been used to reveal Golgi-like pictures of dendritic and axonal arborizations. We have applied this method to determine the form of the neurons of origin of the perforant path by inserting an HRP-laden plug of Gelfoam directly into the dorsal hippocampal formation of Fisher 344 rats. After a survival of 22 hours, the animal was perfused in accordance with the procedure of Rosene and Mesulam (J. Histochem. Cytochem., 26:28, 1978). The brain was frozen-sectioned at 80μm horizontally and processed by a modified version of Adam's diaminobenzidine method (Neurosci., 2:141, 1977). Heavily labeled cells containing both the granular and diffuse reaction products were observed in layer II of the ipsilateral entorhinal cortex. These labeled cells were both stellate and fusiform neurons with the former predominating in pars medialis and the latter in pars lateralis. In agreement with Golgi descriptions of this region, the dendritic ramifications of both cell types were largely restricted to layers I and II. Less intensely labeled pyramidal cells containing only the granular form of reaction product were seen in layer III both ipsilaterally and contralaterally.

Our findings demonstrate for the first time that the layer II neurons of entorhinal cortex which project to the hippocampal formation (LaVail, J.H., et al., Brain Res., 58:470, 1973; Segal, M. and S. Landis, Brain Res., 78:1, 1974; Steward, O. and S.A. Scoville, J. Comp. Neur., 169:347, 1976) are stellate and fusiform cells.

Supported by NIH Grant AG1121 to PDC.

31.7 A DEVELOPMENTAL COMPARISON OF LTP IN AREAS CA1 AND FASCIA DENTATA OF THE RAT HIPPOCAMPAL FORMATION. K. M. Harris, T. J. Teyler, and W. L. R. Cruce. Program in Neurobiology, Northeastern Ohio Universities College of Medicine, Rootstown, OH 44272.

Granule cells of rat dentate gyrus are known to proliferate postnatally with peak proliferation at or about postnatal day 17, while pyramidal cells of area CA1 show their peak proliferation by embryonic day 19 and are not known to proliferate postnatally. With these developmental phenomena in mind we have begun experiments to determine if functional plasticity also follows a differential time course in these two regions. We have used the in vitro hippocampal slice preparation to study long-term-potentiation (LTP) in both of these areas from postnatal day 1 to postnatal day 30 and are continuing studies of more mature animals. As a measure of response plasticity, LTP is observed in the CA1 pyramidal cell layer or dentate granule cell layer as an increase in extracellular evoked population response to monosynaptic activation following a brief tetanus applied to Schaffer collaterals or perforant pathway fibers, respectively.

For each age group, animals were randomly choosen from a litter so that several age groups were represented across litters, and littermates were compared across age groups. Young animals were killed by decapitation and the hippocampus was rapidly dissected free, sliced at 400μm thickness, and several slices transferred to different pools in an incubation chamber (Alger and Teyler, 1976, Brain Research, 110:463-480). In this system the slices remained healthy for at least four hours as shown by absence of decay in responsivity to afferent stimulation of either CA1 or dentate gyrus.

After the slices equilibrated in vitro for an hour, stimulating and recording electrodes were lowered into either area CA1 or dentate gyrus. Since several slices were available for use from each animal, measurements from area CA1 pyramidals were made from one slice and another slice from the same hippocampus was used to measure responses of dentate granule cells. To equate for length of in vitro incubation, area CA1 was examined first in some experiments, whereas the dentate gyrus was studied first in other experiments.

Preliminary results reveal a trend for area CA1 to lead in LTP magnitude until day 20. From day 20 to day 30 the pattern reverses, with the dentate gyrus showing more LTP, and CA1 LTP magnitude declining from earlier levels. Further studies will be required to determine whether the pattern will again reverse itself during maturation. For both areas the magnitude of potentiation is less than that reported for adults in previous studies.

31.8 NEURONAL ACTIVITY IN THE PREFRONTAL CORTEX, CAUDATE NUCLEUS AND MEDIODORSAL THALAMIC NUCLEUS DURING DELAYED RESPONSE PERFORMANCE OF IMMATURE AND ADULT RHESUS MONKEYS. G.E. Alexander, E.D. Witt and P.S. Goldman-Rakic. NICHD and NIMH, NIH, Bethesda, MD; and Yale School of Medicine, New Haven, CT.

For more than four decades it has been known that the dorsolateral prefrontal cortex (DLCx) in adult monkeys participates in the mediation of delayed response performance, since this capacity is impaired in animals which have undergone selective ablations or local cooling of this region. In immature monkeys, however, ablation or functional depression of the DLCx does not result in disruption of the capacity for delayed response performance, and recent studies have demonstrated that the monkey's dependence upon the DLCx in performing cognitive tasks such as delayed response develops gradually over the first three years of postnatal life. In contrast, the head of the caudate nucleus (HCN) and the mediodorsal thalamic nucleus (MDN), the principal subcortical nuclei which are known to participate in delayed response performance and which are connected anatomically to the DLCx, are of critical importance in both adult and infant monkeys. Lesions of either structure, regardless of age, result in impaired delayed response capacity.

We examined the activity of individual neurons in DLCx, HCN and MDN during delayed response performance in a total of 5 adult (36 months) and 7 immature (12 months) rhesus monkeys, using chronic extracellular recording techniques. Of the 261 DLCx units recorded from adult monkeys, 38% were activated during the delay interval between cue and response, whereas only 20% of the 268 units recorded from immature monkeys were so activated ($p<.001$). In contrast, there was no significant disparity between adults and infants in terms of the proportion of subcortical neurons activated during the delay interval. In the HCN 31% of 106 adult neurons and 32% of 140 infant neurons were activated during the delay interval. Similarly, in the parvocellular division of the MDN 34% of 76 adult neurons and 30% of 190 infant neurons manifested delay-related increases in firing.

The present data provide the first elecrophysiological evidence that subcortical mediation of delayed response performance in rhesus monkeys matures early in postnatal life--prior to one year of age. In contrast, the role of the DLCx in delayed response performance continues to grow throughout development and does not become prominent until 3 years of age. This age-dependent increase in the importance of the DLCx may be related to the two-fold expansion in the population of delay-activated prefrontal neurons which appears to occur during postnatal development.

31.9 PSEUDOPODIA BETWEEN MAMMALIAN NERVE TERMINALS ARE POTENTIALLY PLASTIC, PROBABLE POTASSIUM TRAPS. Alan F. Boyne & Sally B. Tarrant*, Dept. Pharm. & Exptl. Therap., Univ. MD, Sch. Med., Baltimore, MD 21201.

Stimulation of Torpedine ray electric organ can cause loss of synaptic vesicles and formation of pseudopodia. These extend from individual nerve terminals and penetrate reciprocal indentations in abutted terminals. Last year, we reported that similar structures occur in axodentritic terminals of unstimulated, perfused rat brains in the central nucleus of the amygdala.

Can significant concentrations of extracellular K^+ accumulate in the narrow space between pseudopodium and indentation during trains of action potentials? Literature values suggest release of 1 p'mole of K^+/cm^2/action potential. Assuming a 15 nm separation between the two membranes, this represents a concentration increment of 0.5 mM/action potential from either pseudopodium or indentation or of 1.0 mM if both fire simultaneously. In order to calculate the manner in which pseudopodial length and firing frequency would influence 'steady state' concentrations of K^+ achieved, the diffusional dissipation of K^+ from the pseudopodial base was calculated using equations for linear diffusion in a cylinder with an extended initial distribution and reflection at one end. The K^+ diffusion coefficient in the extracellular space of the brain has been reported to be 3.1×10^{-6} $cm^2 s^{-1}$. The more rapid the firing rate, the smaller the loss of K^+ by diffusion after each release and before the next and so the higher the 'steady state' achieved. As shown in the Figure pseudopodial length and firing rate interact in such a way that explosive accumulations of K^+ may be expected at physiological firing rates as the length increases above 1 micron.

The mean length in control amygdalae was 0.99 micron (n=6). Since stimulation in electric organ induces pseudopodia, it does not seem unreasonable that applied stimulation of rat brain may lengthen them (e.g., seizures or kindling). If so, subsequent trains of endogenously generated or of applied action potentials may liberate and trap enough K^+ to depolarize the synapses which are immediately adjacent to the pseudopodia. This would alter transmitter output.

31.10 COINCIDENCE OF ACHE-CONTAINING AND SUPRAMAMMILLARY NUCLEUS PROJECTIONS TO THE SUPRAGRANULAR LAYER OF THE RAT DENTATE GYRUS. S.S. Lasher, R.C. Wilson, and O. Steward. Depts. of Psychology, Physiology, and Neurological Surgery, Univ. of VA Sch. of Med., Charlottesville, VA 22908.

Recent anatomical (Wyss , J.M., Swanson, L.W., and Cowan, W.M., Anat. Embryol., 156:165, 1979) and electrophysiological (Segal, M., Br. Res., 162:137, 1979) reports have identified a hitherto unrecognized projection from the supramammillary nucleus of the hypothalamus to the supragranular layer of the dentate gyrus in the rat hippocampal formation. Because the supragranular zone is also the site of termination of a prominent acetylcholinesterase-containing projection of enigmatic origin and because the supramammillary region contains AchE-positive neurons, we sought to determine whether this newly discovered projection did, in fact, have its origin in the AchE-containing cells of the supramammillary nucleus.

Two sets of experiments using adult, male Sprague-Dawley rats were performed. A first series of animals received unilateral injections of HRP (.02-.05ul, 25% solution) into the supramammillary region. Following a 2-day survival the animals were anesthetized and perfused, their brains removed and sectioned and alternate sections were processed for AchE histochemistry and for HRP anterograde (terminal) labeling using the tetramethyl benzidine procedure. Direct comparison of the HRP labeled terminal field and the AchE-positive zone in the dentate supragranular layer revealed that the terminal zones were largely coincidental.

To ascertain whether the cells of origin of the supramammillary projection were AchE-positive, a second series of rats received unilateral HRP injections (0.1-0.5ul) in the dentate gyrus. In these brains, combined AchE histochemical and HRP-TMB procedures were carried out on the same section to permit double-labeling of AchE-containing neurons which also had been filled with HRP transported retrogradely from the dentate gyrus. Numerous neurons were found in the supramammillary nucleus which were lightly stained for AchE and which also contained the HRP reaction product.

Although previous studies have demonstrated that most of the AchE in the hippocampus is derived from direct projections from the medial septal nucleus, evidence for a septal projection to the supragranular layer is not conclusive. While AchE staining of cell bodies is not positive evidence for a cholinergic projection, the present results suggest that some portion of the AchE staining in the supragranular zone may be attributable to the projection arising in the hypothalamic supramammillary nucleus.

31.11 ELECTROPHYSIOLOGICAL IDENTIFICATION OF INTERNEURONES IN THE HIPPOCAMPAL CA1 PYRAMIDAL CELL LAYER: IN VITRO AND IN VIVO ANALYSIS. J.J. Miller, T.S. Miles* and R.W. Turner*. Dept. of Physiology, Univ. British Columbia, Vancouver, Canada V6T 1W5.

Stimulation of the schaeffer/commissural (Sch/Com) input results in a monosynaptic activation of pyramidal cells (P) in the hippocampal CA1 region. This activation is followed by a long duration inhibitory period on spontaneously firing P cells which is presumed to be mediated by basket cell interneurones. In the course of examining the plastic properties of the Sch/Com afferent to the CA1 region using the 'in vitro' hippocampal preparation and intact animals, recordings were obtained from a population of neurones displaying a number of characteristics which differentiate them from both P-cells and basket cells. These are: (1) multiple spike discharge to a single pulse stimulation consisting of 1-8 spikes firing at rates of up to 500 Hz; (2) a subsequent period of inhibition (50-200 msec) of those neurones which fire spontaneously; (3) activation at intensities less than that required to evoke either dendritic or population spike responses; (4) activation at shorter latencies (2.5-4.5 msec) than either the dendritic or population spike response; (5) ability to follow frequencies of up to 100 Hz but with significant jitter in latency; (6) progressive increase in the duration of discharge with increasing stimulus intensity and frequency; (7) alvear stimulation at intensities suprathreshold for the antidromic population spike activated these cells at latencies of 2.5 msec but did not elicit the high frequency response characteristic of basket cells; (8) in intact animals anaesthetized with urethane, single pulse stimulation of the commissural input evoked a spike discharge with comparable characteristics. These data suggest the presence of another population of interneurones in the CA1 pyramidal cell region which may be involved in an excitatory feedback loop that is normally inhibited by basket cells and excited by commissural afferents.

31.12 EFFECTS OF EXTRACELLULAR CALCIUM ON POTENTIATION AND HABITUATION OF CA1 AND DENTATE EVOKED POPULATION RESPONSES IN THE 'IN VITRO' HIPPOCAMPAL SLICE PREPARATION. R.W. Turner* and J.J. Miller (SPON: T.W. Calvert) Dept. Physiology, Univ. British Columbia, Vancouver, B.C., Canada V6T 1W5.

Previous studies have demonstrated that low frequency stimulation (1Hz) of the schaeffer/commissural (Sch/Com) fibers elicits a frequency potentiation of the dendritic and population spike responses of CA1 hippocampal pyramidal neurones. In contrast, low frequency stimulation of the perforant path (PP) results in habituation of the dendritic and granule cell field responses in the dentate gyrus (DG). Inasmuch as these alterations in response amplitude reflect changes in synaptic efficacy and presumably transmitter release mechanisms, the present investigation was undertaken to examine the effects of a high extracellular calcium concentration on the plastic properties of CA1 and DG evoked potentials following low frequency stimulation of the Sch/Com and PP afferents respectively.

Transverse sections of the rat hippocampus were prepared for recording and incubated in a modified Ringer's solution perfused with a 95% O_2-5% CO_2 gas mixture. Incubation of the slices for 20 min in a perfusate containing a high calcium-low magnesium concentration (4 mM Ca^{2+}/1 mM Mg^{2+} vs the standard medium containing 2 mM Ca^{2+}/2 mM Mg^{2+}) resulted in a decrease or elimination of the potentiation of the CA1 dendritic and population spike responses induced by 1 Hz stimulation of the Sch/Com input. The habituation of the PP-evoked dendritic and spike responses in the DG was also decreased or eliminated in the presence of the 4/1 medium. Upon return to the standard medium these responses displayed partial or complete recovery to control levels. The inverse relationship between extracellular calcium concentration and the magnitude of potentiation or habituation induced by low frequency stimulation suggests that different processes may regulate calcium in the CA1 and DG regions and that these underly the selective evocation of opposing responses to low frequency inputs.

31.13 Failure of sparing, or recovery,of recognition memory after early hippocampal resections in the rhesus macaque. L. Rehbein*, S. Zola-Morgan*, H. Mahut and M. Moss*. Psychology Dept., Northeastern Univ., Boston, MA 02115.

Most experiments with animals demonstrate that brain damage in infancy is less deleterious than in adulthood, though opposite effects were seen in patients (Hebb, 1942). The functional sparing is attributed to the plasticity of young brains. However, with a few exceptions (Harlow et al., 1968; Goldman et al., 1970) most studies have been concerned with single sensory or perceptual functions in rodents or carnivores.

In the present study, we assessed the effects of hippocampal lesions at 2 mos. of age, using several spatial and memory tasks. These were: (1) A series of left-right position reversals and (2) Retentions of easy, two-choice object discriminations at 1, 24 or 48-hr intervals. Operated infants and juveniles operated on at 2 yrs of age, together with normal juvenile and infant control groups, were tested post-operatively and twice again, at one year intervals. Post-operatively, infants were as impaired as were juveniles on both types of tasks. On the last re-test, two years after surgery, their performance recovered on the spatial, but not on the retention task, at both short and long intervals.

Long-term effects. (1) Five years after surgery, all operated juveniles, but only 4 of the 8 monkeys operated on in infancy, were impaired on a new spatial task, the one trial delayed - alternation. (2) However, unlike juveniles, monkeys with perinatal damage performed normally on a concurrent discrimination task which requires the learning of multiple (8) stimulus-object-reward associations in the presence of proactive and retroactive interpair interference. (3) In contrast, six years after surgery, monkeys operated on in infancy were as severely impaired as were the juveniles on the delayed non-matching-to-sample task, a trial-unique object recognition test. This deficit was found at 30, 70 and 130 sec, but not at 10 sec, delays between the presentation of the sample and the match. They were also significantly impaired when the number of object samples shown prior to pairing each one with a new, unfamiliar object numbered 1, 3, 5 or 10 (lists of differing lengths).

Thus, early hippocampal damage produced significant and long-lasting impairments one of which became attenuated and the other recovered with practice and time. The most enduring one, however, was the selective deficit in recognition memory.

31.14 BEHAVIORAL AND BIOCHEMICAL CHANGES AFTER HIPPOCAMPAL DAMAGE. D.K. Reinstein*, J.H. Hannigan, Jr.*, and R. L. Isaacson. Dept. of Psychology and Center for Neurobehav. Sci., SUNY-Binghamton, Binghamton, NY 13901.

The hippocampal formation's projections to the nucleus accumbens may act in a modulatory fashion on forebrain mesolimbic mechanisms. In addition, there are parallels between the behavior of animals with hippocampal lesions and those with experimentally-induced alterations of nucleus accumbens. It may be that the striatal-mesolimbic changes are of primary importance for some of these behavioral alterations. Hippocampal lesions may produce certain of its usual behavioral effects through secondary alterations of activity in nucleus accumbens. The present studies were undertaken to explore the possible functional relationship between the hippocampal formation and the nucleus accumbens. Rats were prepared with bilateral destruction of the hippocampal formation, lesions of the overlying cortex, or sham operations. The animals were behaviorally tested at 7, 14, and 28 days after surgery. On each of these testing days animals were examined in two different situations. These were: (1) an activity and exploration measuring apparatus (a rectangular open field with 16 holes in the floor), and (2) a smaller circular open field. All animals were also prepared with cannulae into the nucleus accumbens. Before Test 2, (3,4-dihydroxyphenylamino)-2-imidazoline HCl (DPI) or saline was injected via the cannula. The DPI was always given at a dose of 10 µg in 0.5 µl of fluid.

In the first apparatus the animals with hippocampal lesions had an increased frequency of both peripheral and central locomotion, as well as increased exploratory responses into centrally located holes. An increased number of explorations into peripherally located holes were evident at 28 days after surgery. A decreased response duration of this behavior was found at 14 and 28 days. These animals also showed decreased frequency of rearing relative to controls. The duration of episodes of both rearing and grooming were decreased. In the circular open field the hippocampally-lesioned animals showed increased frequencies of rotations in both ipsilateral and contralateral directions relative to the site of injection. The frequency of rearing was also increased in this apparatus, whereas there was a decrease in the frequency of grooming episodes at 7 and 14 days. The durations of rearing and grooming epsidoes were also decreased. Injections of the dopamine agonist, DPI, tended to normalize the behavior of the animals with hippocampal lesions on the measures of rotation and grooming in animals 7 days after the lesion but not at later times.

31.15 REPETITIVE STIMULATION OF THE SCHAFFER-COMMISSURAL SYSTEM: HOMOSYNAPTIC LONG TERM CHANGES OF POSTSYNAPTIC POTENTIALS. G. Barrionuevo*, K. Negishi* and G. Lynch. (SPON: S. Gerling) Dept. of Psychobiology, Univ. of California, Irvine, CA 92717

Field potential studies have shown that repetitive stimulation of hippocampal pathways produces long term potentiation (LTP) of synaptic responses. Intracellular recording studies using in vitro "slices" indicate that the EPSP is increased for several minutes following repetitive stimulation but there is confusion surrounding the presence or absence of heterosynaptic effects, changes in membrane potentials, and alterations in IPSP's. Since most of the studies on this issue followed the "potentiated" cells for relatively brief periods, it is possible that some of these effects represent transient changes induced by repetitive stimulation which are not directly related to LTP. In the experiments to be discussed intra- and extracellular responses were monitored from 14 cells in field CA1 (resting membrane potentials: 50-80 mV) for at least 30 minutes and up to 2 hours after 3 brief bursts of high frequency stimulation delivered to the Schaffer collateral-commissural projections. In several experiments a second collection of inputs was used to test for generalized changes in the target cell. Pair pulse tests were used to rule out any overlap in the population of axons activated. Background stimulation rate was 0.1 sec^{-1} and the stimulation current was set at levels below that required to spike the target cells.

Three types of effects were observed which persisted without evident change for the duration of the recording session: 1) an increase in the slope and amplitude of the EPSP, typically to a level which triggered the action potential; 2) the appearance in most cells of a depolarizing after potential (DAP) and 3) a depression of the IPSP's which often accompany Schaffer collateral-commissural stimulation. While various other effects were observed in the period immediately after the high frequency train, these were not in evidence at 30 minutes poststimulation. In particular we found no lasting changes in the membrane potential or in the heterosynaptic responses. This pattern of results is reasonably acounted for by the hypothesis that LTP is caused by an enduring facilitation of synaptic transmission restricted to stimulated pathways; if large enough this will produce a DAP which may obscure the IPSP. Other effects are sometimes triggered by the potentiating train but these do not appear to possess the stable character of LTP.

31.16 LONG-TERM POTENTIATION IN THE DENTATE GYRUS FOLLOWING LOW FREQUENCY (0.1 Hz) STIMULATION OF THE PERFORANT PATH IN CHRONIC RATS. Ronald W. Skelton, James J. Miller and Anthony G. Phillips, (SPON: John P.J. Pinel). Depts. of Physiology and Psychology, Univ. of Brit. Columbia, Vancouver, B.C., Can., V6T 1Y7.

Tetanic stimulation of the perforant path (PP) results in a long-term potentiation of the population spike recorded extracellularly in the dentate gyrus (DG). Several reports have indicated that potentiation is produced by tetanic stimulation between 5 and 20 Hz, while lower frequencies may produce either no effect or depression. In our laboratory, control stimuli delivered at < 1 Hz have been observed to produce an immediate enhancement of the DG population spike in chronic rats. The present investigation sought to determine the magnitude and duration of this potentiation following stimulation of the PP at 0.1 and 0.2 Hz.

Under Nembutal anaesthesia, electrodes were implanted in the DG and PP and fixed with dental cement at depths chosen to maximize the evoked population spike in the DG cell layer. After a three week recovery period, input/output functions of the PP-DG response were determined on the freely-moving animals. Evoked potentials were recorded in response to a series of 15 stimulation intensities ranging from 10 to 500 µA, presented in an ascending, logarithmic series. The stimulation frequency was either 0.1 or 0.2 Hz and no stimulations other than those in a series were delivered. Five responses at each intensity were averaged and plotted. The amplitude of the population spikes, plotted against the current intensities of a single series, constituted a single input/output function. Immediately (3-5 min) following the first series, all intensities were retested in the same order. Comparisons of the spike amplitudes recorded in the first and second series revealed large increases at most intensities (often > 500%). Largest percentage increases occurred at lower intensities (20-150 µA). Subsequent stimulation series at 1,24, 48,72, and 96 hrs revealed persistent, although somewhat reduced levels of potentiation. Dramatic reductions in the thresholds for activation of the population spikes (as much as 50%) accompanied the potentiation.

These data demonstrate that stimulation of the PP at frequencies well within physiological ranges of neuronal activity can potentiate subsequent evoked potentials in the DG. They indicate further the extreme sensitivity of this system and the ease with which information transmission through it may be facilitated.

31.17 NORADRENALINE LEVELS AFFECT LONG-TERM POTENTIATION IN THE HIPPOCAMPUS. G. V. Goddard, T. V. P. Bliss*, H. A. Robertson, and R. S. Sutherland*. Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J1.

Rats were depleted of hippocampal noradrenaline by systemic injection of reserpine or by 6-OH-dopamine destruction of the dorsal noradrenergic bundle. Verification was by radioenzyme liquid scintillation count and all experimental levels were less than 7.5% normal. Brief high-frequency electrical stimulation of perforant path fibers was used to cause short-term and long-term potentiation of the synapses onto granule cells as measured by the field potential response to test shocks in the perforant path. Short-term potentiation of the field excitatory post-synaptic potential (EPSP) was unaffected by noradrenaline depletion whereas long-term potentiation of the EPSP was reduced by more than 50%.

In agreement with earlier work (Bliss, T. V. P. and Lømo, T., J. Physiol., 232:331, 1973; Douglas, R. M. and Goddard, G. V., Brain Res., 86:205, 1975) long-term potentiation of the field EPSP and long-term potentiation of the population spike are not always tightly coupled. Careful measurement of input-output curves indicated a lasting shift to the left (greater spike per unit EPSP) following the high-frequency trains, indicating a lasting increase in cellular excitability. This increase in excitability was just as great in the noradrenaline depleted animals as it was in controls, even though the depleted animals showed much less long-term potentiation of the EPSP.

31.18 IMPAIRMENT OF LONG-TERM POTENTIATION FOLLOWING CHRONIC ETHANOL CONSUMPTION IN RATS. D. Durand, P.L. Carlen, P. McMullen. Depts. Medicine, Biomedical Engineering, Physiology, Addiction Research Foundation, Playfair Neuroscience Unit, Toronto Western Hospital, University of Toronto, Toronto, Ontario.

Chronic alcoholic brain damage with impairment of learning and memory has been associated with both malnutrition and alcohol consumption. Long-term-potentiation (LTP) in the hippocampus has been suggested as a neural correlate of memory and learning and has been shown to be impaired in aged animals. The effects of chronic ethanol consumption on hippocampal LTP have been investigated in the rat using the in-vitro hippocampus slice preparation.

For 8 to 9 months, male Sprague-Dawley rats were provided ad-libitum but measured access to a liquid diet containing 35% of its calories as ethanol, while a control group received isocaloric amounts of the same diet with ethanol replaced by maltose-dextrins. In a double blind study, 400 µm slices were prepared and placed in an in-vitro recording chamber. Stimulation was applied to the Schaffer collaterals in 4 trains of 200 pulses each, separated by 10 minute intervals at 25, 50, 100, 200 Hz respectively. The extracellular recording electrode was placed in the CA1 cell layer. The percent increases in the amplitude of the population spike at each frequency were measured 10 minutes after each applied tetanus and labelled P_{25}, P_{50}, P_{100}, P_{200}.

Table 1 shows the means and standard error means at each frequency and the total percent increase, P_T. There was a significant impairment (Mann-Whitney test, see Table 1) of the long-term potentiation in the ethanol-fed animals at P_{25}, P_{50}, P_{100}, P_{200} and P_T. The number of slices with a total potentiation of less than 10% increased from 16 to 85% in the ethanol group.

Morphological analysis of Golgi stained CA1 cells in the contralateral hippocampus of the same animals revealed a significant decrease in the branching (Scholl analysis) and total length of the dendrites in the ethanol group (see abstract, 1980, by McMullen et al).

	P_{25}	P_{50}	P_{100}	P_{200}	P_T
Control	23.1±15.9	13±7	16.7±7.7	9.2±3.7	90.7±30.5
Ethanol	1±3.5	2.5±2.12	-.2±2.85	.8±2.4	2.5±5.7

31.19 A MORPHOMETRIC STUDY OF THE EFFECTS OF POSTNATAL LEAD EXPOSURE ON HIPPOCAMPAL DEVELOPMENT IN RATS. Janelle C. LeBoutillier*, Dennis P. Alfano and Ted L. Petit. Dept. Psychol., Univ. Toronto, West Hill, Ont., Canada, M1C 1A4.

Increased exposure to inorganic lead (Pb) has been observed to have severe consequences on the normal postnatal development of the central nervous system in experimental animals. Recent evidence has suggested that hippocampal dysfunction may possibly underly the behavioral alterations seen in postnatally Pb exposed animals. This study was undertaken to investigate the possible effects of Pb on the development of the mossy fibre pathway of the hippocampal formation.

Timm's method for the histochemical staining of heavy metals results in a precipitate confined selectively to the terminals of mossy fibres, providing a useful means of assessing the development of this hippocampal pathway.

On postnatal day 1 (P1) all litters were cross-fostered, randomly assigned to either a Pb or control group and reduced to 5 and 10 male pups, respectively. Mothers were maintained ad lib on either 4% Pb carbonate or a sodium carbonate control diet from P1 to P25. On P25, 9 animals per group were selected and sacrificed under ether anaesthesia. Consecutive horizontal sections from the ventral portion of the medial hippocampus were collected and stained.

All measurements were performed on a Leitz Image Analyzer. Five sections per brain were measured. Significant reductions were observed in the maximal width of the hippocampus, and the maximal width and length of the dentate gyrus in Pb exposed animals. These reductions in overall hippocampal dimensions are consistent with our previous observations of reduced hippocampal weight following early Pb exposure. Measurements made on the mossy fibre pathway: 1) at it's point of emergence from the hilus of the dentate gyrus; 2) at the point of maximum curvature; 3) just prior to it's termination, and 4) it's overall length, indicated significant reductions for all measures in Pb animals.

These results indicate a severe effect of postnatal Pb exposure on normal hippocampal development. Alterations in the development of this pathway, resulting in a possible disruption of the internal circuitry of the hippocampus, may contribute to the behavioral changes observed in postnatally Pb exposed animals.

This research was supported by Grant Numbers A0292 and G0165 from the Natural Sciences and Engineering Research Council of Canada.

31.20 ALTERATIONS IN DENTATE GRANULE CELL DENDRITIC DEVELOPMENT FOLLOWING POSTNATAL LEAD EXPOSURE. D. P. Alfano and T. L. Petit. Dept. Psychol., Univ. Toronto, West Hill, Ont., Canada, M1C 1A4.

Several lines of evidence have suggested the possibility of hippocampal involvement in the behavioral deficiencies observed in experimental animals following postnatal lead (Pb) exposure. This study was thus conducted to discern the possible effects of Pb on the dendritic development of hippocampal dentate granule cells.

Long Evans hooded rat pups were exposed to Pb from postnatal day 1 (P1) to P25 via the maternal milk. Mothers were fed diets containing either 4% $PbCO_3$ (High Pb), .4% $PbCO_3$ (Low Pb) or 2.2% Na_2CO_3 (Control-10 and Control-5). On P1, High Pb and Control-5 litters were culled to 5 males while Low Pb and Control-10 litters were culled to 10. The use of differential litter size resulted in minimal pup weight differences between Pb treated and Control-10 litters prior to P25.

On P30, pups from at least 3 litters per group were selected and their hippocampi processed with the Rapid Golgi method. Both Pb treated groups had brain weights lower than either Control group. Low Pb hippocampi weighed less than Control-10 hippocampi.

For analysis of dendritic development, granule cells from the infrapyramidal limb of the dentate gyrus were chosen. Five cells from 6 High Pb, 5 Low Pb, 5 Control-10 and 5 Control-5 brains were drawn. Only fully impregnated cells from horizontal sections located at the dorsal aspect of the middle third (medial) portion of the hippocampus were chosen. Dendritic branching was evaluated by the method of Scholl. No differences were observed in the maximal width, however both Pb treated groups showed a reduction in the maximal length of their dendritic fields as compared to either Control group. High Pb animals showed greater dendritic branching at 20 µm from the cell body as compared to either Control group. Low Pb animals showed increased branching at 20 µm as compared to Control-10 animals. Marked reductions in dendritic branching was evident in Low Pb animals at distances from the cell body greater than 100 µm as compared to Control-5 animals and at 180, 200 and 220 µm as compared to Control-10 animals. High Pb animals showed reduced branching at 180 µm as compared to Control-5 animals.

The results of this study indicate increased dendritic branching proximal to the cell body, but both a reduced length of the dendritic field and a reduction in the number of dendritic branches distal to the cell body of dentate granule cells following postnatal Pb exposure. These findings are consistent with a pattern that might be expected as a result of a retardation in the temporal sequence of dendritic development. As such, these results support the suggestion that hippocampal dysfunction may be a contributory factor in producing the behavioral deficiencies observed in experimental animals following postnatal Pb exposure.

32.1 NEURAL INFLUENCE ON MUSCLE HYDROLASE ACTIVITY. R. J. Boegman and T. W. Oliver*. Dept. of Pharmacology, Faculty of Medicine, Queen's University, Botterell Hall, Kingston, Ont. K7L 3N6.

The specific activity of several lysosomal enzymes increases in skeletal muscle undergoing atrophy due to denervation, tenotomy or genetic dystrophy. Axonal degeneration products, increased endocytosis, muscle inactivity and neurotrophic factors have been suggested as being responsible for activation of these hydrolases. In an attempt to avoid direct muscle damage in studying the neural influence on muscle hydrolases we made use of specific neurotoxins which block impulse transmission. Inactivity of mouse soleus or extensor muscles following neural application of 1 µl of either Tetrodotoxin (TTX 1 x 10^{-9}M) or Batrachotoxin (BTX 1 x 10^{-12}M) to the common sciatic nerve innervating the right leg resulted in an increased (2-3 fold) activity of N-acetylgalactosaminidase and acid protease (pH 3.5) over that found in the contralateral sham injected leg. The non-lysosomal enzyme alkaline protease (pH 9.0), did not show a similar increase following neural application of either toxin, indicating that the increased hydrolase activity was not due to invasion of the inactive muscle by macrophages. Since a direct effect of the toxins on muscle has been shown to be unlikely (Boegman et al., Brain Research (1980) 187: 183-196) our results are best explained as a response of the muscle hydrolases to an induced state of functional inactivity.

Supported by the Canadian Muscular Dystrophy Association.

32.2 RESULTS OF CROSSING ELECTRICALLY SILENT NERVES TO FAST AND SLOW MUSCLES IN THE CAT HINDLIMB. L. Eldridge*, M. Liebhold* and W.F.H.M. Mommaerts* (SPON:P.A. Black-Decima). Dept. of Physiology, School of Medicine, Univ. of California at Los Angeles, CA. 90024.

In order to help determine whether the reversal of properties of fast (F) and slow (S) muscles after cross-reinnervation (NX) is brought about by the differential activity patterns imposed on the muscles by the F and S nerves or, alternatively, by trophic specifying substances released by the nerves, cross-reinnervation of F and S hindlimb muscles was conducted in a cat preparation in which the crossed nerves had been rendered chronically electrically inactive by a surgical spinal cord isolation (SI). In this procedure, all dorsal roots between two cord transections enclosing segments lumbar 6 through sacral 4 were severed, leaving the muscles involved in the nerve cross innervated but in permanent flaccid paralysis. At 5 and 8 month intervals after the simultaneous SI and NX operations, the muscles were compared to self-reinnervated or untouched SI muscles, as well as to crossed and self-reinnervated muscles from normal (non-paralyzed) cats. The biochemical, histochemical and contractile characteristics which we tested included myosin light chains, myosin and myofibrillar adenosine triphosphatase activity, lactate dehydrogenase isozymes and activity, calcium^{++} uptake by microsomes or muscle homogenates, histochemical fiber type, time to peak twitch tension, tetanus fusion frequency, and fatigue resistance. On all tests, the nerve-crossed paralyzed muscles consistently failed to show any reversal of F-S properties. All SI slow muscles eventually acquired fast characteristics as a result of the paralysis itself, but the nerve-crossing had no effect on the rate of this change. In contrast, the normal nerve-crossed muscles showed significant reversals of most of these properties even at the comparatively short crossing-test intervals. The failure of electrically silent nerves to effect reversal of F and S muscles in these experiments is in agreement with our previous long-term studies in which nerve crosses performed more than a year after the SI caused no changes even after nerve cross-test intervals of up to 20 months.

32.3 EFFECT OF ESTROGENS ON DENERVATED MUSCLE. Stephen R. Max. Dept. of Neurology, Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Denervation of rat extensor digitorum longus (EDL) muscles results in a nerve stump length-dependent increase in glucose 6-phosphate dehydrogenase (G6PD) activity (Wagner and Max, Brain Res. 170:572, 1979). However, the rate of increase of G6PD activity in EDL following transection of the sciatic nerve is strikingly different in muscles from adult male and female rats. In females G6PD activity was 170% control 24 h after denervation. In males this increase was delayed; G6PD activity was the same as control 24 h after denervation of EDL from male rats but increased to the level observed in females by 48 h. By day 4 G6PD activity was the same in both sexes (200% control). Pharmacological studies with hormone receptor agonists and antagonists showed this effect to be attributable to stereospecific interaction of estrogens with their receptors; androgens do not make a significant contribution (Max and Knudsen, Brain Res., In press). We investigated this phenomenon further by assessing the effects of castration and hypophysectomy on the denervation-induced increase in G6PD activity. Ovariectomy (OVX) for 4 weeks eliminates the significant increase in G6PD observed 24 h after denervation of EDL in intact female rats. Administration of estradiol-17β in silastic implants for 5 days into OVX rats restores the increase in G6PD activity 24 h following denervation. Estradiol-17α has no effect, indicating that estradiol action is mediated via a stereospecific receptor. Hypophysectomy (Hypox) of female rats for 1 week also eradicates the denervation effect on G6PD activity 24 h after denervation. Estradiol-17β restores the denervation effect on G6PD activity in Hypox rats, further supporting the role of estrogens. Treatment of female rats with MER-25, an estrogen antagonist, prevents the increase in G6PD 24 h after denervation and reduces the extent of the increase in enzyme activity by 40% 4 days after denervation. Similarly, treatment of male rats with MER-25 reduces the denervation-mediated increase in G6PD on day 4 by 40%. These data demonstrate that estrogens enhance the increase in G6PD activity following denervation of muscle and provide a model system which will be valuable for further studies on integration of neural and hormonal effects on muscle. (Supported by NIH grants, NS-15760 and NS-15766).

32.4 CONTRALATERAL DENERVATION CAUSES INCREASED SYNAPTIC EFFECTIVENESS IN FROG SARTORIUS. Albert A. Herrera and Alan D. Grinnell. Jerry Lewis Neuromuscular Research Center, UCLA, Los Angeles, CA., 90024.

It has been reported that unilateral denervation of the frog cutaneous pectoris muscle causes nerve terminal sprouting and a concomitant increase in polyneuronal innervation (PI) in the intact contralateral muscle (Rotshenker, S. J. Physiol. 292: 535, 1979; Reichert, F. & Rotshenker, S. Brain Res. 170: 187, 1979). In similar experiments on the frog sartorius we also see an apparent increase in PI but little evidence for sprouting. Further, we find that unilateral denervation causes markedly enhanced transmitter release from nerve terminals in contralateral muscles.

In 23 adult Rana pipiens the left sartorius was denervated by several methods involving crushing the sartorius nerve or the 8th spinal root. The different operative techniques did not produce detectably different results. After 5-16 weeks we stained the intact right sartorius with nerve terminal and cholinesterase stain, and tested synaptic strength. Normal muscles from similar but unoperated frogs were also studied.

The incidence of PI, detected by the usual intracellular recording techniques in curarized muscles, was higher at experimental end plates (EPs) (14%) than at normal EPs (6%). However, this increase did not appear to be due to sprouting. EP size, measured as total postsynaptic gutter length, was not significantly different in experimental (413 ± 13 µm SEM; 258 EPs, 10 muscles) and normal muscles (430 ± 19 µm; 78 EPs, 4 muscles).

In normal muscles lowering [Ca] to 1.0 and 0.6 mM causes nerve-evoked twitch tension to drop to 42 and 4%, respectively, of twitch tension in normal Ringer containing 1.8 mM Ca. Tension falls when all the synapses on some fibers become subthreshold. Experimental muscles showed enhanced synaptic strength, falling only to 70% and 17%, respectively. In Ringer containing 0.3 mM Ca and 1 mM Mg, we also measured quantal content at identified junctions whose morphology was later analyzed. Experimental muscles showed nearly a 4-fold increase both in total quanta released and release per unit terminal length as compared to normal muscles. This enhanced release might explain why PI appeared to increase. If the very weak polyneuronal inputs known to occur in the sartorius (Grinnell, A.D. & Herrera, A.A., Soc. for Neurosci. Abstr., 1980) were made stronger, then these inputs would no longer be obscured by the curare used to assess PI. We conclude that unilateral denervation causes a marked increase in contralateral synaptic effectiveness due to a change in the inherent properties of transmitter release. (Supported by USPHS grant NS06232, a MDA grant, and a NIH fellowship to AAH.)

32.5 CONTRACTILE AND HISTOCHEMICAL PROPERTIES OF THREE RAT MUSCLES IMMOBILIZED IN STRETCHED, RELAXED AND NEUTRAL POSITIONS. C.P. Simard*, S.A. Spector*, M. Fournier*, E. Sternlicht*, J. Vallieres*, and V.R. Edgerton. Neuromuscular Research Lab., UCLA, Ca. 90024.

While it has been shown that muscle immobilized under stretch results in initial muscle weight (MW) enhancement, knowledge of the muscle's functional speed and force-related capacity is sparse. Therefore, this study investigates the effects of muscle maintained in chronic shortened, neutral or stretched positions on isometric contractile and histochemical properties of the soleus (SOL), medial gastrocnemius (MG) and tibialis anterior (TA) of immobilized female rats. A brace consisting of transversely inserted steel pins through the femur and tibia and externally fixed at a specified angle was used to bilaterally fix the hindlimbs, thus stabilizing the joint while permitting normal vascularization. The three muscles were studied under four conditions: maximal stretch (S), moderate stretch (N), maximal relaxation (R) and sham control (C), each group containing seven animals.

Effects of imposed degrees of stretch on MW and tetanic tension (P_o) at 35±1°C are shown in Tables 1 and 2. The SOL, MG and TA of S demonstrated the least decline in MW (13, 16 and 28%, respectively, of C), while greater wasting was seen in all muscles of N and R. While P_o of the SOL, MG and TA was the least in R, about two-fold greater P_o was observed in N, whose P_o values were about half of C. P_o of the SOL and MG of S was similar to that of N, in contrast to P_o of the TA of S, which was only 55% of N values. No changes were seen in time to peak tension (CT) of the MG and TA for all groups. CT of the SOL of R (46.2±10.0) and S (48.3±6.2) were similar to C (47.6±4.8), while a decrease in CT of N (39.9± 4.2) was seen. In parallel, histochemical fiber type conversion of SO (65%) to FOG (35%) of the SOL of N was found, compared to 16% (SO) and 84% (FOG) normally seen in rats of similar age.

Therefore, in the absence of stretch (R), extreme atrophy occurs, and is manifest in decreased tension produced by the muscle. While extreme stretch (S) is a stimulus to maintain MW of the SOL, MG and TA at nearly normal levels after four weeks of fixation, its potency for maintaining muscle force is not great (about 50% for SOL, MG; 32% for TA, compared to C), indicating that elongation of muscle fibers and not increased cross sectional area, is the direct result of fixation under stretch. NIH #10423; MRC #MA-5715.

32.7 STRESS-INDUCED NEUROLOGICAL IMPAIRMENTS AFTER 6-HYDROXYDOPAMINE EFFECT OF LESION SIZE AND AGE. Abigail M. Snyder*, Edward M. Stricker, Michael J. Zigmond, Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15260.

Large dopamine (DA)-depleting brain lesions produce severe behavioral deficits in rats. For example, animals show both akinesia and catalepsy. Although these impairments gradually abate, they are seen again when lesioned rats are exposed to acute regulatory stress (Stricker et al., J. Comp. Physiol. Psychol. 93:512-521, 1979). In the present experiments, selective DA depletions were produced in adult rats by intracisternal administration of 6-hydroxydopamine (6-HDA, 200, 250, or 2 x 250 µg) 30 min after pretreatment with desmethylimipramine (DMI, 25 mg/kg, i.p.) and pargyline (50 mg/kg, i.p.). Following recovery several weeks later, animals were given 2-deoxy-D-glucose (2-DG, 500 or 750 mg/kg, i.p.), a drug which blocks the transport and utilization of glucose producing a functional glucoprivation. Neurological performance was examined 30 and 120 min after 2-DG administration. Measurements included latencies to move 4 limbs when placed on a table (to test for akinesia) and latencies to return all 4 paws to the table when either front or rear limbs were placed up on a 10 cm high block (to test for catalepsy). Those animals with less than 7% DA left in the striatum showed significant akinesia and catalepsy after 500 mg/kg 2-DG, and were even more debilitated after 750 mg/kg 2-DG. In contrast, animals with 7-20% DA left showed no deficits after 500 mg/kg 2-DG, and only moderate deficits with the higher dose. Those animals with more than 20% DA left did not differ from controls at either dose. These results indicate that the debilitating effects of acute glucoprivation occur only when central DA depletions are large, and are pronounced only when glucoprivation is severe.

Additional rats were given intracisternal 6-HDA with DMI in the first week of life and were tested for neurological performance after 2-DG treatment (500 mg/kg, i.p.) as adults. In contrast to the above observations no impairments were seen in most animals even when striatal DA was less than 7% of control values. These results suggest that adaptive compensatory changes may have occurred in animals brain damaged during infancy.

32.6 IN VITRO DEMONSTRATION OF PARASYMPATHETIC DENERVATION SUPERSENSITIVITY OF DISSOCIATED PAROTID ACINAR CELLS. Barbara R. Talamo (with the aid of J.R. Kaltenbach). Depts. of Neurology and Physiolog. Chem., Johns Hopkins Medical Sch., Baltimore, MD.21205

Parasympathetic denervation of parotid glands in the rat produces supersensitivity to cholinergic agonists administered in vivo without increasing the number of muscarinic receptors in glandular membranes (Talamo, Adler and Burt, Life Sci. 24,1573 1979). Since the cholinergic response which is monitored is salivation rate, it is not clear whether the supersensitive target is the acinar cell or a more distal one which might alter blood flow or hormone release. A dissociated acinar cell suspension has been prepared which shows an increased rate of $^{22}Na^+$ uptake in response to carbachol. The effect of carbachol is dose-dependent and is completely blocked by atropine or quinuclidinylbenzilate (QNB). Epinephrine also increases 22Na influx; this effect is blocked by phentolamine. Membranes prepared from dissociated cells have 122 fmol of (^{3}H)QNB receptors/mg membrane protein (n=3) as compared to membranes prepared from intact tissue, with 126.1 ±8.0 fmol/mg membrane protein (n=6). The K_d of the (3H) QNB receptor in dissociated cell membranes is not significantly different from that on membranes of intact glands. Dissociated acinar cells prepared from parasympathetically denervated glands show an enhanced sensitivity of ^{22}Na flux to stimulation by carbachol, indicating that the cells are supersensitive. The EC_{50} for activation is 1.26 x 10^{-7}M for denervated cells (n=3) compared to 5.62 x 10^{-7}M for control cells (n=5). In paired experiments, the EC_{50} for control relative to denervated cells is 3.61 ± 0.28 (P 0.001). Thus, these cells show changes in responsiveness and are useful for studies of the mechanism of muscarinic supersensitivity.

33.1 REINNERVATION OF FROG MUSCLE. P.A. DeCino. UCLA School of Med., Dept. of Physiol., Ahmanson Lab. of Neurobiology, and the Jerry Lewis Neuromuscular Research Center, Los Angeles, CA 90024.

The recovery and reinnervation following nerve crush in the frog cutaneous pectoris (cp) muscle has been described previously by Dennis & Miledi (J. Physiol., 1974, 239:553,571). How the nerve returns to its normal state was examined in more detail by employing intra- and extracellular recordings correlated with histological techniques which visualize pre- and postsynaptic structures from physiologically identified endplates. Reinnervated adult frog (Rana pipien) cp muscles were examined 4-30 days postcrush.

Morphologically, reinnervation occurred quickly with more than 90% of the postsynaptic membrane covered by regenerated neural processes within 10 days. Functional recovery, however, lagged behind. At 10 days miniature endplate potential (mepp) frequency was 26% and quantal content was 30% of control levels. By 30 days both of these parameters approached normal adult values. The time difference in the return of function after the nerve has regenerated might be explained by 1) nonfunctioning portions of the nerve terminal, 2) a proximal-to-distal gradient of spontaneous and evoked release with the more distal portions of a terminal branch releasing less frequently, or 3) overall immaturity of the nerve terminal process. Because low mepp frequency prevented accurate determination of the presence of spontaneous release along an entire branch, the first possibility could not be excluded. However, when mepps were detected, there were no consistent gradients in their frequency or amplitude. 29% of the terminal processes examined showed the expected gradient in mepp frequency and only 13% for mepp amplitude. Similar variability was also seen in adult cp muscles. Once the nerve was capable of evoked release, which often occurred when less than half of the postsynaptic membrane was covered by regenerated nerve, the entire length of a given branch would release in response to nerve stimulation. In a limited number of experiments on 8-12 day reinnervated muscles, it appeared that there was a slight gradient in the probability of evoked release along a branch. Thus, it would appear that early in reinnervation the entire terminal is basically immature, but capable of transmitter release, with gradients in evoked release.

This work was supported by USPHS grant NS 13470.

33.2 EXTRACELLULAR STRUCTURES AT THE NEUROMUSCULAR JUNCTION DIRECT THE GROWTH OF REGENERATING AXONS. Duane R. Edgington*, Damien P. Kuffler and U.J. McMahan, Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Several anatomically well defined extracellular structures are associated with motor nerve terminals at skeletal neuromuscular junctions: 1) the myofiber basal lamina sheath which extends through the synaptic cleft and thus separates the nerve terminal from the myofiber, 2) the basal lamina that overlies the nerve terminal's Schwann cell cap, and 3) the reticular lamina, a layer of collagen fibrils which is situated external to the Schwann cell basal lamina. To this list we add another extracellular structure of the frog neuromuscular junction: a band of filamentous material, 0.05-1.0 μm thick, extends from the Schwann cell basal lamina into the reticular lamina. This layer of extracellular material blankets the entire axon terminal and surrounds the unmyelinated pre-terminal axon, but it does not cover the parent myelinated axon within the nerve trunk, as does the Schwann cell basal lamina and the reticular lamina. Like the glycoprotein-rich basal laminae, the filamentous material stains intensely with ruthenium red in osmium.

Damaged motor axons regenerate to establish neuromuscular junctions at original synaptic sites on myofibers. In previous studies it has been demonstrated that factors associated with synaptic basal lamina influence the differentiation of regenerated nerve terminals. We examined the role of extracellular structures in directing the growth of regenerating motor axons to the synaptic sites by removing the cells of the frog's cutaneous pectoris muscle prior to reinnervation. After damaging the nerve, the region of innervation was frozen, resulting in degeneration and phagocytosis of all cellular elements at the neuromuscular junctions (myofibers and Schwann cells) and in the intramuscular nerve trunk (perineurial and Schwann cells). Extracellular structures, including the basal lamina sheaths of myofibers, Schwann cells and perineurial cells, as well as the layer of filamentous material, remained structurally intact. Within 2 weeks after damage myofibers had regenerated within the basal lamina sheaths of original myofibers. Regenerating axons grew through the original Schwann cell and perineurial basal lamina sheaths of the nerve, and made synaptic contact precisely at the original synaptic sites on the myofiber basal lamina sheaths even though none of the original cells of the synaptic sites were present. Thus, factors contained in or connected to extracellular material direct the growth of axons to the original synaptic sites. (Supported by a Muscular Dystrophy Association Postdoctoral fellowship to D.R.E., a National Paraplegia Foundation and a USPHS NRSA Postdoctoral fellowship to D.P.K., and USPHS Grant NS 14506.)

33.3 MOTOR AXON REGENERATION IN CRAYFISH LIMBS: DISTAL STUMP ACTIVATION FOLLOWED BY SYNAPTIC REFORMATION. M. S. Bouton*, and G. D. Bittner. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

Previous reports have disagreed as to the mechanism of motor axon regeneration in crayfish limbs. These reports have suggested that the proximal ends of these severed motor axons may "fuse" with severed distal processes which almost always survive for at least 70-90 days (Hoy, et al., 1967; Kennedy and Bittner, 1974). Other reports have suggested that outgrowths from the proximal severed stump may reform synapses on target muscles in a process similar to that shown to occur in vertebrates (Nordlander and Singer, 1972). We now suggest that regeneration initially occurs by activation of the severed distal stump from the proximal stump followed by synaptic reformation on the target muscles via continued outgrowth from the proximal stump.

Nerves were cut in the proximal portion of crayfish limbs and examined ultrastructurally at various post-operative times. According to our behavioral tests, 31% of the denervated muscles returned function within 70 post-operative days. Muscles near the cut did not regain function sooner or more frequently than more distal muscles. Two muscles which are located in different limb segments but share a common excitatory axon always regained function simultaneously rather than sequentially.

This return of function to various limb muscles was correlated with ultrastructural events. At one week post-operative, when no function has returned to the denervated muscles, outgrowing processes (satellite axons) from the proximal stump are not seen in the glial sheaths of the surviving distal stumps. At one month, some limbs regain function and satellite axons are seen from 1-2 mm proximal to the cut to 2-5mm distal to the cut. These satellite axons are small in diameter and up to 200 in number within a given motor axon glial sheath. Small axon-like processes are seen to cross the lesion site. From 1-2 months, these outgrowing processes from the proximal stump continue to grow to distal target muscles, but do not reach these muscles until 3-4 months post-operatively. Satellite axons continue to be found in the distal sheaths of regenerated axons at one year after initial regeneration, at which time the original distal stumps can no longer be identified.

We conclude that the severed proximal ends of crayfish peripheral motor axons grow out and contact appropriate distal stumps. The distal stumps are then activated by one of a number of possible mechanisms. We have found no evidence for gap junctions, and little evidence for axonal fusion between satellite axons and the surviving distal stumps. Our data indicates that the surviving distal stumps are ephaptically activated by satellite axons arising from the proximal stumps and that these satellite axons then continue to grow to the target muscles to reform synapses.

33.4 CAN A REGENERATING ALPHA MOTONEURON INNERVATE TWO DIFFERENT TYPES OF INTRAFUSAL MUSCLE FIBRE SIMULTANEOUSLY? R. Butler, Dept. Anat., McMaster Univ., Hamilton, Ontario, L8N 3Z5.

Previous studies indicate that following nerve injury, regenerating sensory and motor fibres can reinnervate muscle spindles, eventually restoring normal function (Brown and Butler (1976) J. Physiol. 260, 253). During reinnervation, an extensive transient, but 'inappropriate' fusimotor innervation by branches of α motoneurons (called β fibres) occurs which diminishes with time as it is functionally replaced by the 'appropriate' γ innervation. A further series of experiments is underway to study in detail this transient innervation by β fibres and their apparent competitive replacement by γ fibres. At selected times following crush or cut injuries of the nerve to the cat's tenuissimus muscle, the state of reinnervation is assessed by recording the response of single spindle afferents while stretching the muscle during stimulation of single fusimotor fibres which innervate that particular spindle. As expected, α fibres with β branches were found sooner following the lesions than γ fibres and they produced either dynamic or static effects on primary endings. When an α fibre with β branches affects more than one spindle, the primary afferent responses are usually all consistent in action, i.e., either all dynamic or all static. Since dynamic and static effects are believed to be due to selective innervation and contraction of two types of intrafusal muscle fibre (slow twitch and fast twitch, respectively), it follows that branches of an α motoneuron which produce dynamic effects probably innervate slow twitch muscle fibres selectively while α motoneuron branches producing static effects probably innervate fast twitch muscle fibres selectively. An interesting result concerns a single α fibre found in a 6 week post-crush regenerate whose collateral β's had static actions on three spindles and, surprisingly, a dynamic action on a fourth spindle. The implication is that this single α motoneuron, through its β branches, functionally innervated two different types of muscle fibre simultaneously. (Supported by grants from the Ontario March of Dimes and the Medical Research Council of Canada).

33.5 Numbers of nerve terminals per motor axon in sartorius and ext. l. dig. IV muscles of the frog. Y.M. Yao* and J.N. Weakly, Dept. of Physiology, Univ. of North Carolina at Chapel Hill, Chapel Hill, N.C. 27514

Histological, histochemical, and electrophysiological techniques were used to estimate the mean number of nerve endings elaborated by motor axons innervating the sartorius or ext. l. dig. IV (toe) muscles of the frog, R. pipiens. The sartorius muscle contains 700-900 extrafusal muscle fibers; the toe muscle, 50-75. Retrograde labeling of motoneurons by horseradish peroxidase applied to the muscle nerves indicates that the sartorius muscle is supplied by 10-14 motoneurons; 4-8 motoneurons innervate the toe muscle. Cholinesterase staining suggests that, on average, each sartorius muscle fiber has about 2.5 end-plates (range, 2-5), whereas the average number of end-plates per fiber in the toe muscle is about 1.3 (range, 1-3). Graded stimulation of the motor nerve revealed that about 7% (range, 1.3-16%) of the end-plates in normal sartorius muscles were polyneuronally innervated, most receiving connections from two motor axons. In contrast, no focal polyneuronal innervation was observed in normal toe muscles. These data suggest that each sartorius motoneuron, on average, gives rise to 135-240 nerve terminals, whereas each toe muscle motoneuron may elaborate as few as 8-24 endings. These observations in normal muscles provide the basis for transplantation experiments designed to determine whether, following reinnervation, the number of terminals per motor axon depends upon alterations in the peripheral field (e.g., numbers of muscle fibers and "old" end-plates) into which the regenerating axons must grow.

33.6 THE RATE OF AXONAL REGENERATION DIFFERS BETWEEN THE CENTRAL AND PERIPHERAL PROCESS OF THE DORSAL ROOT GANGLION (DRG) CELL. J. R. Wujek* and R. J. Lasek, Dept. of Anat., Case Western Reserve Univ., Cleveland, OH 44106

The DRG cell sends out a single axon which bifurcates within the ganglion; one axon proceeds centrally into the spinal cord and the other proceeds peripherally. In the peripheral branch of the DRG cell, the rate of slow axonal transport and the amount of material transported is greater than in the central branch. Furthermore, Black and Lasek (Exp. Neurol., 63: 108, 1979) have hypothesized that the slow axonal transport (SCb) rate will, in part, determine how rapidly regenerating axons will elongate. The DRG cell provides a unique system to test whether the regeneration rates of the two branches differ. If so, will the rates of regeneration vary accordingly with the SCb rates in the DRG axons?

Slow component b of axonal transport was labeled by injection of ^{35}S-methionine into the lumbar five (L5) DRG of albino rats. The radioactivity of a protein (43K daltons), indicative of SCb, was measured and the distance from the DRG to the wave peak and leading edge was used to determine the SCb transport rates. In the regeneration experiments, either the L5 dorsal root or the sciatic nerve was crushed with a jeweler's forceps; then a ^{3}H-proline/lysine mixture was injected into the L5 DRG. The axonally transported radioactivity served as a marker for the regeneration distance of the fastest growing axons.

The regeneration rates of the DRG cell axons were 2.0 mm/day in the dorsal root (central branch) and 4.6 mm/day in the sciatic nerve (peripheral branch). This difference offered the opportunity to further test the hypothesis of Black and Lasek by measuring the SCb rate in two branches of the same nerve cell. Measurements of SCb demonstrate that the transport rate was 1.4 - 2.0 mm/day in the dorsal root and it was 3.9 - 5.5 mm/day in the sciatic nerve. Thus, the rates of axonal regeneration correlated with the rates of SCb in the central and peripheral processes of the DRG cell. These data support the hypothesis that SCb may be a limiting factor influencing the rate of axonal regeneration.

33.7 THE ROLE OF SLOW COMPONENT a (SCa) IN DETERMINING AXON CALIBER: CHANGES DURING REGENERATION. P.N. Hoffman* J.W. Griffin* and D.L. Price* (SPON: S.E. Poduslo). Laboratories of Neuropathology and Neuromuscular Diseases, Johns Hopkins School of Medicine, Baltimore, Md 21205.

Several studies have documented persistent reductions in the caliber of regenerating axons proximal to the site of axotomy. The reversibility of this reduction appears to depend on successful reconnection with target cells in the periphery. Recently Hoffman and Lasek (Brain Res., in press) have demonstrated a decrease in the amount of labeled neurofilament protein and tubulin transported in SCa in regenerating motor neurons of the rat sciatic nerve. The reduced labeling of these proteins was specifically confined to SCa since it was accompanied by an enhanced labeling of proteins in SCb. This reduction in SCa may be related to changes in axon caliber during regeneration because previous studies have shown that axon cross-sectional area is directly proportional to the number of microtubules and neurofilaments. Thus, a decrease in the number of microtubules and neurofilaments entering the regenerating axon, via SCa, could represent at least one mechanism responsible for the reductions in axon caliber which occur during regeneration. If this hypothesis is correct, then axon shrinkage should start near the cell body and spread distally at a rate equal to the velocity of SCa (1.7 mm/day).

In order to test this idea we have analyzed axon caliber at three different levels of the L_5 ventral roots following crush injuries to the rat sciatic nerve. We have found that axon diameter at the root entry zone was significantly reduced in relation to contralateral controls at 1 week post-axotomy. By 3 weeks this reduction was present along the entire 25 mm length of the ventral roots. Clearly, these findings are consistent with our hypothesis that the reduced transport of neurofilaments and microtubules in SCa plays an important role in reduction in axon caliber during regeneration. They also suggest that SCa is a major intrinsic determinant of axon caliber.

33.8 THE INFLUENCE OF AXOTOMY ON GLUCOSE UTILIZATION IN RAT SUPERIOR CERVICAL GANGLION EXPLANTS IN VITRO. C. W. Montgomery*, A. Jerkins*, A. Dombrowski* and F. C. Kauffman., Univ. MD, Sch. Med. Pharm. & Exptl. Therap., Baltimore, MD 21201.

Axotomy of the rat superior cervical ganglion produces marked alterations in metabolism associated with the accumulation of lipid, protein and nucleic acids during the initial period of the retrograde response (Harkonen & Kauffman, Brain Res. 65: 127-157, 1974). Mechanisms underlying these anabolic responses are poorly defined and difficult to study in vivo. Consequently, comparative biochemical studies of explants from normal and axotomized rat superior cervical ganglion were carried out under conditions that promote outgrowth of neurites from these tissues in vitro. Explants obtained from adult rat superior cervical ganglion display consistent growth of neurites when cultured in Eagle's minimum essential medium supplemented with 1% bovine serum albumin and nerve growth factor (100 units/ml). In the present study, ganglia which were axotomized for three days in vivo and contralateral intact ganglia were prepared for explant culture and maintained in vitro for 24 h in the presence or absence of 0.5 mM glycerol. In the absence of glycerol, glucose utilization and lactate production were the same in explants of control and 3-day axotomized ganglia. Addition of glycerol to the media increased glucose utilization nearly two-fold in axotomized ganglion explants (1.68 + 0.07 vs 2.95 + 0.16 μmol/mg dry wt/24 h) but had no effect on glucose utilization in explants from intact ganglia (1.26 + 0.45 vs 1.28 + 0.14 μmol/mg dry wt/24 h). The increase in glucose utilization in the axotomized ganglion explants was accompanied by a significant increase in lactate production after the addition of glycerol (4.62 + 0.38 vs 6.34 + 0.59 μmol/mg weight/24 h). Stimulation of glucose utilization in explants from axotomized ganglia by glycerol does not appear to be related to gross alterations in energy state of the tissue since ATP concentrations in explants from control and axotomized ganglia were the same in both the presence and absence of glycerol. However, in the absence of glycerol concentrations of α-glycerophosphate in explants from axotomized ganglia were only one-half the values noted in control ganglia (1.39 + 0.24 vs 0.66 + 0.08 μmol/mg dry wt). Addition of glycerol to the media increased concentrations of α-glycerophosphate in explants from axotomized ganglia but did not alter concentrations of this metabolite in explants from control ganglia. Thus, in the absence of exogenous glycerol, lipid synthesis may be limited in explants from axotomized ganglia, by the glycerol moiety as suggested by lower concentrations of α-glycerophosphate in this tissue. Addition of glycerol to the culture medium may enhance lipogenesis and thereby stimulate glucose utilization.

(Supported in part by U.S.P.H.S. Grant NS-14728.)

33.9 Axonal Transport of Adenyl Cyclase in Frog Sciatic Nerve: Alterations Following Axotomy

Richard C. Carlsen and Lana J. Anderson*. Department of Human Physiology, University of California, School of Medicine, Davis, CA 95616

Orthograde axonal transport of adenyl cyclase occurs in normal, intact, frog sciatic nerves. There is no evidence for retrograde transport in the same nerves. Transport was measured as a progressive increase in adenyl cyclase activity occurring in the 5 mm nerve segment just proximal to a constricting suture placed around the nerve. The increase in enzyme activity reached 179% of control values 24 hours following nerve constriction. Activity in the 5 mm segment distal to the tie was not different from control values.

Twenty four hour accumulation experiments were also performed in sciatic nerves transected 1,3,5,7 and 9 days previously. While control, presumably non-mobile, enzyme activity levels remained equivalent to those in intact nerves, transported enzyme activities were altered following nerve transection. Orthograde adenyl cyclase transport declined progressively after axotomy. Twenty four hour accumulation of activity proximal to a constriction reached 141% of control in nerves transected 3 days previously, 119% 5 days after transection, and was not different from control values in nerves 7 and 9 days postaxotomy. In contrast to normal, intact, nerves, accumulation of enzyme activity distal to a constriction increased significantly ($p<.05$) above control values in nerves transected 3 and 5 days previously. Activity increased to 132% of control in 3 day axotomized nerves and to 113% in 5 day nerves. Distal accumulation was not different from control 7 and 9 days after transection. The time course of this novel appearance of retrograde adenyl cyclase transport in injured nerves compares closely to our previous demonstration of a transient increase in cyclic AMP concentration in axotomized spinal roots (Exp. Neurol. 66:556, 1979). We are now attempting to determine what function the normal orthograde transport of adenyl cyclase subserves, and that "signal" may be associated with the transient retrograde transport appearing in injured nerves (Supported by NIH NS15065).

33.10 PROTEIN SYNTHESIS AND AXONAL TRANSPORT FOLLOWING PERIPHERAL NERVE DAMAGE. G.W. Perry* and David L. Wilson. Dept. of Physiology and Biophysics, U. of Miami, Sch. of Medicine, Miami, FL. 33101.

Previous studies have suggested that following peripheral nerve damage some changes can be detected in rapidly transported protein during subsequent regeneration.[1,2] These studies employed one-dimensional gel electrophoresis for analysis of rapidly transported proteins. However, such techniques were unable to distinguish differences arising as a result of changes in relative amounts of transported proteins from differences caused by the appearence of new species of transported protein. Also, previous studies have shown that changes in the synthesis of specific proteins occurs in sympathetic ganglia as a result of axotomy.[3] Here we explore these issues utilizing the excellent resolution afforded by two-dimensional gel electrophoresis.

Sciatic nerves of the Bullfrog, Rana catesbeiana, were severed or crushed unilaterally in vivo, approximately 30 mm from the 8th and 9th dorsal root ganglia (DRG). One, two or four weeks after nerve damage the sciatic nerves together with the 8th and 9th DRG were removed and the ganglia selectively labelled with ^{35}S-met. for 8 hrs in vitro (see ref.4). Rapidly transported proteins were collected at a ligature placed just proximal to the site of nerve injury (usually 30 mm), and at a similar distance in the unoperated contralateral control nerves. After 24 hrs at 18°C the labelled ganglia, and protein which had accumulated in the 3 mm segment proximal to the ligature, were subjected to two-dimensional gel electrophoresis. Qualitative and quantitative comparisons between experimental and control ganglia and rapidly transported proteins were made from fluorographic patterns of the dried gels. Qualitative comparisons of changes after 1,2 and 4 weeks revealed similar patterns; consequently these data were pooled.

No new rapidly transported protein species were detected following either nerve crush or cut. However, significant changes in the relative abundance of label in a few transported proteins were observed. These changes were present irrespective of whether the sciatic nerve had been crushed or cut. Also, the relative synthesis rates of several proteins in the ganglia were changed. Furthermore, qualitative comparison between control and normal, unoperated animals detected no differences.

These results support the hypothesis that peripheral neurones are capable of effecting regeneration without gross readjustment in their protein synthesis and transport.

33.11 SPONTANEOUS ACTIVITY IN PRIMARY AFFERENT NEURONS PRIOR TO REINNERVATION OF THEIR MUSCLE. M. DeSantis and J. W. Duckworth*. Dept. of Biological Sciences and WAMI Medical Program, Univ. of Idaho, Moscow, ID 83843

Discharge properties of primary afferent neurons were studied for up to 20 days after freezing the nerve to the medial head of the gastrocnemius (MG) muscle with dry ice in adult male and female cats anesthetized with pentobarbital. Units were recorded in the L7 and S1 dorsal roots, after acute denervation of the hind limb save for the previously lesioned MG nerve, and from the MG nerve itself. Units recorded in the dorsal root were identified by the all-or-nothing, time-locked action potential elicited on stimulation of the MG nerve proximal to the lesion. Comparison was made with recordings from cats in which the muscle nerves were unoperated, sham-operated and crushed. The last category gave the same results as when the lesion was made by freezing.

As the MG nerve was frozen, the neurons being damaged fired a barrage of spikes, but then no more spikes occurred during recordings of up to several hours. From 2 to 20 days after the lesion, there was spontaneous discharge in some MG primary afferents, although an even greater number had none. About half of the active units discharged continuously. The other half fired trains of spikes in a cyclic pattern. The train duration varied for a given unit and in an independent fashion for units recorded simultaneously. The interspike interval was constant and typical for a given cyclic unit regardless of the variability in train duration.

Except for a few units recorded at 20 days after the lesion, neither the quiet nor the spontaneously active units were responsive to static lengthening of the MG muscle or to succinylcholine. Most units, whether quiet or spontaneously active, responded to dynamic lengthening of MG; a majority of only the spontaneously active ones fired a series of action potentials to stimulation of the MG nerve.

In recordings from dorsal roots, most MG units with spontaneous discharge continued to be spontaneously active after we cut the MG nerve and then the sciatic nerve at the hip. Lidocaine placed on the spinal ganglion quieted these units. In other cats, recordings were made from the proximal and distal ends of the MG nerve cut between the ganglion and the previous freeze lesion. Multi-unit activity was greater in the proximal than in the distal cut end of the MG nerve. Subsequent lumbosacral laminectomy followed by cutting the dorsal and ventral roots had no effect on the spontaneous activity in the proximal cut end. Lidocaine placed on the spinal ganglia abolished the discharge.

Thus, some primary afferent neurons from muscle show spontaneous activity after a lesion of their peripheral processes. The spikes may be initiated in the cell body region.

33.12 A COMPARISON OF REINNERVATION OF CAT CAROTID BODY BY CAROTID SINUS AND LINGUAL NERVES. L.J. Stensaas, B. Dinger*, S.J. Fidone. (SPON: K. Horch). Dept. Physiol., Sch. Med., Univ. Utah, Salt Lake City, UT 84108.

The relative contributions of afferent nerve fibers and carotid body type I and type II cells in chemosensory transduction have not been completely clarified. One possible approach to this problem is to compare the chemosensory function of the carotid body following reinnervation by foreign or normal nerves. Previous authors have found chemosensory activity elicited from carotid bodies reinnervated by the superior laryngeal n. (s.l.n.). The relevance of these results to the issue of the specific functions of type I and type II cells has been criticized because the s.l.n. contains fibers innervating receptors in the upper respiratory tract which respond to 100% CO_2. Another interesting result following reinnervation of the carotid body by the s.l.n. is that these foreign fibers did not form normal anatomical relationships with type I cells of the carotid body. We have readdressed these questions by reinnervating the carotid body with either the lingual branch of the IXth n., or with the carotid sinus n. (c.s.n.) so as to provide necessary control information.

Quantitative electron microscopic examination of carotid bodies from normal and cross-anastomosed animals 2-19 months following surgery reveals a 90% reduction in the number of afferent terminals contacting type I cells (n = 5). Similar studies of tissue reinnervated by the c.s.n. shows that the number of synaptic contacts per type I cell nucleus is reduced by only 30% (n = 3). That these differences are not due to failure of foreign fibers to invade the carotid body is demonstrated by several types of data. (1) Application of tritiated amino acids to the petrosal ganglion results in the build-up of labeled material in the carotid body over a period of several days in cross-anastomosed animals. (2) Light microscope autoradiography of this tissue has shown that nerve fibers are distributed around the lobules in very much the same manner as in normally innervated tissue. (3) Further examination of the tissue with the electron microscope has demonstrated many unmyelinated fibers invading the lobules, but few of these contact type I cells because of interposed slender processes of type II cells. The histological results from both groups of animals are correlated with the physiological findings: chemoreceptor activity is present following foreign innervation but the threshold is greatly elevated with respect to natural and pharmacological stimuli; carotid bodies reinnervated by the c.s.n. respond similarly to normal carotid bodies.

Our results demonstrate specific properties of c.s.n. afferents and, in addition indicate an important role for carotid body parenchymal cells in chemosensory transduction. Supported by USPHS research grants NS 12636 and NS 07938.

33.13 EFFECT OF THYROID HORMONE ON NERVE REGENERATION.
W.H.A. Yu* and R. Srinivasan* (Sponsor: J.Shriver). Department of Anatomy, Mount Sinai School of Medicine, New York, N.Y. 10029.

We have reported previously (Anat. Rec. 196: 212A, 1980) that administration of testosterone enhanced nerve regeneration. The action of testosterone could be mediated by the nerve growth factor (NGF) even though it is controversial whether testosterone could raise the level of NGF in rats. Since thyroxine treatment significantly increased the NGF concentration in the rodent brain (Walker et al., Science, 204: 427, 1979), the present study was undertaken to examine the effect of thyroxine (T_4) on axonal outgrowth during nerve regeneration. The right hypoglossal nerve was transected in female rats aged 5 weeks. From the 1st postoperative (PO) day the experimental group received 50 µg of T_4 daily s.c. for a week and then 10 µg daily thereafter. The control group received normal saline. Animals from both groups were killed at the end of 2nd, 3rd and 4th PO weeks. 24 hours prior to sacrifice 20ul of 10% HRP solution was injected into the tongue. After suitable fixation 50µ serial frozen sections of the caudal brain stem were cut and reacted histochemically for demonstration of HRP activity. Comparative quantitative analysis of the HRP labeled neurons of the right and left hypoglossal nuclei revealed that during the 2nd PO week few axons had regenerated in both the control and T_4-treated animals. During the 3rd PO week there was a substantial increase in the number of axons regenerated in control animals but none in T_4-treated animals. Both the control and T_4-treated animals showed almost complete regeneration of axons during the 4th PO week. These results indicate that thyroxine at the dose used had no effect on the rate of axonal elongation in the transected hypoglossal nerve.

36.1 GATING KINETICS OF THE TRANSDUCTION ELEMENT IN A VERTEBRATE HAIR CELL: EVIDENCE FOR A THREE-STATE MODEL. D. P. Corey and A. J. Hudspeth, Division of Biology, California Institute of Technology, Pasadena, CA 91125

A large variety of ionic channels in cell membranes can be thought of as existing in either open or closed states. The probability of a channel being in a given state is determined by the relative energy of that state, and the relative energies are changed - the channel is gated - by factors such as voltage and binding of ligands. We have evidence that the opening of transduction channels in vertebrate hair cells involves a redistribution between states; here the energy change is effected by displacement of the hair bundle.

An in vitro preparation was used, wherein a small portion of the bullfrog's sacculus was stimulated and the transepithelial receptor current was measured. Step displacements of the otolithic membrane were complete within 80 μs, and the voltage clamp included series-resistance compensation to reduce its response time to <10 μs. The preparation was maintained at 4 °C to slow the gating kinetics.

Following a 0.1-μm step displacement of the otolithic membrane in the positive direction - toward the kinocilium - the current increases with a roughly exponential time course with a time constant of 400-500 μs. Larger displacements elicit larger currents and shorter time constants; with displacements larger than 0.5 μm the current saturates but the time constant continues to decline. Negative displacements decrease the current but also decrease the time constant; the negative saturation occurs with displacements of >0.1 μm. The relationship between steady-state current and displacement (displacement-response curve) is roughly sigmoidal, consistent with a probability distribution between two states. The roughly exponential approach to steady state and the bell-shaped variation of time constant with displacement imply an energy barrier to transition between the states of ∿12 kcal/mol whose height is influenced by bundle displacement. Thus energy states of the transduction channel appear to be directly and continuously modified by hair bundle position.

The two-state model is only qualitatively satisfactory, however: a sigmoidal rise at the onset of current, a two-phase fall at the offset, and an asymmetry in the displacement-response curve are all inconsistent with two states and a single transition. Good quantitative agreement requires a model with three states. The transition from the first (nonconducting) state to the second (nonconducting) state is relatively slow and very displacement-sensitive; the subsequent transition to the third (conducting) state is faster and less displacement-sensitive.

36.2 ELECTROPHYSIOLOGY OF SOLITARY CONES FROM THE TIGER SALAMANDER RETINA. P. R. MacLeish and M. Tachibana*. Dept. of Neurobiology, Harvard Med. Sch., Boston 02115.

Solitary cones, obtained by enzymatic dissociation of the retina of the tiger salamander, could be maintained in vitro for several days during which time their responses to light and their electrical properties could be studied using intracellular recording techniques. These solitary cones retained the morphological features of cones and were easily distinguished from solitary rods, whose physiological properties already have been reported (Bader, MacLeish and Schwartz (1979), J. Physiol. 296:1).

The average resting potential of dark-adapted solitary cones was -35 ± 8 mV (mean, ± S.D.); the range was from -19 to -50 mV. In response to a brief flash of white light, dark-adapted solitary cones gave hyperpolarizing responses whose time-course was similar to that of cones in the intact retina but faster than that of solitary rods. In the intact retina, a similar difference in time-course between responses of cones and rods has been reported (Lasansky and Marchiafava (1974), J. Physiol. 236: 171). The amplitude of the responses in solitary cones increased over about 3 log units of light intensity and reached a saturating value, Vmax, of 18 ± 3 mV. The relationship between the peak amplitude of the response, V, and light intensity, I, was described by the equation V/Vmax= I/(I + K), where K is the light intensity that produces a response with a half-maximal peak amplitude. A reversal potential for the light response was found in the range of 0 to +10 mV.

In the fully dark-adapted state, solitary cones were less sensitive to light than were solitary rods; the light intensity that gave a just barely detectable response in cones was 2.2 log units brighter than that in rods. At this higher light intensity the responses in rods were near saturation.

Both solitary cones and rods had a transient component in the response to a bright flash but this was less prominent in that of cones (11-17% of peak response amplitude) than in that of rods (33-47% of peak response amplitude). Voltage- and time-dependent mechanisms generate the transient in the case of rods, and are likely to generate at least part of the transient in the case of cones; passage of rectangular pulses of hyperpolarizing current in solitary cones gave rise to an on-transient that was similar in amplitude and time-course to the transient seen in the responses to bright flashes. The presence of voltage-dependent mechanisms in solitary cones is further demonstrated by the steady-state current-voltage relationship which revealed outward-going rectification. The number and characteristics of these voltage- and time-dependent mechanisms remain to be determined.

36.3 TEMPERATURE DEPENDENCE OF A VOLTAGE DEPENDENT JUNCTIONAL CONDUCTANCE. A.L.Harris, D.C.Spray, and M.V.L. Bennett, Div. Cellular Neurobiology, Dept. Neuroscience, A. Einstein Col.Med.,BX,NY 10461

The conductance of electrotonic junctions between Ambystoma blastomeres is strongly voltage dependent (Spray et al., Science 204: 432,'79). The effect of temperature between 17.5 and 25°C on steady state and kinetic properties was studied by means of a dual voltage clamp technique. Previous data are consistent with mediation of this conductance by intercellular channels exhibiting first order transitions between open and closed states and energy differences between open, closed and transition states linearly affected by transjunctional voltage. The junctional conductance measured at the onset of a small transjunctional voltage step decreased with decreasing temperature with a Q_{10} of 1.2. The voltage sensitive component of the steady state conductance decreased with decreasing temperature with a Q_{10} of 1.7 at 15 mV and a Q_{10} of 2.9 at 27 mV. The time constant of the exponential decline of junctional conductance at each transjunctional voltage increased with decreasing temperature. At 15 mV, the time constant had a Q_{10} of 2.35, and at 27 mV, the time constant had a Q_{10} of 2.15. Since a Q_{10} of 1.2 is expected for an electrolyte filled pore, we conclude that at V=0 temperatures over the range studied do not significantly affect the distribution of channels between open and closed states. The larger Q_{10}'s are reasonable for conformational changes in macromolecules. The steady state conductance during voltage steps permits calculation of the ratio of open to closed channels which is equal to the equilibrium constant of the transition between states. If the voltage sensitivity of the energy difference between states is assumed temperature independent, the Q_{10} of the equilibrium constant permits calculation of the change in enthalpy (ΔH) between the open and closed states from the integrated form of the van't Hoff equation. By this method, ΔH equals approximately 11 kcal/mole. From ΔH, together with ΔW, about 2 kcal/mole, the difference in energy between open and closed states at V=0 derived from analysis of the voltage dependence (Spray et al., ibid.), one obtains the difference in entropy of the two states as approximately 31 cal/°C/mole. At 27 mV transjunctional voltage the time constant is dominated by the closing rate constant. Application of the Arrhenius equation yields an energy of activation (E_a) of 13 kcal/mole at this voltage. From the voltage sensitivity of opening and closing rates and their linearity with transjunctional voltage, one calculates that at V=0 the E_a for closing is 15.3 kcal/mole and the E_a for opening is 13.3 kcal/mole. These calculations assume that the temperature changes act on the free energy of the channel molecule directly and not via secondary mechanisms.

36.4 CONDUCTANCE OF GAP JUNCTIONS IS HIGHLY SENSITIVE TO CYTOPLASMIC pH. D.C.Spray, M.V.L.Bennett & A.L.Harris. Div. Cellular Neurobiology, Dept. Neuroscience, A. Einstein Col.Med., BX,NY 10461

Conductance of gap junctions (g_j) between mechanically dissociated pairs of embryonic cells from axolotl (Ambystoma mexicanum) and killifish (Fundulus heteroclitus) was measured directly with a dual voltage clamp technique or calculated from current clamp data using the π-T transform. Intracellular pH (pH_i) was measured in one cell of the pair using a microelectrode with sealed pH-sensitive glass recessed inside the tip (Thomas type). Response time constants of the pH electrodes were hundreds of msec for voltage changes and seconds for pH changes. A pH electrode was considered to be intracellular only if it recorded the same steady state voltage during current pulses as a KCl filled electrode in the same cell. Normal internal pH for isolated pairs of morula stage Ambystoma blastomeres was 7.75 ± 0.06 (SD;n=9) and for 32-64 cell stage Fundulus blastomeres pH_i was 7.67 ± 0.06 (SD; n=9). On addition of saline equilibrated with 100% CO_2 to the bath, pH_i and g_j decreased; the relationship between pH_i and g_j was sigmoid. There was little hysteresis for values obtained during intracellular acidification and recovery on washing. The sigmoid g_j vs.pH_i relations for both species are well fit by titration curves of the form $G_j=K^n/K^n+H^n)$ where G_j is normalized g_j, K is about 50nM (pK about 7.3) for both Ambystoma and Fundulus, and n, the equivalent number of titratable sites, is 4 to 5 for both species. Bathing for up to 10 min with strong acids or impermeant buffers at pH 6 had no effect on g_j. Bathing with the weak organic acids propionate, acetate, and lactate (120 mM, pK's 4.87; 4.75; 3.08 respectively) could reduce pH_i and g_j. The speed and degree of reduction depended inversely on the external pH and their effects at low external pH (6.5) could be reversed by treatment with the same solutions at higher pH (7.5). We conclude that these weak acids decrease pH_i by crossing the cell membrane in the undissociated form. Kinetic parameters of voltage dependence of Ambystoma junctions were unaffected over the entire titration curve for g_j. This observation suggests that separate sites mediate pH and voltage sensitivity of the gap junction channel macromolecule. The precise dependence of g_j on pH_i and the absence of hysteresis during relatively rapid changes support the hypothesis that hydrogen ions act directly on the channel macromolecule and not through changes in cytoplasmic concentration of some other substance such as Ca^{++}. Constancy of pCa_i during marked changes in g_j induced by weak acids was reported previously (Biol. Bull. 155: 428, 1978). DCS is a McKnight Scholar in Neuroscience.

36.5 INTERNAL PERFUSION OF NEUROBLASTOMA CELLS AND THE EFFECTS OF DIPHENYLHYDANTOIN ON VOLTAGE-DEPENDENT CURRENTS. Fred N. Quandt* and Toshio Narahashi (Spon: A.I. Farbman). Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611.

Neuroblastoma cells represent an excellent material for the pharmacological study of neurons. They are mammalian cells, and can be subjects to a variety of measurements including those of ionic conductances, receptor binding and ionic fluxes. We have successfully applied the internal perfusion and voltage clamp techniques originally developed for snail neurons by Lee et al. (J. Gen Physiol. 71, 489, 1978) to neuroblastoma cells (N1E-115) using one or two suction pipettes. This technique offers significant advantages over the two microelectrode voltage-clamp technique. First, current through the Na, K, or Ca channels can usually be observed for over an hour without much deterioration. This is critical for any drug action to be monitored over a certain period of time. Second, better resolution of the fast currents can be obtained with this technique than with the conventional two microelectrode method. Third, current through the K channel can be blocked by replacing internal as well as external K^+ with Cs^+. This enables a more detailed analysis of the currents through Na^+ and Ca^{2+} channels to be made. Normal internal perfusion had the following composition: 100 mM K glutamate, 100 mM sucrose, 20 mM Na HEPES (pH 7.25). Na currents were recorded at 10°C. Currents through the Ca channel were examined at 30°C after equimolar replacement of Na^+ with either 20 mM Ca^{2+} or 60 mM Sr^{2+} in order to increase their amplitude. Residual Na currents were blocked with 0.5 µM tetrodotoxin. As an example of the use of neuroblastoma cells for pharmacological study, the effects of the anticonvulsant diphenylhydantoin (DPH) on the action potential and voltage-dependent ionic currents of these cells were examined. Repetitive firing of action potentials often occurred following the termination of anodal polarization at 30°C. External application of 20 to 50 µM DPH suppressed the repetitive firing obtained under these conditions. However, the initial anodal break action potential appeared normal in the presence of DPH within this range of concentrations. Peak inward Na currents in response to step depolarizations from a holding potential of -80 mV were reduced only 10% by DPH. Peak current through the Ca channel appeared to be reduced 25% in the presence of DPH. This latter effect may underly the ability of DPH to block repetitive firing in these cells. DPH did not reduce either current to a greater extent during repetitive depolarizing voltage steps which is characteristic of compounds exhibiting "use-dependent" block.

36.6 SOME ELECTROPHYSIOLOGICAL PROPERTIES OF PITUITARY TUMOR CELLS. A. R. Martin. Dept. of Physiol., Univ. Colorado Med. Sch.,Denver, CO 80262.

Electrophysiological measurements were made on mouse anterior pituitary tumor cells (AtT-20/D-16v) which secrete ACTH/endorphin (B.A. Eipper & R.E. Mains, Endocrine Rev., 1: 1, 1980). Dishes containing low density cultures were mounted on the stage of a compound microscope and perfused with a saline solution containing 10% modified Eagle's medium and kept at 36°C. Cells were observed with interference contrast optics at 320X. Cell penetrations were made with microelectrodes of 150 - 200 MΩ resistance. Standard techniques were used for single electrode recording and current passing. Successful penetrations lasted for up to 2 hours.

Resting potentials of the cells ranged from 40 to 80 mV, with a mean (±S.D.) of 57 ± 10 mV (n = 34). Input resistances and time constants were measured by passing current pulses through the recording electrode. Time constants ranged from 3.5 to 24 msec with a mean of 10 ± 6 msec; mean input resistance was 250 ± 130 MΩ. When input resistance was plotted against time constant, the points were scattered around a straight line corresponding to a cell capacitance of about 40 pF. Morphology of the cells varied considerably, but the "average" cell had a surface area of about 2300 μm^2. Thus the specific membrane resistance averaged about 5750 Ωcm^2 and the specific capacitance 1.7 $\mu F/cm^2$. When resting potential was plotted against time constant, there was, if anything, a slight negative correlation rather than the positive correlation expected if the variability of the passive properties were due to cell damage by the micropipette.

All but three of the 34 cells studied had some sort of regenerative response to depolarization, ranging from a barely detectable "hump" to repetitive action potentials. Two cells displayed spontaneous activity. Regenerative responses were unaffected by tetrodotoxin (10^{-6}gm/ml) and blocked by $CoCl_2$ (0.2 mM). In general the active and passive properties of the cells varied between two extreme states. At one extreme, cells had low resting potentials, long time constants and well-developed action potentials ("active"); at the other, resting potentials were high, time constants short and regenerative responses small or absent ("inactive"). Transitions from the active to the inactive state were observed during the period of recording in four cells; no transitions were observed in the opposite direction.

AtT-20 cells secrete about 15% of their content of ACTH/endorphin per hour. Norepinepherine (10^{-5}M), which approximately doubles this basal rate of secretion, had no electrophysiological effect on six cells to which it was applied.

36.7 ELECTRICAL ACTIVITY IN CONTINUOUSLY CULTURED SMALL CELL CARCINOMA OF THE LUNG (SCCL). Frances V. McCann, Olive S. Pettengill* and Jerome A.G. Russell*. Depts. of Physiology and of Pathology, Dartmouth Medical School, Hanover, NH 03755.

Electrical activity in cultured pulmonary small-cell carcinoma cells has been measured with intracellular electrodes coupled to a current injection bridge (WPI-Ks 700). Electrode and current monitor signals were digitized and stored on floppy discs by a New England Digital Corp. Able-40 computer. Determinations of cell membrane resistances, capacitances and time-constants were computed from the digitized records using a special curve fitting program.

DMS 53, a continuous cell line, was isolated from a primary SCCL tumor (Pettengill, et al., Cancer 45:906, 1980). Cells were plated at 10^5 cells/ml in Waymouth's medium with 20% FCS and buffered with 25 mM Hepes. Experiments were carried out at 36° ± 0.5°C, four days after plating. Only isolated cells, independent of contact with their neighbors were impaled.

Patterns of electrical behavior were of three types: passive, local and regenerative. Ranges of passive characteristics measured in 50 cells were:

Resting potential	-34 to -58 millivolts
Time-constant	5.37 to 8.87 milliseconds
Input resistance	25 to 115 megohms
Input capacitance	60 to 116 x 10^{-12} Farads

For the calculation of surface area the cell was assumed to be an oblate spheroid whose thickness is 1/2 its projected diameter. Surface areas ranged from 216 to 1951 μ^2. A typical value for specific membrane resistance was 1480 Ωcm^2 and specific capacitance was 6 $\mu F/cm^2$.

Local responses in many cells were elicited by injecting depolarizing current pulses, and the resulting peak voltages were proportional to the magnitude of the injected current. Delay in the appearance of the peak voltage was inversely related to the magnitude of injected current. A depolarizing rectification was also found to be characteristic of these cells.

In some cells, action potentials could be evoked by anodal break excitation. The amplitude and latency of these spikes were related to the level of membrane polarization.

These data strongly suggest that SCCL cells in this culture exhibit neural-like transmembrane electrical behavior.

Supported by USPHS Grant # CA 27845.

36.8 IDENTIFICATION OF THE LINEAR PROPERTIES OF A NEURON. C.I. Valenzuela.* Neural and Behavioral Biology Program, University of Illinois, Urbana, IL 61801.

The aim of this work is to characterize (identify) the linear electrical behavior of a neuron composed of a spherical soma concatenated to a cylindrical axon (or dendrite). The neuron input function is defined as the electrical current injected into the neuron soma (by means of a microelectrode) and the neuron output function is defined as the transmembrane voltage response recorded at the neuron soma (by means of a microelectrode).

The following parameters of the neuron in question are identified (the membrane is assumed to be homogeneous regarding its specific parameters):

1. τ_{sm}: soma time-constant (τ_{sm}=membrane time-constant, τ_m).
2. $\{\tau_n, n=1,2...\}$: axon "equalizing time-constants".
3. L: axon electrotonic length.
4. ρ: axon to soma conductance ratio.
5. R_n: neuron input resistance (as "seen" from the soma's microelectrode).
6. R_{ax}: axon input resistance (as "seen" from the soma's microelectrode).
7. R_{sm}: soma resistance.
8. C_{sm}: soma capacitance.

Also, the following functions of the neuron are identified:

1. $h_{sm}(t)$: soma impulse response.
2. $h_{ax}(t)$: axon impulse response (as "seen" from the soma).
3. $h_n(t)$: neuron impulse response (as "seen" from the soma).

The identification process employs the following techniques:

1. Rall's classical analysis of passive neuronal models (c.f. W. Rall, Biophys. J. 9:1483, 1969 and W. Rall, In "Handbook of Physiology: The Nervous System I, E.R. Kandel, ed., 1977).
2. Provencher's algorithm and program for the analysis of multicomponent exponential decay data (S.W. Provencher, J. Chem. Phys. 64:2772, 1976 and S.W. Provencher, Biophys. J. 16:27, 1976).
3. A program to deconvolute the output function and the impulse response function of a linear system. Written by the author.

The relevance of this work to the study of the non-linear (active) properties of neurons in non-isopotential experimental situations as well as to voltage clamp studies of somata of whole neurons is discussed. Supported by a scholarship awarded to C.I. Valenzuela by the Consejo Mexicano de Ciencia y Tecnologia (CONACYT) and by PHS-NS15186 to J.A. Connor.

36.9 A PRACTICAL METHOD FOR INDIRECT ESTIMATION OF THE BIAS OF AN EXTRACELLULAR RECORDING EXPERIMENT TOWARDS LARGE NEURONS.
Charles Abzug. Department of Physiology, University of Maryland School of Medicine, Baltimore, MD 21201.

Despite the overwhelming preponderance of small neurons in most of the mammalian CNS, when extracellular recording techniques are used the larger neurons are represented in the sample to a much greater extent than is warranted by their numbers alone. The excessive representation of large neurons reflects the bias of extracellular recording techniques in favor of large neurons. In a previous communication(Abzug, C.(1978). Society for Neuroscience Abztracts, 4: 387) I reported on the participation of several significant parameters, some neuronal(i.e., anatomical and biophysical) and some experimental(e.g., speed of electrode advancement), in determining the chances of detecting neurons of different size. The present communication describes a technique for indirect experimental measurement of the bias. The probability of detection of a neuron in a single electrode track can be expressed as:

$$P(\delta) = k \cdot D^{j} \cdot V_{min}^{-m},$$

where D is the neuron's diameter, V_{min} is the smallest size of extracellular "action potential" that can be reliably detected with the particular electrode and recording system in use, and k, j and m are positive constants subject to the constraint that $j = 2m$. The value of V_{min} can be experimentally manipulated to any arbitrary value larger than the smallest possible value, V_{spv}, by rejecting all action potentials observed whose amplitudes are smaller than V_{min}. Thus, in general we can have $V_{min} = n \cdot V_{spv}$. $N(D)$ is defined as the distribution of neurons of size D in the structure to be examined. The expected number of neurons to be encountered during a single track is given by:

$$E_n(N) = \sum_D N(D) \cdot kD^{j} (V_{min})^{-m},$$

and therefore:

$$E_n(N) = n^{-m} \cdot E_1(N).$$

Thus, by plotting $E_n(N)$ as a function of n the value of m, and hence also of j, can be determined. The above derivation implies the assumption that the speed of microelectrode advancement is uniform throughout the experiment. Thus, determination of the value of j must be made by means of a motorized microdrive.

Supported by USPHS grant number NS12736(NINCDS).

37.1 INTERACTIONS OF LOCUS COERULEUS TRANSPLANTS WITH POSTNATAL DEVELOPING CEREBELLUM: DOES TARGET AGE INFLUENCE GROWTH?

R.H.Schmidt, U. Stenevi* and A. Björklund*, Dept. Histology, Univ. Lund.

Locus coeruleus afferents to the cerebellum have a marked capacity for regenerative growth after 6-hydroxydopamine treatment, but only during a limited developmental critical period. This growth period may be regulated to an important extent by the target tissue because it is temporally independent of developmental and regenerative growth of locus coeruleus collaterals to other CNS targets. To test this hypothesis we are looking for age-dependent differences in cerebellar reinnervation by locus coeruleus transplants to postnatal rat hosts.

Hosts consisted of postnatal rat pups between 2 and 20 days old, denervated 1-3 days earlier by an 80-100 µg intracisternal dose of 6OHDA. Brain stem tissue containing the locus coeruleus was obtained from 14-25 mm CRL rat embryos, and was implanted into the cerebellum using a glass needle inserted via the cisterna magna. After 4-12 weeks survival the rats were processed for catecholamine histofluorescence. Transplants were successful to host cerebella at all ages attempted, and contained up to 400 noradrenergic neurons with normal morphology and visible dendrites. These were usually found partially within the IVth ventricle fused to the vermis, with axons distributing toward the host accross the sites of fusion, thus leading to at least partial reinnervation of the cerebellum. Rats receiving transplants at younger ages generally had considerably higher densities of cerebellar noradrenergic innervation, even profound hyperinnervation, than rats transplanted when greater than 7 days old. In control material processed in parallel without transplants a variable quantity of endogeneous innervation was present in younger hosts, thus precluding a definative conclusion of the extent of transplant mediated reinnervation. The fact that detectable growth from the transplants has occurred has been shown with cerebellar injections of a fluorescent tracer compound, propidium iodide, which lead to retrograde labelling of noradrenergic neurons within the transplants.

In a related study, embryonic cerebellar tissue transplanted to the cerebellum of hosts at various ages does become innervated by host locus coeruleus axons, regardless of host age. These experiments represent a feasible strategy by which the source of axonal growth control during development and regeneration, ie. source neuron or target, can be identified.

37.2 AXONAL TRANSPORT AND TRANSCELLULAR TRANSFER OF NUCLEOSIDES AND POLYAMINES IN THE GOLDFISH VISUAL SYSTEM: A MODEL FOR AXONAL REGULATION OF PERIAXONAL CELL METABOLISM.

N.A. Ingoglia, and J. Pilchman*. CMDNJ-New Jersey Med. Sch., Newark, NJ 07103

The axonal transport (AT) and transcellular transfer of uridine, adenosine, and polyamines have been compared in intact and regenerating optic axons of goldfish. Both optic nerves of fish were crushed and 18-30 ds later, as regenerating fibers are reentering the tectum, ^{3}H-uridine, or ^{3}H-adenosine, was injected into the right eye. At various times after injection, right and left tecta were analyzed for trichloroacetic acid (TCA) soluble and insoluble radioactivity. AT was determined by comparing left-right difference in radioactivity, and since the majority of incorporation of small molecules into macromolecules occurs in periaxonal cells, transcellular transfer was indicated by the levels of TCA insoluble radioactivity, and confirmed by light autoradiographic analysis. Results demonstrated AT, transcellular transfer, and periaxonal cell utilization of both nucleosides in intact axons and several fold increases of all of these processes in regenerating axons. Following lyophilization of TCA soluble tectal radioactivity, approx. twice as much radioactivity was lost from the right tecta (which receives only blood borne radioactivity) compared with radioactivity in the left tecta, (which primarily receives axonally transported material). These results suggest that axonally transported uridine and adenosine are protected from degradation and thus relatively more available for periaxonal cell utilization than radioactivity reaching these cells via the blood.

In order to determine if axonally transported polyamines are transferred to periaxonal cells, regenerating optic axons were labelled with ^{3}H putresine or spermidine for 3 or 6 ds before removing the axons from the tectum by cutting the optic nerve. After allowing one week for degeneration to occur, approx. 55% of the radioactivity following ^{3}H-putrescine injections and 74% following ^{3}H-spermidine injections was still present in the tectum, suggesting that following AT ^{3}H-putrescine and ^{3}H-spermidine are transferred to periaxonal cells.

On the basis of these and previous findings, we propose that the AT and transcellular transfer of uridine, adenosine, the polyamines and perhaps other small molecules, is a means of communication between axons and periaxonal cells, that the axon can effect RNA and protein synthesis in periaxonal cells by regulating the availability of these small molecules, and that during nerve regeneration the increased metabolic needs of periaxonal cells, are met by increased axonal supply of precursors (adenosine and uridine) and other molecules (polyamines) critical for protein synthesis. Supported by EI-02887 from NIH.

37.3 MUSCARINIC-NICOTINIC CHANGES IN THE CHOLINERGIC RECEPTORS INVOLVED IN IRIS ACTIVATION DURING DEVELOPMENT.

R. Nuñez*, G. Pilar, and Ken Vaca*, Physiology Section, Bio. Sci. Grp., Univ. of CT, Storrs, CT 06268.

The mature avian iris is formed by striated muscle cells multiply innervated by ciliary ganglion neurons making nicotinic junctions. They respond to repetitive nerve stimulation (20-30 Hz) with a maintained contracture accompanied by action potential activity for the stimulation period. It was previously shown that profound alteration of the cells' ultrastructure occurs during development (Pilar, Landmesser, Burstein, 1980, J. Neurophys); they originate from the inner retinal layer, and migrate to iris location to form myoepithelial cells at St 34; and later, under nerve influence, myofibrils are organized. In the present study the mechanical properties of the iris muscle were investigated, as was its synaptic activation from Stage 36 (the time of formation of neuromuscular contacts) until reaching maturity after post hatching.

At St 36 repetitive nerve activation (30 Hz) causes a slowly developing contracture, elicited after 1.2 sec of the beginning of the electrical pulse, and maintained after the termination of the stimulation. This nerve mediated response was blocked by quinuclidinyl benzilate (QNB) (0.5 nM) and atropine (10^{-7} g/ml), but was unaffected by αBTX (1ug).

One day later (Stage 38) the mechanical response showed two distinct components, a fast initial deflection followed by a later slow response, which overlasts the stimulus, a twitch is elicited after single stimulation. The initial component is sensitive to αBTX, leaving unmodified the slow component which is sensitive to atropine. Postsynaptic electrical responses disappear after αBTX. Acetylcholine and carbachol elicited contractions in the superfused iris. αBTX and atropine each partially block this mechanical response, and in combination both cholinergic antagonists cancelled the ACh response altogether. It was therefore concluded that the iris cells are initially similar to the smooth muscle type and synaptically activated by muscarinic receptors; later the mechanical response becomes fast as in skeletal twitch muscle, and dependent on nicotinic receptors. The changeover occurs between St 38 and 1 day after hatching.

The changes described in the iris during embryonic development provide a clear example of normal transdifferentiation in the absence of experimental intervention. In the accompanying abstract (Vaca, Nuñez, Pilar this volume) evidence is presented showing that the switchover of the mechanical contracture as well as its receptor activation is dependent on the presence of innervation. Supported by NIH NS10338, Muscular Dystrophy Assn. of America & the Univ. of Conn. Research Foundation.

37.4 NEURAL CONTROL OF ACETYLCHOLINE RECEPTOR AND CONTRACTION IN AVIAN IRIS.

Ken Vaca*, Ramon Nuñez*, and Guillermo Pilar. (SPON: K. Morest). Physiol. Section, Biol. Sci. Grp., Univ. of CT, Storrs, CT 06268.

At the earliest stages of neuromuscular transmission in the chick iris (St. 34-36), no specific binding of ^{125}I-α-bungarotoxin (αBTX) can be detected, just as the mechanical response of the iris to nerve stimulation is insensitive to αBTX (see abstract by Nuñez, Pilar and Vaca this volume). Two days later a small amount of specific ^{125}I-αBTX appears and increases progressively to maturity. The specific ^{125}I-αBTX binding is displaced by unlabeled αBTX, is saturated at a concentration of 10 nM and reaches equilibrium within 1 hr of incubation. At St. 36, when neuromuscular transmission is completely blocked by quinuclidinyl benzilate (QNB) or other muscarinic antagonists, irises specifically bind ^{3}H-QNB (close to 20 fmoles per iris). ^{3}H-QNB binding has an apparent dissociation constant of approximately 1nM, is saturated at 4nM, is displaced by unlabeled QNB or atropine and reaches equilibrium in less than an hour. However, while neuromuscular transmission becomes less sensitive to QNB, specific ^{3}H-QNB binding increases with the mass and protein content of the iris.

At two days post-hatching, iris muscle exhibits highly organized sarcomeres and pupillary constriction is blocked by αBTX but not QNB. If the iris is denervated at this time and acetylcholine (ACh) sensitivity of the mechanical response examined seven days later, it is found that the response to ACh is virtually eliminated by QNB but little affected by αBTX. However, the specific binding of ^{3}H-QNB is unchanged while specific binding of ^{125}I-αBTX increases slightly in the denervated iris. In response to the denervation, the ultrastructure of the iris shows a marked disintegration of the sarcomeres which are replaced by a loose filamentous cytoplasm not unlike that of smooth muscle. If the ciliary ganglion is denervated by section of the oculomotor nerve, mydriasis is maintained as in the case of denervation of the muscle, but changes in sensitivity of the iris to αBTX or QNB are not observed. It is concluded that the presence of the ciliary nerve can influence the cholinergic receptors and the muscle mechanical response by some means other than activity. Supported by NIH NS10338, Muscular Dystrophy Assn. of America, and The Univ. of Conn. Research Foundation.

37.5 RETROGRADE AXONAL TRANSPORT OF PROTEINS SYNTHESIZED BY CILIARY GANGLION TARGET TISSUES. I. A. Hendry* and C. E. Hill* (SPON: R. Porter). Department of Pharmacology, John Curtin School of Medical Research, Australian National University, Canberra, A.C.T. 2601, Australia.

The normal developmental pattern of the neurones of the ciliary ganglion requires the presence of target tissues derived from the optic cup. Removal of the target tissues during early development results in the death of the neurones (Landmesser, L. and Pilar, G., Fedn. Proc. 37:2016, 1978). Media conditioned by various non-neuronal tissues contain factors that result in the survival of dissociated ciliary neurones in culture. The chick iris, ciliary body and choroid contain large amounts of such factors (Adler, R., Landa, K., Manthorpe, M. and Varon, S., Science. 204:1434, 1979). It is likely that these factors are the target tissue derived trophic factors that ciliary neurones require for their in vivo survival.

We have grown combined cultures of iris, choroid and ciliary body in medium containing tritiated amino acids. The medium from these cultures contained labelled proteins synthesized by and released from the tissues. The medium was concentrated and separated from labelled amino acids by pressure dialysis against 154 M NaCl. The concentrated labelled proteins were introduced into one eye of chickens to come into contact with the intraocular terminals of the ciliary ganglion. The chicks were killed 16 hours later, both ciliary ganglia removed and the radioactivity in each ganglion estimated by scintillation counting. There was an accumulation of radioactivity on the injected side showing the retrograde axonal transport of labelled proteins by the neurones of the ciliary ganglion. Isoelectric focusing of the accumulated radioactivity in the ganglion showed five major protein species. It is likely that at least one of these proteins synthesized by the target tissues and accumulated by neurones of the ciliary ganglion after retrograde axonal transport represents the factor required for the target tissue dependent survival of neurones of the ciliary ganglion in vivo. This technique may provide a convenient method for the demonstration of these factors (retrophins) in other neuronal systems.

37.6 MASSIVE DESTRUCTION OF DORSAL ROOT GANGLION NEURONS PRODUCED BY IN UTERO EXPOSURE TO MATERNAL ANTIBODIES TO NERVE GROWTH FACTOR (ANTI-NGF). E. M. Johnson, P. D. Gorin, L. D. Brandies* and J. Pearson. Dept. of Pharmacol., Washington Univ. Med. School, St. Louis, MO 63110 and Dept. of Pathology, New York Univ. Med. Center, New York, New York 10016.

Nerve growth factor has been shown to enhance the survival of embryonic avian and mammalian dorsal root ganglion (DRG) neurons in vitro. The role of NGF in sensory neurons in vivo is unclear. Adult rats and guinea pigs immunized against mouse NGF produce antibodies which cross react with their own NGF and which are transferred to developing fetuses in utero. Adult rats which had been exposed to anti-NGF in utero or in milk (cross-foster protocol) showed a 90% reduction in numbers of sympathetic neurons in the superior cervical ganglion (SCG). Sensory neurons in the 8th cervical DRG were reduced 70% as a result of in utero exposure to maternal anti-NGF but were unaffected by postnatal exposure in milk. The effects of in utero exposure to maternal anti-NGF in guinea pigs is more extensive, probably due to the fact that guinea pigs achieve higher serum titers of anti-NGF and their offspring receive much more antibody prenatally than do rats. Newborn guinea pigs exposed to maternal anti-NGF had a greatly increased pain threshold, developed corneal opacities within two days of birth, and have failed to gain weight and thrive. Neuronal numbers in newborn guinea pigs exposed to anti-NGF in utero were reduced by over 99% in the SCG and 80% in the 8th cervical DRG. Neuronal numbers in nodose ganglia were unaffected. In both affected rats and guinea pigs size-frequency histograms of DRG neurons were very similar to those of control animals, indicating a loss of sensory neurons across the size spectrum. These results indicate that at least 80% of sensory neurons in DRG go through a phase of NGF dependence during embryonic development. This experimental approach may prove useful in studies of the development and physiology of the sensory and sympathetic nervous system. 37.7 NERVE GROWTH FACTOR STIMULATES DEVELOPMENT OF SUBSTANCE P IN THE EMBRYONIC SPINAL CORD. J.A. Kessler and I.B. Black. Dept. of Neurology, Cornell Univ. Medical College, New York, NY 10021.

Development of the putative neurotransmitter, substance P (SP), in the embryonic rat dorsal root ganglion (DRG) and spinal cord was defined in vivo. SP was not detectable by radioimmunoassay before day 17 of gestation (E17). On E17, cervical sensory ganglia contained 4 pg SP/ganglion, rising to 49 pg/ganglion at birth. The dorsal horn of the cervical spinal cord contained 0.75 ng SP/mg protein on E17, rising to 6 ng SP/mg protein on postnatal day 3. The ventral horn of the spinal cord contained approximately 20% of the SP content in the dorsal horn at each gestational age. Intrauterine forelimb amputation partially prevented the normal developmental increase of SP in sensory ganglia destined to innervate that limb, suggesting that target structures regulate the development of peptidergic neurons. Conversely, treatment with nerve growth factor (NGF) stimulated development of SP in the DRG. Moreover, NGF treatment increased SP in the dorsal horn of the spinal cord, suggesting that NGF can modulate development within the CNS, as well as peripheral structures. However, treatment with antiserum to NGF failed to significantly inhibit development of ganglion SP. The system of SP-containing neurons in the DRG may provide a convenient model for defining events regulating peptidergic maturation.

37.8 CHRONIC EXPOSURE TO NERVE GROWTH FACTOR ANTIBODIES IN THE ADULT RAT: EVIDENCE FOR ATROPHY AND DEATH OF LONG ADRENERGIC NEURONS. Pamela D. Gorin and Eugene M. Johnson. Dept. of Pharmacology, Washington University School of Medicine, St. Louis, Mo. 63110

An autoimmune method was used to determine the effects of long-term nerve growth factor (NGF) deprivation on a number of cell types in the mature mammalian nervous system. Adult rats were immunized and boosted with 2.5S mouse NGF in complete Freund's adjuvant for a 5-6 mo. period. In the superior cervical ganglion, a paravertebral ganglion which contains the cell bodies of long adrenergic neurons, there was a marked neuronal atrophy and an apparent decrease in neuronal number, which was accompanied by a pronounced biochemical atrophy (80 and 60% reductions in tyrosine hydroxylase and dopamine-β-hydroxylase, respectively). Significant reductions of these adrenergic synthetic enzymes were also measured in the celiac ganglion, a prevertebral ganglion. Norepinephrine was reduced by approximately 90% in heart and brown fat and by 50% in the pineal gland. Thus, neuronal terminals, as well as cell bodies, were affected by chronic exposure to anti-NGF. No effects were observed on short adrenergic neurons innervating the vas deferens, adrenal medullary chromaffin cells, peripheral sensory neurons (which share a common embryological origin with long adrenergic neurons in the neural crest), or on central noradrenergic neurons.

In order to determine whether the biochemical changes observed in sympathetic ganglia and in their innervated targets represented neuronal atrophy or neuronal death, morphometric studies were carried out in the superior cervical ganglion. These studies showed a 35% reduction in cell number ($p < .001$) and a 50% decrease in cell volume.

The results reported here suggest that although NGF deprivation is less devastating for the adult mammal than for the immature mammal, mature long sympathetic neurons remain dependent of NGF throughout life for survival, as well as for maintenance of normal biochemical function. The autoimmune approach described here may be useful in elucidating the role of NGF (or other polypeptide growth factors) in the maintenance of other cell types and in providing an animal model for pathophysiological processes.

38.1 DISTRIBUTION OF SUBSTANCE-P (SP), METHIONINE-ENKEPHALIN (ENK) AND SOMATOSTATIN (SOM) IMMUNOREACTIVITIES IN THE SPINAL CORD OF THE DOMESTIC FOWL. A.L. LaValley* and R.H. Ho. (SPON: D. Clark) Dept. Anat., Coll. Med., The Ohio State University, Columbus, Ohio, 43210.

The indirect antibody peroxidase anti-peroxidase method of Sternberger was used to study the distribution of SP, ENK and SOM immunoreactive elements in the spinal cord of the domestic fowl, Gallus domesticus. Immunohistochemical localization was performed on 10μm sections of spinal cords that were fixed by intracardiac perfusion with Bouin's fluid. Immunoreactivities for all three peptides could be localized in the gray matter, except for laminae III as described by A.H. Martin (Acta Morphol. Neerl.-Scand., 17: 105-117, 1979). SP immunoreactive elements were densest in laminae I, II, IV, V and VI and around the central canal. In contrast, the ventral horn exhibited only sparse staining. The distribution of ENK immunoreactive elements was similar to that just described for SP. However, ENK immunoreactivity was most prominent around the central canal, within the intermediate gray matter and the ventral horn. Sparse SOM immunoreactive elements were present in laminae I, II, X and the ventral horn. The specificity of immunostaining was established in control experiments in which the primary antiserum for each peptide, pretreated with an excess of the corresponding synthetic antigen, failed to demonstrate the aforementioned structures on adjacent sections. We conclude that SP, ENK and SOM immunoreactivities are present in the domestic fowl spinal cord. (Supported by the Snyder Fund, The Graduate School and Department of Anatomy, The Ohio State University.)

38.2 PRELIMINARY STUDIES OF 5 HYDROXYTRYPTAMINE-LIKE IMMUNOREACTIVITY IN THE SPINAL CORD OF THE DOMESTIC FOWL. R.H. Ho, A.L. LaValley* and F.J. DiTirro. Dept. Anat., Coll. Med., The Ohio State University, Columbus, Ohio, 43210.

Spinal 5 hydroxytryptamine (5HT)[+] projections have been implicated in centrally induced analgesia and motoneuronal activity. To obtain baseline data for developmental studies, we examined the distribution of 5HT elements in the adult domestic fowl spinal cord. Animals were fixed by intracardiac perfusion with either Zambonie's or 4% paraformaldehyde solution. The indirect immunofluorescent technique of Coons and collaborators was utilized to localize 5HT on 10μm thick cryostat sections taken from representative spinal cord levels. With the exception of lamina III as described by A.H. Martin (Acta Morphol. Neerl.-Scand., 17: 105-117, 1979), a moderate density of 5HT containing elements are present throughout the gray matter. These very fine elements are interpreted to be axons and terminals. 5HT varicosities are densest around the central canal and in areas adjacent to the glycogen body. Immunoreactive varicosities also abut on large motoneurons. The specificity of immunostaining was established in control experiments in which anti-5HT serum, pretreated with an excess of 5HT, either prevented or greatly diminished such staining on adjacent sections. We conclude that 5HT is present in the spinal cord of the domestic fowl. (Funded by the College of Medicine Progress Endowment Fund and the Snyder Fund, The Ohio State University, College of Medicine; The Graduate School and the Department of Anatomy, The Ohio State University; Upjohn's Company and N.I.H. Grant NS-10165. We thank Dr. Robert P. Elde for the anti-5HT serum.)

[+]For convenience, the indolamine's immunoreactivity was referred to by its name.

38.3 SEROTONIN (5HT) IMMUNOREACTIVITY IN THE SPINAL CORD OF THE NORTH AMERICAN OPOSSUM, DIDELPHIS VIRGINIANA. F.J. DiTirro, R.H. Ho, and G.F. Martin. Dept. Anat., Coll. Med., The Ohio State University, Columbus, Ohio, 43210.

The opossum spinal cord, like that of the cat, receives projections from brainstem areas known to be indolaminergic, at least in part. Such connections have been implicated in endogenous opiate analgesia. Also, intrinsic enkephalin-containing elements within the dorsal horn are thought to function as an intermediate in this brainstem-spinal system. To date, we have shown that the spinal cord of the North American opossum contains enkephalin and substance P elements in various regions of the spinal gray including the dorsal horn. We have since examined the adult opossum spinal cord for the presence and distribution of 5HT immunoreactivity. Antibodies against serotonin were raised in rabbits; tissues fixed with 4% paraformaldehyde were processed by the indirect immunofluorescent method of Coons. Cryostat sections from all spinal levels were examined. Immunoreactive fibers were present in the dorsolateral funiculus. Immunoreactivity in presumed terminals and fibers was present throughout the gray matter with the exception of lamina III. Immunofluorescent staining was densest in the intermediolateral cell column at thoracic and rostral lumbar levels. Staining exhibiting moderate density was observed in lamina X, specific areas of the ventral horn, including laminae VIII and IX, and in the intermediate zone. The dorsal horn exhibited an even but sparse distribution of 5HT elements at all levels. The specificity of immuno-staining was established in control experiments wherein anti-5HT serum, pretreated with an excess of 5HT, failed to localize the aforementioned structures on semi-adjacent sections. We conclude that 5HT-containing elements are present throughout the rostral-caudal extent of the adult opossum spinal cord and that the coexistence of 5HT and ENK elements within the dorsal horn suggests their possible participation in endogenous opiate analgesia. (Funded by the College of Medicine Progress Endowment Fund and the Snyder Fund, The Ohio State University, College of Medicine; the Graduate School and the Department of Anatomy, The Ohio State University; Upjohn's Company and N.I.H. Grant NS-10165 and U.S.P.H.S. Grant NS-07410. We thank Dr. Robert P. Elde for the anti-5HT serum.)

38.4 ORIGINS AND TERMINATIONS OF SEROTONERGIC PROJECTIONS TO THE SPINAL CORD. R.M. Bowker*, K.N. Westlund, H.W.M. Steinbusch*, and J.D. Coulter. Marine Biomedical Inst., and Dept. of Psychiat. and Physiol., Univ. of Texas Med. Branch, Galveston, TX. 77550 & Dept. of Anat. & Embryol., Univ. of Nijmegen, Nijmegen, The Netherlands.

The distribution of serotonin (5HT) containing neuronal cell bodies and terminals was localized in the brainstem and spinal cord of monkeys by means of immunohistochemistry using an antiserum to serotonin (Steinbusch et al., 1978). Animals were perfused and tissue sections were processed for immunohistochemistry using the peroxidase-antiperoxidase method (Sternberger, 1974). Cell bodies demonstrating 5HT-immunoreactivity were widely distributed through the medial medulla, pons and caudal midbrain. In the medulla, 5HT-containing neurons comprized a relatively homogeneous population of small to medium-sized cells located in the nucleus raphe pallidus and raphe obscurus. In addition, many cells were found in the adjacent medial third of the nucleus gigantocellularis and extending in a band laterally over the inferior olive. In the pons, 5HT-containing cells were concentrated in the nucleus raphe magnus and adjacent medial reticular formation. Substantial numbers of cells were also in the medial half of the pontine-central grey and extended laterally and ventrally over much of the reticular formation to the lateral margin of the brainstem. In the caudal midbrain, large concentrations of 5HT-containing perikarya were located in the ventral half of the periaqueductal grey and the adjacent medial reticular nuclei ventrally (nucleus supratrochlearis and nucleus centralis superior of Olszewski and Baxter, 1954). In the rat, which has a similar distribution of 5HT neurons, cells projecting to the spinal cord were identified by retrograde transport of either HRP or wheat germ agglutinin using $CoCl_2$ in the reaction to yield a black punctate reaction product. Sections were then stained with 5HT antiserum to give a brown reaction product. Spinally projecting neurons containing 5HT, identified by the presence of both the black and brown labels in the same cell, were found in the raphe nuclei and reticular formation of the medulla and pons and in the ventral periaqueductal grey of the midbrain. In the monkey, spinal cord 5HT immunoreactivity was in fiber bundles in the white matter, including the dorsal lateral funiculus of all cord levels, with fibers and terminals having a wide distribution in the spinal grey matter. The most dense concentrations of 5HT-containing fibers and varicosities were localized in the ventral horn surrounding motor cells in the region corresponding to Rexed's (1952) lamina IX, in the dorsal horn (lamina I, II, IV), in the intermediolateral cell column of the thoracic and sacral cords, and in the zone surrounding and dorsolateral to the central canal. (Supported by NIH Grants NS12481 and NS11255).

38.5 ORIGINS AND TERMINATIONS OF DESCENDING NORADRENERGIC CELL GROUPS IN RAT. K.N. Westlund, R.M. Bowker*, M.G. Ziegler*, and J.D. Coulter. Marine Biomedical Institute, Depts. of Psychiat., Physiol., and Pharm., Univ. of Texas Med. Branch, Galveston, TX. 77550.

The origins of descending noradrenergic projections to the spinal cord were demonstrated using retrograde transport of antibody to dopamine-β-hydroxylase (DβH), the enzyme converting dopamine to norepinephrine. DβH antiserum produced in goat was prepared against DβH purified from bovine adrenal medulla and formed one band on immunoprecipitation (Jacobowitz et al., 1975). Four µl of a 50% solution of DβH antiserum was injected into various levels of the spinal cord in rats. After survival for 3-4 days, animals were perfused with 3% paraformaldehyde. Frozen sections were processed using rabbit-anti-goat IgG and goat peroxidase-antiperoxidase (PAP) as modified from the method of Sternberger (1974). In the brainstem, cells showing DβH immunoreactivity contained punctate granules and a diffuse light staining of the proximal dendrites and cell cytoplasm, exclusive of the nucleus. Labeled neurons were confined to known noradrenergic cell groups. DβH immunoreactive cells were localized mainly in the nucleus locus coeruleus, the nucleus subcoeruleus, the medial parabrachial nucleus and the Kölliker-Fuse nucleus. Cells in these nuclei were seen following injections of DβH antiserum at all spinal cord levels including thoracic and sacral-coccygeal segments. Localization of DβH immunoreactivity in terminals was mapped in the spinal cord using the Sternberger PAP method. While fibers possessing many large, darkly-staining varicosities course diffusely over much of the spinal grey matter at all spinal cord levels, labeled fibers and varicosities were concentrated in specific regions: the ventral horn, around large motoneurons in the region corresponding to Rexed's (1952) lamina IX; in the marginal layer of the dorsal horn (lamina I) and extending into laminae II and III of the substantia gelatinosa; and around the central canal in lamina X. Very heavy fiber and terminal labeling was also seen in the intermediolateral spinal grey matter, around preganglionic sympathetic and parasympathetic motoneurons, extending medially in a band toward the central canal. Although most of the terminal label observed with immunocytochemical localization agrees with histofluorescence data presented previously, DβH localization associated with the sacral autonomic preganglionic motoneurons has not been reported. Together, the results suggest a major role of pontine noradrenergic cell groups in the mediating descending influences on autonomic, somatic sensory and motor cell groups of the spinal cord.
(Supported by NIH Grants NS12481 and NS11255).

38.6 BRAIN-STEM RETICULAR FORMATION CONNECTIVITY IN THE WHITE RAT. A STUDY UTILIZING RETROGRADE FLUORESCENT TRACERS AND MONOAMINE TECHNIQUES. W.R. Buck and A.O. Humbertson, Jr. Dept. Anat., Coll. Med., The Ohio State University, Columbus, Ohio, 43210.

Recently the investigation of systems possessing axonal collateralization have received much attention in the neuroanatomical community. Through the use of retrograde fluorescent tracers combined in double labelling experiments neurons that project to more than one area can be positively identified. By combining monoamine techniques with fluorescent tracers one can also speak to the aminergic nature of these neurons.

Classically, the reticular formation has been described as a system whose organization within the brain-stem is diffuse in nature. Our experiments suggest a somatotopical organization at least to the medullary reticular formation. Our results indicate that cell which project to lumbar and cervical areas of spinal cord area clustered along median areas (raphe obscurus) and paramedian areas (nucleus reticularis paramedians, nucleus interfascicularis nervus hypoglossi, nucleus reticularis gigantocellularis) of the ventral reticular formation. Also, at pontine levels there appears to be a somatotopical organization to the lateral vestibular nucleus and to locus coeruleus. Preselected cross-sectional plots through the medulla and pons will be presented and discussed in detail. (Supported by U.S.P.H.S. Grant NS-07410.)

38.7 ELECTRON MICROSCOPIC IMMUNOCYTOCHEMICAL CHARACTERIZATION OF NORADRENERGIC AND PEPTIDEGIC NEURONS AND SYNAPSES WITHIN THE AREA POSTREMA OF RAT. D.M. Armstrong, V.M. Pickel, R.J. Miller, T.H. Joh, D.J. Reis, Laboratory of Neurobiology, Dept. of Neurology, Cornell Univ. Med. College, New York, NY 10021. (RJM) Dept. of Pharmacol. & Physiol. Sci., Univ. of Chicago, Chicago, IL.

By light microscopic immunocytochemistry, using antibodies to the catecholamine synthesizing enzymes and two neuropeptides, we have shown that the area postrema (AP) of rat contains processes of neurons containing catecholamine, predominately noradrenalin, and the neuropeptides (Leu^5)-enkephalin ((Leu^5)-enk) and substance P (SP). The AP also contains perikarya of noradrenalin and enkephalin neurons (Armstrong et al., JCN in press). We sought to characterize the ultrastructure by electron microscopic immunocytochemistry of catecholaminergic and peptidergic neurons in the AP.

Specific antisera to tyrosine hydroxylase (TH), (Leu^5)-enk, and SP were raised in rabbits. Antisera were localized by the peroxidase-antiperoxidase method in vibratome sections of brains fixed by vascular perfusion with 4% paraformaldehyde and 0.2% glutaraldehyde.

Electron micrographs were taken throughout the rostro-caudal and dorsoventral extent of the AP. Although light microscopy showed peptidergic and catecholaminergic processes and perikarya close to the ventricle and/or blood vessels, electron microscopy showed no such association. In the AP, TH was contained only within neurons including perikarya, dendrites, axons, and axon terminals. TH-labeled dendrites and dendritic spines formed asymmetric contacts with unlabeled axon terminals containing both large dense vesicles (LDVs) and small clear vesicles (SCVs). Occasionally two TH labeled dendrites were in apposition, suggesting dendrodendritic contacts. Enkephalin-like immunoreactivity (ELI) was usually localized in dendrites, axons, and axon terminals and rarely in perikarya. The labeled dendrites formed asymmetric axodendritic contacts with unlabeled terminals containing predominately SCVs. Axons and axon terminals with ELI contained many SCVs and few LDVs and were more heavily labeled than dendrites. SP immunoreactivity was localized only to axons and axon terminals. The SP labeled terminals contained numerous SCVs and a few LDVs and formed synaptic contacts with dendrites which received unlabeled axon terminals containing numerous LDVs and SCVs. We conclude that in the AP dendrites and axon terminals of neurons containing noradrenalin and enkephalin and axons of neurons containing SP form asymmetric synapses. These are predominately axodendritic and are upon other neurons in the region.

(Supported by NIH grants MH 24285, HL 18974)

38.8 IMMUNOHISTOCHEMICAL LOCALIZATION OF GLUTAMATE DECARBOXYLASE IN CELL BODIES OF THE SUBSTANTIA NIGRA AND OTHER AREAS OF RAT BRAIN. W.H. Oertel, D.E. Schmechel*, D.H. Ransom*, M.L. Tappaz*, E. Mugnaini and I.J. Kopin (SPON: D.C. Jimerson). Laboratory of Clinical Science, NIMH, Bethesda, MD 20205.

Antiserum prepared in sheep against rat brain glutamate decarboxylase (GAD; E.C.4.1.1.15), the biosynthetic enzyme for γ-amino butyric acid (GABA), has been employed to localize GAD-containing neurons in the rat CNS using the indirect (PAP) immunohistochemical method of Sternberger.

Rats were perfused with 0.1M sodium phosphate buffer (pH 7.3) containing 4% paraformaldehyde and 0.1% glutaraldehyde and the brains postfixed in phosphate buffered 4% paraformaldehyde for 1 h at 25°C and 4 h at 4°C. 20-25 µm Vibratome sections were treated with 0.25% TX 100 in Tris buffered saline (pH 7.6) for 5 minutes and then processed for the indirect PAP method (GAD-antiserum 1:1500 or 1:4000; rabbit antisheep IgG 1:50; goat PAP complex 1:60). With primary antiserum (1:4000) nerve endings were stained in the cerebellum, olfactory bulb, hippocampus and the substantia nigra in agreement with previous reports using an anti-mouse GAD antiserum. Electron microscopic studies in the cerebellar cortex revealed reaction product in nerve endings of stellate, basket and Golgi cells and in Purkinje cell axon recurrent collaterals. Mossy and climbing fibers, granular neurons and glia cells were not stained.

With GAD-antiserum diluted 1:1500, GAD-immunoreactive somata of Purkinje, basket, stellate and Golgi cells in the cerebellar cortex, periglomerular and granule cells in the olfactory bulb and basket cells in the hippocampus were faintly stained in light microscopy. In addition lightly stained medium-sized somata were distributed throughout the substantia nigra. After injection of colchicine (5 µg in 0.5 µL) into the rostro-medial substantia nigra pars compacta, the number and intensity of GAD-immunoreactive cell somata in the substantia nigra was substantially increased.

This provides morphological evidence for the existence of GABAergic neurons in the substantia nigra previously postulated on the basis of electrophysiological, behavioral and biochemical studies.

38.9 SUBSTANCE P IN HUMAN DORSAL HORN AND PALLIDONIGRAL AXIS --A COMBINED SILVER IMPREGNATION AND IMMUNOPEROXIDASE STUDY. R. Defendini,* G. Nilaver,* E.A. Zimmerman, V.M. Tennyson. Div. of Neuropathology and Depts. of Pathology, Neurology, and Anatomy, College of Physicians and Surgeons, Columbia University, New York, NY 10032.

The combination of silver impregnation and immunoperoxidase staining for substance P (SP) on the same section demonstrates new details about the anatomic relation of SP fibers to target structures.

Paraffin embedded lumbosacral and pallidonigral blocks obtained 4-16 hr post mortem were sectioned in sagittal oblique, horizontal oblique, and transverse planes. Bielschowsky's silver method defined large and medium axons consistently and the soma and dendrites of neurons variably. Brown immunoreactive products to rabbit anti-SP serum (1:500/30 min; PAP method) stood out against the black silver stain. Preincubation of the immune serum with lug of SP prevented staining.

In the human dorsal spinal cord, SP is mostly in Rexed's laminae I,II, and III. Most prominent in the marginal zone (I), SP products form cords with punctate accentuations, representing terminals on thick, long, occasionally branched dendrites of Waldeyer's marginal neurons (MC). The SP-innervated dendrites run rostrocaudally in I but also transversely into ths substantia gelatinosa (SG) proper (II & III) and Lissauer's tract (LTx). The irregular outline of the cords suggests SP contacts on long dendritic spines. Some MC bodies too are superficially studded by SP terminals. In transverse section, the dense SP band on the lateral (sometimes also medial) margin of the horn, alongside nucleus proprius (IV,V,VI) levels, corresponds to embracing extensions of I. Except for penetrating MC dendrites, the SP pattern in SG is much finer and includes many fine beaded axons oriented rostrocaudally.

The SP patterns in nigra and pallidum are identical. Punctate SP products in great profusion outline a forest of thick, long, poorly branched dendrites. Their appearance as hollow tubes of uniform caliber suggests SP contacts on spineless membranes. In the nigra, they are concentrated rostrally and in the pars reticulata. They also run tangentially in the internal capsule. In the pallidum, they are restricted to the internal segment, stopping abruptly at the internal medullary lamina. These observations raise the possibility that SP-innervated pallidal dendrites are continuous with those of the nigra across the capsule.

39.1 INFLUENCE OF BRAIN MONOAMINES ON BARBITURATE SENSITIVITY
W. M. Bourn and C. E. Reigel, Jr.,* Div. of Pharmacology and Nuclear Pharmacy, School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.

Evidence exists which suggests that central monoamines play a role in barbiturate tolerance and/or dependence. Although these findings would allow reasonable speculation that monoamines are directly involved with the acute effects of barbiturates, the relationship may be strictly of a secondary nature. For example, the previous finding that depletion of brain catecholamines results in an increase in the intensity of barbiturate withdrawal convulsions could be explained by the fact that norepinephrine appears to be a "modulator" of many types of experimentally induced convulsive seizures.

In the present study agents which enhanced or reduced the activity of monoaminergic systems in the brain were administered to rats which were subsequently tested for sensitivity to sodium methohexital (MH) using EEG burst suppression as an indicator of barbiturate effect on the CNS.

RO4-1284, a drug which produces a drastic reduction of brain norepinephrine, dopamine and serotonin, decreases MH sensitivity. 6-Hydroxydopamine, which selectively depletes catecholamines, produced a slight increase in MH sensitivity. Neither parachlorophenylalanine, an agent which selectively depletes brain 5-HT, nor α-methyltyrosine, an agent which selectively depletes catecholamines altered sensitivity to MH. Likewise, the uptake blockers desipramine and fluoxetine, agents which selectively block uptake of norepinephrine and serotonin, respectively, did not alter MH sensitivity.

Since the alterations in MH sensitivity produced by RO4-1284 and 6-hydroxydopamine are in conflict and may possibly be explained on a basis of peripheral drug distribution, these results support the hypothesis that the acute effects of barbiturates are not a result of a direct effect on catecholaminergic nor serotonergic system.

39.2 PSYCHOPHYSICAL ASSESSMENT OF PHENCYCLIDINE AND KETAMINE ON SENSORY AND MOTOR PROCESSES IN THE BABOON. Scott E. Lukas, Robert D. Hienz* and Joseph V. Brady*. Dept. of Psychiatry and Behavioral Sciences, The Johns Hopkins University, Baltimore, MD 21205.

Only limited research has been conducted in the area of behavioral pharmacology to experimentally determine the precise effects of pharmacological agents on basic sensory function and motor performance in animals. Drugs that are self-administered by humans (e.g. phencyclidine (PCP) and ketamine) are of particular interest because of the potential relationship between drug-induced changes in sensory and motor processes and relative abuse potential. Baboons (Papio anubis) were placed on a restricted feeding schedule and trained to perform under a standard psychophysical procedure to determine auditory and visual thresholds and reaction times (RT). Subjects were housed in double-walled sound attenuating chambers and were trained to hold a lever depressed for a variable interval until a 1.5 sec white light flash on a 1" radius stimulus patch or a 1.5 sec tone burst occurred, signaling the availability of food reward (190 mg banana pellet) following a lever release. Auditory and visual thresholds were determined by systematically varying the intensities by the method of constant stimuli and interpolating from percent correct detections at each intensity to that intensity which produced a detection score halfway between the false alarm rate and 100%. From each test session four independent within-session estimates of sensory thresholds were obtained. Drugs were administered intramuscularly one-half hour before testing with visual tests beginning after 30 min of dark adaptation. PCP produced a slight decrease in visual sensitivity with a corresponding 7% increase in RT at the 0.032 mg/kg dose. There was, however, no effect on auditory sensitivity in the dose range of 0.0032-0.1 mg/kg though there was a 29% increase in RT at 0.1 mg/kg. At doses of 0.32 mg/kg and above, PCP completely disrupted performance. In contrast, ketamine impaired auditory sensitivity by 40-60% at 0.32, 1.0, and 3.2 mg/kg. Motor performance was impaired only at the highest dose of 3.2 mg/kg (28% increase in RT). PCP was ten times more potent than ketamine in disrupting sensory and motor performance. Analysis of the individual within session trials revealed that ketamine produced maximal disruption of performance within one hour after injection and complete recovery was evident by 1½-2 hr. In contrast, PCP impaired performance throughout the entire session (approx. 2 hr) with no indication of recovery during the session. Thus, the present study has shown that while PCP and ketamine are qualitatively similar in their effects on motor performance, they may not be similar in regards to their effects on auditory and visual acuity. This difference may be attributable to PCP's greater potency and longer duration of action. (Supported by DEA contract #78-9).

39.3 ACUTE BEHAVIORAL EFFECTS OF PHENCYCLIDINE IN THE DOG. James L. Boren* and Paul Consroe. Dept. of Pharmacol. and Toxicol., Univ. of Arizona, Tucson, AZ 85721.

The behavioral effects of phencyclidine (PCP) in humans are complex and varied, ranging from intense agitation and excitement in some cases to a deep coma accompanied by respiratory depression in others. In addition to these extremes of excitement and depression, other commonly reported behavioral effects of PCP in humans include a "blank-stare" appearance, ataxic gait, stereotyped head and limb movements, muscular rigidity, horizontal and vertical nystagmus, excessive salivation, repetitive jaw snapping, opisthotonic posturing, and clonic and tonic seizures. A similar diversity of behavioral effects has not been reported in other species. In general, PCP elicits predominately excitatory effects in rodents and mainly depressant effects in most other laboratory animal species.

In the present investigation, the behavioral effects of intravenous doses of .25, .5, 1, 2.5, and 5 mg/kg of PCP were examined in 8 male mongrel dogs tested in an open field arena. The order of injection of doses was randomized for each dog with a minimum of 2 days between injections. Injection of PCP at each dose produced initial sedative effects with a dose-related latency to onset (ranging from means of 390 to 40.5 sec in the .25 and 5 mg/kg groups, respectively) and duration (ranging from means of 32.6 to 312.7 min in the .25 and 5 mg/kg groups, respectively). During this phase, animals rapidly lost the ability to stand, fell to their side, and exhibited an apparent lack of visual, auditory and tactile responsiveness. Other effects soon merged with these including tremors, rigidity, stereotyped limb movements and head weaving, tail stiffening, and copious salivation. In addition to the above effects, larger doses (1, 2.5 and 5 mg/kg) of PCP produced opisthotonic posturing, clonic and tonic convulsions, and repetitive jaw snapping. Termination of the first phase of PCP action was indicated by successful execution of a righting response, after which animals entered a phase of behavioral hyperactivity which was monitored for 2 hours after righting. Although an ataxic gait was initially apparent, animals evidenced dramatic increases in locomotor activity at all doses. In addition, dose-related increases in the duration of stereotyped circling, in latency to rear, and in latency to vocalize were observed. No deaths occurred at any dose and animals appeared completely normal 24 hrs later.

These results demonstrate that the behavioral effects of PCP in the dog bear a striking similarity to those observed in humans and suggest that this species may be an excellent laboratory animal model for studying the pharmacology and toxicology of PCP. (Supported by NIDA Grant DA 02137).

39.4 DISTRIBUTION OF AMPHETAMINE AND ITS EFFECTS UPON GLUCOSE UTILIZATION IN DISCRETE AREAS OF RAT BRAIN DURING CONTINUOUS AMPHETAMINE ADMINISTRATION. Michael S. Eison, Arlene S. Eison*, and Gaylord Ellison, Dept. Psychology, UCLA, Los Angeles, CA 90024.

A regimen of continuously administered amphetamine (AMPH) induces in rats a behavioral syndrome characterized by initially uninterrupted stereotypy (2 days) followed by aberrant social behavior (5 days). The late stage of this continuous AMPH syndrome can serve as a useful animal model of amphetamine psychosis. Biochemical alterations in the brain as animals undergo the behavioral transitions observed during continuous AMPH may model neurological changes associated with this psychosis. The regional distribution of 3H-d-AMPH and accumulation of 3H-deoxy-d-glucose (2DG) were therefore studied in 22 regions of rat brain during continuous AMPH administration using liquid scintillation and microdissection techniques.

AMPH counts were highest in the cortex and sensory regions of naive rats acutely administered label, and were lowest in the brainstem. AMPH derived counts in the accumbens, olfactory bulbs, hippocampus, and frontal cortex increased progressively relative to other brain regions as chronicity of exposure to AMPH increased from acute to 2 or 5 days of continuous administration, while retention by the other cortical samples, thalamus, and caudate decreased. The accumbens retained more AMPH than any other region following 5 days of continuous AMPH administration.

Altered regional differences in glucose utilization 45 mins after 2DG administration paralleled changes in AMPH distribution for many regions studied. 2DG counts observed in mesolimbic regions (accumbens, olfactory tracts, amygdala, hippocampus, frontal cortex) increased progressively with increasing duration of exposure to AMPH; after 5 days of continuous AMPH, 2DG counts in the accumbens increased more than any other region following any other regimen of amphetamine administration while decreasing in many non-limbic brain structures, such as the caudate. These changes did not persist 90 days after cessation of continuous amphetamine administration.

39.5 INHIBITION OF INTRAVENOUS COCAINE SELF-ADMINISTRATION BY RATS AFTER MICROINJECTION OF SPIROPERIDOL INTO THE NUCLEUS ACCUMBENS. A.G. Phillips and C.L. Broekkamp. Department of Psychology, University of British Columbia, Vancouver, B.C. Canada, V6T 1W5.

Numerous experiments have confirmed that rats will self-administer psychomotor stimulants (amphetamine, cocaine) via chronically indwelling intravenous (iv.) catheters. The reinforcing property of amphetamine is attenuated in a dose related manner by pretreatment with neuroleptic drugs (Yokel & Wise, 1976). Neuroleptics are known to serve as dopamine (DA) receptor antagonists and therefore it has been hypothesized that the psychomotor stimulants maintain self- administration behavior by a direct action on the ascending DA pathways in the brain. Further confirmation of this hypothesis comes from the disruption of cocaine self-administration after 6-hydroxydopamine lesions of the mesocorticolimbic DA pathway at the level of the nucleus accumbens (Roberts et al, 1977). In the present experiment, rats were trained to barpress for an iv. injection of cocaine (0.75 mg/kg/injection) during a daily 2 hr. test session. Following the establishment of stable iv. self-administration rates (25-40 presses/2 hrs.), one group of rats (N=5) received bilateral cannulae implants into the nucleus accumbens under stereotaxic control. A second group (N=6) was prepared with bilateral implants into the head of the caudate nucleus. Control tests after stereotaxic surgery confirmed that iv. self-administration rates remained at pre-operative levels. The following doses of spiroperidol (0.25, 0.4, 0.5, 0.6 µg/0.5 µl) were microinjected bilaterally into either the nucleus accumbens or caudate 30 min. prior to a self-administration test. Cocaine self-administration was blocked by 0.5 µg and 0.6 µg spiroperidol into the nucleus accumbens. This effect was locus specific, as no dose of spiroperidol attenuated the behavior when injected into the caudate nucleus. In a control experiment, microinjections of spiroperidol (0.25, 0.5 µg) into the nucleus accumbens had no significant effect on barpressing for food. These data provide further support for the involvement of the mesocorticolimbic pathway in the rewarding effects of psychomotor stimulant drugs.

39.6 EFFECTS OF HYPOTHALAMIC KAINIC ACID LESIONS ON SELF-ADMINISTRATION OF HEROIN AND COCAINE. Michael D. Britt* and Roy A. Wise. Center for Research on Drug Dependence, Dept. Psychol., Concordia Univ., Montreal, P.Q., Canada H3G 1M8.

The posterior lateral hypothalamic area (LHA) has been suggested (M.E.Olds, Brain Res., 168:351, 1979) as a possible site of action for the reinforcing effects of opiates on the basis of the finding that rats would lever-press for direct opiate microinjections into this region. The present study reports the effects of kainic acid (KA) induced LHA cell loss on the intravenous self-administration of heroin. If LHA opiate receptors mediate the rewarding properties of heroin, then selective damage to the bed nucleus of the LHA should eliminate the reinforcing effects of intravenous injections. The effects of LHA cell damage on cocaine self-administration was also assessed as a control for non-specific debilitating effects of KA; cocaine self-administration is thought to depend on dopamine fibers of passage, but not the bed nucleus of the LHA.

Rats implanted with jugular catheters were allowed to lever press for cocaine (1.0 mg/kg/infusion) in daily 4h sessions. After stabilization of this behavior they were given access to heroin (50 µg/kg/inf.). Once stable responding for heroin was observed rats were tested in an alternating daily sequence of heroin or cocaine for six days (3 days each). Kainic acid was then injected stereotaxically (flat skull coordinates: AP -3.5, V 8.4, L 1.5) with 0.2 µg of kainic acid in 0.5 µl of saline. Following a one week recovery period the rats were again allowed access to heroin or cocaine in an alternating daily sequence for six days.

Comparison of mean pre- vs post-lesion drug intake for cocaine (7.5 -1.7 vs 7.1 -1.6:means and SDs in mg/kg/hour) and heroin (4.4 -1.9 vs 4.8 -1.5 µg/kg/h) revealed no significant difference for either drug. Histological analysis of pilot animals revealed major loss of cells in the bed nucleus of the LHA with the injection regimen used; histological analyses of animals tested behaviorally are in progress.

The failure of LHA kainic acid injections to disrupt intravenous cocaine or heroin self-administration suggests that the bed nucleus of the lateral hypothalamic area plays no critical role in either the rewarding effects of opiates or the response capacity for opiate self-administration. Confirmation of this suggestion awaits detailed histological analysis of the brains of the animals tested, and the demonstration that damage to cells in other regions can effectively disrupt this behavior.

39.7 OPIATE EFFECTS ON SOCIAL COMFORT AND IMPRINTING. P. Bishop*, J. Panksepp, T.L. Sahley*. Dept. of Psychology, Bowling Green State University, Bowling Green, OH 43403.

These experiments were designed to evaluate the proposal that brain opioids participate in the mediation of social affect and social attachments (Biol. Psychiat. 1978, 13, 607). When young animals are separated from their normal social environment they distress vocalize (DV), and this response can be inhibited by stimuli to which the animal has been imprinted. For instance, young chicks which have been communally housed DV less in the presence of their own image (i.e., in a mirrored environment) than in one which has no reflective surfaces. Pharmacological analysis of this inhibition of DVs in young chicks indicated that blockade of opioid (1 mg/kg naloxone, i.p.), serotonin (0.5 mg/kg methysergide), and cholinergic (5 mg/kg atropine) systems could attenuate the inhibition of DVs produced by mirrors. Morphine (1 mg/kg) could amplify this comfort response, while quipazine and pilocarpine (at 10 mg/kg) did not. Formal imprinting experiments were conducted in which dark-reared chicks were exposed to mirrored environments for 10 mins at 1 day of age and retested at 4-5 days of age. Following naloxone (1 mg/kg i.p.) chicks DVed as much in mirrored chambers as in plain ones, while under control conditions mirrors reduced DVs by 42%. When chicks were imprinted to mirrors under various drug conditions at 1 day of age, retrieval testing indicated that saline trained animals DVed 57% as frequently at 3 days of age in a mirrored environment as in a plain one, morphine (1 mg/kg) trained animals cried 72% as much as controls and naloxone trained birds (2.5 mg/kg) cried at 97% of control levels. These results suggest that opioid systems participate in mediating the comfort which young birds derive from social stimuli, and suggest that the process of imprinting may be partially due to endogenous opioid release.

39.8 SIMILARITIES AND DIFFERENCES IN DEPENDENCE AND ABSTINENCE PROFILES DURING SELF-ADMINISTRATION OF CYCLAZOCINE, PENTAZOCINE, NALBUPHINE, AND BUTORPHANOL IN MORPHINE POST-ADDICT RATS. G.F. Steinfels, G.A. Young, and N. Khazan. Univ. of Maryland School of Pharmacy, Dept. of Pharmacology and Toxicology, Baltimore, Maryland 21201.

Adult, female Sprague-Dawley rats were prepared with chronic EEG and EMG electrodes and intravenous cannulae. Rats were first made tolerant to and physically dependent on morphine by a series of automatically administered i.v. injections. The rats were then trained to lever press on a fixed ratio 20 schedule of reinforcement to receive morphine injections. After one week of stabilized responding rats were removed from the experimental cages and allowed to withdraw from morphine for two weeks. Each rat was then returned to the experimental cage and given the opportunity to establish self-administration of morphine (10 mg/kg/inj), cyclazocine (0.5 mg/kg/inj), pentazocine (1 mg/kg/inj), nalbuphine (5 mg/kg/inj), or butorphanol (0.5 mg/kg/inj). When morphine post-addict rats were given the opportunity to relapse to the self-administration of these narcotics, the mean daily number of self-injections gradually increased over days and was stabilized within a week. With all the narcotics REM sleep was suppressed during the first two days of the relapse period and then increased in amount and stabilized by days 5-7. A comparison of the total REM sleep times on day 7 of dependence with control values demonstrated that rats that self-administered cyclazocine, pentazocine, nalbuphine, or butorphanol had daily REM sleep times that were not significantly different from control values; however, the values during the dependence period were in the lower range for control. Withdrawal was initiated on day 8 by substitution of saline for each narcotic and was accompanied by increased numbers of self-injections in all animals. During withdrawal REM sleep was suppressed in rats previously dependent on morphine and pentazocine. In contrast, REM sleep times increased in cyclazocine, nalbuphine, and butorphanol rats. Abstinence from morphine and pentazocine was associated with behavioral symptoms such as diarrhea, wet-dog shakes, irritability, while abstinence from cyclazocine, nalbuphine, and butorphanol was not. These findings suggest that there was considerable physical dependence in rats dependent on morphine and pentazocine but relatively less physical dependence on cyclazocine, nalbuphine, and butorphanol. The above data also seem to differentiate between drugs which induce both psychological and physical dependence such as morphine and pentazocine, and drugs which produce a similar psychological and apparently less physical dependence such as cyclazocine, nalbuphine, and butorphanol.

39.9 NEUROPHARMACOLOGIC EFFECTS OF N-ALLYLNORMETAZOCINE (SKF-10047).
Edgar T. Iwamoto. Dept. of Pharmacology, Univ. of Kentucky, Lexington, KY 40536.

N-allylnormetazocine (SKF-10047; Win-19,631) possesses potent psychotomimetic activity in man and also is an effective antagonist of meperidine analgesia in the rat having little or no detectable antinociceptive properties itself. In the chronic spinal dog, SKF-10047 caused mydriasis, tachypnea, tachycardia and mania, effects which were quite unlike those induced by morphine or ketocyclazocine (Martin and co-workers, 1976).

The bizarre behavior--consisting of mild ataxia, lateral head movements, pivoting of hindpaws, walking backwards and peculiar circular movements--induced by cyclazocine in the rat is purportedly caused by its σ (for SKF-10047) activity, activity which is also shared by other opioids such as nalorphine, levallorphan and pentazocine in addition to SKF-10047. The present study was designed to characterize further some of the pharmacologic effects of N-allylnormetazocine.

Locomotor activity in Sprague-Dawley male rats was stimulated for periods up to 90 minutes after 2.5, 5 and 10 mg/kg of SKF-10047. The locomotion induced by 10 mg/kg of SKF-10047 was diminished by: 20 mg/kg of naltrexone by 69 percent; 0.15 mg/kg of spiperone by over 94 percent; 0.03 mg/kg of spiperone by 50 percent; and a low dose of 0.1 mg/kg of apomorphine, which presumably causes presynaptic inhibition of dopamine-containing neurons, by 54 percent. SKF-10047 did not produce analgesia as assessed by the 49.5°C hotplate; significantly, however, 1.5 mg/kg s.c. of SKF-10047 did antagonize the analgesic effects of both morphine and ketocyclazocine.

Using the unilateral 6-hydroxydopamine-induced mesostriatal lesion model of circling behavior, SKF-10047 administration caused high intensities of ipsilateral circling behavior; circling towards the lesioned side is also caused by the indirect-acting dopamine-mimetic, d-amphetamine. SKF-10047-induced circling was antagonized by 0.15 and 0.05 mg/kg of spiperone; the same circling behavior, on the other hand, was not altered by 0.01 mg/kg of spiperone.

The data suggest that the pharmacologic effects of SKF-10047 include indirect activation of the mesostriatal and/or "mesolimbic" ascending dopamine pathways which result in enhanced central dopamine receptor activity expressed as locomotor activity and circling behavior; this action can be blocked by presynaptic inhibition of the ascending dopaminergic pathways after 0.1 mg/kg of apomorphine or by postsynaptic dopamine receptor blockade after spiperone.

40.1 DIETARY TRYPTOPHAN REVERSAL OF PATHOLOGICALLY ELICITED SHOCK-INDUCED FIGHTING. Kathleen M. Kantak, Linda R. Hegstrand and Burr Eichelman. Univ. of Wisconsin and William S. Middleton Veterans Administration Hospital, Madison, WI 53706.

Using two pathological procedures known to facilitate shock-induced fighting and muricide,ie septal lesions and intraventricular 5,7-dihydroxytryptamine (5,7-DHT) infusions, male rats were tested for the reversibility of these lesion effects by the addition of 5% tryptophan to the diet. Both septal lesions and 5,7-DHT infusions produced significant increases in shock-induced fighting within a few days following surgery. In animals fed the 5% tryptophan loaded diet, which was initiated 4 days prior to surgery, the level of shock-induced fighting did not differ in the septally lesioned or 5,7-DHT infused groups compared to sham operated or vehicle infused groups and compared to their own baseline levels of fighting. In confirmation of our earlier findings, a 5% tryptophan loaded diet failed to modulate shock-induced fighting in non-lesioned control animals. When tested for muricide, both septal lesions and 5,7-DHT infusions facilitated the incidence of predatory killing which could not be reversed by the addition of 5% tryptophan to the diet. Body weight and food intake substantially decreased following the septal lesions and 5,7-DHT infusions regardless of chow or tryptophan feeding regimens. These data demonstrate that under normal conditions a 5% tryptophan loaded diet produces no observable changes in shock-induced fighting or muricide but that under pathological conditions a 5% tryptophan loaded diet reverses the aggression enhancing effects of septal lesions and 5,7-DHT infusions on shock-induced fighting but not muricide. This reversal of shock-induced fighting following 5% dietary tryptophan loading is postulated to occur via a serotonergic mechanism.

40.2 HOW GO-NO GO DISCRIMINATION LEARNING AFFECTS BRAIN MONOAMINES AND ENZYME ACTIVITY IN CATS. Anne Kitsikis and Andrée G. Roberge, Laval University, School of Medicine, Que, G1K 7P4, CANADA.

The aim of this investigation was to determine whether learning produces changes in brain monoamine content and where these changes take place. Twelve cats were trained five days a week on a go-no go discrimination task. On go trials animals learnt to displace, within 5 sec, a black (S^+) cover in order to retrieve a piece of meat. On no go trials, they had to refrain from displacing a white (S^-) cover for 7 sec. Correct no go responses were not rewarded. A group of 6 trained and 3 untrained cats (group 1) was sacrificed on day 5 for biochemical assays. Another equivalent group was sacrificed after reaching criterion performance of 90% correct response on 5 consecutive days (group 2).

Cats in group 2 took between 500 and 950 (mean 766) trials to reach criterion performance. In both groups, practically all errors were made on no go trials and significantly ($P<0.001$) more go and no go errors were made by cats in group 2 during the first 5 days of training compared to the period between day 6 and criterion performance. Response latencies were significantly ($P<0.01$) longer on no go (error) trials than on go trials, suggesting that cats did not always respond " blindly ".

The biochemical effects observed in group 1 revealed a significant increase in tryptophan hydroxylase activity in the raphe nuclei of pons and medulla whereas in group 2, the enzyme activity was significantly increased in all raphe nuclei of the brainstem. Moreover, the increase observed in group 2 was significantly higher ($P<0.01$) than in group 1. Corresponding to this enzymatic activity, the concentrations of serotonin (5-HT) and 5-hydroxyindoleacetic acid(5-HIAA) were measured in 12 different brain structures. The 5-HT content in group 1 was found decreased in the mesencephalon, thalamus and frontal cortex whereas the 5-HIAA content remained constant. In group 2, however, the 5-HT content did not change significantly but the 5-HIAA content was significantly decreased in all structures of the brainstem, thus suggesting a low turnover rate. The concentration of noradrenaline was also measured in 12 structures and was found to be significantly decreased only in the pons and hypothalamus. The present findings reveal that go-no go discrimination induced an important reactivity of the serotoninergic metabolism in the brainstem and a well localized involvement of the NA metabolism. Moreover, biochemical changes occurring at criterion performance (group 2) differed markedly from those observed after a 5-day training period (group 1). The step by step acquisition of the go-no go task seems therefore to be mirrored by the deployment of biochemical mechanisms.

40.3 Differential effects of three learning tasks on brain amine synthesis in cats. Andrée G. Roberge, L. Vachon, C. Roberge and Anne Kitsikis, Laval Univ. Sch. of Medicine, Quebec, G1K 7P4, Canada.

Several studies have indicated the involvement of biogenic amines in different learning situations. Recently, we have shown that in intact, undrugged cats learning is accompanied by changes in monoamine concentrations, turnover rate and synthetising enzyme activities. Using a modified WGTA apparatus for conditioning, three different learning situations were successively used in an attempt to define the respective roles of biogenic amines in respect to behavioral parameters. The delayed response (DR) situation was a visual discrimination learning with interposed delays (0,9, 27 and 54sec). The successive discrimination (SD) situation was a 2-choice successive learning, implicating the association of a color with the direction of the response and the third situation was an asymmetrically reinforced go-nogo visual discrimination (VD).

No significant biochemical change was observed between a non-manipulated baseline group and a manipulated no learning group that was put through the experimental procedure but did not learn the task. All trained animals that reached criterion performance revealed the involvement of 5-HT metabolism whatever task learned. In go-nogo VD, a low turnover rate was demonstrated in all dissected brainstem structures including the raphe nuclei of mesencephalon, pons and medulla as suggested by a 5-HT:5-HIAA ratio higher in trained cats (2.61 ± .12) than in control cats (1.09 ± .14).In the DR situation, the low 5-HT turnover rate in the brainstem was circumscribed to the pons and medulla without raphe nuclei accompanied by a higher 5-HT:5-HIAA ratio in trained animals (2.02 ± .23) than in controls (1.17 ± .27). In these two learning situations, the tryptophan hydroxylase activity was significantly increased in all raphe nuclei. Moreover the 5-HT metabolism was also modified in other cerebral structures such as neostriatum, hippocampus, amygdala or frontal cortex in two ways: either by increasing both 5-HT and 5-HIAA content (DR and SD) or decreasing only the 5-HIAA content (go-nogo VD) thus suggesting different mechanisms. The NA metabolism was largely affected by the SD situation. In fact, a significant increase in the NA content was observed in the amygdala, thalamus, frontal cortex, neostriatum whereas a lower NA content was found in the amygdala and the frontal cortex. In DR and go-nogo VD tasks, the NA content was decreased in either the frontal cortex and amygdala or in the pons and hypothalamus.

These findings indicate that learning affected the 5-HT metabolism differently according to the degree of difficulty inherent to the performance of the task. (Supported by M.R.C. of Canada MA-6950)

40.4 EFFECTS OF PERIPHERAL STIMULI ON NEURONAL ACTIVITY IN THE VENTRAL TEGMENTAL AREA, SUBSTANTIA NIGRA AND MIDBRAIN RETICULAR FORMATION IN RATS. H. Maeda* and G. J. Mogenson (SPON: J. J. Seguin). Department of Physiology, University of Western Ontario, London, Ontario, Canada N6A 5C1.

Extracellular single unit recordings were obtained from the ventral tegmental area (VTA), substantia nigra, pars compacta (SNC) and pars reticulata (SNR), midbrain reticular formation (RF), and adjacent areas of urethane- or chloral hydrate-anesthetized adult female rats. Units from the VTA and SNC were divided into two groups based on their electrophysiological characteristics: Type A neurons had rather long-duration action potentials (> 2.6 ms) and slow firing rates (< 6 Hz), and type B neurons had shorter-duration action potentials and wider range of firing rates. The responsiveness of the two types of VTA and SNC neurons to peripheral stimuli such as cervical probing with a glass rod, foot pinching with bare forceps and tail pinching with padded sponge forceps was investigated. Prior to recording experiments, behavioral responses to cervical probing and tail pinching were observed and vaginal smears were taken to determine the estrous state of each rat.

Type A neurons, located exclusively in the VTA and SNC and considered to be dopaminergic, were mainly suppressed by foot pinching. With cervical probing three-quarters of Type A neurons were suppressed and one-quarter were activated. Equal numbers of Type B neurons were activated or suppressed by foot pinching. With cervical probing two-thirds of Type B neurons were suppressed and one-third were activated. For approximately 80% of Type B neurons the direction of effect was the same. Most neurons in RF and SNR were activated by the two peripheral stimuli. Responses to tail pinching were usually similar to those to foot pinching, although the magnitude tended to be less. There was no significant difference in responsiveness during the various estrous states.

The two stimuli, cervical probing and foot pinching, have quite different behavioral effects. In response to cervical probing the female rat assumes the lordosis posture and is relatively immobile, whereas foot pinching is a nocioceptive stimulus resulting in escape and other forms of behavioral activation. Thus when neurons respond in the same way to these two peripheral stimuli it is likely the result of a non-specific reaction. This is the case for RF and SNR neurons and for a majority of VTA and SNC neurons. In contrast the response of the remaining VTA and SNC neurons was variable and depended on the nature of the stimulus. It seems likely that these VTA and SNC neurons are related to specific response patterns to peripheral stimuli and do not merely reflect changes in arousal.

40.5 L-DOPA, NASAL MARKING AND AROUSAL IN THE SQUIRREL MONKEY (SAIMIRI SCIUREUS). Sherry L. Berg*, Daniel L. Jones and Russell E. Dill. Dept. of Microscopic Anatomy, Baylor College of Dentistry, Dallas, TX. 75246

Videographic samples were taken and an analysis of the behavioral topography was made from squirrel monkeys treated systemically with 50 mg/kg L-DOPA plus 20 mg/kg carbidopa and 4 mg/kg ascorbic acid injected i.p. Primates were confined in a 30 x 28 x 60 cm plexiglass test chamber and photographed in the presence of the experimenter. Incidences of two types of nasal marking, sneezing and nasal rubbing, were documented as early as 10 min into the test and occurred in filmed behavioral samples taken one hour later.

Observations of nasal marking are particularly relevant to the inference that L-DOPA induces a heightened state of arousal as experimental and naturalistic reports on this behavior (Schwartz, G.G. & Rosenblum, L.A., Behav. & Neural Biol., 28:116-122, 1980) suggest an excitatory state as well as implications for olfactory communication and thermal regulation. (Supported by the Huntington's Chorea Foundation and NIH Grant NS-15020)

40.6 FAILURE TO ALTER ANXIETY OR THE ANXIOLYTIC PROPERTIES OF CHLORDIAZEPOXIDE AND ETHANOL BY DESTRUCTION OF THE DORSAL NORADRENERGIC SYSTEM. G.F. Koob, R.E. Strecker*, D.C.S. Roberts and F.E. Bloom. A.V. Davis Ctr. for Behavioral Neurobiology, The Salk Institute, San Diego, California 92138.

It has been hypothesized that the noradrenergic projection from the locus coeruleus plays a role in the manifestation of anxiety. It was therefore of interest to examine the effect of lesions to the forebrain projection from this nucleus on a behavioral task in which "anxiety" or conflict influences performance. The effect of these lesions on the behavioral effects of two anxiolytic drugs (alcohol and chlordiazepoxide) was also examined.

Rats were trained on a Geller-Seifter conflict test modified for incremental shock (Pollard and Howard, Psychopharm. 62, 117-121 (1979)) and consisting of three components: reward, time-out and conflict. Responses during the reward component were reinforced on a random interval (RI) schedule--30 sec; responses during the time out component were never reinforced and responses during the conflict component were continuously reinforced with food and foot shock (scrambled constant current, biphasic, square wave produced by a SGS-003 stimulator-BRS/LVE). However, the current increased by 0.1 mA with each successive shock during the conflict component until reaching 2.2 mA where it remained for the duration of the conflict period. A session consisted of two cycles each consisting of a 5 min reward period, 2 min time out and 2 min conflict period presented in succession. This procedure yielded a total testing time of 18 min.

Unoperated rats averaged 21 total shocks (incrementing to 1.0 MA) during each daily session without drug. Chloridiazepoxide (5 mg/kg) produced a significant release of punished responding during the conflict period and a small increase in responding during the reward component. Alcohol produced a significant release of punished responding during the conflict component. Virtual total destruction (98% depletion in hippocampus) of the dorsal noradrenergic innervation of the forebrain by 6-hydroxydopamine lesion to the central tegmental tract failed to significantly alter baseline conflict responding or the release of punished responding to chlordiazepoxide (5 mg/kg) or ethanol (0.5, 0.75 and 1.00 g/kg). These results do not support the hypothesis that the locus coeruleus forebrain projections have a role in anxiety or in the anxiety reducing properties of chlordiazepoxide or alcohol (supported by AA 03504).

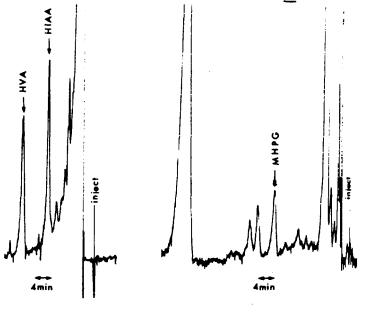
40.7 TRANSIENT OR PERMANENT HYPERACTIVITY FOLLOWING NEONATAL 6-HYDROXYDOPAMINE: A FUNCTION OF BRAIN DOPAMINE DEPLETION. Thomas Heffner Frederick Miller*, Connie Kotake*, Alfred Heller and Lewis Seiden. University of Chicago, Chicago, IL 60637.

Selective destruction of brain dopamine (DA) neurons by the neurotoxin 6-hydroxydopamine (6-HDA) results in locomotor hyperactivity in neonatal rats but not in adults (Shaywitz et al. Sci. 191:305,1976; Erinoff et al. Br. Res. 164:195,1979). Whereas Shaywitz et al. reported that the hyperactivity decreases with maturation, Erinoff et al. reported that hyperactivity can persist into adulthood. We sought to determine if the duration of 6-HDA-induced hyperactivity is related to the extent of destruction of central DA neurons. Neonatal male rats were given ivt. injections of 6-HDA (25,35,50 or 100 µg) or the vehicle following desmethylimipramine (20 mg/kg,s.c.) at 3 and 6 days of age. Adult male rats received a single ivt. injection of 6-HDA (125,200, or 275 µg) or the vehicle following pargyline (50 mg/kg,i.p.) and desmethylimipramine (25 mg/kg,i.p.) at 48 days of age. From day 16 to 32 of life, locomotor activity in all groups of rats treated neonatally with 6-HDA was significantly increased compared to controls. During this period, rats given either 2 x 50 µg or 2 x 100 µg of 6-HDA displayed consistently high levels of locomotion (150 counts/hr compared with 30 counts/hr in controls). In contrast, the hyperactivity seen in neonatal rats given 2 x 25 µg or 2 x 35 µg of 6-HDA decreased from 150 counts/hr at day 18 of life to 75 counts/hr at day 32 of life. When neonatally-lesioned rats were tested as adults (days 55-66 of life) only those given 2 x 100 µg of 6-HDA displayed higher levels of locomotion than controls (4.5 times the control level). None of the rats treated with 6-HDA as adults displayed increased locomotion. Analysis of the effects of 6-HDA on the regional levels of DA in brain revealed dose-dependent selective depletion of DA in both neonatally-treated and adult-treated rats. Rats given the 2 x 100 µg 6-HDA dose showed the greatest DA depletions of any neonatally-treated group. The extent of DA depletion in 8 nerve terminal fields was comparable in neonatal and adult rats. These results support previous findings that locomotor hyperactivity induced by 6-HDA depends upon the stage of development at the time of 6-HDA treatment. The present results further indicate that the duration of locomotor hyperactivity in neonates is related to the extent of DA neuron destruction. Near-total loss of central DA neurons in neonates is followed by hyperactivity that is sustained throughout neonatal as well as adult life. However, smaller losses of central DA neurons is accompanied by locomotor hyperactivity in neonatal but not adult life. (Supported by USPHS NS-12324; MH-10562; MH-14274).

40.8 DETERMINATION OF BIOGENIC AMINE METABOLITES IN HUMAN LUMBAR CEREBROSPINAL FLUID BY HPLC WITH EC DETECTION. L. Tune, R. Zaczek* and J.T. Coyle. Dept. of Pharmacol. and Expt. Therapeut., Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205.

Simple, sensitive and inexpensive methods for measuring biogenic amine metabolites in human cerebrospinal fluid (CSF) havebeen developed in which the compounds are separated by HPLC and quantified by electrochemical detection. For measurement of 5-hydroxyindole acetic acid (HIAA) and homovanillic acid (HVA), 20 1 of CSF was injected directly with the following chromatographic parameters: a HIBAR II, LiChrosorb RP 18 5.0 m column (VWR) with a mobile phase of 50 mM sodium acetate buffer, pH 2.8, containing 0.01% (w/v) disodium EDTA and 3.5% (v/v) N-propanol at a flow rate of 1.0 ml/min; the potentiometer (BAS-Model LC-4 with glassy carbon electrode) setting was 0.72V. HIAA eluted at 9.0 min with a response of 13.0 nAMP/ng and HVA eluted at 14.0 min with a response of 5.2 nAmp/ng. 3-Methoxy-4-hydroxy phenylglycol (MHPG) was first separated from CSF by acidifying 200 1 CSF with 20 1 of 4 N formic acid and then extracting twice with 1.0 ml of ethyl acetate with an 60% recovery. The organic phases were combined and dried under a gentle vacuum at 50°C. The concentrate was then dissolved in 200 1 of the mobile phase buffer (50 mM sodium acetate, pH 2.8 containing 0.01% (w/v) disodium EDTA); 100 1 was run over the same column as above with a flow rate of 1.0 ml/min. MHPG eluted at 20.4 min with a response of 7.8 nAmp/ng.

Lumbar CSF samples were obtained from 40 patients undergoing mylograms who ranged in age from 17-86 and had a variety of neurologic diagnoses; the CSF was frozen on dry ice within 15 min of lumbar puncture. HVA levels for the 35 patients ranged from 7.7 to 75.2 ng/ml with a mean of 38.4 ± 3.0 ng/ml (± S.E.M.); the range for HIAA was 10.5 to 39.5 ng/ml with a mean 22.1 ± 2.1 ng/ml. Analysis of the effects of freeze-thawing (5 times) of the CSF did not reveal any alterations in HVA or HIAA values. MHPG levels from 15 patients averaged 4.9 ± 0.8 ng/lf. The results obtained with this technique compare favorably with those reported by others using gas chromatographic - mass spectrometry or fluormetric assay methods.



41.1 EXCITATORY DRIVE FROM THE MESENCEPHALIC CORE TO MEDIAL AND INTRALAMINAR THALAMIC NEURONS PROJECTING TO THE CAUDATE NUCLEUS AND NEOCORTEX. Loyd L. Glenn and Mircea Steriade. Lab. Neurophysiol., Fac. Med., Laval Univ., Québec, Canada G1K 7P4.

The medial and intralaminar thalamic nuclei are major rostral targets of neurons in the midbrain reticular formation (MRF). To elucidate the electrophysiological properties of pathways underlying cortical activation processes, we made extracellular recordings in the ventralis medialis (VM) and centralis lateralis-paracentralis (CL-Pc) thalamic nuclei. Some cats were prepared acutely and others chronically. Recording sessions were conducted 7 to 20 days after lesioning the ipsilateral pontine tegmentum just caudal to the MRF stimulating electrodes. The anterograde degeneration that followed ensured that MRF-evoked responses did not result from the stimulation of fibers of passage.

Two hundred CL-Pc and VM neurons were identified by antidromic invasion from multielectrode arrays inserted in cortical areas 4 & 6, anterior suprasylvian areas 5 & 7, and the caudate nucleus. Ninety-nine percent were backfired selectively from one of these three targets. As a rule, neurons recorded in CL-Pc projected to areas 4,6, or 5, while VM neurons restricted their projection to the precruciate areas. Our disclosure of CL-Pc and VM neurons projecting to the anterior neocortex is the electrophysiological counterpart of data obtained by others using retrograde and anterograde tracing techniques. In CL-Pc, about 40% of tested neurons were antidromically activated from the precruciate gyrus and 30% from the anterior suprasylvian gyrus. In VM, about 25% were activated from the precruciate gyrus. The median conduction velocity of CL or Pc → precruciate axons was significantly higher (≈10 m/sec) than that of VM axons (≈6.5 m/sec), reflecting in all likelihood the larger size of cells in the dorsolateral CL.

MRF-evoked monosynaptic excitation, as inferred from latencies below 1.5 msec and the ability to follow high-rate stimuli, was obtained in 70 CL-Pc and VM neurons, 27 of which projected to caudate or cortical areas. The facilitatory nature of the MRF influence was demonstrated by (1) increased probability of antidromically elicited discharges in CL-Pc neurons to cortical or caudate volleys and (2) transformation of their abortive or broken spikes into full spikes following a conditioning MRF stimulation.

A direct excitatory MRF → thalamic pathway has thus been demonstrated, providing a rapid route for transferring activating MRF influences to anterior neocortical areas.

Supported by MRC grant MT-3689 and NSF grant SPI79-14817.

41.2 EXCITABILITY OF MEDIAL AND INTRALAMINAR THALAMIC NEURONS DURING WAKING AND SLEEP STATES. Mircea Steriade and Loyd L. Glenn, Lab. Neurophysiol., Fac. Med., Laval Univ., Québec, Canada G1K 7P4.

The characteristics of the reticular afference and telencephalic efference of centralis lateralis-paracentralis (CL-Pc) and ventralis medialis (VM) neurons are described in a companion abstract (Glenn and Steriade, this volume). The spontaneous discharge rate and probability of antidromic and/or synaptic activation in a group of 22 neurons located in CL-Pc and the subjacent VM territory were analyzed during the natural sleep-waking cycle in unanesthetized, behaving cats. Chronic lesions of the ipsilateral pontine tegmentum, with consequent anterograde degeneration of ascending fibers coursing through the midbrain reticular formation (MRF), ensured that MRF-evoked synaptic responses did not result from the stimulation of fibers of passage.

During synchronized sleep (S), CL-Pc and VM units discharged in high-frequency, protracted bursts separated by long periods of silence. Burst frequencies paralleled the range for cortical spindle waves (7 to 14/sec); this relation could be established for either single neurons or neuronal pairs. In wakefulness (W) and desynchronized sleep (D), the firing rate increased and the burst-silence sequence during S either decreased in duration or was completely blocked, resulting in a single spike background of regular discharge.

The stimulation current for antidromic and synaptic responses was adjusted to straddle the threshold, so that fluctuations in excitability across behavioral states were detectable. In all instances, the probability of antidromic invasion increased by >100% during W and D as compared to S. In one CL neuron that projected to area 5, spikes with an initial segment-somadendritic break during S developed into unbroken discharges in W. Interestingly, this enhanced antidromic responsiveness was detected 10 sec prior to cortical desynchronization of W or D, when the EEG was in full synchrony.

Neurons discharging singly to MRF stimulation at monosynaptic latencies had a strikingly increased response probability in W and D. A group of cortically-projecting neurons in CL responded to MRF stimuli with high-frequency (>600/sec), long bursts. In W and D, both the latency and duration of the burst decreased. This phenomenon was concurrent with enhanced antidromic conduction during W and D. The diminished number of spikes within the synaptically-evoked burst may be ascribed to a reduction in the latency of postexcitatory inhibition during cortical activation.

All evidence is consistent with the hypothesis that CL and VM neurons, with their wide cortical projections, may mediate activating influences over the neocortex in W and D states.

Supported by MRC grant MT-3689 and NSF grant SPI79-14817.

41.3 LOCALIZATION OF BRAINSTEM NUCLEI AND THEIR ASCENDING PATHWAYS THAT CONTROL THE HIPPOCAMPAL EEG. Robert P. Vertes. Dept. Physiol., Univ. of Mich. Med. Sch., Ann Arbor, MI 48109.

In a previous report in the anesthetized rat we mapped the entire brainstem with stimulation to determine its effect on hippocampal slow-wave activity. The results of that study (Vertes EEG, in press) showed that: (1) The most effective brainstem synchronizing sites were those within the reticular nucleus pontis oralis (RPO) and those in and around the medial longitudinal fasciculus (MLF) at the pontine level. We suggested that the nucleus pontis oralis was the brainstem source for hippocampal theta generation and that its fibers primarily exit the brainstem via the MLF. (2) The median raphe nucleus (MR) was the only brainstem site at which stimulation produced hippocampal desynchronization. Desynchronization at the MR was accompanied by a sharp reduction in the amplitude of hippocampal EEG activity.

In the present investigation, also in the anesthetized rat, the rostral brainstem was re-stimulated and we confirmed the existence of the RPO and the MR as strong synchronizing and desynchronizing sites, respectively. In addition, the entire midbrain was systematically stimulated in an attempt to follow the synchronizing (RPO) and desynchronizing (MR) systems rostrally. The results showed that three separate synchronizing pathways and one desynchronizing pathway could be followed through the midbrain into the caudal diencephalon. The three synchronizing pathways were: (1) MLF - A very effective synchronizing system could be followed along the entire length of the MLF as it traversed the midbrain. (2) Medial Forebrain Bundle (MFB) - A synchronizing system lying ventral to nucleus cuneiformis was evident throughout the midbrain. This pathway moved progressively ventral as it ascended and appeared to join the MFB at the level of the diencephalon. (3) Central Tegmental Tract (CTT) - A third system that was weaker than the other two was found dorsally lateral to the midbrain central grey and corresponding to the position of the CTT. This pathway could be followed as far rostral as the thalamic intralaminar nuclei. The sole desynchronizing system traveled forward from the MR along the midline and progressively maintained a more ventral position as it ascended. Throughout approximately the caudal two-thirds of the midbrain this tract ran parallel to and about 1mm below the MLF synchronizing system. At the level of the interpeduncular nucleus this system turned lateral and continued forward in a region corresponding to the ventral medial part of the MFB. These results suggest that specific brainstem nuclei are directly involved in controlling hippocampal EEG activity and that their axons ascend to the forebrain in discrete fiber tracts.

Supported by Grant BNS78-10136, National Science Foundation.

41.4 L-PROLINE BLOCKS HIPPOCAMPAL EXCITATORY SYNAPTIC ACTIVITY. A. Van Harreveld and F. Strumwasser. California Institute of Technology, Pasadena, CA 91125.

Field potentials, elicited by stimulation of the Schaffer collaterals, were led off from the stratum radiatum of CA1 in rat hippocampal slices suspended on a nylon net in a chamber perfused with a physiological salt solution. The slices were completely submerged. L-proline in suitable concentrations was applied in the salt solution. The responses to the stimulus consisted of a negative synaptic potential and one or more population spikes preceded by a small spike ascribed to conduction in the Schaffer collaterals. In a concentration of 2 mM, L-proline had no noticeable effect, but 3 mM enhanced the response, the population spikes becoming larger and more numerous. At 5 mM or more the synaptic responses were reversibly abolished but the presynaptic spike was not affected. This effect was counteracted by simultaneously applied 4-amino pyridine (0.5 mM), which prolonged the presynaptic spike and was postulated to increase the release of the transmitter, believed to be L-glutamate and L-aspartate (see e.g., Nadler et al., Nature 260, 538, 1976). This can be expected to favor the binding of the transmitter to the postsynaptic membrane in its competition with L-proline for glutamate receptors. These observations support the postulate that L-proline is a glutamate antagonist, as has been suggested for instance by its blocking effect on the responses of hippocampal neurons to applied glutamate (Segal, Br. J. Pharmacol. 58, 341, 1976), and on the crustacean neuromuscular junction, which is believed to be glutamate mediated (Van Harreveld, J. Neurobiol., in press).

It has been suggested that L-proline binding with extrasynaptic glutamate receptors causes a moderate increase in Na^+ permeability of the dendritic membrane and a release of K^+ (Van Harreveld, J. Neurobiol. 10, 355, 1979). The enhancement of the synaptic response to Schaffer collateral stimulation in 3 mM proline may be due to this K^+ release, which was supported by the observation of a similar enhancement by an increase in the K^+ concentration in the perfusion fluid. However, for the time being the possibility that the enhancement is due to an initial agonistic effect of L-proline (Shank and Freeman, J. Neurobiol. 7, 23, 1976) cannot be excluded. D-proline even in 10 mM concentration had no effect on the responses to collateral stimulation. (Supported by NS 07071 and the Pew Foundation.)

41.5 ELECTROPHYSIOLOGICAL GUIDANCE OF HIPPOCAMPAL ELECTRODES FOR INTRACRANIAL SELF-STIMULATION (ICSS) IN ANGULAR BUNDLE, PERFORANT PATH AND DENTATE GYRUS.
T.J. Collier*, J.S. Miller* and A. Routtenberg. Cresap Neuroscience Laboratory, Northwestern University, Evanston, ILL 60201.

The entorhinal cortex (EC) provides a massive projection to the molecular layer of the dentate gyrus and supports stable ICSS responding (Collier, et al., 1977, Br. Res., 137:188). The present study investigates ICSS in the EC-dentate projection system. If ICSS derived from EC is mediated by activation of the EC projection to the dentate gyrus, then ICSS should be observed in the perforant path and the dentate gyrus.

Male albino rats were chronically implanted with bipolar stimulation electrodes using electrophysiological guidance. Probes were guided into the angular bundle/perforant path system by stimulating at 50 μm steps during electrode penetration, while recording evoked granule cell population responses from the dorsal dentate. Reversal of potential in the molecular layer confirmed the local nature of the stimulation effect, as did silver impregnation studies following lesions at these stimulation sites. ICSS electrodes aimed at the dentate gyrus were guided into position by recording, in sequence, CA1 and granule cell spontaneous activity during electrode penetration.

Low to moderate ICSS rates (50-150 responses/15 min) were derived from dorsal angular bundle and dentate gyrus. In comparison to hypothalamic sites, onset (in days) to begin ICSS responding was slower in the EC-dentate system, and peak rates were substantially less than those derived from hypothalamic sites. However, ICSS in dentate gyrus, like that derived from hypothalamus, was not decreased by administration of an inebriating dose of ethanol prior to testing.

The use of this electrophysiological guidance procedure enables: (a) fine resolution (< 50 μm) of electrode location, (b) relative homogeneity of implanted groups, (c) explicit placement and confirmation that electrodes are activating axonal pathways, and (d) postponement of death of the animal necessitated by histological analysis. Supported by N.I.M.H. 25281 and N.S.F. 20630 to A.R.

41.6 PARAMETRIC VARIATIONS IN GROUND POTENTIALS DO NOT AFFECT INTRACRANIAL SELF STIMULATION RATES.
F. Gimino†, R. Feldstein*, S.S. Steiner, C. Steiner, and E. Coons. Behav. Physiology Lab., City College of N.Y., NY 10031.

A long standing notion has been that intracranial self-stimulation (ICSS) behavior is delineated by the path of the stimulating current and its intensity. Many authors have contended that for this reason no arguement could be made for the site specific effects of ICSS since the path of the electrical current with respect to ground varied throughout the course of an experimental session. Thus, this study investigates this problem of the existence of ground potentials with respect to the stimulating electrode during ICSS.

Eight Sprague-Dawley rats were stereotaxically implanted with bi-polar electrodes aimed at various diencephalic self-stimulation sites. After recovery from surgery, all rats were shaped to respond for 700 msec. trains of .1 msec. monophasic rectangular pulse pairs of intracranial stimulation. The first pulse in a pair (C-conditioning pulse) was followed by a second (T-test pulse) which was parametrically varied in time.

Animals were placed in a paradigm in which they received C-T stimulation from either a capacitance coupled or from an optically isolated constant current stimulator. The capacitance coupled stimulator was constructed from several BRS/LVE 200 series DIGIBIT logic modules and had a reference impedance which was 120 ohms relative to ground. The constant current stimulator was designed with two GE 4N26 optoisolators and had a reference impedance of two megaohms with respect to ground.

All animals tested demonstrated no significant differences between C-T response rate functions obtained on the capacitance coupled vs. the opto-isolated stimulation units. Thus, this study indicates that direct manipulation of ground potentials between 120 ohms to 2 megaohms do not significantly alter ICSS responding. Furthermore, since the locus of ground with respect to the stimulating current plays no significant role in ICSS, stimulation's effects can be more fully understood from the vantage point of site specific neural ICSS loci rather than from one advocating current spread or any such non-specificity hypothesis.

41.7 RELATIVE PREFERENCE AS A MEASURE OF THE REINFORCING VALUE OF ELECTRICAL BRAIN STIMULATION.
P.J. Fray* (SPON: L.T. Rutledge). Neurosci. Lab., Univ. Michigan, Ann Arbor, Mich. 48109.

Attempts to establish the neurochemical systems involved in the rewarding effects of electrical brain stimulation have been frustrated by the lack of a consistent and sensitive measure of reinforcement value. Although rate of responding, in relation to current intensity, has been widely employed, its reliability has been questioned by findings that rats will often choose current intensities for which they respond at a low rate over current intensities for which they respond at a high rate. Choice provides the only unambiguous way of determining a preference. However, animals given simultaneous access to two alternatives will usually choose one almost exclusively. Thus, a small difference between the alternatives leads to as great a preference as a large difference. Nevertheless, Herrnstein and others have demonstrated that if two alternative probabilities of food reinforcement are made available on independent, concurrent variable interval schedules, the distribution of responses and time between the alternatives is proportional to relative reinforcement frequency. If a relationship can be established between relative reinforcement and relative responding and time allocation, the relationship between two unknown levels of reinforcement can be assessed by measuring relative preference in this paradigm. Five rats were trained to work on such schedules for electrical stimulation of the lateral hypothalamus. Relative responding and time allocation on the two alternative schedules were found to vary reliably as a function of relative reinforcement frequency, and to be independent of the total amount of reinforcement delivered. With relative probability of reinforcement held constant, responding and time allocation were found to be functions of relative current intensity and relative number of stimulation trains earned per reinforcement opportunity. The technique provides a sensitive measure of reinforcement value that is independent of absolute rate of responding and reinforcement, and should prove useful in the investigation of the neurochemical basis of reward.

41.8 AN ASSESSMENT OF THE REINFORCING PROPERTIES OF FOODS FOLLOWING AMYGDALOID LESIONS IN THE MONKEY.
J. P. AGGLETON* AND R. PASSINGHAM* (SPON: B. RICHMOND). Dept. of Exp. Psychol., Oxford University, United Kingdom.

One of the most striking effects of amygdalectomy in monkeys are dietary changes: the ingesting of previously rejected items such as meat and even faeces. To characterise this abnormality further comparisons were made of the food preferences in fifteen rhesus monkeys (Macaca mulatta) before and after a variety of amygdaloid lesions. The surgical targets in the experimental groups were: (a) lateral amygdala (LAT n=4), (b) basolateral amygdala (n=4), (c) dorsal amygdala (n=2), (d) the white matter of the temporal albal stalk adjacent to the amygdala (n=2) and (e) total amygdala (AMX n=3). All animals received bilateral radiofrequency lesions centered in the appropriate nuclei.

Relative food preferences were estimated from the frequency with which a particular food was chosen when paired with another A profile of such preferences was thus established. None of the monkeys with subtotal amygdaloid lesions displayed changes in food preferences after operation, though all of the AMX monkeys would now eat raw meat and would occasionally choose meat rather than a previously accepted food. The remainder of the AMX group's food choices appeared normal.

In an attempt to obtain an absolute measure of preference for various foods the LAT and AMX groups were trained to press a panel on a Progressive Ratio (PR) schedule. This schedule consists of a sliding "fixed ratio" such that each reward causes the number of panel-presses required for the next reward to be increased by five. The PR score represents the ratio at which the animal stopped responding for an arbitrary criterion period (120 secs). The PR scores were sensitive to alterations in the size and type of food reward and the degree of deprivation. However, neither AMX nor LAT groups showed any changes from their preoperative response patterns on these PR schedules.

This study thus found no evidence of a specific lesion site within the amygdala sufficient to bring about dietary changes, nor evidence of any alterations in food preferences other than meat-eating following total amygdalectomy. These results suggest that amygdalectomy may result in a normal appreciation of food rewards and that only the readiness to sample and eat "unpleasant" foods is changed.

42.1 THE EFFECTS OF PRIOR TRAINING AND DRUG PRETREATMENT ON PIMOZIDE-INDUCED AVOIDANCE DEFICITS. R.J. Beninger, A.G. Phillips and H.C. Fibiger. Depts. Psychology and Psychiatry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5.

There are numerous reports of the deleterious effects of neuroleptic drugs on one way avoidance behavior. Observing the rate of acquisition, neuroleptic-injected animals were retarded in a dose-related manner when compared to vehicle-treated controls. Some controversy surrounds the effects of prior training. Using a small number of drug sessions, some authors have suggested that prior training attenuates the effects of neuroleptics whereas others used more extensive drug testing and reported that avoidance responding was disrupted. In the present experiment the amount of training prior to the initiation of treatment with pimozide was varied. Four groups of rats received either 2 or 10 training sessions (10 trials/session; intertrial interval = 30 sec; CS = 10-sec tone; US = 2.4 mA footshock). Drug treatments began with i.p. injections of pimozide (0.5 or 1.0 mg/kg) occuring 90 min prior to each testing session. Four additional groups received the same prior training and drug treatment but pimozide injections were given in the home cage on the 3 days preceding the first drug session. These groups were included to determine any possible cumulative effects of repeated injections. The results revealed that the number of avoidance responses per session of all drugged groups deteriorated over sessions in a dose related manner. There was no effect of prior training on the rate of decline in responding of the 0.5 mg/kg groups but the group receiving 10 prior training sessions was more resistant to the effects of the higher dose than the group receiving 2 prior training sessions. Pretreated groups showed the same effect as the nonpretreated groups except that the effect of prior training in the groups receiving the higher dose no longer was observed. Thus, 10 sessions of prior training attenuated the effect of 1.0 mg/kg pimozide. This effect of prior training was not observed following pretreatment with pimozide.

42.2 EVALUATING CYCLIC AMP MEDIATION OF MEMORY. Douglas L. Chute, John W. Villiger*, and Mike Dragunow*. Department of Psychology, University of Otago, Dunedin, New Zealand.

A number of authors have hypothesized that postsynaptic cyclic adenosine 3',5' monophosphate, by its action on protein kinases, may be an important mediator of memory formation. One consequent prediction would be that increased intracellular cAMP ought to facilitate memory. In a series of experiments involving latent learning, maze learning, and passive avoidance tasks, a performance facilitation was observed in several varieties of mice. They had received either a phosphodiesterase inhibitor, papaverine or RO-20-1276/1, or dubutyryl cAMP raising intracellular levels of cAMP. The injection was given immediately after acquisition which, in conjunction with other experimental controls, tends to preclude such non-specific factors as arousal, attention, fear, motivation and motor performance as possible explanations of the observed performance facilitation. Increased intracellular cAMP has a prophylactic effect on catecholamine depletion amnesia.

We speculate that the behavioural evidence of a performance facilitation, which can be interpreted as memory facilitation, supports hypotheses of cAMP mediation of memory.

42.3 LONG TERM CHANGES IN EMOTIONAL REACTIONS AND NOT IN LEARNING AFTER INTRACEREBRAL INJECTIONS OF CYCLOHEXIMIDE OR GLUTAMATE IN NEONATAL CHICKS. Paul R. Sanberg, Ian J. Faulks*, Judith M. Anson* and Richard F. Mark* Department of Behavioural Biology, Research School of Biological Sciences, Australian National University, Canberra, ACT, 2600, Australia.

It has previously been demonstrated that an injection of cycloheximide (CXM) into the forebrain of newly-hatched chickens can cause permanent slowing of learning in later life[1]. Cycloheximide has been shown to increase the concentration in the brain of glutamate (GLU) in neonatal chicks, and injection of this amino acid can also cause slow learning similar to that seen following CXM. It has been suggested that an accumulation of glutamate may underlie the slow learning[2] induced by cycloheximide. Slow learning has been measured mainly with a pebble floor task.

We have assessed the effects of bilateral intracerebral injections of CXM (20µg in 25µl saline) or GLU (210µg in 25µl saline) in 2 day-old chicks on the subsequent performance, in operant, open-field and tonic immobility behaviors in order to find out the nature of the behavioral deficits. Birds were tested between 4 and 8 weeks after injection.

There were no significant differences between birds injected with saline and birds injected with CXM or GLU on acquisition, performance or extinction of a continuous reinforced pecking response as measured in modified pigeon operant boxes. In the open-field test birds injected with either CXM or GLU were less active, as reflected by longer latencies to leave the first square, reduced ambulation, preening episodes and pecks at the floor. They defecated more too. Tonic immobility was increased in duration. All effects were greater in birds treated with CXM.

The failure to find any differences in the operant experiment does not support the conclusion that either treatment causes a primary impairment in the ability to form memory traces. Instead the results of experiments in the open field and measurements of tonic immobility suggest that injections of CXM or GLU in neonatal chicks enhance emotional reactions and may increase the fear of novelty. The learning deficit previously reported is most likely to be a consequence of disordered emotional responses.

42.4 IMPAIRED BEHAVIORAL SENSITIZATION TO COCAINE IN VASOPRESSIN DEFICIENT RATS. R.M. Post, N.R. Contel,* P. Gold.* NIMH, Bethesda, Maryland 20205.

Vasopressin (VP) exerts effects on a variety of learning and memory paradigms in animals and man. In addition, VP has been shown to influence the development of tolerance to drugs, which has been conceptualized as a form of cellular learning (de Wied, 1978). We postulate that reverse tolerance or behavioral sensitization, in which there are long-lasting increases in stimulant responsivity based on previous drug exposure and environmental context, could also represent a model of learning and memory. In order to elucidate a possible role of VP in the process of behavioral sensitization to psychomotor stimulants, rats with a genetic deficiency in VP were administered repeated injections of cocaine and effects on motor activity and stereotypy examined. Twelve male Brattleboro homozygotes who show absolute VP deficiency resulting in diabetes insipidus (D.I.) were studied in parallel with 10 litter mate heterozygote controls (H.C.). All were housed in groups with ad lib food and water on a 7-7 light-dark schedule. Rats were injected with cocaine (10 mg/kg, i.p.) once daily for 10 days, rechallenged with cocaine 3 weeks later (Challenge I), given daily cocaine again for 15 days, and rechallenged after an interval of 16 weeks (Challenge II) and 21 weeks (Challenge III) to test for persistence of differential response. Horizontal and vertical motor activity were measured and stereotypy rated for two 10-minute baseline periods prior to each injection and 40 minutes following cocaine.

Over the first 10 days of cocaine H.C., but not D.I. rats, showed significant cocaine sensitization, as evidenced by increases in vertical hyperactivity and stereotypy ($p < .01$). D.I. rats eventually showed evidence of sensitization, but it was slower in onset and less robust than in H.C. Moreover, on all cocaine rechallenges (I-III) at intervals of 3 to 21 weeks following cocaine, H.C. rats showed greater cocaine-induced hyperactivity than D.I. animals ($p < .01$). Although H.C. weighed more (454 ± 9 gms) than D.I. animals (377 ± 17 gms), this would not appear to account for the differential response to cocaine as cocaine-induced hyperactivity did not differ on day 1 and baseline exploratory activity 20 and 10 minutes prior to each of the cocaine challenges did not differ between groups.

The decreased responsivity in VP-deficient rats compared to H.C. suggests that the neuropeptide VP is involved in the development and persistence of behavioral sensitization to repeated cocaine. Vasopressin thus appears to be involved in the long-term coding of cocaine-induced motor activity and stereotypy and related behaviors of psychiatric relevance. This extends previous reports of VP's role in enhancing learning and memory to the model of pharmacologically-induced behavioral sensitization.

42.5 AMPHETAMINE COUNTERACTS DECREMENTS OF AGGRESSION IN MICE. James T. Winslow* and Klaus A. Miczek. Dept. Psychology, Tufts Univ., Medford, MA 02155.

The decline in aggressive behavior as a result of repeated episodes of fighting may represent a habituation phenomenon. At present, the stimulus conditions determining this decremental process and the underlying mechanisms have been primarily investigated in fish, but little is known about the habituation of aggression in mammals. The objectives of our experiments were (1) to investigate the features of the declining rate of attack during the course of consecutive episodes of fighting between two male mice, and (2) to intervene pharmacologically at different phases of the habituation process with the catecholamine-releasing drug d-amphetamine. The effects of d-amphetamine were studied on the initial high rates of attacks and threats as well as on later phases of the decremental process when aggressive behaviors reached stable low frequencies. Aggressive behavior was generated in a male mouse, housed with a female, by introducing an unfamiliar group-housed male mouse into the homecage (n=10 resident males). Initial experiments investigated the parameters of intruder presentation and found that ten consecutive resident-intruder confrontations, each 5 min long, every 10 min resulted in an orderly decline of attack and threat behavior toward the intruder. The rate of decrement in attacks and threats by resident mice over the 10 trials was reliably reproduced in consecutive sessions, each 7 days apart. In 3 additional trials with a new intruder, the rate of attacks and threats recovered to about 50% of the original level suggesting fatigue as well as habituation contributing to the decrement in aggression. Further experiments examined the effects of d-amphetamine (0.63-5.0 mg/kg, i.p.) on the declining rate of aggressive behavior as well as on non-agonistic locomotion. Administration of d-amphetamine, 5 min before the first trial, counteracted the decrement of attacks and threats. Initial high rates of attacks were unaffected, whereas the low rates of attacks in the late phase were greatly increased, 1.78 mg/kg being the most effective dose. By contrast, d-amphetamine increased locomotion in a dose-dependent monotonic manner, the largest increase occurring in the initial trials with the highest dose (5 mg/kg). d-Amphetamine produced no reliable effects on behavior in the 3 dishabituation trials. Further experiments investigate the possible different mechanisms controlling initial and late phases of habituation of aggression. The selective effects of d-amphetamine on attacks and threats when these behaviors have declined to a low level suggest an excitatory role for catecholamines in the habituation process.

42.6 NEUROTRANSMITTER INTERACTIONS IN CHEMICAL KINDLING. C.G. Wasterlain, V. Jonec, Epilepsy Research Laboratory, VA Medical Center, Sepulveda, CA 91343, Dept of Neurology and Brain Research Institute, UCLA School of Medicine.

Injection of subconvulsive amounts of muscarinic agonists into the amygdaloid complex of Holzman rats resulted in the progresive kindling of epileptic seizures. This kindling was dependent on dose and on interstimulus interval, long-lasting, induced by 3 different muscarinic agonists, completely blocked by 3 different blockers of muscarinic receptors, stereospecific, potentiated by cholinesterase inhibitors, and the kindling potencies of muscarinic ligands in vivo were closely related to their affinities for muscarinic receptors in vitro.

Amygdaloid injection through stereotaxically implanted chemitrodes of other agonists and antagonists of putative transmitters modified kindled seizures. Nanomole amounts of dopamine and norepinephrine, injected in a 1 µl sterile isotonic solution inhibited seizures compared to their antagonists, propranolol and haloperidol. Naloxone, glutamate and nicotinic blockers had no effect. Muscimol (3 nmoles), GABA(50-150 nmoles) were profoundly inhibitory.

Diazepam and phenobarbital were very effective, valproate moderately effective and dilantin poorly effective in blocking seizures in kindled animals. While seizure suppression was of short duration for most pharmacological agents intraamgdaloid muscimol produced a lasting loss of excitability.

These result suggest that GABAergic and catecholaminergic systems exert an inhibitory influence on seizures induced by excitation of muscarinic receptors in or around the rat amygdala.

42.7 ENHANCEMENT OF AGED RODENT RETENTION VIA PHARMACOLOGICAL MODULATION OF CHOLINE AVAILABILITY. R.T. Bartus, R.L. Dean, K. Sherman, and E. Friedman. Med.Res.Div. of Amer. Cyanamid, Pearl River, NY and N.Y.U. School of Medicine, New York, NY.

Loss of memory and other cognitive functions is commonly recognized to be one of the most serious neurobehavioral dysfunctions associated with old age. Evidence from many neuroscience disciplines suggests that dysfunctions in central cholinergic mechanisms may play a critical role in these impairments. Recently, in vitro neurochemical assays indicate that increasing the availability of choline should stimulate cholinergic activity. However, no clear evidence of improved performance on geriatric cognitive tasks has yet been reported. One possibility for this apparent paradox may be that the very cholinergic dysfunction which contributes to the age-related memory deficit may prevent choline from being effectively converted to acetylcholine in the aged brain. For example, choline uptake, choline actyltransferase and oxidative metabolism have all been reported to be decreased in aged brain. These deficiencies may not allow choline to be incorporated into acetylcholine as easily as occurs in younger brain. One manner of attempting to compensate for this possibility might be to improve ATP synthesis, while simultaneously increasing choline availability.

We studied this possibility in aged Fisher 344 rats (20 to 28 mo. old). All animals were administered either choline, piracetam (a cyclic derivation of GABA purported to enhance ATP synthesis), or both agents simultaneously for a period of 1 week. All rats were trained on a passive avoidance task and tested for retention 24 hr. later. Aged F344 rats had previously been shown to suffer severe retention impairments on this task. Those rats administered only choline exhibited retention scores only slightly higher than control rats given saline ($p < .1$). Although the rats administered piracetam exhibited better retention than the saline and choline groups ($p < .02$), the rats administered the choline/piracetam mixture exhibited retention scores several times better than those rats given piracetam alone ($p < .0001$). These data, therefore, provide preliminary evidence that the effects of cholinergic manipulation, particularly increased precursor availability, may be greatly enhanced by the simultaneous administration of a pharmacological agent purported to enhance oxidative metabolism. Further tests are currently in progress to determine the generality of these behavioral effects and to help establish what neurochemical changes in the brain may have been induced by the combined treatment.

43.1 CONNECTIONS BETWEEN THE CEREBRAL CORTEX AND AMYGDALA IN THE RAT. B. TURNER and J. ZIMMER*. Dept. Anat., Howard Univ. Med. Sch., Washington, D.C. 20059, and Inst. Anat. B, Aarhus Univ., Aarhus, Denmark.

Anterograde and retrograde tracing techniques were used to determine the presence and extent of connections between the cerebral cortex and the amygdala of the rat. Caustic heat lesions of varying size and cortical location were made in 25 rats, their brains processed by the Fink-Heimer and cupric silver techniques, and the amygdalae examined for degenerating afferents. In another 5 rats, the possibility of a reciprocating amygdalo-cortical relationship was explored by injecting small quantities of retrogradely transported fluorescent dyes into the cortical areas shown to project to the amygdala. To assist in defining both the subdivisions of neocortex where lesions or injections were made, and the nuclei within the amygdala shown to be connected with the cortex, topographical maps of the cerebral cortex and amygdala were constructed on the basis of cell, fiber, Timm's, and AChE staining patterns in normal brains. Results showed that no part of the neocortex of the rat projects directly to the amygdala. However, all sensory cortices send topographically arranged efferents to the periallocortex lying along the rhinal fissure, i.e., areas 35, 36, 13, and 14. Of these, the supra-rhinal parts of areas 13 and 35 project heavily to the amygdala. Anteriorly, area 13 sends efferents to the central nucleus, and to the anterior half of area X and the lateral and basal nuclei; this cortex receives afferents from the lateral and basal nuclei, and from the prepiriform and periamygdaloid cortices. Caudally, area 13 projects to the anterior part of the basal nucleus, and to the entire extent of area X and the lateral nucleus. Area 35 projects lightly to the caudal part of area X, and heavily to the posterior two-thirds of the lateral nucleus; a restricted portion of the lateral nucleus projects back to area 35.

43.2 DOUBLE AND TRIPLE LABELING OF RAPHE NEURONS FOLLOWING INJECTIONS OF FLUORESCENT SUBSTANCES INTO THREE SEPARATE LIMBIC FOREBRAIN STRUCTURES. L. Heimer and J. de Olmos. Inst. of Anatomy, Univ. of Aarhus, Denmark, and Inst. "M. y M. Ferreyra", Argentina.

A retrograde labeling procedure utilizing fluorescent substances (van der Kooy et al. 1978) was used to establish the presence of branching axons in the ascending raphe system of young rats. The three fluorescent substances, propidium iodide (PI), granular blue (GB) and nuclear yellow (NY), which were dissolved in 2% DMSO or water, were injected in the amount of 0.1-0.2 µl each by the aid of a hydraulic pressure injection system using glass pipettes with tip diameter of 100-150 µm. 5% GB and 3% PI were injected into the medial thalamus and the septum 3 days before sacrifice whereas 1% NY was injected into the olfactory bulb or olfactory cortex on the same side 18-20 hours before the time of sacrifice.

Whereas the number of double labeled cells in various combinations was relatively large in both the dorsal and median raphe nuclei, triple labeled cells occurred more rarely, and usually in a restricted part of the dorsal raphe nucleus. Generally, the intensity of the fluorescence decreased with the number of fluorescent substances incorporated by the neuron, and it was in several instances almost impossible to decide if a neuron was triple or even double labeled. The number of clearly double and triple labeled neurons, therefore, is probably smaller than the number of cells that actually project to two or three of the injected limbic structures. Nevertheless, the fact that each class of neurons, i.e. single, double and triple labeled neurons, were shown to have a predominant distribution within specific parts of the raphe nucleus seems to indicate that double and triple labeling with fluorescent substances is a useful technique for unraveling functionally important subdivisions within a nuclear complex. (Supported by NIH and the Danish Medical Research Council).

43.3 BIOCHEMICAL AND PHYSIOLOGICAL PHENOMENA INDICATIVE OF HIPPOCAMPAL - HYPOTHALAMIC - PITUITARY - THYROID AXIS INTERACTIONS. H. M. Murphy, C. H. Wideman and T. S. Brown *. John Carroll Univ., Cleveland, OH 44118 and DePaul Univ., Chicago, ILL 60614.

At the last meeting of the Society for Neuroscience data were presented indicating that rats with hippocampal lesions had disturbances in the hypothalamic - pituitary - thyroid axis. Animals with hippocampal lesions had significantly lower levels of TSH (thyroid stimulating hormone), total T_4 (thyroxine), and free T_4. These findings would lead one to suspect that such animals might be hypothyroid. The present study examined several parameters indicative of the hypothyroid state. The parameters studied were: blood urea nitrogen levels in the plasma, SGOT (serum glutamic oxaloacetic transaminase or aspartate aminotransferase) levels in the plasma, body temperature at room temperature, body temperature after being in a warming chamber, and arterial blood pressure after being in a warming chamber.

The results strengthened the hypothesis of hypothyroidism in rats with hippocampal lesions. Animals with such lesions had significantly higher blood urea nitrogen levels than control animals ($p = .002$). A positive nitrogen balance is associated with hypothyroidism. Animals with hippocampal lesions had significantly higher SGOT levels than control animals ($p = .02$). Elevated SGOT levels are associated with the hypothyroid state. At room temperature animals with hippocampal lesions did not differ from controls in body temperature. However, after 15 min. in a warming chamber, animals with hippocampal lesions had a significantly lower body temperature than did controls ($p = .002$). This phenomenon has also been observed in hypothyroid animals. Arterial blood pressure was significantly lower in animals with hippocampal lesions than control animals ($p = .002$). This may be due to the fact that in order to obtain blood pressure readings, animals had to be placed in a warming chamber before the blood pressure was recorded. Rats with hippocampal lesions were quite docile in this situation and readily entered the heated restraining chamber for blood pressure recording. Control rats were quite active and somewhat reluctant to enter the chamber.

This study indicates that animals with hippocampal lesions are mildly hypothyroid. It is postulated that the hippocampus has an excitatory effect on the hypothalamic - pituitary - thyroid axis via neuronal connections between the hippocampus and the tubero-infundibular neuron which in turn ends on a median eminence portal capillary. The median eminence is one of the areas of the brain that releases TRH (thyrotropic releasing hormone).

43.4 SUB-THRESHOLD STIMULI ALTER IPSILATERAL/CONTRALATERAL AFTERDISCHARGE DURATIONS. H. Scott Swartzwelder, D.A. Mobray* and R.S. Dyer. The American Univ. and U.S. Environmental Protection Agency, Research Triangle Park, N.C.

Electrically induced hippocampal (HPC) afterdischarges (ADs) and their post-ictal sequelae vary as a functinn of the relationship of the eliciting stimulus intensity to the threshold for AD production. Thus it is clear that AD threshold determination is a methodological necessity when such variables are under consideration. Two AD threshold determination methods have most often been employed (Pinel et al.,1976; Racine, 1972). These methods involve dramatically different procedures. Method A (adopted from Pinel, et al.) involves presentation of a series of ascending subthreshold stimulus intensities, at one min intervals, until an AD is induced. Typically, 15-25 unsuccessful stimulations are presented prior to AD induction. Method B (adopted from Racine) involves zeroing in on the AD threshold through a series of successful and unsuccessful stimulations presented at 48h intervals. Usuially 4-5 unsuccessful stimulations and 4-5 successful stimulations are presented prior to threshold localization. Recent evidence has demonstrated that these methods yield different AD threshold values. Furthermore, AD thresholds determined under method A were lower following a 45-day interval, while repeated threshold assessments using method B showed no such fluctuations.

The present report describes yet another aspect of the HPC AD which is influenced by the procedural differences of these two methods. Rats implanted with bilateral HPC electrodes had AD thresholds determined using methods A and B (in that order). Threshold level ADs produced under method B were longer in the HPC contralateral (contra) than in the HPC ipsilateral (ipsi) to the stimulated side. No such variations in the ratio of ipsi to contra AD durations were observed using method A. Furthermore, similar differences in the ratio of ipsi to contra AD durations were observed when ADs were induced with stimuli at 115% and 400% of AD threshold when thresholds were determined by method B, prior to the initiation of method A procedures. Thus the ipsi/contra AD duration ratios are not related to the tendency of method B to produce slightly lower AD thresholds, or to the order in which the methods are employed.

It has been shown that stimuli below the threshold for motor seizure (MS) production but above AD threshold produce alterations in MS thresholds (kindling). The present data indicate that stimuli below AD threshold alter the properties of subsequently elicited ADs.

43.5 THALAMOCORTICAL CONNECTIONS OF CINGULATE CORTEX AND THE PRESUBICULUM IN THE MONKEY. Douglas L. Rosene, Brent A. Vogt and Deepak N. Pandya. Dept. of Anatomy, Boston University School of Medicine, Boston, MA 02118 and Veterans Administration Medical Center, Bedford,MA 01730.

Injections of horseradish peroxidase into the cingulate cortex or the parahippocampal gyrus have demonstrated the major thalamic nuclei which send afferents to these limbic cortical areas. As previously reported (Sci. 204: 205, 1979), injections in the anterior cingulate cortex (area 24) result in labelling of neurons in the midline and intralaminar thalamic nuclei as well as some labelling in the medial dorsal nucleus, but injections in the posterior cingulate cortex (areas 23 and 29) result mainly in labelling of the anterior thalamic nuclei and some labelling in the medial dorsal and lateral dorsal nuclei. In addition, HRP injections into either the hippocampus or the parahippocampal gyrus that involve the presubiculum resulted in retrograde labelling of neurons in the lateral dorsal thalamic nucleus.

While these HRP results establish a definite topographic pattern of thalamocortical projections to these limbic areas, the exact distribution of thalamocortical termination in these areas can only be determined by examining the anterograde termination of these afferents. In order to accomplish this, injections of radioactively labelled amino acids (RLAA) have been placed in some of these nuclei. An injection involving both the midline nuclei and the anteromedial nucleus resulted in termination in areas 24a, 24b, 23a and 23b on the medial surface of the cingulate gyrus. An injection limited to the anteroventral nucleus without any involvement of the midline or intralaminar nuclei produced anterograde termination in area 29b of the retrosplenial granular cortex, but not in areas 23 or 24. In contrast, an injection into the medial dorsal thalamic nucleus resulted in anterograde termination in areas 24c and 23c within the depths of the cingulate sulcus. Finally, an injection into the lateral dorsal thalamic nucleus resulted in heavy termination throughout the presubiculum as well as significant termination in the adjacent area 29a, the part of granular retrosplenial cortex which extends below the corpus callosum. In this case there was no evidence of termination in area 23 or any other subdivision of area 29. These findings clearly demonstrate that the thalamocortical connections to the limbic cortex in the rhesus monkey are not homogeneous but display a topographic specificity.

43.6 MULTIPLE NEUROTRANSMITTER STUDIES IN THE ISLANDS OF CALLEJA COMPLEX OF THE BASAL FOREBRAIN: I. LIGHT MICROSCOPY. S. Isaacs*, J.H. Fallon and C.E. Ribak. (SPON: M. Poo)Department of Anatomy, University of California, School of Medicine, Irvine, CA 92717.

A series of combined light and electron microscopic studies in the basal forebrain has again directed our attention to the eight intriguing clusters of granule (7-9μm) cells in the deep olfactory tubercle called the Islands of Calleja. Our previous studies (J. Comp. Neur. 181: 375-396, 1978) examined the anatomy and some connections of the cells with nearby allocortical structures. We have extended these studies of the small cells and associated larger cells, defined here collectively as the Islands of Calleja Complex (ICC), to experiments aimed at the localization and interrelationships of neurotransmitters within the ICC of the albino rat. At the light microscopic level, acetylcholinesterase (AChE) staining of cell bodies (DFP pretreatment technique) reveals that the large cells located within the core of an ICC, or immediately adjacent to an ICC, stain intensely for AChE. Immunohistochemical staining for GAD indicates a very strong staining in the ICC region, especially in the core and neuropil surrounding an ICC. It appears as if GABA terminals are contacting large somatic and dendritic processes, perhaps of the large AChE cells. Dopamine fibers (DA), originating in the SN-VTA, are also present within the core and neuropil adjacent to an ICC. This intense and multiple neurotransmitter-specific staining suggests a strong relationship between the ACh, GABA and DA systems in the ICC of the basal forebrain. A second abstract in this volume will detail some of the features of the ICC using electron microscopic techniques. A third abstract will focus on some of the connections of the large cells in the ICC and will also attempt to correlate the neurotransmitter histochemistry and pathways that are associated with the Islands of Calleja Complex of the basal forebrain.

Supported by NIH grants NS 15321, NS 16017 and NS 15669.

43.7 MULTIPLE NEUROTRANSMITTER STUDIES IN THE ISLANDS OF CALLEJA COMPLEX OF THE BASAL FOREBRAIN. II ELECTRON MICROSCOPY. L. Richman*, C.E. Ribak, S. Isaacs*, C.R. Houser and J.H. Fallon (SPON: R.A. Giolli) Dept. of Anatomy, Univ. of Calif., Irvine, CA 92717 and Div. of Neurosci., City of Hope Res. Ctr., Duarte, CA 91010

An initial analysis of the cells and their processes within the Islands of Calleja Complex (ICC) was first made in normal ultrastructural preparations to determine the synaptic relationships of the various neurotransmitter elements found within this brain region. As indicated by our previous light microscopic description, the ICC consists of two cell types, small granule cells and large multipolar cells. In electron microscopic preparations, the somata of granule cells are grouped together, and each is apposed to one another. Specialized junctions (4-6nm wide) which occur at these sites of somal apposition suggest ephaptic coupling of granule cells. The granule cell somata have nuclei that contain clumps of heterochromatin adjacent to smooth nuclear envelopes. The perikaryal cytoplasm of these cells consists of a relatively thin rim containing mitochondria, microtubules, cisternae of Golgi complex and many free ribosomes. Spinous dendrites of small diameter are occasionally found in continuity with these cells. Axon terminals rarely form synapses with the somata of granule cells, but are more frequently found to synapse on their dendrites and dendritic spines.

The somata of the large cells are found either within the core or around the perimeter of an ICC. The large cells have infolded nuclei and an abundant perikaryal cytoplasm that contains many cisternae of granular endoplasmic reticulum and Golgi complex, relatively few free ribosomes, many mitochondria, and occasional microtubules and neurofilaments. Large diameter dendritic shafts emanate in many directions from these somata. Axon terminals cover nearly the entire surface of these somata and dendrites where they commonly form symmetric synaptic junctions. An immunocytochemical localization of glutamic acid decarboxylase in the ICC shows specific reaction product for GABA within many of these axon terminals.

In sections of the ICC from rats injected with DFP, acetylcholinesterase was localized using a modification of standard histochemical techniques. The reaction product that is specific for this enzyme was located in only the large cells within the inner surfaces of their cisternae of granular endoplasmic reticulum and Golgi complex, and within their nuclear envelopes. In these preparations, granule cells lacked this specific reaction product. These results indicate that the large cells of the ICC may use acetylcholine as a neurotransmitter. The synaptic pattern of axon terminals with these cells suggests a strong GABAergic-cholinergic interaction in this part of the basal forebrain. (Support from NIH Grants NS 15669, NS 12116, NS 15321, and NS 16017.)

43.8 MULTIPLE NEUROTRANSMITTER STUDIES IN THE ISLANDS OF CALLEJA COMPLEX OF THE BASAL FOREBRAIN: III. Connections, Correlations and Reservations (C.C.+ R's). J.H. Fallon and C.E. Ribak. Department of Anatomy, University of California, Irvine, CA 92717

This is the third abstract in a series on the Islands of Calleja Complex (ICC) in the basal forebrain of the albino rat. In this study we attempted to determine some connections of the ICC, especially of the large AChE-positive cells within the core and the surrounding neuropil. Injections of HRP were made into various forebrain structures, including the ICC, and retrograde and anterograde transport of HRP was traced with the TMB technique. Fluorescent retrograde tracers, such as Nuclear Yellow and True Blue, were also used. The efferents of the large cells of the ICC were found to project to the lateral and supramammillary region of the hypothalamus, including the nuclei gemini, and the midline and adjacent dorsomedial nuclei of the thalamus. Labeled fibers were also observed in the ipsilateral and contralateral stria medullaris. Reciprocal projections were observed from these same hypothalamic and thalamic regions. Additional afferent connections from the medial septum, amygdala, piriform cortex and periamygdaloid cortex confirm previous studies on connections of the ICC (Fallon et al, J.Comp. Neur. 181: 375-396, 1978). We had suggested earlier that the ICC may be involved in the central neural control of reproduction. To explore this possibility further, we used the ^{3}H-estradiol binding technique in conjunction with the AChE-technique. The results clearly show that the large AChE-positive cells in the ICC form part of the basal forebrain system of ^{3}H-estradiol-binding cells. Together with a recent report (Phillips et al, Anat Rec. 196: 148A, 1980)of LHRH positive fibers projecting to the ICC, these results make a strong case for the participation of this brain region in reproductive function. In addition, the high density of GABA-ergic terminals on AChE-positive cells in the ICC are reminiscent of the pattern observed in the globus pallidus. The afferent connections from surrounding allocortical-associated ventral striatal structures, and efferents to the diencephalon generally support the notion that the ICC environs form a ventral-pallidal component of the basal forebrain. In this sense, topographical limbic cortico-striatal-pallidal-subcortical loops could be surmised (e.g.,Superficial piriform-olfactory-amygdaloid-septal "cortex"→Deep piriform-olfactory-amygdaloid-septal "striatum"→ICC "pallidum"→Lateral mammillary-supramammillary area (→hippocampus) + medial-midline thalamus (→ventral striatal structures). These loops would, therefore, be parallel to analagous loops defined for the dorsal forebrain. One functional correlate of this segment of ventral pallidum (ICC) and its limbic and olfactory inputs appears to be the neural control of reproduction. (Supported by NIH grants NS 15321, NS 16017 and NS 15669.)

44.1 CATEGORIES OF AXONS IN BLADDER NERVES. C.E. Hulsebosch and R.E. Coggeshall. Depts. of Anatomy and of Physiology and Biophysics and the Marine Biomedical Institute. The University of Texas Medical Branch, Galveston, Texas 77550.

There are three main nerves which innervate the bladder: the pelvic nerve (parasympathetic), the hypogastric nerve (sympathetic) and the pudendal nerve (somatic). The number and types of fibers in these nerves are obviously important in considerations of bladder function. Previous light microscopic studies counted the number of myelinated axons (MY) but unmyelinated axons (UN) could not be resolved by these techniques. The present ultrastructural study determined the number of unmyelinated axons as well as myelinated axons. The number of axons in these bladder nerves are shown in the following table:

	PUDENDAL NERVE		PELVIC NERVE		HYPOGASTRIC NERVE	
	MY	UN	MY	UN	MY	UN
1	1682	3845	913	3758	152	940
2	1664	4660	994	4678	171	1105
3	2306	4458	1177	5641	245	1476
4	2348	4087	1297	6343	271	1221
5	1580	3298	843	2667	437	1763
6	1534	3755	924	3647	433	1991
7	1430	2974	860	3346	117	1295
8	1275	3506	1072	4359	114	1092
9	1836	3500	821	3462	163	1339
10	--	--	886	3440	74	1366
Mean	1737	3786	979	4134	250	1513

Note that the hypogastric nerve has the fewest number of axons and that the pelvic and pudendal nerves have approximately equal numbers of axons. Also note that there are three times as many unmyelinated axons as myelinated axons in these nerves.

Selective surgical procedures to determine the origin of the various fibers which comprise these nerves are underway. The results of these experiments will be discussed. Supported by grants NS 06246, Ns 10161, NS 11255 and NS 07377.

44.2 RETROGRADE TRANSPORT OF HRP BY PERIVASCULAR AFFERENTS AND EFFERENTS AROUND CEREBRAL ARTERIES. M.A. Moskowitz, M. Mayberg* and R.S. Langer*. Laboratory of Neural and Endocrine Regulation, MIT, Cambridge, MA 02139; Department of Neurosurgery, Mass. General Hospital, Boston, MA 02114; Section of Neurology, Peter Bent Brigham Hospital, Harvard Medical School, Boston, MA 02115.

The proximal segments of large cerebral arteries are one of the few structures within the cranium which when stimulated give rise to the sensation of pain. Afferent nerve fibers which convey this information have not been identified, although the area to which pain is referred (e.g., the forehead) implicates the trigeminal nerve. We have recently become interested in the existence of perivascular pathways which arise from the trigeminal system as a possible neuroanatomical explanation for the sharply circumscribed unilateral head pains associated with certain vascular syndromes. We have therefore initiated neuroanatomical studies in cats to identify the existence of perivascular nerve endings and to localize their cell bodies within trigeminal and other ganglia.

HRP was applied to the middle cerebral artery in seven cats. To prevent the spread of peroxidase from around the blood vessel, HRP was impregnated into a polymer and applied as a viscous solution to the proximal segment of the cat middle cerebral artery. The treated polymer was coated and surrounded by either untreated polymer, or a second polymer. Spread of the marker enzyme was limited to less than 7 mm lateral to the vessel and 5 mm beneath the adjacent cerebral cortex. (In vitro experiments have established that 70% of the protein was liberated from impregnated polymer within 24 hours and that during this period, there was no decrease in the specific activity of the peroxidase enzyme.) After 72 hours, animals were perfused with 2.5% glutaraldehyde in 0.1 M phosphate buffer. Both trigeminal ganglia were serially sectioned (30 µM) and prepared for HRP histochemistry using the chromogen, tetramethyl benzidine. In all seven cats, peroxidase-containing cells were found in the ipsilateral trigeminal ganglia. Cell bodies containing HRP were found among clusters of cells that project via the supraorbital nerve to innervate the forehead. Peroxidase-containing cell bodies were also found in the ipsilateral superior cervical ganglia.

The above studies provide useful information about perivascular afferent and efferent neurons within sensory and autonomic ganglia. The existence of perivascular sensory pathways provides an important explanation for the hemicranial distribution of headaches associated with strokes and migraine.

44.3 SYMPATHETIC INNERVATION OF MURINE THYMUS: RELATION OF ADRENERGIC FIBERS TO MAST CELLS. J.M. Williams* and D.L. Felten (SPON: P.A. Shea). Dept. of Anatomy, Indiana Univ. School of Med., Indianapolis, IN 46223

Sympathetic innervation of vascular and parenchymal elements in the normal murine thymus has been implicated in the modulation of lymphocyte development and activity (Williams, J.M. and D.L. Felten, Anat. Rec. 196:205A, 1980). This study was undertaken to further examine the relationship of sympathetic fibers to cellular elements of the murine thymus. Autofluorescent yellow, granular mononuclear cells were observed in the C3H mouse thymus. These cells demonstrated several characteristics of mast cells, including metachromasia with toluidine blue staining and fluorescence spectra characteristic of mast cells. These fluorescent cells were found adjacent to noradrenergic fiber plexuses in perivascular and subcapsular locations, and frequently clustered around the terminal arrays of noradrenergic varicosities in the thymic parenchyma. Some single mast cells were also scattered within the thymic parenchyma. NZB mice, which characteristically develop spontaneous hemolytic anemia, exhibited a greater number of varicosities and linear profiles of noradrenergic fibers in the thymic parenchyma, and also showed a many-fold increase in the number of mast cells associated with these fibers compared with the control C3H mice. Catecholamines have been shown to inhibit mast cell degranulation, and histamine has been shown to have an in vitro role in both lymphocyte differentiation and the activity of T-cell subpopulations. The noradrenergic fibers and their associated mast cells, described in the present study, may represent the substrate for a modulatory role of sympathetic nerve fibers over lymphocyte development and responsiveness, either directly through the release of norepinephrine within lymphoid organs, or indirectly by alteration of histamine release from mast cells. The increased number of noradrenergic varicosities and mast cells within the NZB murine thymus may be a part of the abnormal thymic microenvironment which has been proposed as a causative factor in their spontaneous autoimmunity. Supported by an Alfred P. Sloan Foundation Fellowship (D.L.F.).

44.4 THE SEGMENTAL ORIGIN OF SYMPATHETIC PREGANGLIONIC AXONS IN THE UPPER THORACIC SPINAL CORD OF THE CAT. B.J. Oldfield* and Elspeth M. McLachlan*, (SPON: L.P. Renaud) Neuropharmacology Group, Dept. Physiol. Monash Univ. 3168 Australia.

It has been conventionally thought that the axons of sympathetic preganglionic neurons pass from the spinal cord via the ventral roots of the segment in which their cells of origin lie. However, recent anatomical evidence has been interpreted as indicating that preganglionic axons may follow an intraspinal pathway traversing several segments before entering a ventral root. (Faden, A.I. and Petras, J.M., Brain Res., 144:358, 1978; Chung, K. et al., J. Comp. Neurol., 185:23, 1979). We have investigated this problem by applying horseradish peroxidase (HRP) to the cut ends of individual white rami.

In separate experiments on adult cats (either sex, 2.6-3.5 kg) HRP was applied selectively to the cut end of the T_1, T_2 or T_3 white ramus. HRP was completely isolated from the surrounding tissue by either enclosing the sectioned end of the ramus within a perspex bath (T_1 and T_2) or within a length of polyvinyl chloride tubing (T_3). Generally the tissue underlying the application, including the cut end of the descending sympathetic chain was further protected with a thin sheet of plastic film. After 24-28 hrs the animals were perfused with a buffered aldehyde solution and sections of spinal segments C_8 to T_5 (or T_7 in one case) were incubated using either diaminobenzidine or tetramethylbenzidine for the demonstration of reaction product.

In all cases HRP was localised within ipsilateral sympathetic preganglionic neurons. These were restricted in their longitudinal extent to the length of only one spinal segment adjacent to the treated ramus; however, the rostral and caudal limits of this population of labelled cells did not correspond exactly to the boundaries of the segment as defined by the position of dorsal rootlets. All axons in the T_1 ramus which were labelled were derived from cells in the rostral 2/3 of T_1 but cells containing HRP after T_2 or T_3 application were always found in the rostral 2/3 of the segment corresponding to the treated ramus and in the 1/3 of the segment immediately rostral to it. Labelled neurons were found within each of the autonomic subdivisions in the thoracic spinal cord. Neurons projecting axons in the T_1 ramus were widely distributed between the lateral funiculus and the medial autonomic nuclei, whereas the majority of neurons (74-98% in different experiments) with axons in the T_2 and T_3 rami were restricted to the principal part of the intermediolateral column. These data are therefore not consistent with the concept of an intraspinal pathway for axons leaving the spinal cord in the upper thoracic rami but rather suggest that these preganglionic axons are segmentally derived. (Supported by grants to E. McL. from the NHMRC and NHF of Australia).

44.5 LOCALIZATION OF CELL BODIES OF ORIGIN OF THE CERVICAL AND SUBDIAPHRAGMATIC PORTIONS OF THE VAGUS NERVE. S.J. Dennison*, B.L. O'Connor*, M.H. Aprison, V.E. Merritt* and D.L. Felten (SPON: C. Loullis). Depts. of Anatomy and Biochemistry, and the Inst. of Psychiatric Research, Indiana Univ. Sch. of Medicine, Indianapolis, IN 46223.

Efferents of the cervical and subdiaphragmatic branches of the vagus nerve were traced to their cell bodies of origin in the brain stem utilizing the retrograde horseradish peroxidase (HRP) transport method. Cell bodies in these two areas occupy a continuous longitudinal, spindle-shaped column, thinner caudally than rostrally. This column was present rostral to the classically described dorsal motor nucleus of the vagus (DNV), was present throughout the DNV itself, extended caudally into the nucleus commissuralis, where it became attenuated, and further extended into the spinal cord in the midline and paramedian portion of the dorsal commissural gray of the upper six segments of cervical spinal cord. This entire longitudinal cell column is called the DNV cell column, and extends both rostrally and caudally beyond the boundaries of the classically described DNV. In addition, cell bodies contributing axons to the cervical vagus, but not the subdiaphragmatic vagus, are also found in the nucleus ambiguus.

Cells of the cervical vagus were found diffusely throughout the ipsilateral DNV and nucleus ambiguus. Cells of the subdiaphragmatic portion of the vagus established a viscerotopic localization, and were found in the lateral-most portion of the rostral region, the anterolateral portion of the middle region, and the anterior one-half of the caudal region of the clasically described DNV. Fibers from the anterior subdiaphragmatic vagus had their cell bodies located primarily in the left DNV cell column, while the posterior subdiaphragmatic vagus derived from bilaterally situated cells, with 60% of the cells found in the right column and 40% in the left column. These findings suggest that the subdiaphragmatic vagus derives from cells of the DNV which are viscerotopically organized, and further suggest that the cells of origin of the vagus nerve are more extensive both rostrally and caudally than has previously been reported.

Supported by N.I.H. Grant NS16205 and by an Alfred P. Sloan Foundation Fellowship (D.L.F.).

44.6 THE CENTRAL DISTRIBUTION WITHIN LISSAUER'S TRACT AND THE SPINAL GRAY MATTER OF PRIMARY AFFERENTS FROM THE PELVIC NERVE AND PUDENDAL NERVE OF THE CAT DEMONSTRATED BY TRANSGANGLIONIC TRANSPORT OF HRP. Charles Morgan, William C. de Groat, Irving Nadelhaft. Dept. Pharmacol., Univ. of Pittsburgh Sch. of Med. and V.A. Hospital, Pittsburgh, PA 15261

Previous studies identified a prominent visceral primary afferent (PA) projection in the cat sacral spinal cord in Lamina I on the lateral side of the dorsal horn (DH) extending into the sacral parasympathetic nucleus (SPN). Present experiments show a substantial medial pathway and an extensive intersegmental distribution of sacral PA.

HRP was applied to the central cut ends of the pelvic n. or its branches to colon or bladder and to the pudendal n. HRP in central PA axons was demonstrated with benzidine or TMB processing. After pelvic n. labelling HRP reaction product (RP) was detected in Lissauer's tract (Ltr) from L_5 to C_{X2}. The heaviest RP was found in $S_{1,2,3}$ from the dorsal root entry to the lateral edge of the DH but considerable RP was also present in medial Ltr. In lumbar and coccygeal segments RP occupied a decreasing area in mid-lateral Ltr. Smaller amounts of RP were noted in adjacent dorsal columns and dorsolateral funiculus.

In S_2, axons from Ltr entered the dorsal surface of Lamina I extending medially and laterally around the DH into Laminae V, VI, VII & X. The prominent lateral projection was traced into lateral Lamina V (the dorsal band and an interneuronal area of the SPN) and divided into 4 groups: one reached the lower 1/3 of the dorsal commissure; a second continued to the intermediomedial nucleus; a third turned dorsad to the lateral part of the internal basal nucleus (IBN); the fourth entered Lamina VII (lateral band of the SPN). From the medial DH axons reached three areas: the ipsi-and contralateral IBN (upper 2/3 of the dorsal commissure) and the lateral IBN. Rostral and caudal to the SPN PA decreased in frequency but had many of these same patterns. The other nerves labelled could not be traced so extensively. Colon and bladder n. contribute to medial and lateral Ltr while pudendal n. tends to the medial Ltr. All three enter the gray on both sides of the DH but bladder PA are stronger on the lateral side, pudendal PA are stronger medially.

In conclusion it appears that the central projections of sacral PA exhibit a striking correspondence with the soma and dendritic distribution of preganglionic neurons and interneurons in the SPN. Sacral visceral PA also send projections via LTr to lumbar and coccygeal segments of the cord. These projections may be involved in the coordination of somatic mechanisms during defecation and micturition.

44.7 ANATOMIC EVIDENCE OF RECIPROCAL CONNECTIONS BETWEEN THE AMBIGUUS NUCLEI OF THE CAT. John T. Paul, Betty L. Hamilton and Richard A. Gillis. Depts. of Anatomy and Pharmacology, Georgetown Univ. Schs. of Med. & Dent., Washington, D.C. 20007.

Numerous studies have demonstrated that the nucleus ambiguus (NA) is an important central nervous system site for the control of a cardio-inhibitory mechanism. The data from Gunn et al. (1968) and Thomas and Calaresu (1974) suggested that in addition to its projections via the ipsilateral vagus nerve, NA projected decussating fibers to the contralateral NA and/or vagus nerve. These studies were based solely on electrophysiologic evidence, but our laboratory (Hamilton et al. 1979) demonstrated these crossing fibers using silver degeneration techniques following kainic acid lesions of NA.

By employing the horseradish peroxidase method we have now verified the presence of these reciprocal fibers between the two ambiguus nuclei in the brainstem of the cat. HRP was injected into the rostral pole of NA in three cats, and labeled soma were observed in the contralateral NA of each animal. Injections in more caudal portions of NA, to date, have failed to demonstrate these reciprocal connections, although this area is very active in cardiac control. This apparent difference in the rostral and caudal NA projection systems and the data from Ciriello and Calaresu's (1980) study suggesting a ventrolateral-dorsomedial organization of the NA indicate that this is a complex nuclear area that will require careful and systematic study in terms of physiological, biochemical, and anatomical mapping.

44.8 CONNECTIONS OF VISCERAL AFFERENT CORTEX IN THE RAT. C.B. Saper and A.D. Loewy. Dept. of Neurology, New York Hospital-Cornell Medical Center, New York, NY 10021 and Dept. of Anatomy/Neurobiology, Washington University School of Med., St. Louis, MO 63110.

We have recently delineated a system of highly interconnected cell groups in the mammalian brainstem and basal forebrain, which appear to play an important role in central autonomic control (Saper and Loewy, Efferent connections of the parabrachial nucleus in the rat, Brain Research, in press) and identified a direct projection from the medial parabrachial nucleus to the granular insular cortex, a region which has been found to receive taste and other visceral afferent information. We now report the results of a horseradish peroxidase (HRP) study of the afferents and efferents of the granular insular cortex.

Small (20-30 nl) injections of a 10% solution of HRP were placed in the granular insular cortex in adult albino rats. The brains were processed by standard histochemical methods using tetramethylbenzidine as a chromogen. Retrogradely labeled neurons were seen in layers III and V of the contralateral homologous cortex, in the lateral and basolateral amygdaloid nuclei and in the lateral hypothalamic area and zona incerta. In the thalamus retrogradely labeled neurons were seen in the reticular, ventroanterior, ventrobasal, ventromedial basal (VPMpc), reuniens, centromedial, paracentral, centrolateral and parafascicular nuclei. In the pons a collection of labeled neurons was seen in the ventromedial part of the parabrachial nucleus bilaterally. Retrograde labeling in the subthalamic nucleus, the substantia nigra and the pedunculopontine nucleus seemed to depend primarily upon the extent of spread of HRP from the injection site into the underlying caudate-putamen.

Anterograde labeling could also be traced in these experiments but the apparent transport of HRP into collaterals of axons with terminals at the injection site makes interpretation somewhat hazardous. Nevertheless, there appeared to be anterograde transport to layers II, III and V of the contralateral homologous cortex and to each of thalamic cell groups which contained retrograde labeling, as well as in the medial part of the dorsomedial nucleus. Anterograde labeling was also seen ipsilaterally in the central amygdaloid nucleus, the lateral hypothalamic area, the zona incerta, the medial part of the parabrachial nucleus and, on the contralateral side of the brain in the dorsomedial spinal trigeminal nucleus and adjacent lateral and anteromedial parts of the nucleus of the solitary tract.

Supported by USPHS grant number NS12751 and by a grant-in-aid from the American Heart Association (80-723).

45.1 CIRCADIAN RHYTHMS OF RETINAL SEROTONIN N-ACETYLTRANSFERASE ACTIVITY AND MELATONIN CONTENT IN THE CHICKEN. H. E. Hamm* and M. Menaker, Zoology Dept. Univ. of Texas, Austin Tx 78712.

The chicken retina appears to be another active site, with the pineal gland, of melatonin synthesis. There is a large amplitude circadian rhythm of serotonin N-acetyltransferase (NAT) activity and radioimmunoassayable (RIA) melatonin content in the chicken retina-pigment epithelium, with 15-fold higher levels at night than during the day in LD12:12. The rhythm persists in constant darkness (DD); there is a 4-fold increase in NAT activity and and RIA melatonin during the subjective night after 2 days in DD. NAT activity and melatonin levels are sensitive to light; one hour of light (1400-1500 lux) given at midnight causes NAT activity and melatonin to fall to daytime levels ($t_{1/2}$ = 10 min for NAT activity).

The characteristics of retinal indoleamine metabolism are similar under several conditions to those of the pineal gland. The pineal is not responsible for controlling these rhythms, since the circadian rhythm of NAT activity in the retina persists in pinealectomized chicks. Localization studies show that rhythmic NAT activity and RIA melatonin are found predominantly in the retina; very low levels were found in the pigment epithelium.

To investigate whether retinal melatonin contributes to circulating melatonin levels, serum melatonin levels were measured at mid-light and mid-dark in intact, sham pinealectomized, pinealectomized (pin-x), blinded, or blind-pinealectomized chicks. There is a 2.5 to 3 fold day-night difference in serum melatonin levels in intact, sham-pin-x, and blinded chicks ($p<.01$). In pin-x and blind-pin-x chicks, the day-night change is lost (pin-x, 1.25-fold, $p>.05$; blind-pin-x, 1.1-fold, $p>.05$); however, daytime levels ($\sim$0.5 ng RIA melatonin/ml serum) are still present in both groups. Thus it appears that retinal melatonin is not a major contributor to the circulating melatonin rhythm; rather, it may play a local role. Because of the circadian rhythm in retinal melatonin, and since melatonin is known to affect circadian parameters in some systems, it could function as a circadian signal to regulate and synchronize the many functions in the retina, and particularly in the photoreceptors, that show rhythmic fluctuations.

45.2 CIRCADIAN RHYTHM OF NEUROSECRETORY ACTIVITY IN THE ISOLATED EYESTALK OF CRAYFISH. Hugo Aréchiga, Teresa de la Vega* and Victor Anaya. Dept. Fisiol. Ctr. Estud. Avanzados, I.P.N. México 14, D.F.

The eyestalk of crustaceans is known to produce several neuropeptides and to participate in the regulation of circadian rhythmicity. However, its role as an endogenous oscillator has been a matter of controversy. With the aim of deciding whether it is capable of sustaining a circadian rhythm of neurosecretion, the activity of neurodepressing hormone (NDH) (Aréchiga, H. Cabrera-Peralta, C. and Huberman, A. J. Neurobiol. 10: 409, 1979) was determined at different times in isolated eyestalks maintained in organ culture for several days. NDH activity was quantified by determining the reduction in firing rate of isolated abdominal stretch receptors, kept under constant tension. The eyestalks were incubated in culture medium (MEM, Gibco) at constant temperature (17°C) and NDH was obtained by extracting in chloroform and acetone and then successively passing through G-25 and G-15 Sephadex columns (see Huberman, A. et al. Europ. J. Biochem. 99: 203, 1979). Four groups of eyestalks were studied. a) eyestalks excised from animals entrained to a normal L:D cycle, and cultured in continuous darkness. b) eyestalks from animals in normal L:D cycle and cultured in continuous illumination. c) eyestalks from animals kept under a reversed L:D cycle for one week and cultured in continuous darkness, and d) eyestalks from animals kept in reversed L:D cycle for one week and then cultured in continuous light. In groups a) and b), NDH activity fluctuates in a circadian manner from 1-5 units during the subjective night, to 30-40 units during the subjective day. The rhythmicity was followed for up to one week without dampening. In groups c) and d), NDH cycle is reversed, being the secretion higher at night than at day time. In eyestalks excised from animals kept in either normal or reversed L:D cycles, and entrained "in vitro" to a different light schedule, a corresponding phase-shift was obtained. These results suggest that the eyestalk is capable of sustaining an endogenous, circadian rhythm of neurosecretion, and that it contains the photoreceptive mechanism for entrainment.

45.3 ROLE OF THE SUPRACHIASMATIC NUCLEI (SCN) IN THE SHORT-DAY-INDUCED ATTENUATED CASTRATION RESPONSE. F. Turek, S. Losee*and G. Ellis*. Dept. of Biol. Sci., Northwestern Univ., Evanston, IL 60201.

Castration of hamsters that have regressed testes due to their maintenance on short days (e.g., LD 6:18) results in only a slight increase in serum gonadotropins. If castrated hamsters are transferred from short to long days (e.g., LD 14:10), serum gonadotropin levels increase to normal high post-castration values. The neural components involved in mediating the effects of light on this steroid-independent response to the photoperiod have not been identified, and in the present investigation we examined the potential role of the SCN in this response.

Ten-week-old hamsters that had been maintained on LD 14:10 since birth were transferred to LD 6:18. Nine weeks later blood was collected via cardiac puncture under light ether anesthesia from a subsample of 10 animals. The animals were then castrated and divided into 4 treatment groups (11-16 animals/group): 1) Sham- or non-lesioned and maintained on LD 6:18, 2) Sham- or non-lesioned and immediately transferred to LD 14:10, 3) SCN-lesioned and maintained on LD 6:18, 4) SCN-lesioned and immediately transferred to LD 14:10. Blood was collected from each animal on days 3, 10, 20, and 35 after surgery. Prior to castration serum follicle stimulating hormone (FSH) levels were 100 ± 21 ng/ml. Mean (±SE) serum FSH levels (ng/ml) over the 35-day period following castration are shown below.

		Days			
Lesion	Photoperiod	3	10	20	35
None	6L → 6L	451±130	177± 17	199± 22	386±103
None	6L → 14L	508± 94	856±121	2490±195	2748±225
SCN	6L → 6L	1006±212	1061±201	1823±228	2303±349
SCN	6L → 14L	857±134	989±250	1749±253	2341±277

Non-lesioned animals that were castrated and maintained on LD 6:18 showed the attenuated castration response and mean serum FSH levels never rose above 500 ng/ml. In contrast, transfer to LD 14:10 induced an increase in serum FSH levels in the non-lesioned animals. Similarly, lesioning of the SCN resulted in a rapid increase in serum FSH levels, and this response appeared to be independent of the photoperiod. On days 10, 20 and 35, serum FSH titres in the non-lesioned animals transferred to LD 14:10 and in the SCN-lesioned animals exposed to either photoperiod were similar and significantly greater ($p < 0.01$) than those observed in the non-lesioned animals maintained on LD 6:18. These results demonstrate that ablation of the SCN abolishes the short-day-induced attenuated castration response, suggesting that the SCN mediate the steroid-independent effect of short photoperiods on pituitary gonadotropin release. (Supported by USPHS Grants HD-12622, HD-09885, and HD-00249.)

45.4 PINEAL MELATONIN RHYTHMS IN THE SYRIAN HAMSTER MAINTAINED IN ENVIRONMENTAL AND LABORATORY CONDITIONS. G.C. Brainard*, L.J. Petterborg*, and R.J. Reiter. Department of Anatomy, University of Texas Health Science Center, San Antonio, TX 78284.

The objective of the following study was to compare the pineal melatonin rhythms of hamsters maintained in outdoor versus laboratory conditions. One hundred and forty-four adult male hamsters were employed in this experiment. On November 29, half the animals were caged under controlled laboratory conditions: LD cycle of 10:14 (lights on 0700 hours), 22°C, and 50% humidity. The remainder of the animals were maintained under outdoor conditions in a well ventilated, three-sided shelter open to the southeast. At this time of year, the photoperiod is short (approximating LD 10:14) and is decreasing in length. During the experiment, mean sunrise time was 0700 hours and mean sunset time was 1612 hours. Though protected from the rain, these animals were exposed to natural temperature fluctuations ranging from -4°C to 27°C, and humidity changes from 15% to 100%. Animals in both groups were kept 5 per cage and given food and water ad libitum. On December 20th and 21st, eight animals from each group were sacrificed at the following times: 0800, 1200, 1700, 2000, 2200, 2400, 0200, 0400 and 0600 hours. Pineal glands were immediately dissected out, placed in a 1 ml of phosphate buffered saline, disrupted by sonication and stored at 4°C until ready for assay. Radioimmunoassay (Rollag and Niswender, Endocr. 98:482, 1978) was used to determine melatonin content of pineal glands. The significance of the results was assessed by analysis of variance and Student's t test.

Both groups of animals displayed a distinct circadian pattern of pineal melatonin content. Peak nighttime levels of melatonin (between 0200 and 0600 hours) were five to ten fold greater than daytime levels in both groups of animals. At 0200 and 0600 hours, the pineal melatonin content of animals maintained outdoors was higher than that of animals kept in the laboratory $P<.05$ and $P<.005$, respectively.

Two implications may be discerned from the above results. First, animals maintained outdoors witness a graded and changing photoperiod as well as dramatic changes in temperature and humidity. These and/or other factors present in the winter environment but not in the laboratory appear to cause the pineal to produce more melatonin. Second, caution should be used in generalizing results produced in the laboratory to animals living in the wild.

45.5 INHIBITION OF MELATONIN-INDUCED GONADAL ATROPHY BY TWICE DAILY MELATONIN INJECTIONS. P. K. Rudeen, S. K. Symmes* and W. O. McKinley*. Department of Anatomy, Bowman Gray School of Medicine, Winston-Salem, NC 27103.

A daily injection of melatonin for 9 weeks (25 µg) will induce gonadal atrophy in golden hamsters, if the injection is given within a three-hour period prior to the onset of darkness when animals are maintained in a long photoperiod. A subcutaneous implant of melatonin (1 mg) will block the antigonadal effects of afternoon injections of melatonin. It is unknown if the inhibitory effects of continual melatonin administration is mediated due to the constant presence of melatonin. Eight groups of adult hamsters were given two daily subcutaneous injections. Hamsters received either ethanolic saline, or melatonin dissolved in ethanolic saline (25 µg) late in the photoperiod, combined with a subcutaneous injection of ethanolic saline, or various concentrations of melatonin (1 µg, 5 µg, 25 µg, 100 µg or 500 µg) early in the photoperiod. Animals were treated 6 days per week for 9 weeks after which testicular and accessory sex organ weights were measured. Hypothalamic LHRH content, serum LH and serum testosterone were measured by RIA. Severe testicular and accessory sex organ atrophy occurred in animals subjected to morning injections of either ethanolic saline, 1 µg or 5 µg of melatonin combined with late afternoon injections of melatonin. Serum LH levels and serum testosterone levels were lowered in these animals when compared with animals that received saline in the morning and afternoon. There was a tendency for hypothalamic LHRH content to be increased in the animals subjected to low doses of melatonin in the morning combined with melatonin given in the afternoon when compared with saline injected animals. Injections of 25 µg or 100 µg of melatonin in the morning partially blocked the effects of the afternoon melatonin injection, whereas a 500 µg injection of melatonin was capable of completely blocking the effects of the afternoon injection of melatonin. The results are consistent with the hypothesis that melatonin present at times other than a "sensitive" period will result in a "down regulation" of melatonin receptors inhibiting gonad atrophy when melatonin is presented during the sensitive phase. Inhibition of gonadal atrophy by a single injection of melatonin at another period of time during the day suggests that melatonin may not need to be continuously present to inhibit melatonin-induced gonadal atrophy.

45.6 CONTRIBUTION OF WATER AND ANGIOTENSIN TO CIRCADIAN CHANGES IN VENTRICULAR WEIGHT TO BODY WEIGHT RATIO IN RATS. Maurice S. Holder*, Estrellita Howard*, Willie Pennick* and Charles A. Walker. Florida A&M University, School of Pharmacy, Tallahassee, FL 32307.

Ventricular hypertrophy in rats have been assessed by ventricular weight to body weight ratios (VW/BW). These measurements are generally taken at different times in the normal light dark cycles of animals. At the same time, tissue water levels and hormonal levels are thought to influence these results depending on when in the cycle readings are made. The circadian pattern of water and Angiotensin and their relationship to VW/BW was investigated in male Sprague Dawley rats that were acclimatized in an environmental chamber and exposed to a fixed 12 hour light - 12 hour dark cycle. After a period of adjustment, animals were sacrificed at three hour intervals. Blood was collected; hearts were weighed, and 1 mg samples were taken for Angiotensin I (AI) and II (AII) using radioimmunoassay. Ventricles were weighed, dried in a constant temperature oven and re-weighed to determine water content. AI and AII levels in the heart demonstrated circadian patterns that were similar. Peak concentrations occurred at 0300 hours of the dark phase while the troughs occurred some 12 hours later (0300) hours light phase). Water content of the ventricle remained essentially unchanged throughout the 24 hour cycle. (Average = 76.9%; high = 78.2%; low = 75,7%). VW/BW was highest during the dark phase with the peak occurring between 2300 hours and 300 hours. The lowest VW/BW recorded was during 1100 and 1600 hours of the light cycle after which gradual increases were obtained up to the peak response. These results demonstrate that VW/BW is significantly different during various periods of the light dark cycle and that the level of Angiotensin II in the tissue parallel this finding. The results support the idea that AII levels may influence protein synthesis in the myocardium and thereby the elevation in ventricular mass. (Supported by a grant from the National Aeronautics and Space Administration).

45.7 ALTERED CNS-PITUITARY FUNCTION IN ZUCKER (fa/fa) FATTY RATS: ABSENT CIRCADIAN PERIODICITY OF ACTIVITY, FEEDING, AND PLASMA CORTICOSTERONE (B) CONCENTRATIONS AND ELEVATED BRAIN AND PITUITARY NEUROINTERMEDIATE (NI) LOBE BETA-ENDORPHIN (B-Ep) CONCENTRATIONS. Marie J. Gibson and Dorothy T. Krieger, Division of Endocrinology, Mount Sinai Medical Center, New York, New York, 10029.

Recent data have indicated interrelationships between feeding and B rhythmicity and with pituitary B-Ep concentrations. Genetically obese animals (ob/ob mice, fa/fa rats) are reported to have normal or absent circadian periodicity of plasma B, elevated or normal plasma ACTH and/or B concentrations, and elevated pituitary B-Ep concentrations. The present studies were designed to further delineate these parameters in the (fa/fa).

Studies were performed on seven (fa/fa) and seven lean (Fa/?) female rats, two months of age. The circadian periodicity of plasma B was determined by sequential sampling, q. 4 h over a 24-h period. Such periodicity was absent in (fa/fa) and present in (Fa/?). Mean plasma B concentrations were: (fa/fa): 20.3 ± 2.0 µg/100 ml; (Fa/?): 18.4 ± 2.7 µg/100 ml. Circadian rhythmicity of feeding and drinking behavior and of activity was absent in (fa/fa) and present in (Fa/?). Total food consumption was 23.3 ± 1.1 gm (fa/fa) vs. 17.1 ± 1.0 gm (Fa/?), $p<0.01$, and water consumption was 34.8 ± 1.8 ml (fa/fa) vs. 28.4 ± 2.1 ml (Fa/?), $p<0.05$. Body temperature patterns were similar in both groups, although the overall mean temperature of (fa/fa) animals (36.4° ± 0.1) was less than (Fa/?) animals (36.8° ± 0.1), $p<0.05$. Plasma B following 30 minutes of immobilization stress did not differ between the groups.

Immunoreactive B-Ep and ACTH concentrations were assayed in anterior and NI pituitary lobes and in brains of 10-month-old animals. Animals were sacrificed by decapitation. Brain and pituitary lobes were homogenized in 0.2 N HCl and frozen until assay.

	Body Wt (gm)	Brain Wt (mg)	Pituitary Wt (mg) Ant	NI	B-Ep Ant	NI	Brain
fa/fa	524±21	1438±39	10.9±1.2	2.2±.3	.12±.02	.98±.18*	35.3±7.3*
Fa/?	259±10†	1528±15	11.2±1.0	2.2±.2	.09±.01	.39±.15	17.8±3.0
					(µg/mg wet wt)		(pg/mg wt)

*$p<0.05$ †$p<0.01$

There were no differences between groups in concentrations of ACTH in either pituitary lobe or in the brain. Sephadex gel characterization of these peptides is in progress.

These studies indicate significant neuroendocrine disturbances with regard to circadian periodicity in (fa/fa) rats which are not present in their lean littermates. This may be related to reported abnormalities in neurotransmitter concentrations and/or their periodicity. The present findings also indicate an increase in both brain and pituitary B-Ep concentrations, with the latter specific to the NI lobe.

45.8 EPENDYMAL TANYCYTES ON THE FLOOR OF THE THIRD VENTRICLE OF EWES EXHIBIT SUBTLE ALTERATIONS IN SURFACE FEATURES DURING THE ESTROUS CYCLE. Penelope W. Coates and Steven L. Davis*. Dept. of Anat. Texas Tech Univ. Health Sci. Center., Lubbock, TX 79430 and Dept. of Animal Sci., Univ. Idaho, Moscow, ID 83843

Ultrastructural surface features of ependymal tanycytes on the floor of the third ventricle in a group of normally cycling mature female sheep (ewes) were evaluated by scanning and transmission electron microscopy (SEM and TEM). Three ewes each in luteal and follicular phases and one estrual ewe were analyzed. Blood was taken from the same animals at the time of sacrifice to determine luteinizing hormone (LH) concentration by radioimmunoassay (RIA). (Cycle stages were confirmed by LH concentrations of 43.5 ng/ml in the estrual ewe as compared to 126.0 pg/ml ± 16.2 for the luteal group and 141.4 pg/ml ± 51.5 for the follicular group of ewes). With SEM, tanycytes of follicular phase ewes demonstrated a relatively bare surface with fewer microvilli compared with estrual and luteal phase ewes. Miniblebs were present. At estrus, SEM revealed a predominantly microvillous covered tanycyte surface. Luteal phase ewes exhibited many microvilli on the luminal aspect of tanycytes, compared to follicular phase ewes. However, since some tanycytes were not completely covered with microvilli, a patchy appearance resulted. Miniblebs were also evident in luteal phase ewes. TEM showed that tanycytes in follicular ewes possessed few microvilli at their surfaces, reinforcing the data from SEM. TEM of tanycytes in the estrual ewe revealed a proliferation of luxuriant, often branched microvilli. This continued into the luteal phase where both microvilli and miniblebs were evident with TEM. Miniblebs contained cell cytoplasm as well as some organelles. The SEM appearance of tanycytes at estrus and in the luteal phase is similar to our previous findings for estrous ewes compared with estrogen-progesterone treated anestrous ewes respectively. (Coates & Davis, Biol. Reprod. 17:567-573, '77). The onset of appearance of a fully developed microvillous coat on tanycytes in the normally cycling ewe third ventricle appears to coincide with estrus and a peak LH concentration, while the continued maintenance of the microvillous state coincides with levels of estradiol that are known to fluctuate and an elevated progesterone level. These data, in combination with previous studies, showing that estrogen can cause proliferation of certain features, may suggest that there is a functional relationship in ewes between the development of microvilli in tanycytes and the preovulatory surge of estrogen. (Supported by grant no. HD12833 from the NIH and a grant from the Inst. Biomed. Res., TTUSM).

46.1 FREE AND CONJUGATED SEROTONIN, CATECHOLAMINES AND NORMETANEPHRINE IN HUMAN PLATELETS. G.B.Picotti+, C.Ravazzani+, A.M.Cesura+ and M.Da Prada+° (SPON: L.Valzelli) Inst. Pharmac.Univ. of Milan,Italy and °Pharm.Res.Dept., Hoffmann-La Roche & Co., CH-4002, Basle, Switzerland.

Platelets of all mammalian species so far investigated contain variable amounts of free (unconjugated) amines, e.g. 5-hydroxytryptamine (serotonin 5-HT), histamine, catecholamines (CA) and octopamine, which are prevalently accumulated in storage vesicles, i.e. the so called "5-HT organelles". A recently developed radioenzymatic assay for normetanephrine (NMN) has permitted to establish the presence of this noradrenaline (NA) methoxyderivative in platelets of various species, including man (M.Da Prada et al., in "Platelets:...", J.Wiley & Sons Ltd., 1980 in press).

The enzyme phenol sulfotransferase has been recently demonstrated in human platelets (Hart et al., Life Sci. 24, 125, 1979). In order to assess whether platelets contain sulfoconjugated amines, free and total (acid hydrolysis at 100°C) 5-HT, CA and NMN were measured radioenzymatically in human and animal platelet extracts. Apparently following acid hydrolysis only sulfoconjugated derivatives are hydrolyzed, glucuronoconjugated being acid-resistant. In human platelets (six healthy subjects) conjugated 5-HT, dopamine, adrenaline, NA and NMN corresponded to about 10, 93, 69, 33 and 76%, respectively. Only trace amounts (< 5%) of these amines were found in conjugated form in rabbit, rat and guinea-pig platelets, suggesting that, among the different mammalian platelets investigated, only human platelets contain high sulfotransferase activity.

Accordingly, in vitro studies showed that human, but not rat, rabbit or guinea-pig platelets are able to sulfoconjugate the ^{14}C-5HT, -NA or -NMN (1 uM) taken up by platelets on incubation in plasma (37° for 30 min). In these experiments most (over 80%) of ^{14}C-NMN accumulated by human platelets was found to be sulfoconjugated, whereas ^{14}C-5HT and -NA were conjugated to a lesser extent (10 and 35% of the accumulated radioactivity, for ^{14}C-5HT and -NA respectively). Reserpine (10 uM) effectively released free but not conjugated radioactive amines from preloaded platelets(G. B.Picotti et al., Br.J.Pharmac., 1980 in press).

From these and other results it appears that human platelets differ substantially from animal platelets, since they apparently have an extragranular cytoplasmic pool of sulfoconjugated CA, NMN and 5HT. Presumably the conjugated amines are in dynamic equilibrium with an additional pool of free amines within the cytoplasmic compartment and with the bulk of free amines stored in the 5-HT organelles.

46.2 COMPARISON OF SEROTONIN BINDING PROTEINS OF NEURONAL AND MESENCHYMAL (MAST CELL + BASOPHIL) ORIGIN. H. Tamir, P.W. Askenase*, T.C. Theoharides and M.D. Gershon. N.Y. State Psych. Inst.; Dept. of Psychiatry and Anatomy, Columbia University and Dept. of Internal Medicine, Yale Univ.

Serotonergic neurons of both brain and gut contain a specific serotonin binding protein (SBP) that is probably a component of the amine storage mechanism. Serotonin (5-HT) is also stored in mast cells (mouse and rat), platelets and enterochromaffin cells. The properties of neuronal SBP differ from those of the platelet proteins that bind 5-HT. The present study was done to determine if 5-HT binding proteins are present in rat mast cells and rat basophil leukemia (RBL) cells and if so, to compare them with the SBP of neurons. RBL cells were maintained in culture and harvested at log phase. Rat mast cells were obtained by peritoneal lavage and purified on BSA gradients. The 5-HT binding capacity of non-membranous macromolecules of disrupted cells (100.000g supernatant) was measured using [^{3}H]-5-HT (0.2 uM) and molecular sieve chromatography. 5-HT binding macromolecules were detected in both cell types; however, since RBL cells could be obtained in greater abundance, the properties of the macromolecules from RBL cells were studied more extensively. Binding was specific (inhibited by excess of non-radioactive 5-HT but not by an excess of histamine) and linear up to 100 ug protein/ml (7pmole 5-HT/mg Protein). Neuronal SBP and the RBL macromolecule that bound serotonin showed similarity in trypsin sensitivity; in enhancement of binding by Fe^{+2} and in inhibition of binding by high salt media (Krebs-Ringer) and ATP. They differed in the following properties: 1) Only one dissociation constant was observed for RBL protein (K_D=3.9x10^{-7}M), the neuronal high affinity binding was lacking. 2) Ca^{+2} (10^{-3}M) did not inhibit the RBL protein. 3) The RBL protein showed partial heat lability (45% decrease of binding; 80°C; 10 min). 4) When RBL cells were disrupted by gentle homogenization, the binding capacity for 5-HT was only partially inhibited by reserpine (50%; 5 x 10^{-5}M) but when extensively homogenized (Polytron) the binding capacity was increased three-fold and was more sensitive to reserpine (>80% inhibition; 5 x 10^{-5}M). We suggest that vigorous homogenization causes release from intracellular granules of a second 5-HT binding protein which is reserpine sensitive. The reserpine insensitive protein may originate from an extra granular compartment. It is concluded that neuronal SBP is different from the 5-HT binding proteins of mast cells and RBL cells.

46.3 MG·ATP AND BICARBONATE DEPENDENT STIMULATION OF ACETYLCHOLINE UPTAKE BY TORPEDO SYNAPTIC VESICLES. Stanley M. Parsons, Robert Koenigsberger,* and Joan E. Rothlein. Department of Chemistry, University of California, Santa Barbara, CA 93106.

Uptake and storage of [^{3}H]acetylcholine (ACh) by cholinergic synaptic vesicles isolated from Torpedo californica electric organ is being studied. [^{3}H]ACh was taken up passively with a half-life of 8 min by [^{14}C]mannitol equilibrated vesicles, to give an osmotically labile concentration inside equal to that outside as determined by ^3H to ^{14}C ratios. Passive uptake was directly proportional to the external [^{3}H]ACh concentration up to 50μM. In the presence of MgATP, uptake of [^{3}H]Ach was inhibited about 2-fold. Addition of HCO_3^- stimulated uptake 6-fold, so that a 3-fold concentrative uptake resulted. The effects were not dependent on Na^+, K^+, Cl^-, or ionic strength and HCO_3^- stimulation required MgATP. Incorporated [^{3}H]ACh migrated with synaptic vesicles in equilibrium ultracentrifugation in a glycerol density gradient. [^{14}C]Choline behaved identically with [^{3}H]ACh in passive and suppressed uptake, but its uptake was not stimulated by HCO_3^-. Stimulated uptake of [^{3}H]ACh was inhibited at low temperature, and stimulated uptake was dependent on the MgATP and HCO_3^- concentration in a saturable way. CaATP and HCO_3^- also stimulated uptake. A Ca^{2+}/Mg^{2+}-ATPase associated with vesicles similarly is stimulated by HCO_3^-. It seems likely that acetylcholine uptake by synaptic vesicles is linked to a bicarbonate stimulated Ca^{2+}/Mg^{2+}-ATPase. (Supported by the Muscular Dystrophy Association and NINCDS).

46.4 TRANSMEMBRANE POTENTIAL AND Na^+ GRADIENT IN ISOLATED SYNAPTIC VESICLES: A POSSIBLE MODEL FOR ENERGIZATION OF VESICULAR UPTAKE OF ACETYLCHOLINE. J. B. Suszkiw and M. O'Leary*. Physiol.Section, Biol.Sci. Group, Univ. of Conn. Storrs, CT 06268.

Synaptic vesicles isolated from the electromotor nerve terminals of Narcine and purified in iso-osmotic NaCl-sucrose gradients accumulate the lipophylic cation [^{3}H]methyltriphenylphosphonium (MTPP) as well as [^{3}H] choline (Ch) or [^{3}H]acetylcholine (ACh) but exclude the lipophylic anion thio[^{14}C]cyanate. Membrane potential of isolated vesicles, estimated from the steady-state distribution of MTPP ranges from 50 mV to 150 mV, inside negative. The accumulation of Ch or ACh by the vesicles parallels the accumulation of MTPP and ranges from 8x to over 80x the medium concentration of these cations.

Using the potential-sensing fluorescent probe 3,3'diethylthiadicarbocyanine, it can be demonstrated that gramicidin D hyperpolarizes vesicles and stimulates an electrogenic influx of Ch (ACh) but valinomycin is ineffective in either respect, confirming the observation by Carpenter&Parsons (J. Biol. Chem.(1978) 253: 325). However, vesicles purified in KCl-sucrose gradients can be hyperpolarized by valinomycin,but in this case subsequent electrogenic influx of Ch (ACh) is not observed.

The foregoing results are interpreted to mean that concentrative translocation of ACh into the synaptic vesicles is a function of vesicle membrane potential and is stimulated by imposition of a suitable ΔNa^+ (in>out) across the vesicle membrane. It is suggested that in situ, exocytotic release of ACh and simultaneous generation of ΔNa^+ due to rapid equilibration between the intravesicular and the extracellular medium may be prerequisite for energization of ACh uptake by the reformed vesicles, and might explain preferential charging of the mobilized but not the reserve vesicles with the newly synthesized transmitter.

Supported by the USPHS Grant # NS-15674.

46.5 REGULATION OF ACETYLCHOLINE BIOSYNTHESIS DURING DEVELOPMENT AND AGING. M. Marchi*, D.W. Hoffman*, E. Giacobini and R. Volle. (SPON: W.A. Wilson). Lab. of Neuropsychopharmacology, Dept. of Biobehavioral Sciences, Univ. of Connecticut, Storrs, CT 06268, and Dept. of Pharmacology, Univ. of Connecticut Health Center, Farmington, CT 06032.

The relationship among biochemical parameters of cholinergic metabolism in autonomic nerve terminals in the chick iris were determined throughout the lifespan of the animal. Choline (Ch) uptake, acetylcholine (ACh) content and ACh turnover increase steadily up to the adult stage (3 months - 1 year) and then decline in aged animals (5 years). These changes appear to reflect the activity and the state of the cholinergic innervation of the iris. Other changes which occur with age include a steady decline in the ratio Ch:ACh, and a decrease in the ratio of endogenous Ch concentration relative to exogenous (^{3}H)Ch taken up from the medium. However, the ratio of (^{3}H)Ch to (^{3}H)ACh does not vary significantly with age from 10 days of incubation (d.i.) up to 5 years of age.

Experiments were also performed to examine the influence of age on the effects of drugs, temperature, and Na^+, on uptake and metabolism of (^{3}H)Ch, and on the mechanism of inhibition of uptake by cholinesterase inhibitors. Uptake of (^{3}H)Ch and synthesis of (^{3}H)ACh are both inhibited by these treatments, and cholinesterase inhibitors appear to inhibit uptake by increasing intracellular ACh, confirming previous reports.

Age related changes in the nervous system appear to be more evident in pre- rather than postsynaptic elements. Our reseach has lead us to the view that peripheral nerve terminals are both a major locus for aging in the nervous system, and a valuable model for studying these changes.

46.6 DIRECT ACTIONS OF CHOLINOMIMETICS ON RABBIT SYMPATHETIC NEURONS. A.E. Cole and P. Shinnick-Gallagher, Dept. of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550.

In a previous report (Br. Res. 187, 1980), we suggested that the slow inhibitory postsynaptic potential (S-IPSP) in sympathetic ganglia may be caused by a direct action of acetylcholine (ACh). To test this possibility, we applied ACh and the muscarinic agonists methacholine (MCh) and muscarine (MUS) to the ganglia to mimic the nerve-evoked response.

We recorded in vitro from rabbit superior cervical ganglia (RSCG) using an extracellular, sucrose-gap technique. All drugs were added to the physiological solution superfusing the preparation. Hexamethonium (5×10^{-4}M) was added routinely to all solutions to block the nicotinic response. Control and drug responses were compared in the same ganglion.

ACh (10^{-3}M) and muscarine (10^{-5}M) produced a biphasic response in the ganglia that was similar to the S-IPSP and the slow excitatory postsynaptic potential (S-EPSP), i.e. a hyperpolarization ($.1 - .44$ mV) followed by a depolarization ($.08 - .4$ mV). MCh (10^{-3}M) had a similar effect.

The response of the ganglion to the cholinomimetics diminished with repeated application. However, application at one hour intervals avoided this phenomenon and elicited consistent reproducible responses.

When synaptic transmission was blocked by a zero Ca^{++}/high Mg^{++}, EGTA (1 mM) solution, as evidenced by elimination of the evoked slow potentials, ACh, MCh and MUS still hyperpolarized and then depolarized the ganglion membrane. The biphasic response was also maintained in the presence of tetrodotoxin (TTX) (10^{-6}M). Both the evoked slow potentials and the drug-induced responses were blocked by atropine (10^{-7}M).

These data suggest that the nerve-evoked slow potentials, possible modulators of ganglionic transmission, are generated by a direct action of ACh on postganglionic muscarinic receptors. Our results question the existence of a disynaptic pathway and the involvement of catecholamines in the mediation of the S-IPSP.

46.7 ALPHA-BUNGAROTOXIN BINDING SITES IN SENSORY GANGLIA. G. Polz-Tejera*, A. Reiner and J. Schmidt. Department of Biochemistry, State Univ. of New York, Stony Brook, N.Y. 11794.

Sensory fibers are known to be sensitive to acetylcholine and nicotinic-cholinergic ligands (Paintal, A.S., Pharmacol. Rev., 16:341, 1964). We therefore undertook to analyze sensory ganglia of rat for alphabungarotoxin (αBuTX) binding.

For biochemical analysis, freshly dissected trigeminal ganglia were homogenized and binding of ^{125}I-αBuTX (10^6Ci/mole) to particulate matter was measured with a centrifugation assay. Toxin receptor concentrations of approximately 1 femtomole per mg wet tissue and a K_D of 2×10^{-11}M were found. Inhibition constants for nicotine, d-tubocurarine and atropine were determined to be 1.2×10^{-6}, 4×10^{-6} and 1.0×10^{-4}M, respectively, indicating the nicotinic nature of the binding sites.

Autoradiography was carried out to identify the location of binding sites. It revealed labeling of large neuronal cell bodies. No binding over glia or neuropil was detectable.

High levels of toxin binding sites have been reported in the substantia gelatinosa of rat spinal cord (Hunt S. and Schmidt J., Brain Res., 157:213, 1978). Is it possible that toxin receptors are synthesized extrasynaptically in the perikaryon of ganglia cells and then transported to a presynaptic location at the central sensory fiber terminal in the spinal cord? To test this possibility, several consecutive lumbosacral dorsal roots were sectioned on one side. However, no effect on toxin binding in the substantia gelatinosa was observed 6-8 days after rhizotomy, although substand P levels, determined immunochemically, did decrease at the site of the sectioned roots. These findings indicate that cholinergic fibers are most probably restricted to the peripheral process of their sensory neuron. The modality of the toxin-positive sensory fibers is currently being investigated. An autoradiographic survey of the mesencephalic trigeminal nucleus revealed no label, indicating that proprioceptive fibers may not carry αBuTX binding sites.

46.8 POOR CORRELATION BETWEEN [^{3}H] QNB BINDING AND A MUSCARINIC CHOLINERGIC RESPONSE IN DISPERSED RAT PAROTID CELLS. Edward Olender* and James N. Davis, (SPON: E. Busse). Department of Medicine (Neurology) and Pharmacology, Duke University Medical Center and Veterans Administration Medical Center, Durham, N. C. 27705.

The radioligand [^{3}H] quinuclidinyl benzilate (QNB) has been used to study muscarinic cholinergic binding sites in many tissues. We used a model system, dispersed rat parotid cells to correlate [^{3}H] QNB binding to a muscarinic cholinergic response, K^+ release. [^{3}H] QNB bound to a homogeneous population of sites on dispersed cells and membranes from cells (18 fmole [^{3}H] QNB bound/mg protein). Computer modeling of the ability of agonists to compete with [^{3}H] QNB for binding was also consistent with one class of sites on these cells. However the potency of a small series of agonists and antagonists in eliciting or blocking K^+ release differed from their ability to compete for binding. The two antagonists studied, QNB and atropine, were equipotent in competing for [^{3}H] QNB binding but QNB was 20 times more potent than atropine in blocking carbachol-induced K^+ release from cells. Agonists competed for [^{3}H] QNB binding with the relative potency oxotremorine > carbachol > acetylcholine. By contrast acetylcholine was more potent than carbachol in eliciting K^+ release. Although difficult to measure, oxotremorine appeared to be a more potent partial agonist than carbachol or acetylcholine. Oxotremorine produced only a slight release of K^+ at maximum concentrations compared to the K^+ release elicited by maximum concentrations of carbachol. The EC_{50} values for K^+ release for carbachol and acetylcholine suggests that only 10% of the [^{3}H] QNB binding sites participate in K^+ release. Since parotid [^{3}H] QNB binding appears similar to binding described in other tissues, our results suggest caution must be employed before equating [^{3}H] QNB binding with the muscarinic cholinergic receptor.

47.1 RETINAL PROJECTIONS IN A FRUGIVOROUS MICROCHIROPTERAN AND AN ECHOLOCATING MEGACHIROPTERAN. M.R. Braford, Jr. and R.A. Suthers. Department of Anatomy, Georgetown University, Washington, D.C. 20007 and Physiology Section, Medical Sciences Program, Indiana Univ. School of Med., Bloomington, IN 47401.

Among bats, detailed studies of the retinal projections have been reported for several insectivorous microchiroptera of the genus Myotis, which depend heavily on audition for echolocation, and two frugivorous megachiroptera of the genus Pteropus, which depend heavily on vision. These two groups probably represent the two extremes among the Chiroptera in terms of the development of the visual system. We have examined, with autoradiographic methods, the retinal projections in two species which might be expected to be intermediate between Myotis and Pteropus in this respect: a frugivorous microchiropteran, Phyllostomus hastatus, and an echolocating megachiropteran, Rousettus aegyptiacus. In both species the majority of the retinal fibers cross in the chiasm and distribute to the contralateral diencephalon and mesencephalon; the ipsilateral components are, however, substantially larger in Rousettus than in Phyllostomus. In Phyllostomus the retina projects contralaterally to the following cell groups: suprachiasmatic nucleus; ventral lateral geniculate nucleus; dorsal lateral geniculate nucleus; nucleus of the optic tract; the olivary and posterior pretectal nuclei; the medial, lateral and dorsal terminal nuclei of the accessory optic tract; and the superior colliculus. Ipsilateral terminations are present in the suprachiasmatic nucleus, ventral lateral geniculate nucleus, nucleus of the optic tract, olivary pretectal nucleus, and possibly very sparsely in the dorsal lateral geniculate nucleus. In Rousettus the retina projects contralaterally to all of the targets seen in Phyllostomus and, in addition, to the lateral posterior nucleus of the thalamus and the anterior pretectal nucleus. Ipsilateral input in Rousettus is distributed to the suprachiasmatic nucleus, ventral lateral geniculate nucleus, dorsal lateral geniculate nucleus, lateral posterior nucleus, nucleus of the optic tract, the olivary and anterior pretectal nuclei, and restricted portions of the superior colliculus. The dorsal lateral geniculate nucleus is small and relatively simply organized in Phyllostomus, whereas in Rousettus it is large and consists of three major cellular laminae and five major terminal laminae. The retinal input in Phyllostomus is more extensive than that in Myotis and that in Rousettus appears to be similar to but slightly less extensive than that in Pteropus. (Supported by NSF Grant BNS 76-01716 to RAS.)

47.2 NEW OBSERVATIONS ON THE RETINAL PROJECTIONS TO THE HYPOTHALAMUS AND ACCESSORY OPTIC NUCLEI IN THE GOLDEN HAMSTER AS DEMONSTRATED BY ANTEROGRADE HRP. G.E. Pickard and A.J. Silverman, Department of Anatomy, Columbia University, P&S, New York, NY 10032.

The available anatomical data on the central organization of the optic projections in the hamster is limited and often conflicting. Controversy has centered on the existence of an inferior accessory optic fasciculus (Eichler and Moore, Acta Anat., 89:359, 1974; Lin et al., Anat. Rec., 186:451, 1976) and the route taken by retinal fibers destined for the hypothalamus (Printz and Hall, Anat. Rec., 179:57, 1974; Eichler and Moore, 1974). The central projections of the retinal ganglion cells of the golden hamster were re-examined in this study using horseradish peroxidase (HRP) as the anterograde tracer molecule.

Monocular injections of four ul of a 30% HRP (Sigma,type VI) solution (0.05 M Tris, pH 7.6) were made into the vitreous. Following survival times of 6, 12, 24, 36 or 48 hrs, the animals were perfused with 0.9% saline followed by 2% glutaraldehyde. Following overnight fixation in a 1.5% glutaraldehyde solution containing 5% sucrose, the brains were sectioned in the coronal plane at 60 um. HRP in optic fibers and terminals was demonstrated histochemically using the tetramethylbenzidine (TMB) procedure (Mesulam, J. Histochem. Cytochem., 26:106, 1978).

The sensitivity of the TMB procedure allowed the clear demonstration of previously controversial projections, clearer definition of established projections and the discovery of a new retinofugal pathway. An inferior accessory optic system was shown to be unequivocally present in this species and to consist of both crossed and uncrossed components. A projection to the suprachiasmatic nucleus (SCN) of the hypothalamus was confirmed but the distribution of terminals as seen by this procedure was substantially different than previously reported; both rostral-caudal and medial-lateral asymmetries in the distribution of label between the ipsi- and contralateral SCN were observed. Substantial differences in the retinal projection to the SCN in the hamster and the rat were also noted. It is suggested that these differences may reflect the different effects light has on the neuroendocrine-gonadal axis in these two species. Finally, labeled retinal axons were followed leaving the optic tract and coursing anteriorly through the plexiform layer of the piriform cortex; other labeled fibers were seen to enter the septal region. The physiological significance of these previously undescribed retinal projections is not known.

47.3 DIRECTION-SELECTIVE NEURONS IN THE FROG'S VISUAL SYSTEM. S.L. Cochran, W. Precht*, and N. Dieringer*. Neurobiol. Abt., Max-Planck-Inst. für Hirnforschung, 6 Frankfurt/Main 71, FRG.

Two midbrain nuclei have been found to respond selectively to optokinetic stimulation. Both are innervated by retinal ganglion cells from the contralateral eye. One of these nuclei, the basal optic nucleus, is composed of neurons which respond preferentially to large targets (striped or random dot patterns) moved vertically. These cells have no resting discharge. Some are activated exclusively by upward movement, while others are only activated by downward movement. A proportion of these cells also respond to horizontal, naso-temporal optokinetic stimulation, but none of these cells respond to temporo-nasal movement. A nucleus distinct from the basal optic nucleus is sensitive to horizontal movement. Its neurons are spontaneously active. A temporo-nasal movement of a large pattern (presented to the contralateral eye--optimally moving less than 10°/sec) results in a brisk increase in the firing frequency of these cells, while such stimulation in the naso-temporal direction results in a reduction in frequency and in a silencing of these cells. These neurons vary in their sensitivity to vertical movement, but all are predominantly sensitive to horizontal movement, and all are excited by temporo-nasal movement. Ejection of horseradish peroxidase from the recording microelectrode and subsequent histological processing reveals the location of these cells to be approximately 1 mm ventral to the rostral tectal surface, dorsolateral to the oculomotor and basal optic nuclei. This region may thus correspond to the pretectal nucleus of the frog (see Scalia, 1976) and may be homologous to the nucleus of the optic tract and/or the dorsal terminal nucleus of higher vertebrates. The basal optic nucleus is likely homologous to the ectomammillary nucleus of the bird and the medial and ventral terminal nuclei of the mammal. Electrolytic lesions, confined to the region of these horizontally-sensitive neurons result in a marked diminution in movement of the head to the lesioned side with temporo-nasal stimulation of the contralateral eye. Similar lesions of basal optic neurons result in no impairment of horizontal following of the head. It would thus appear that these horizontally-sensitive neurons are the first necessary, central link for the nervous system's ability to mediate head, and possibly eye, movements causal from and compensatory to horizontal movement of the visual surround.

47.4 BASAL OPTIC PROJECTION IN THE FROG (Rana pipiens). Edward R. Gruberg and Keith L. Grasse*. Res. Lab. of Electronics, Mass. Institute of Technology, Cambridge, Mass. 02139 and Psychology Dept., Dalhousie Univ., Halifax, Nova Scotia.

We have investigated the physiology and anatomy of the basal optic projection (BOP) using single-unit extracellular recording and HRP injections.

With the animal on its back and using a ventral penetration through the upper mouth, we have been able to record routinely single units in the BOP which are driven primarily by the contralateral eye. We have found 3 classes of units: 1) those responsive to stimuli moving in a vertical direction, 2) those responsive to stimuli moving in a horizontal direction, 3) those responsive to changes in ambient light but not to moving stimuli. All directional units have significant maintained activity. Vertical units increase firing to either slow upward movement or slow downward movement; stimulus motion in the opposite direction gives a reduced response. Horizontal units increase firing either to slow naso-temporal movement or to slow temporo-nasal movement. They, too, give reduced responses in the opposite direction. All these units yield broad tuning curves of response vs direction. A wide variety of sizes and shapes of stimuli elicit responses. The best response is obtained for most units when stimuli are moved with angular velocity in the range of 0.1° to 1°/sec. Those units which did not respond to moving stimuli had maintained activity that was greater in the dark than in the light.

For HRP injections, electrophysiological recordings were first made to ascertain location and depth of the BOP in each animal. Since the target region is very small, we injected HRP solution in volumes of 1/2 nl or less. We have followed efferent fibers from the BOP through the posterior commissure to the opposite side. We have also followed a set of stained fibers which course caudally through the ipsilateral ventral medulla. We have not been able to trace the terminal fields of either set of fibers. We have found ipsilateral afferent projections to the BOP from 3 principal areas: the posterolateral tegmental field, the posterior nucleus of the thalamus, and a wide extent of the ventral thalamus particularly in the anterior part. HRP-filled cells in the retina are primarily found in the ganglion cell layer; however, in keeping with Montgomery et al (1979), some large displaced ganglion cells are also stained.

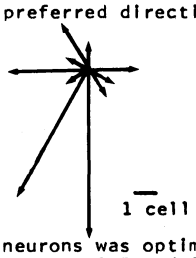
47.5 DIRECTIONAL SELECTIVITY IN THE MEDIAL TERMINAL NUCLEUS OF THE CAT. Keith L. Grasse* and M. S. Cynader (SPON: J. Rutherford). Psychol. Dept., Dalhousie University, Halifax, Nova Scotia, Canada.

Single unit recordings were made from 30 cells in the medial terminal nucleus (MTN) of the accessory optic system in anesthetized, paralyzed cats. Receptive field sizes were very large and located primarily in the contralateral, and to a lesser extent, ipsilateral visual fields. Most cells were found to be contralaterally driven and responsive to chiasmatic stimulation. In response to a 40° x 40° square wave grating pattern (period 8°) moving in a direction normal to the stripe orientation, the majority of cells exhibited marked directional selectivity. Typically, a unit's response consisted of an excitation exceeding the resting discharge by 2-3 times for movement along one axis, coupled with an inhibition which could fall to 1/2 to 1/3 of the maintained rate for motion in another direction. The general axes of preferred directions were:



The activity of MTN neurons was optimally modulated at stimulus velocities between 0.5 and 10°/sec. Local targets such as small light bars proved to be ineffective stimuli for these cells. A variety of diffuse light sensitivities were seen for the directional units ranging from 'on' or 'off' to 'on-off'. An additional but much smaller population of cells was also found (8 cells) which were responsive to chiasmal shock and some aspect of diffuse light stimulation, yet showed no directional properties. Taken together, the large receptive fields, slow velocity specificity and marked directional selectivity are reminiscent of visual units reported in the NOT of the cat. Unlike those units, however, the cells of the MTN mostly prefer the vertical down direction.

47.6 BRAINSTEM PROJECTIONS TO THE CAT'S LATERAL POSTERIOR-PULVINAR THALAMIC COMPLEX. M.Rodrigo-Angulo* and F. Reinoso-Suárez. Departamento de Morfología, Facultad de Medicina, Universidad Autónoma, Madrid-34, Spain.

The lateral posterior-pulvinar thalamic complex (LP-Pu) has been considered as a nodal link in the extrageniculate pathways of the visual system toward the posterior association cortex. It is known that the LP-Pu receives fiber projections from the superior colliculus, pretectum and cerebral cortex. Other roles attributed to this complex have been the following: 1) a nucleus of the so-called 'dorsal spindle system', 2) a station in the most important path mediating the thalamocortical volleys which trigger the penicillin epileptic burst and 3) a participant in the integration of some motor activities. These functions suggest the existence of a broad spectrum of brainstem projections to the LP-Pu. With the aim of studying these brainstem afferents we have made stereotaxic injections of 0.04-0.10 ul of a solution of HRP in the various parts of the LP-Pu in adult cats. After a survival time of 40-48 hr. animals were perfused and brains processed according to Mesulam (1978) technique to reveal HRP brainstem neurons. The injected HRP was always confined to the LP-Pu. Fairly large numbers of labeled neurons were found in some or all of the following brainstem and cerebellar formations: 1) the pretectum, 2) the superficial and/or the deep layers of the superior colliculus, 3) the nucleus tegmenti pedunculo ponti, 4) the locus coeruleus complex, 5) the lateral cerebellar nucleus. Likewise scattered labelled neurons can be found in 6) the central gray matter, 7) the oculomotor nucleus, 8) the mesencephalic raphe nuclei, 9) the dorsal oral pontine tegmentum, 10) the dorsal tegmental nucleus, 11) the nucleus incertus and 12) the nucleus praepositus hypoglossi. The topographical selectivity of these findings depended both on the size and the location of the injection. Control injections were made in the neighbouring thalamic nuclei. These findings of a widespread origin of brainstem projections to the LP-Pu, and specifically those coming from the ponto-mesencephalic tegmentum, can provide a morphological substrate for the functions described above that have attributed to the LP-Pu.

Supported by Grant from CAICT n° 3021/76.

47.7 VISUAL CORTICAL AND SUBCORTICAL CONNECTIONS OF THE CENTRAL LATERAL NUCLEUS IN THE CAT. Elin F. Spring and Alan C. Rosenquist. Dept. Anat., School of Medicine, University of Pennsylvania, Philadelphia, Pa. 19104

Using the horseradish peroxidase (HRP) retrograde tracing technique, we have studied the connectivity of the central lateral nucleus (CL) of the intralaminar thalamic group with subcortical structures and electrophysiologically defined visual cortical areas in the cat (Tusa et.al., 1978). In a first set of experiments, we mapped visual receptive field locations using a micropipette filled with an HRP/tritiated leucine mixture. This recording technique was used to guide the placement of 0.05-0.10 ul pressure injections into visual cortical areas 17, 18, 19, 20a, 20b, 21a, AMLS, ALLS, PMLS, PLLS, DLS, and VLS. In a second series of experiments, we made similar injections stereotaxically which were confined primarily but not exclusively to CL. The tissue was processed for HRP histochemistry using the chromagen o-dianisidine.

We observed HRP-labelled neurons in the ipsilateral CL after injections into each of the above visual cortical areas except 17. We found no evidence for any retinotopic organization in the CL projections to visual cortex. After injections into the CL, a number of subcortical structures were found to contain HRP-labelled neurons. These included the stratum griseum intermedium and stratum griseum profundum of the superior colliculus, the nucleus of the optic tract of the pretectum, the periaqueductal grey of the midbrain, the periventricular grey of the pons, and the pontine tegmentum.

We conclude that CL projects to all visual cortical areas that we have studied except area 17 and that these projections are not retinotopically organized. Further, it is likely that cells in CL which project to visual cortex convey information from subcortical structures such as the pretectum and superior colliculus. This may represent another parallel pathway for visual and non-visual information to reach visual cortex. (Supported by 5T32 GM07517 and 1R01 EY02654).

47.8 SUPERIOR COLLICULUS NEURONS WHICH PROJECT TO THREE THALAMIC NUCLEI IN THE CAT. J.V. Harrell*, R.B. Caldwell, L.H. Reed*, and R.R. Mize. Department of Anatomy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163

We have quantitatively examined the cells of the cat superior colliculus which project to the ventral lateral geniculate (VLG), dorsal lateral geniculate (DLG), and lateral posterior (LP) nuclei of the thalamus. Cells were labeled following HRP injections made 24 hours prior to sacrifice. Four parameters were measured. Topographic distribution was studied by plotting cell location on projection drawings. Cell depth was measured with an eyepiece reticule. Cell area was measured using a computer controlled digitizer. Estimates of cell type were made from camera lucida drawings based on criteria used in Golgi studies.

Our results show that superior colliculus neurons which project to all three thalamic nuclei vary dramatically in depth, size, and morphology. On the other hand, differences between the three groups can be demonstrated quantitatively for these three parameters. Depth: 248 cells labeled after VLG injections ranged in depth from 51-1472 μm (mean=375 μm). After DLG injections, 364 labeled cells were 67-2247 μm deep (mean=502 μm). 107 cells labeled after LP injections ranged in depth from 120-2141 μm (mean=627 μm). Area: Cells projecting to VLG had a mean area of 142 μm^2. Cells projecting to DLG had a mean area of 165 μm^2. Cells projecting to LP had a mean area of 243 μm^2. Morphology: Four morphologies were distinguished. The number of labeled vertical and horizontal cells was relatively constant in all three groups. By contrast, the VLG group had many labeled granule cells and few labeled stellate cells. The DLG group had fewer labeled granule and more labeled stellates. The LP group had the highest percentage of labeled stellates and the lowest percentage of labeled granule cells.

Three conclusions can be drawn from these results. 1) There is no strict laminar segregation of cells projecting to the three thalamic nuclei as reported in other species. Cells throughout the superficial gray and optic layers project to all three nuclei. A few projection cells lie even deeper. 2) No single cell class projects exclusively to any one of these thalamic nuclei. All three nuclei receive colliculus efferents from cells with several differing morphologies. 3) There are clear differences in the weighting of the inputs to the three nuclei. VLG projection cells are on average the smallest and most superficial, and many have a granule morphology. LP projection cells are on average the largest, deepest, and many have a stellate morphology. The DLG projection group is intermediate in size, depth, and percentage of cell types. These gradients must reflect differences in the functional input to the three nuclei (Supported by EY-02973).

47.9 REGIONAL DIFFERENCES IN THE RETINORECEPTIVE LAYERS OF PIGEON OPTIC TECTUM. T. A. Duff, G. Scott* and R. Mai*. Depts. of Surgery (Neurosurgery) and Anat., Univ. Wisc., Madison, WI 53792.

We previously described a regional variation in the size of pigeon retinotectal axons, characterized by a population of small fibers arising from temporal retina and projecting to anteroventral tectum (avT) and a more heterogeneous collection arising from nasal retina and projecting to posterodorsal tectum (pdT). Because of these findings, we undertook an ultrastructural investigation of the retinoreceptive layers (2-7) in avT and pdT and have found a number of regional differences in the morphology of optic terminations and of their post-synaptic elements.

The most obvious ultrastructural difference between avT and pdT is the presence of large, primarily horizontally-oriented dendrites in the latter region. These dendrites are most conspicuous from the upper boundary of layer 2 to the superficial aspect of layer 4. In order to quantitate the difference in dendritic size, tracings were made of the perimeters of all dendrites, excluding those clearly cross-sectioned in a tangential manner, within 1000 μm^2 sample areas of layers 2-3; mean dendritic diameter in pdT was 0.77 μm and in avT was 0.43 μm. Measurements were also made of all dendrites with which one or more optic terminals formed synaptic junctions, defined by the presence of a post-synaptic density. The mean diameter of such dendrites in pdT was 0.75 μm and in avT was 0.51 μm.

In order to quantitate possible differences in bouton size, tracings were made of each sectioned optic terminal, or when grouped, of an entire islet, within 1000 μm^2 areas from the midportion of each of the retinoreceptive layers. No clear differences in these size measurements was seen among layers within either tectal region, but mean diameter values in pdT were uniformly larger than those in avT: (1.14 μm vs. 0.78 μm).

A more detailed analysis of synaptic organization was made within layer 5. Specifically, the number of post-synaptic elements contacted by each terminal or, when grouped, by the entire islet, was counted within 1000 μm^2 areas, and the mean values for avT and pdT were 1.12 and 1.87 respectively.

The regional differences in optic terminations and in tectal dendritic size show interesting parallels to the variation in retinal fiber input, providing evidence that anatomical, and presumably functional, differences extend beyond the mere transmission of information from the eye to the optic tectum. The architecture of pdT suggests a circuitry which imposes relatively greater dispersion of retinal input at least at the initial synaptic level and which may be designed to enhance the detection of movement stimuli.

47.10 SENSORY REGIONS OF THE CAT'S CLAUSTRUM: AN ANATOMICAL AND PHYSIOLOGICAL STUDY. C.R. Olson* and A.M. Graybiel (SPONS: W.J.H. Nauta) Dept. Psychology, Mass. Inst. of Technology, Cambridge, MA 02139.

In axon transport experiments, we have identified regions of the claustrum related to the somatic sensory and visual cortex. We explored these regions in electrophysiological mapping experiments. The findings suggest that specific subregions of the cat's claustrum are specialized for processing visual and somesthetic information within the context of topographic maps.

Primary visual cortex projects densely to a small dorsocaudal region of the claustrum. Neurons recorded in this division responded exclusively to visual stimulation, were binocular (except in the monocular crescent) and had receptive fields ranging from a few to a few hundred deg^2. The region was organized retinotopically. During downward traverses through its center, receptive fields progressed from the extreme contralateral periphery to the midline. Lower fields were plotted in more rostral tracks. Regions mapping the upper and lower peripheries were not found but could exist in compressed form. We used the distinguishable retrograde (and anterograde) tracers nuclear yellow (NY*) and horseradish peroxidase (HRP) and also ^{3}H-amino acids (^{3}H-AA) to study the connections of this region. 1) ^{3}H-AA deposits in claustrum labeled all layers of ipsilateral area 17 and peristriate cortex, with dense label in layer I; they also weakly labeled visual cortex contralaterally. 2) Claustral projections to areas 17, 18 and 19 appeared to arise from neurons organized retinotopically and in register: tracers injected into different parts of area 17 labeled nonoverlapping slabs in claustrum, whereas largely overlapping uptake occurred when retinotopically matched regions of two cortical areas were injected. 3) NY deposits in claustrum labeled neurons in layer VI of area 17; HRP injected simultaneously into the LGN_d labeled an almost totally distinct set of layer VI cells. 4) Injections of HRP or ^{3}H-AA in area 17 labeled the part of contralateral claustrum representing the visual-field midline.

In parallel tracer experiments we found that primary somatic sensory cortex is reciprocally connected with a rostral zone of the claustrum. Double-label findings showed that the claustrocortical projection is somatotopic at least along the body's longitudinal axis. Neurons recorded in somatosensory claustrum responded to moderate pressure applied to restricted areas of the contralateral body surface. Somatotopic ordering was present, with hindparts dorsal, foreparts and face ventral.

We have not detected HRP in the claustrum following injections in primary auditory cortex (AI).

*We thank Drs. H. Loewe and O. Dann for fluorescent tracers. Supported by NIH R01EY02866-02, EY05316-01 and NSF 5T32GM07045.

48.1 AFFERENT INPUTS TO THE CAT'S MOTOR CORTEX FROM AREA 5: A PHYSIOLOGICAL STUDY. O. Favorov*, R. S. Waters, A. Mori* and H. Asanuma. The Rockefeller University, New York, N. Y. 10021.

In this study we examined the physiological characteristics of neurons lying along the caudal bank of the ansate sulcus (area 5) that were activated from sites around the pericruciate region of the motor cortex (area 4γ). Under halothane anesthesia the motor and parietal cortices were exposed and a double-barreled closed chamber was installed over the skull. Through the anterior chamber an array of 8 microelectrodes, 1.5 mm apart, was driven into the motor cortex and fixed at a depth of 1.2 mm. Receptive field and muscle response information was obtained for each electrode in the array. Through the posterior chamber, a single microelectrode was driven down the caudal bank of the ansate sulcus while intra-cortical microstimulation (ICMS) was delivered through the motor cortex electrodes. Whenever an activated neuron was encountered within the area 5 the responsible stimulating electrode was identified and its receptive field was examined and compared with the receptive fields of neurons around the stimulating electrode in the motor cortex.

Altogether, 99 neurons were activated in area 5. Of these neurons, 65% were antidromically activated, 7% were orthodromically activated, and 28% were unclear. Of the antidromically activated neurons, 32% had clear receptive fields. In the majority of these cases the receptive fields of neurons projecting to the forelimb area of the motor cortex were confined to only a part of that limb, while 26% had much broader receptive fields. The projection of neurons in area 5 was restricted to a small region of the motor cortex, since no cases were found in which the same area 5 neuron could be activated from more than one stimulating site. There were small clusters of neurons of similar receptive fields around the ansate sulcus, which were activated from two or more sites in the motor cortex.

In 18 cases receptive field information was obtained from both motor cortex neurons around the stimulating electrode and area 5 neurons. They were classified into three categories: (a) overlapping-identical (44%), (b) contiguous (28%), and (c) non-contiguous (28%). The projections to motor cortex from antidromically activated neurons along the caudal bank of the ansate sulcus appear to be organized in the following manner: neurons in the deep part of the medial ansate gyrus and neurons at all depths in the lateral ansate gyrus project to the paw and forearm region of the motor cortex, while those in the upper and middle bank of the medial ansate gyrus project more diffusely throughout the entire motor cortex.

Supported by NIH Grant NS-10705

48.2 PHYSIOLOGICAL PROPERTIES OF CORTICO-CORTICAL CONNECTIONS FROM AREA 2 TO AREA 4γ IN THE CAT.
R. S. Waters and H. Asanuma. The Rockefeller University, New York, N. Y. 10021.

Anatomical studies have shown that HRP injected into the forelimb region of motor cortex is retrogradely transported to a number of cortical sites including somatosensory area 2. In the present study, we examined the physiological properties of the cortico-cortical connections between area 2 and area 4γ. Under halothane anesthesia, a double-barreled closed chamber was installed over the sensory and motor cortices. An electrode holder housing 8 microelectrodes was placed on the anterior chamber and each electrode was separately inserted to a depth of 1.2 mm below the surface of the cortex. Receptive fields of neurons and muscle responses to intra-cortical microstimulation (ICMS) were examined through each electrode. Through the posterior chamber, a single recording electrode was inserted along the entire bank of the ansate sulcus while delivering ICMS from the 8 electrodes in the motor cortex. Upon isolation of antidromic responses of the sensory neurons the effective stimulating electrode for each neuron was determined and examination was made of the receptive field of the neuron. This receptive field was then compared with that of the neurons around the stimulating electrode. The results could be classified in one of three categories: a) identical receptive fields, b) contiguous receptive fields, and c) non-contiguous receptive fields. In addition, the receptive field was routinely examined throughout each penetration.

Altogether, 157 neurons in 9 cats were antidromically activated by stimulation through the 4γ electrodes. From these neurons, the receptive fields of 44 neurons could be compared to those of cortical neurons located near the responsible electrodes. Of these pairs, 52% had identical receptive fields, 25% had contiguous receptive fields, and 23% had non-contiguous receptive fields. In addition, the ansate region could be subdivided into a medial and lateral division. Projections to motor cortex from the lateral division were generally localized to the forelimb region of the motor cortex, whereas projections from the medial division were more diffuse. In the largest number of cases, but not without exception, area 2 neurons simultaneously recorded from a given depth could only be activated from a single motor cortex electrode. These results will be discussed in relation to our previous report concerning the strength of the connection of the input to the motor cortex from sensory area 3a.

(Supported by the NIH Grant NS-10705)

48.3 SOMATOSENSORY INPUTS TO CORTICO-CORTICAL AND PYRAMIDAL TRACT NEURONS OF CORTICAL AREAS 1 AND 2. P. Zarzecki and D. Wiggin*. Dept. Physiol., Queen's Univ., Kingston, Ont., Canada K7L 3N6.

Neurons of somatosensory cortex may be involved in motor control by way of their projections upon the motor cortex or directly upon the spinal cord. For the purpose of assessing the information which might be carried by these projections, we have investigated cortico-cortical and PT neurons of cortical areas 1 and 2 for inputs from cutaneous and muscle afferents in the Nembutal-anesthetized cat.

Extracellular recordings were made from neurons in areas 1 and 2 which were antidromically activated by microstimulation of the motor cortex (area 4γ) or from the medullary pyramid. Such identified cortico-cortical or PT neurons were tested for influences originating from the following nerves of the contralateral forelimb: deep radial (muscle), superficial radial (cutaneous), median (mixed) and the dorsal cutaneous and palmar (muscle) branches of the ulnar. Nerve stimuli were graded and controls made for stimulus spread between nerves using volleys recorded from proximal nerve trunks. Collision-extinction techniques and nerve-evoked alterations of antidromic spike shape verified that the peripheral inputs influenced the same neurons which projected to the motor cortex or through the pyramidal tract. With these techniques supra- and subthreshold excitatory inputs could be detected.

Most cortico-cortical neurons of areas 1 and 2 were not modality specific. Of 29 cortico-cortical neurons, 27 (93%) showed evidence of excitatory inputs from more than one peripheral nerve; 26 (90%) from both cutaneous and muscle nerves. In addition, most received excitation from dorsal plus ventral (80%), and distal plus proximal (86%) aspects of the forearm.

Pyramidal tract neurons of areas 1 and 2 also receive convergent somatosensory inputs. Excitatory inputs from both cutaneous and muscle nerves reached 13 of 19 PT neurons (68%). Inputs from more than one region of the forearm were evident for 12 (63%).

This extensive convergence is similar to that which we have previously reported for cortico-cortical and PT neurons of area 3a (Neurosci. Abstr. 5, 1979). Whatever their effects upon the motor cortex or the spinal cord, the cells of origin of cortico-cortical and PT projections from somatosensory cortex are potential sites for the integration of information from several somatosensory modalities.

(Supported by the MRC of Canada.)

48.4 NEURONAL TYPES IN THE MOTOR CORTEX OF CATS AS REVEALED WITH INTRACELLULAR HRP-INJECTIONS AND GOLGI METHODS. C.E. Ribak and C.D. Woody. Department of Anatomy, Univ. of Calif., Irvine, CA 92717 and Departments of Anatomy and Psychiatry, Univ. of Calif., Los Angeles, CA 90024.

The pericruciate cortex of cats was studied in Golgi-stained preparations in order to confirm the neuronal types observed following intracellular recording and labelling with horseradish peroxidase (HRP). Pyramidal and non-pyramidal cells were prevalent in both of these preparations. In the Golgi-stained sections, small pyramidal cells were observed in supragranular layers while larger pyramidal cells, including Betz cells, were found in the deeper cortical layers. These pyramidal cells had apical and basal dendrites that displayed numerous spines. Axons arose from the base of these cells, and then descended into the white matter after giving rise to a few collaterals. Some large pyramidal cells in layer V possessed a unique apical dendrite in that one of its thick dendritic branches curved down toward the cell body and then turned upwards. A few dendrites arose from this bowed dendrite, and they ascended toward the pial surface along with the main apical dendrite. In addition, inverted pyramidal cells were observed in the deep cortical layers, and these cells had their apical dendrite directed toward the white matter. In contrast to other pyramidal cells, the inverted cells were largely aspinous. Non-pyramidal cells that were found in all cortical layers were characterized by either spinous dendrites or beaded dendrites with smooth surfaces. The somata of these cells were either round or fusiform-shaped, and their locally-distributed axons arose from dendrites or somata.

Preliminary electron microscopic studies have confirmed the light microscopic appearance of spinous and beaded dendrites in both Golgi-stained and HRP-labelled cortical neurons. In addition, axon terminals were observed to form synaptic junctions with both of these kinds of dendrites. The electrophysiological properties of non-pyramidal cells were compared using intracellular recording methods to determine if different dendritic morphologies correlated with different functional properties. Preliminary data indicate no significant differences in the electrophysiological properties of these cells. In conclusion, the use of both intracellular HRP-injections and Golgi methods has been helpful in identifying the various types of neurons in the motor cortex of cats.

48.5 DISCHARGE OF NEURONS IN CAT MOTOR CORTEX DURING VOLUNTARY MUSCLE CONTRACTION. D. Vicario, J. Martin* and C. Ghez. Div. of Neurobiol. & Behav, Depts. of Physiology & Neurology, Columbia P&S & Rockefeller University, New York, N.Y. 10032.

We have shown that accurate responses with reaction times of 60-70 msec are commonly observed in cats performing an isometric tracking task (Exp. Brain Res. 33:173, 1978). The present study was undertaken to determine if neurons in the motor cortex could contribute to the initiation of such rapid responses to exteroceptive cues.

Cats were trained to apply force isometrically with their forearms to a strain gauge to match a target level which was stepped at random times. They were provided with a display of their force error and responded to target shifts by rapidly adjusting the force applied. Neurons were recorded within areas of motor cortex where microstimulation produced contraction of muscles active during task performance. Projection neurons were identified antidromically from electrodes in the cerebral peduncles; receptive fields and the effects of microstimulation (under 20 μa) at recording sites were routinely determined.

Task related units recorded in the pericruciate cortex of three cats could be divided into two groups. The majority (85%) modulated their activity after response initiation. Most of these neurons had clear superficial or deep receptive fields in the forelimb, to which their activation could be attributed. The remainder showed changes in activity preceding (mean: 30 msec) the contraction of agonist muscles (lead cells). Such neurons either were not clearly driven by peripheral stimuli, or had receptive fields with complex features (directional specificity, temporal lability, multiple foci etc). Neurons with these properties were characteristically located at anterior sites in the pericruciate cortex, suggesting functional specialization.

Eighty percent of lead cells were antidromically driven from the cerebral peduncles. Their task-related discharge reflected both the direction and magnitude of force exerted. Equal numbers of cells varied their activity with the level of force, its first derivative, or both. This distribution is similar to that reported for motor cortex neurons in the monkey and differs from the predominantly phasic properties previously shown to characterize red nucleus neurons in the cat. In short reaction time movements (60-70 msec), task related activity of lead cells occurred 30-40 msec after the change in target location. The latency of this activity is comparable to that of the "intended response" of neurons in the primate motor cortex to proprioceptive inputs (Evarts & Tanji, J. Neurophysiol. 39:1069, 1976) and supports the notion that similar mechanisms underlie voluntary responses with the most rapid reaction times, irrespective of the stimulus modality (Exp. Brain Res. 33:173, 1978).

48.6 INTRACORTICAL SEIZURE PROPAGATION IN EXPERIMENTAL FOCAL EPILEPSY. M. David Fairchild*, Patricia R. Callahan* and John A. Kusske. Division of Neurological Surgery, University of California, Irvine, CA 92717

To study the patterns of seizure propagation within vertical cortical columns neuronal activity has been recorded from the midportion of the suprasylvian gyrus of cats subsequent to the placement of four tungsten microelectrodes into the cortex; the tip of each successive microelectrode positioned 350 micra deeper than the one above it. Recordings were obtained from a column extending from the most superficial to the deepest layers of the cortex. Histological controls were utilized to confirm electrode position. Periodic, recurring of afterdischarge was produced by electrical stimulation of the homotopic, contralateral cortex utilizing bipolar silverball electrodes. Both multineuronal unit activity and slow waves were recorded on magnetic tape; the time course of seizure activity was studied by transcribing the magnetic tape records on paper by means of a Honeywell Visicorder. Triggered correlations of unit activity and field potentials recorded by each electrode were performed utilizing a PDP 11/20 computer. The multineuronal unit activity was passed through voltage discriminators so that two populations of units from each channel were analyzed. In preseizure recordings it was unusual to detect spontaneous unit activity in all electrodes simultaneously; usually activity was recorded on one or two electrodes of the four and in most instances it was unit activity of low amplitude. Seizures were characterized by the spread of ictal activity from the deeper layers of the cortex to the most superficial; usually burst firing was detected in the deepest layers first with subsequent involvement of the more superficial layers. Latencies in the range of 5-8 msec were also observed between bursts and their accompanying field potentials recorded in deeper cortical layers as compared to similar activity recorded in superficial layers. Units, with large potentials, were recorded subsequent to the onset of the seizure while the units of lower amplitude often stopped discharging following the appearance of the afterdischarge. As each seizure progressed in time the latencies observed between activity recorded in deeper layers and superficial layers disappeared and a marked degree of synchronous discharge was noted at all cortical levels.

This preparation serves a useful role in the study of the spread of ictal activity through the cortex and allows for a quantitative description of the nature of neuronal activity at various cortical depths during the spread of a seizure into otherwise normal cortex.

48.7 A REMOTE EFFECT TO A FOCAL INJURY OF THE CORTEX. W.G. Dail, D.M. Feeney, H.M. Murray, R.T. Linn and M.G. Boyeson. Depts. of Anatomy and Psychology, Univ. of New Mexico, Albuquerque, NM 87131.

The morphological reaction of the brain to injury has been well-documented. Typically, attention has been focused on the fate of cells in the area of necrosis and in the reaction of neurons and glia immediately adjacent to the area of focal necrosis. Less is known of the reaction to neurons and glia which are distant to the site of primary injury. As a part of a broader study of the reaction of the brain to injury, we report here an interesting loss of the activity of an enzyme in areas quite remote from the site of direct injury. Craniotomies were performed over the hindpaw area of the motor cortex of rats. Weights which produced a known force were dropped on the cortex to produce a contusion injury while the cortex was undercut to produce a laceration injury. Both types of injury produced a well-defined and reproducible area of necrosis in the underlying cortex. The most notable feature of the injury site was the gradual appearance of a cavity bordered by cells reactive for acid phosphatase. At 36 hrs following the injury, a peculiar loss of staining for the enzyme alpha-glycerophosphate dehydrogenase (α-GDPH) was noted. α-GDPH activity was markedly depressed in cortical layers II and III on the side of the injury. Although the cavitation site was in the hindpaw area of the motor cortex, loss of staining occurred throughout the hemisphere. The depression of α-GDPH activity extended far laterally across the rhinal fissure into the pyriform cortex. A similar loss was seen in the anterior-posterior extent of the hemisphere. The decrease in α-GDPH staining was prominent four days after the injury; however, the staining pattern had returned to normal at nine days. To determine if the response was peculiar to an injury of the motor cortex, additional animals were lesioned in the occipital cortex. The reaction in these animals paralleled that seen in animals with a lesion in the motor cortex. Further studies were performed to determine if an area of the cortex which had received an earlier lesion would show a specific loss of α-GDPH activity after a second lesion. Animals which had received an undercut lesion in the motor cortex 56 days earlier were contused in the occipital cortex. The old injury site presented the same sequelae of changes as seen in other lesioned animals. Additionally, a suction ablation injury involving only a small part of motor cortex resulted in the same widespread reduction of staining for α-GDPH in layers II and III. The derangement in energy metabolism suggests that cells in layers II and III of the cerebral cortex may be particularly vulnerable to perturbations induced by cortical trauma. These findings may be related to the diffuse and transient functional losses observed in head injury in man. (Supported by NIH Grant NS13684-02.)

48.8 COOPERATIVITY IN BRAIN FUNCTION: ASSEMBLIES OF 30 NEURONS. Gordon L. Shaw, Physics Dept., Univ. of California, Irvine, CA. 92717, Erich Harth, Physics Dept., Syracuse, Univ. Syracuse, N. Y. 13210 and Arnold B. Scheibel, Anatomy Dept., Univ. of California, Los Angeles, CA. 90024.

One of the most intriguing features of higher brain function is the occurrance of considerable fluctuations in spike train responses of individual neurons to a repeated, specific "meaningful" stimulus in situations where there is a reliable behavioral response. We propose that the brain deals with these neuronal fluctuations in the cortex by the cooperative interaction of assemblies having a minimum of roughly 30 pyramidal cells. These small assemblies then form the fundamental subunits of neural networks (as in the organizational scheme of Mountcastle, V. B., Neurosc. Fourth Study Program, 1979, p. 31) and provide the basis for a) statistical reliability, b) safety factor against local damage and c) maintainance of firing activity for ~sec in the network. Our suggested minimum of ~30 neurons is roughly an order of magnitude smaller than previous estimates of assembly size (e.g. ,Hebb, D. O., The Organization of Behavior, 1949). We present six, separate arguments to support this minimum number of ~30: 1) Number of repeated stimuli presentations needed to obtain reproducible post stimulus histograms. 2) Number of pyramidal neurons in an orientation column. 3) Number of apical dendrites in a dendritic bundle (Roney, K. J., A. B. Scheibel and G. L. Shaw, Brain Res. Rev. 1, 225 (1979)). 4) Analytical calculation of assembly size from a memory storage model (Shaw, G. L. and Roney, K. J. Phys. Lett. 74A 146 (1979)). 5) Computer calculation on maintainance of firing activity in the network versus assembly size (Harth, E., N. S. Lewis and T. J. Csermely, J. theor. Biol. 55, 201 (1975)). 5) Reliability calculation comparison showing size for which a stochastic system dominates over a deterministic system of neurons (Lewis, N. S., Ph.D. Thesis, Syracuse Univ., 1974). We discuss the experimental and theoretical significance in brain function of these small assemblies. Finally, we speculate on the "purpose" of the neuronal fluctuations as related to fast switching from one sustained firing response to another.

48.9 ENTROPY CORRELATIONS WITH DRUG-INDUCED CHANGES IN SPECIFIED PATTERNS OF NERVE IMPULSES: EVIDENCE FOR "BYTE" PROCESSING IN THE NERVOUS SYSTEM. C. J. Sherry and W. R. Klemm. Dept. of Biology, Texas A & M Univ., College Station, TX 77843.

Entropy, a major information theory descriptor, was calculated on the basis of relative interval coding techniques that encode the serial relationships of 2-5 neuronal action potential intervals as a series of symbols (+, 0, -). Entropy was used to determine the relative amount of 'information' associated with each symbol or set of symbols. It was also used to describe the relative amount of 'information' associated with the relative positive of a specific symbol in a string of symbols.

Average entropy, percent total entropy, and the variability of entropy (standard deviation, coefficient of variation) all correlated with the number of patterns (symbol groups) whose probability of occurrence changed in a statistically significant way in response to ethanol injections. Thus, the overall 'message', or at least the change in the message, induced by ethanol, seems to be encoded by the relative changes in the probability of occurrence of certain quadgrams (i.e. the grouping of four symbols based on the serial relationships of 5 intervals). The ethanol-induced 'message' may be based on the combination of certain quadgrams that increase in incidence and those that decrease in incidence (i.e. the quadgrams whose incidence changes in opposite directions may be 'linked' in some way). This suggests some higher order pattern analysis or 'byte' processing by neurons in the nervous system.

The fact that the 'message' or at least the change in the 'message' is involved in the complex interactions of a series of 'linked' trigrams (three symbols based on the serial relationships of 4 intervals) or quadgrams, might explain why it has been difficult to extract the signal from the noise and, in fact, why some, particularily those who use non-sequential analysis techniques, believe that inter-spike intervals are all noise.

48.10 A THEORETICAL STUDY OF SPATIAL-TEMPORAL INTEGRATION IN BRANCHING DENDRITIC SYSTEMS. Barry Horwitz, Physics Department, Texas Woman's University, Denton, Texas 76204.

There have been a large number of theoretical studies which have investigated the ways by which single neurons integrate their synaptic inputs to produce a neuronal output. In most of these studies either the spatial distribution of the synapses has been ignored, or else the temporal differences in the firing of these synapses have been neglected, although a few computer models have dealt with both (e.g., Pellionisz and Llinás, 1977). In general however, there have been few efforts to study spatial-temporal integration analytically, especially in neuronal models in which the dendritic branching pattern can be varied.

I have developed a theoretical method which enables one to calculate analytical expressions for voltage transients at specific locations in neuronal systems with branching dendritic trees. These time-varying voltages are in response to current inputs at one or more other locations in the dendritic trees. Model systems are studied in which we vary parameters associated with the geometry of the tree (e.g., branch lengths, number of sister branches, number of branches distal to a given bifurcation), with the strength of each synaptic input, and with the relative time of firing of each input. A number of examples will be presented which will illustrate how the voltage transient at a given point depends on these parameters. These examples will be used to examine the concept of the dendritic tree as a computational device, and how the computation which occurs depends on spatial integration, temporal integration, synaptic efficacy, and dendritic geometry. I shall also indicate how this method can be generalized to take account of other parameters, especially the electrical cable parameters.

49.1 REGULATION OF RECEPTOR POPULATIONS IN FEEDING. E. Omand and J. Zabara. Temple University Health Sciences Center, Depts. of Physiology and Biophysics, Philadelphia, PA 19140

In that the fly's sensorium consists of single chemoreceptors extending into projecting hairs, it is possible to measure individually the output of numbers of single receptors within an overall population. This can be done in succession, since, for instance, most labellar hairs can be sampled in a single preparation. This results in the response of a single type of distributed receptor, i.e., the sugar, salt or water receptor. We recorded the single unit potentials of the chemoreceptors of the fly (Phormia or Musca) to attempt to determine the response profile of the receptor population. Receptor response was measured by placing a glass micropipette containing the stimulus over a sensory hair on the mouth parts. A second, indifferent, glass capillary electrode containing (Bodenstein's) saline was inserted into the proboscidal sinus. The stimulus was chosen to be largely effective for the sugar, salt or water receptors. Feeding and photophase conditions were altered to determine possible changes in membrane receptor sensitivity. Our results indicate that all receptors of a single type do not respond identically. Rather there is a frequency range of response, including a null, which is characteristic of a critical condition of feeding, photophase or age. In the sugar receptor, the range of frequency response is least after eclosion and for several hours thereafter. The range increases with continued fasting to reach its largest value (100 Hz) at approximately 78 hours after eclosion. This is approximately the upper limit of recording during fasting before morbidity effects set in. Then, after feeding these animals, the range of response decreases to approximately half (50 Hz). In addition, the number of null responses is much greater following feeding. Thus, with fasting, there is not only a greater range of frequency responses, but also, a greater variation of frequency response between receptors. In all conditions, null responses were present, but these decreased greatly as fasting continued. During the course of fasting, the receptors increasingly tend toward higher frequencies. Also, the number of receptors with null responses progressively decreases during fasting. After feeding, there is a marked increase in the number of receptors demonstrating a null response. The increase or decrease in the frequency range and the number of null responses are in direct correspondence. A similar effect to fasting and feeding was observed with light and darkness. The similarities of effects do indicate a similar, or same, mechanism involved in both modalities, which possibly might explain their strong interactive effects. These results support the hypothesis of a regulatory factor which can progressively increase or decrease the sensitivity of the receptors.

49.2 MEMBRANE RECEPTOR POLARIZATION IN FEEDING. J. Zabara and E. Omand Temple University Health Sciences Center, Depts. of Physiology & Biophysics, Philadelphia, PA 19140.

The nature of the regulation of chemoreceptors in feeding is at present unknown. It would appear that irrespective of whether the efferent regulation of the receptor is humoral, ionic or neural, the net effect is to change its response characteristics. A possible experimental approach is based on the assumption that the change in the receptor is related to an alteration of the polarization of the receptor membrane. This polarization might be related directly to a change in the receptor potential. The receptor preparation of the fly offers the advantage here over the mammal in that the receptor potential and membrane impulse discharge can be correlated directly. Single unit and dc potentials were measured by placing a glass micropipette containing the stimulus over a sensory hair on the mouth parts (Musca). Another glass capillary containing (Bodenstein's) saline was inserted into the proboscidal sinus to serve as a second, indifferent electrode. With dc coupling of the amplification system, it is possible to observe a steady potential which represents either the actual receptor potential or the postulated generator current between the receptor and spike initiating sites. In these experiments, a combined dc recording at relatively low amplification to monitor this steady potential is compared with a simultaneous ac recording at relatively high amplification to monitor the spike discharge. The dc potential is initiated by contact of the capillary electrode with the sensillum, and the initial oscillating current (surge) usually observed in ac recordings is absent. The current surge often will block temporarily the preamplifier preventing initial observation of receptor response. This indicates that the current surge oscillation is based on a relatively short time constant of the recording system. The rise of the dc potential apparently represents partially a contact potential between electrode and sensillum. Our observation that the polarization change is of opposite polarity to the spike potential is consistent with a receptor process in this preparation based apparently on a separation between receptor and spike initiation sites. Further, after the rapid, initial rise in potential at electrode contact, a slow, steady increase in the level of polarization (dc recording) parallels a corresponding decrement of impulse frequency. A linear relationship between spike frequency and dc potential change would indicate a direct action of this potential on the spike generation site. This dc potential shift reflects a membrane change which might be the basis of observed receptor sensitivity control. These results are incorporated into a model for the regulation of receptor populations based on an apparent time constant effect in membrane receptor state.

49.3 AFFERENT AND EFFERENT PROJECTIONS OF THE NUCLEUS MEDIANUS: AN HRP STUDY. Victor M. Grazi*, Richard R. Miselis. Animal Biol. Sch. Vet. Med., Inst. Neurol. Sci., Univ. of Pennsylvania, Philadelphia, PA 19104.

The nucleus medianus (NM) of the medial preoptic area is a prominent structure of the anteroventral third ventricular (AV3V) area which is involved in the behavioral and physiological control of water balance. Little is known of its connectivity; however, recent anatomical studies have demonstrated projections from the subfornical organ (SFO) to the NM, and from the NM to the supraoptic nuclei (SON) (Miselis et al. Science, 205:1022, 1979). The connectivity of the NM was examined using horseradish peroxidase (HRP) histochemistry. 100 nl. of HRP (100 ug/ul; Sigma type VI, lot #20F-9600) were injected via a stereotaxically placed 33g cannula aimed for the anterior border of the NM. An anteriorly angled approach was used to avoid disruption of fibers directly above the NM. Ten SD male rats were included in this study and were sacrificed 48 hrs. post-injection. The brains were sectioned at 40 um and processed histochemically using the tetramethyl benzidine procedure. Three animals were injected with a cannula terminating just anterior to the NM. These injections primarily involved the ventral and middle portions of the NM and there was some spread of HRP into the medial septal nuclei (MS) and the nucleus of the vertical limb of the diagonal band (DBB). Both retrograde and anterograde labelling occurred. We observed retrogradely labelled HRP-positive neurons lying peripherally within the SFO, confirming the previously reported projections from the SFO to the NM. These labelled neurons were vertically oriented bipolar neurons. In addition, retrogradely labelled cells were observed in the horizontal DBB, and within the vicinity of the SON, initially lateral to the SON and then dorsolaterally and lastly medial to it at its caudal end. Efferent fibers were observed leaving the injection site and passed along the same trajectory adjacent to the SON where retrogradely labelled neurons were observed. Labelled fibers of passage orient from this area to the SON and terminate just short of it, but sparse terminals within the SON do occur. Terminals from these efferent projections of the NM also occur along this course. Differences and similarities of the projections from the NM from those of the MS and DBB will be discussed. This data further supports the involvement of the NM in the neuronal circuitry of thirst and the physiological control of body fluid balance and extends the description of this neural substrate.
(Supported by the Sloan Foundation, RR-07083, and Grass Foundation).

49.4 GLUCORECEPTORS FOR FEEDING AND HYPERGLYCEMIA: EVIDENCE AGAINST THEIR LOCATION IN THE FOREBRAIN. Peter G. Slusser*, Steven L. Stone* and Robert C. Ritter (SPON: R.W. Clark). Department of Veterinary and Comparative Anatomy, Pharmacology and Physiology, College of Veterinary Medicine, Washington State University 99164 and Department of Veterinary Science, University of Idaho, Moscow, ID 83843.

Intracerebroventricular (ICV) infusion of 2-deoxy-D-glucose (2DG) causes increased feeding and hyperglycemia in the rat. However, the anatomical loci of the receptors which mediate these responses are unknown. The traditional bias toward the hypothalamus as the receptor site is not supported by convincing evidence. In addition, the relatively high molar concentrations of ICV 2DG required to cause feeding and hyperglycemia limit the usefulness of this analogue in the search for the glucoreceptors. Recently, we have demonstrated that ICV infusion of 5-thioglucose (5TG) is 10 to 100 times more effective than 2DG for eliciting feeding and hyperglycemia. Therefore, we have been using 5TG in a series of experiments designed to localize the brain glucoreceptors which mediate feeding and hyperglycemia. We have compared the feeding and hyperglycemia produced by lateral ventricle infusion of 5TG, with that which occurs in response to fourth ventricular infusion. Furthermore, we have examined the effect of lateral ventricle infusions of 5TG prior to and subsequent to blockade of the cerebral aqueduct with silicone plugs. We have found that fourth ventricular infusions of 5TG (45, 90, or 180 µg/3 µl) cause greater elevations of blood glucose than do lateral ventricle infusions. Also, we have found that rats which feed in response to lateral ventricle infusion of 5TG prior to occlusion of the cerebral aqueduct fail to respond after aqueductal occlusion. Rats with aqueductal obstruction also fail to exhibit hyperglycemia in response to lateral ventricle infusion of 5TG. Aqueduct-obstructed rats do exhibit both feeding and hyperglycemia in response to subcutaneously injected 2DG. Our data suggest that the brain glucoreceptors which mediate glucoprivic feeding and hyperglycemia may not be located in the forebrain. Rather, these receptors may be located in the vicinity of the fourth ventricle. Experiments in progress are designed to test this hypothesis.

49.5 CONTRIBUTIONS OF PERIVENTRICULAR STRUCTURES OF THE ROSTRAL THIRD VENTRICLE TO THE MAINTENANCE OF DRINKING RESPONSES TO HUMORAL DIPSOGENS AND BODY FLUID HOMEOSTASIS. E.E. SHRAGER* & A.K. JOHNSON (SPON: L.D. MITCHELL). Dept. of Psychol., Univ. of Iowa, Iowa City, Iowa 52242.

Both the subfornical organ (SFO) and the periventricular tissues surrounding the anteroventral third ventricle (AV3V) have been implicated in the regulation of body fluid homeostasis and, in particular, the drinking responses to specific humoral stimuli, e.g., angiotensin(AII) and hypertonic saline (HTS). Moreover, neural and vascular connections between these regions have been reported. The purpose of the present analysis was to compare the effects of systematic ablation of subsections of tissue along the dorso-ventral extent of the rostral third ventricle on the drinking responses to AII and HTS. The acute effects of differential brain damage on ad lib water intake and fluid related body weight loss were also examined.

Rats were screened presurgery to 4 doses each of subcutaneously administered AII and HTS. Subjects were then divided into 4 lesion groups: 1) Dorsal placements in which electrodes were aimed at the SFO; 2) Midrostral placements aimed to include the median preoptic nucleus (MnP); 3) Ventral placements in which electrodes were directed at the organum vasculosum of the lamina terminalis (OVLT); and, 4) Sham lesions. Approximately 6 wk. after surgery all surviving subjects were again tested to the range of doses of AII and HTS.

Lesions of the ventral-rostral third ventricular region, but not the MnP or SFO regions, produced severe adipsia and associated weight loss. This was the only lesion placement which resulted in terminally adipsic animals. Dose-response analyses for drinking to AII and HTS indicated that damage limited to the ventral level produced no long term response deficits to these thirst challenges. Lesions at both the level of the MnP and of the SFO produced deficits to AII but not HTS.

These data support the independence of the drinking responses to AII and HTS and indicate, furthermore, that the acute period of adipsia associated with AV3V lesions is independent of chronic deficits to either humoral dipsogenic stimulus. The results suggest that initially, adipsia may reflect a primary disruption of thirst mechanisms but that extended adipsia may be largely related to the dehydration which results from the inability to conserve fluid. Finally this study found that tissue of both the SFO and the MnP are necessary, but neither alone is sufficient, for the maintenance of the drinking response to systemically administered AII. (USPHS NIH HLP-14388 & 1 RO1-HL24102; NIMH 1-KO2-MH00064).

49.6 TRANSIENT APHAGIA FOLLOWING LESIONS TO QUINTO-FRONTAL TRACT IN GROWING CHICKS. Wayne J. Kuenzel*(SPON: S. Brauth). Dept. of Poultry Science, University of Maryland, College Park, MD 20742.

The quinto-frontal tract (QFT) is reported to be a critical structure controlling feeding behavior in the pigeon. Lesions of quinto-frontal structures produce periods of aphagia ranging in duration from several days to several weeks (Zeigler, H.P. and H. J. Karten. J. Comp. Neurol., 152:59, 1973). The QFT and adjacent neural structures were ablated in growing chicks, Gallus domesticus, to evaluate their effects on food intake.

Three groups of chicks (2-3 weeks of age) were bilaterally lesioned using stainless steel insect pins (#1), anodal D.C., 1 mA for 15 or 30 sec. A fourth group served as sham-operated controls. An unpublished chick atlas was used to direct lesions to three areas of the brain: QFT near mid-hypothalamus, far-lateral hypothalamic area, and posterior hypothalamic-midbrain region. Group 1 was designated QFT chicks. Stereotaxic coordinates used were comparable to A 7.5, D 4.0, L 2.0 published for adult hens (vanTienhoven, A. and L. Juhasz. J. Comp. Neurol., 118:185, 1962). Group 2 included the far-lateral hypothalamic chicks. Stereotaxic coordinates used were comparable to A 7.5, D 3.5, L 2.5 (vanTienhoven and Juhasz, 1962). Group 3 was designated the posterior hypothalamic-midbrain chicks. Coordinates used were comparable to A 4.5-5.0, D 2.5, L 1.75 (vanTienhoven and Juhasz, 1962).

The QFT chicks (n = 6) were aphagic for an average of 3.7 days, lost 15.7% body weight, and took an average of 5 days to return to their pre-operational weight. Neural structures damaged included the QFT, ansa lenticularis (AL), n. intercalatus (IC), stilus corpus geniculatus (SG), and lateral hypothalamic n. (LH). The far-lateral hypothalamic chicks (n = 5) were aphagic for 1.2 days and lost only 6.8% body weight. Neural structures damaged included the ventrolateral geniculate body (GV), SG, IC, AL, n. entopeduncularis superior (ES) and the medial portion of the n. rotundus (ROT). The posterior hypothalamic-midbrain chicks (n = 6) were aphagic for 5 days, lost 24.0% body weight, and took an average of 7 days to return to their pre-operational weight. Neural structures damaged included the QFT, AL, and stratum cellulare externum (SE).

It is concluded that large bilateral lesions are necessary to render growing chicks aphagic. Although QFT lesions disrupt feeding behavior, more permanent aphagia occurs when other structures are destroyed concurrently such as the AL and SE.

49.7 ALTERED DIETARY PREFERENCE BUT NORMAL CALORIC REGULATION IN RATS WITH AREA POSTREMA LESIONS. Robert C. Ritter and Gaylen L. Edwards. Department of Veterinary Medicine, University of Idaho, Moscow, ID 83843 and Department of VCAPP, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

The area postrema (AP) is a circumventricular organ (CVO) of the caudal brain stem. We have previously shown that lesions of the AP cause rats to over-ingest a preferred diet during short (30 min) tests (Edwards, G. and Ritter, R., Neurosci. Abstr., Vol. 5, p. 215, 1979). In subsequent studies, we have found that AP-lesioned rats also ingest significantly more than intact rats when offered 23.7% glucose during 30 min ingestion tests. These results suggested an enhanced responsiveness to preferred tastes in AP-lesioned rats. The results presented below were obtained in order to determine whether exaggerated ingestion of a normally preferred diet by AP-lesioned rats had any consequences for their caloric regulation. Male AP-lesioned and intact rats ingested virtually identical amounts of lab chow and water ad lib or after 21 hr food deprivation. When given continuous ad lib access to lab chow and a preferred liquid food (milk-instant breakfast), AP-lesioned and intact rats displayed the same total caloric intake. However, intact rats consumed 40% of their calories as lab chow, whereas lesioned rats took at least 90% of their calories as instant breakfast and virtually ignored the lab chow. This difference between the two groups of rats was apparent immediately upon presentation of the preferred diet and persisted for the entire 14-day conduct of the experiment. When caloric concentration of the liquid diet was halved or doubled, both groups adjusted their intake and kept caloric consumption constant. However, under both calorically diluted or concentrated conditions, the lesioned rats ate more liquid diet than intact rats and consumed very little lab chow.

Our data demonstrate that over-ingestion of a preferred diet by AP-lesioned rats persists when that diet is continuously available. Our results also suggest that caloric control of intake is not disrupted in AP-lesioned rats. The findings reported here and those previously reported raise the possibility that the AP's role in the control of ingestive behavior may be to modulate responsiveness to taste cues rather than to adjust caloric intake.

49.8 FEEDING DEFICITS FOLLOWING LESIONS TO THE AREA POSTREMA AND ADJACENT PORTIONS OF THE NUCLEUS OF THE SOLITARY TRACT. Thomas M. Hyde* and Richard R. Miselis. Dept. of Anatomy, Sch. of Med. and Sch. of Vet. Med., University of Pennsylvania, Phila. PA 19104.

The area postrema (AP), a circumventricular organ, lies caudal to the 4th ventricle and dorsomedial to the nucleus of the solitary tract. The AP lacks a blood-brain and a total CSF-brain barrier making this structure a suitable receptor for substances in the blood or the CSF. There is a reciprocal connectivity between the AP and NTS. The subdiaphragmatic vagal afferents may project directly into the AP and to the NTS ventrolateral to the AP. These features suggest a role for the AP in ingestive behavior either as a chemoreceptor or as an integrator of peripheral visceral afferent input via the vagus. Aspiration lesions were made under direct visual guidance in male and female adult rats. All rats were maintained on an ad libitum diet of laboratory chow and water. Sham lesioned males returned to preoperative levels of food intake and body weight by the 3rd day after surgery. Lesioned rats remained hypophagic for at least 3 weeks postoperatively and were at 75% of prelesion levels on day 21. Body weights declined 25% below prelesion levels on day 12 and then progressively increased by 2 g/day to 78% of prelesion body weight on day 21. Lesioned rats displayed a mild hypodipsia for the first 7 days after surgery whereas sham lesioned rats return to baseline levels on day 2. Female rats displayed a similar pattern. All lesioned rats displayed no obvious postural or motor deficits. Lesioned rats were tested with 2-deoxyglucose (160 mg/kg of body weight, injected IV via a jugular catheter) within 10 days of surgery. Lesioned rats did not increase feeding from saline controls within the 1st hour after injection. When tested with insulin (4 U Iletin, injected SC), they responded normally except for a longer latency to feeding. In order to assess reactivity to aversive stimuli, lesioned and sham lesioned rats were given access to 0.01% Quinine-adulterated water for a 3 hr. period after 22 hrs. of water deprivation on day 6 postoperatively. Lesioned rats drank only 28% (in ml/g of body weight) of the sham totals. Under a similar paradigm, lesioned rats drank 58% of the sham totals when given access to plain water. In another group, prelesion experience with this test attenuated this difference. Histological examination of lesioned rats revealed a loss of the AP and varying degrees of damage to the NTS. Ingestive behavior is disturbed by loss of the AP and adjacent NTS. Since this area is a likely site for the termination of abdominal vagal afferents, this lesion may provide a means of studying the effect of the loss of abdominal afferents without major loss of vagal motor fibers.

49.9 ALTERATIONS IN FEEDING BEHAVIOR AND BODY WEIGHT FOLLOWING GLOBUS PALLIDUS LESIONS IN RATS: EFFECTS OF PREOPERATIVE DIETING. Carlos V. Grijalva. Dept. of Psychology, University of California, Los Angeles, CA 90024.

Lateral hypothalamic (LH) damage produces a well-defined syndrome characterized by initial periods of aphagia, anorexia, and adipsia, followed by recovery of ingestive behaviors although certain homeostatic deficits persist (Teitelbaum & Epstein, Psychol. Rev. 69: 74, 1962). Powley and Keesey (J. comp. physiol. Psychol. 70: 25, 1970) showed that rats preoperatively reduced in body weight by dieting recovered feeding behaviors sooner after LH lesions than rats at normal body weight prior to surgery. However, groups of rats either preoperatively dieted or at normal body weight maintained equivalent lower body weight levels after LH lesions relative to nonlesioned controls. Because lesions of the globus pallidus (GP) produce feeding deficits quite similar to those following LH lesions (e.g., Morgane, Am. J. Physiol. 201: 420, 1961; Neill & Linn, Physiol. Behav. 14: 617, 1975), the present study was conducted to examine the effects of preoperative dieting on feeding behavior and body weight maintenance after GP lesions.

Four groups of 8 male hooded rats were matched for initial body weight. Two groups were reduced to 80% initial weight by dieting (Grijalva et al. J. comp. physiol. Psychol. 90: 505, 1976) over a 14 day period. The remaining two groups were fed ad lib during the same calendar period to maintain normal weight. One dieted and one normal weight group received bilateral electrolytic GP lesions. The remaining dieted and normal weight group were given control operations.

The results showed that preoperative dieting significantly shortened the period of aphagia induced by GP lesions. The GP lesion-dieted group was aphagic for 2.4 days while the GP lesion-normal group was aphagic for 5 days. Both groups, however, were anorexic for about 2 to 3 days. Two months following surgery both the GP lesion-dieted group and the GP lesion-normal group were approximately 20% lower in body weight relative to both control-operated groups which were at similar body weight levels.

These findings indicated that dieting attenuated the period of aphagia but did not alter body weight maintenance which was chronically reduced following GP lesions. These findings support the view that certain disruptions in feeding behavior and body weight regulation after LH lesions may be due to interruption of fibers of passage originating in the globus pallidus or other structures of the corpus striatum.

49.10 FEEDING AND DRINKING FOLLOWING ELECTROLYTIC LESIONS OF THE MEDIAN RAPHE NUCLEUS, Karen E. Asin and David Wirtshafter. Dept. of Psychology, Univ. Illinois-Chicago, Chicago, IL. 60680

Since the median nucleus of the raphe (MR) appears to be profusely interconnected with forebrain structures, including the hypothalamus, this study sought to investigate the effects of electrolytic MR lesions on ingestive behaviors under various conditions.

Albino, male rats served as subjects. One group of rats had A.M. and P.M. food and water intakes and body weight recorded and, after a baseline period, the animals were either sham operated (C) or given a MR lesion (1ma/8sec). Intakes and body weight were followed for several weeks. Postoperatively, only a few rats showed a transient hyperdipsia. Lesioned subjects lost significantly more weight than C's for the first 4 days postop.,after-which body weight was maintained at a lower level but weight gain paralleled that of C's. Following a 4-day decrease in overall food intake, MR lesioned rats consumed as much food as C's during a 24 hour period but ate significantly less during the day. Later tests revealed no difference in food intake between groups during a 24 hour water deprivation period or 1,2 or 6 hours after an injection of insulin or 2-deoxy-D-glucose (2DG), although lesioned rats showed a greater suppression of food intake 24 hours after 2DG compared to controls. All MR lesioned rats were hyperactive.

Another group of rats had water intakes recorded before and after surgery; again, only an occasional subject was hyperdipsic, although all were hyperactive in the open field. During 24 hours of food deprivation, lesioned subjects sharply reduced their water intakes, often to less than 5mls. There were no differences in intakes following injections of hypertonic NaCl, isoproterenol, or polyethelene glycol when measured at 1 and 3 hours after treatment.

A third group of rats was allowed a 2 week postsurgical recovery period and was then placed on a 23 hour food deprivation schedule. Again, lesioned subjects drank significantly less in the absence of food and as the deprivation schedule continued, MR lesioned rats drank almost exclusively during the 1 hour feeding period in amounts greater than C's. Furthermore, during feeding MR lesioned rats took significantly more drinks and showed significantly more spillage than C's, although the amount eaten was the same.

In a final group, MR's and C's were maintained in a cage which monitored the amount and pattern of food and water intake.Lesioned rats showed marked prandial drinking, with small draughts occuring frequently within a meal, sometimes after each 45mg pellet. This behavior is reminiscent of that seen in an LH lesioned rat.

50.1 ALTERATIONS OF SODIUM-POTASSIUM ATPase DURING CEREBRAL ISCHEMIA AND RECIRCULATION. R.B. Schwartz*, A. Spatacco*, and F.A. Welsh* (SPON: B. Uzzell). Division of Neurosurgery, University of Pennsylvania, Philadelphia, PA 19104.

The purpose of this study was to determine whether cerebral ischemia alters the activity of Na^+,K^+-ATPase measured in vitro and, if so, whether that alteration persists in recirculated brain which has been irreversibly damaged. Incomplete ischemia, of sufficient severity to deplete tissue levels of ATP and phosphocreatine, was produced in cat brain by occlusion of the common carotid arteries plus rapid arterial hemorrhage to a mean arterial pressure of 30 torr. After 30 min of ischemia, the brain was recirculated for 2-4 hours prior to in situ freezing with liquid N_2. The frozen brain was sampled regionally for analysis of Na^+,K^+-ATPase activity and of ATP content.

Thirty min of ischemia caused Na^+,K^+-ATPase activity in cerebral cortex to increase from control values of 7.4 ± 0.7 to 11.5 ± 1.1 mmol/min per kg wet weight ($p < 0.01$). In recirculated brain, the activity of Na^+,K^+-ATPase returned to control (6.4 ± 0.4 mmol/min kg) in regions which resynthesized ATP to greater than 63% of preischemic levels. However, in brain regions with severe energy failure (ATP less than 40% of control), Na^+,K^+-ATPase activity remained markedly elevated: 12.1 ± 1.0 mmol/min kg ($p < 0.01$). The activity of Mg^{++}-activated (ouabain insensitive) ATPase did not change significantly during ischemia or recirculation.

These results demonstrate that ischemia causes a 55% increase in the in vitro activity of Na^+,K^+-ATPase and that this increase persists only in brain regions which have undergone irreversible energy failure. We speculate that the activation of Na^+,K^+-ATPase may result in excessive hydrolysis of ATP during the post-ischemic recivery period, thereby preventing restoration of tissue levels of ATP and, thus, contributing to the ultimate energy failure.

50.2 RELATION BETWEEN MEAN ARTERIAL BLOOD PRESSURE, LACTIC ACID ACCUMULATION, AND BRAIN INJURY FROM MARKED HYPOXIA IN RHESUS MONKEYS. K.R. Wagner, M.E. Brown*, S. Yamaguchi, R.E. Myers. Lab. of Perinatal Physiology., NIH, Bethesda, Md. 20205

Animals exposed to 25 minutes of marked hypoxia (PaO_2=15 mmHg) not accompanied by reductions in mean arterial blood pressure (MABP) below 65 mm Hg do not injure their brains (Myers, et al, J Neuropath Exp Neurol, 1980). Animals exposed to marked reductions in MABP and high serum glucose concentrations during hypoxia elevate lactic acid of cisternal CSF to values above the 16-18 mM threshold required for brain injury (deCourten, et al, J Neuropath Exp Neurol, 1980) as established previously (Myers, Adv Neurol 26:195, 1979). The present study exposes food-deprived rhesus monkeys to marked hypoxia (PaO_2=12-18 mm Hg) by respiring them with 3.5% oxygen for 2.5 to 25 minutes. Their brain metabolite concentrations were preserved by in situ freezing (Welsh & Rieder, J Neurochem 31:299, 1978) and tissue extracts assayed for glycogen, glucose, lactate, ATP and phosphocreatine using enzymatic-fluorometric methods. The animals exposed to 2.5 and 5 minutes of hypoxia elevated their cortical lactic acid (control=1.5-2.5 µmoles/g) to 7 and 9-10 µmoles/g, respectively. They then showed no further increase in lactic acid concentration for up to 25 minutes of hypoxia unless they experienced blood pressure troughs (MABP < 60-80 mm Hg) or a cardiovascular collapse. They decreased phosphocreatine at all times during hypoxia (3.5 µmoles/g; control=4.0 µmoles/g) and maintained glycogen, glucose and ATP concentrations unchanged from control values (5.0, 3.5, 2.1 µmoles/g, respectively) as long as they maintained blood pressure > 60-80 mm Hg. Animals that reduced MABP < 60 to 80 mm Hg at any time during hypoxia markedly elevated their cortical tissue lactic acid to concentrations >20-30 µmoles/g. They also significantly reduced their brain tissue glycogen, glucose, and high energy phosphates. These results, which strongly support our pathologic studies, indicate that animals exposed to hypoxia that maintain MABP > 60-80 mm Hg do not accumulate lactic acid to concentrations sufficient to injure their brains. Animals that experience marked reductions in MABP, and, therefore, in cerebral perfusion producing a near-anoxia of their brains, elevate lactic acid concentrations to values sufficiently high (>18-20 µmoles/g) as to induce brain injury.

50.3 COLUMNAR ALTERATIONS OF NADH FLUORESCENCE DURING HYPOXIA-ISCHEMIA IN NEWBORN RATS. A. Spatacco*, F.A. Welsh*, R.C. Vannucci*, and P. Campbell* (SPON: T.W. Langfitt). Division of Neurosurgery, University of Pennsylvania, Philadelphia, PA 19104 and Department of Pediatrics, Hershey Medical Center, Hershey, PA 17033.

Exposure of 7-day postnatal rats with unilateral carotid artery ligation to 8% oxygen for 3 hours causes necrosis in the cerebral cortex, which frequently occurs in columns oriented at right angles to the pial surface (Rice et al., submitted to Ann. Neurol.). A similar columnar pattern of NADH fluorescence has been demonstrated during incomplete ischemia in cat brain (Welsh et al., Science 198, 951-953). In order to determine whether columnar alterations in metabolism occur in the above model of hypoxia-ischemia in newborn rats, we have measured NADH fluorescence and regional levels of ATP and phosphocreatine in brain frozen at various times during the insult.

At 60 min of hypoxia-ischemia, intensely fluorescent columns of NADH appeared in the cortex ipsilateral to the carotid occlusion. However, since tissue levels of ATP and phosphocreatine were depleted throughout the ipsilateral cortex, it was apparent that hypoxic alterations of high energy phosphate levels were not restricted to brain regions with increased NADH fluorescence. At 3 hours of hypoxia-ischemia, NADH fluorescence intensity had returned to normal levels, except in 2 of 5 animals in which faint columns of increased NADH persisted. At the same time, tissue levels of ATP and phosphocreatine remained lower than 0.1 mmol/kg.

Although the regional pattern of NADH fluorescence during hypoxia-ischemia corresponded well with the ultimate pattern of neuropathology, columnar necrosis cannot be explained simply by columnar depletion of high energy phosphates. Rather, the secondary decline of NADH fluorescence intensity between 1 and 3 hours may signify, in the presence of continued energy depletion, irreversible damage to the citric acid cycle-catalyzed generation of NADH.

50.4 NEUROCHEMISTRY OF IODOTHYRONINES. J. T. Gordon*, F. L. Crutchfield*, A. S. Jennings* and M. B. Dratman. V. A. Hospital, Philadelphia, Pa. 19104.

The work to be reported was aimed at clarification of the action of thyroid hormones in the autonomic and central nervous systems. It has been reported that accumulation of 3',3,5-triiodothyronine (T_3) derived from thyroxine (T_4) occurs more extensively in brain than in other tissues. Sucrose gradient fractionation of rat brain homogenate in this laboratory showed further enhancement of T_3 relative to T_4 in synaptosomes (Dratman, M. B. and Crutchfield, F. L., Am. J. Physiol. 4:E638, 1978). We now report the presence in rat brain of additional iodothyronines, 3',5',3-triiodothyronine (rT_3) and 3',3-diiodothyronine (3',3-T_2). In two separate experiments, rat pups reared perinatally on $^{125}I^-$ were sacrificed at intervals beginning at 5 days from birth up to 17 days. In each experiment brain, muscle, liver and serum were extracted and evaluated for ^{125}I-compounds. Extraction was by $CHCl_3$-CH_3OH (2:1, v/v) and was followed by solvent partitioning by addition of 0.05% aq. $CaCl_2$ and freeze-drying of the separated aq. CH_3OH layers. Samples were redissolved in CH_3OH for analysis by two-dimensional paper chromatography and autoradiography with subsequent excision of ^{125}I-regions for quantitative measurement of radioactivity. The chromatographic systems were 1-butanol, ethanol, 0.5 N NH_4OH (5:1:2, ascending) followed by t-amyl alcohol, hexane, 2 N NH_4OH (5:1:6, descending). Co-chromatography of authentic ^{125}I-rT_3 and ^{125}I-3',3-T_2 with duplicate extracts established the identity of the metabolites.

At 5 and 7 days rT_3 and 3'3-T_2 were present in brain and not detected in muscle, liver or serum. Thus it can be concluded that at those ages concentrations of rT_3 and 3',3-T_2 relative to T_4 are larger in brain than in the other tissues studied. In 13 to 17 day old pups rT_3 decreased to a trace in brain and appeared as a trace in the other tissues, while 3',3-T_2 continued to be detected only in whole brain, brain subcellular fractions and individual brain regions. That levels of 3', 3-T_2 relative to T_4 varied from 10 to 24 (average 16) % while rT_3 levels decreased from 21% to a trace is attributed to an increase in T_3 relative to T_4 after day 13. Ingbar and associates (J. Clin. Endocrinol. Metab. 46:916, 1978) have shown that T_4 deiodination in humans is a sequential process. Our findings suggest the nerve cell or nerve ending as a functional site for sequential deiodination of thyroid hormones. These observations may be relevant to understanding the potent analeptic and ß-adrenergic effects of thyroid hormones. Supported by funds from the NIMH Grant #MH29549, and Med. Res. Service, VA Hospital, Philadelphia, PA.

50.5 INTERACTIONS BETWEEN GLUCOSE AND KETONE BODY USE BY DEVELOPING BRAIN. A.L. Miller, C.A. Kiney,* D.H. Corddry* and D.M. Staton.* Mailman Research Center, McLean Hospital, Belmont, MA 02178.

Human and rat brain have considerable capacity to use blood acetoacetate and β-hydroxybutyrate (BHB) as fuels. Use of these ketone bodies by brain is most rapid in developing brain and, at all ages, varies directly with their blood levels. Some studies have found that loss of lactate from brain occurs when ketone body uptake increases. Whether brain glucose utilization is also affected has been unclear.

To examine the interactions between glucose and ketone body use by developing brain, we injected 20 day old rats with sodium DL-β-hydroxybutyrate (0.4 mmoles/rat, I.P.) and studied them under normocapnic and hypercapnic (20% CO_2, 21% O_2, 59% N_2) conditions. Brains were obtained with a freeze-blowing apparatus at 2, 6, 10 and 15 min after BHB administration. Brain glucose utilization was determined with [2-^{14}C]glucose and [^{3}H]deoxyglucose as tracers. Metabolites were assayed enzymatically.

In normocapnic rats, rates of glucose utilization by brain progressively decreased after BHB administration. These decreases were found with both radioisotopes, but were greater with [2-^{14}C]glucose as tracer. Brain concentrations of glucose 6-phosphate, pyruvate, citrate, α-ketoglutarate, malate and glutamate increased in the BHB-treated animals. During hypercapnia brain glucose utilization fell to a greater extent in BHB-treated rats than in saline-injected rats. Decreases in brain concentrations of pyruvate, lactate, citrate, α-ketoglutarate, malate and glutamate were not so rapid, however, in the BHB-treated hypercapnic rats as in the hypercapnic saline group.

We conclude that ketonemia produced by BHB injection into 20-day old rats results in decreased brain glucose utilization and increased loss of labeled lactate from brain. The decrease in glucose utilization is quantitatively more important. The increased size of the pools of Krebs cycle intermediates and of glutamate indicated an imbalance between the rate of entry of ketone bodies into the Krebs cycle and the rate of oxidative decarboxylation. The inhibition of brain glucose utilization that occurs during hypercapnia is not lessened by concurrent ketonemia but the rate of depletion of intermediary metabolites and glutamate is slowed. These observations confirm the ability of ketone bodies to partially replace glucose as an oxidative fuel for brain, but also show the limitations on short-term regulation of their use. Thus, in the normocapnic, ketonemic rats, the decrease in glucose carbon entry into the Krebs cycle did not balance the increase from ketone bodies and in hypercapnic, ketonemic rats entry of ketone bodies did not increase sufficiently to compensate for the inhibition of glucose utilization.

50.6 TEMPERATURE EFFECTS IN THE RESPIRATORY CHAIN OXIDATION OF REDUCED NICOTINAMIDE ADENINE DINUCLEOTIDE OF NEURONS. Carlos Rodríguez-Estrada. Cátedra de Fisiología. I.M.E. Fac. Medicina, U.C.V., Caracas, Venezuela.

Previous work (Brain Res. 6:217) has shown in soma neurons that excitation at 5°C produced a metabolic response characterized by a single change, oxidation, but re-warming at 25°C this metabolic response shows its normal metabolic change, that is oxidation, followed by reduction of nicotinamide adenine dinucleotide. This work studied the effect of temperature on the steady state level of reduced nicotinamide adenine dinucleotide (NADH). Fluorometric determinations of NADH were done on in vitro preparations of dorsal root ganglion neurons of frogs (Rana palmipes spix). Each preparation was placed in a moist chamber at a constant temperature of 25°C controled by a water flow under the floor of the chamber. This temperature was changed to 5°C and controled in the same way. A record of the temperature of the chamber was taken near the preparation with a thermistor. This chamber was provided with an outlet and inlets for gases. Recordings were done of the pO_2 at the outlet of the chamber. A sudden change of temperature from 25°C to 5°C in aerobic conditions produced a sudden increase of NADH level. This level did not stayed high and constant. It decreased (oxidation) slowly towards the level observed previously to temperature change. Returning the temperature to 25°C there was a sudden decrease of NADH level. This level did not stayed constant; it returned slowly towards the level observed previously to temperature change. A sudden change of temperature from 25°C to 5°C in anaerobic conditions produced a sudden increase of the NADH level. The new level stayed constant. Returning the temperature to 25°C there was a sudden change of NADH; the NADH level returned to a level previously recorded to temperature change. In anaerobic conditions at 5°C a change to aerobic conditions produced a sudden decrease (oxidation) of NADH level. The rate of change of NADH oxidation observed at 5°C is similar to that one observed at 25°C. Indicating that the rate of change of respiratory chain oxidation at 25°C as well as at 5°C is similar.

50.7 CONSTANCY OF OXYGEN CONSUMPTION DURING TOTAL ISCHEMIA IN THE GERBIL CEREBRAL CORTEX. R. Martin and J.H. Halsey*. Dept. of Neurology, Univ. of Alabama in Birmingham, The Medical Center, Birmingham, Alabama 35294.

The constancy of oxygen consumption of the cerebral cortex during total ischemia was determined by analysis of the rate of falling pO_2 as measured by an oxygen microelectrode during transient bilateral carotid occlusion in barbiturate-anesthetized gerbils. Measurements were performed in animals under hyperbaria, heavily barbiturate-suppressed metabolism, or Metrazol seizure.

Occlusion produced an immediate (within .5 second) fall in pO_2. Under normoxia, oxygen was depleted usually within 5 seconds. However, as the pO_2 of occlusion was raised via hyperbaria, some measurements exhibited an initial linear fall in pO_2 followed by a "quasi-exponential" decay indicating slowing metabolism. In several instances this decay continued until the slope became zero leaving residual oxygen within the tissue. The EEG during this decay became increasingly inactive.

In the hyperbaric experiments, the rate of oxygen consumption was calculated for those measurements where the occlusion was performed at tissue pO_2 above 100 torr. This was necessary to avoid the slowed rate of oxygen disappearance found at normal tissue pO_2 due to the desaturation of capillary hemoglobin. In ten animals, the range of oxygen consumption for parietal cortex was found to range from 1.6-7.4 cc/100 cc tissue-min. with a mean of 4.4.

Both the barbiturate-suppressed group and Metrazol group had control and treatment phases. Of all control measurements, 47% were found to exhibit a period of decreasing slope of these, 45% changed slope within the first 2 seconds following ischemic onset and 55% changed in 2-5 seconds. In the barbiturate-suppressed phase, 37% had a change in slope with 86% changing within 2 seconds and 14% changing in 2-5 seconds. Of the measurements made during the Metrazol seizures, 47% had a change in slope and all of these changed within 2 seconds of ischemic onset. It may be that this slowing metabolic rate is a result of metabolite accumulation due to the ischemia. If true, the higher metabolic rate produced by Metrazol administration should generate more metabolite per unit time while the highly suppressed metabolism following high doses of barbiturate should require a longer period to produce this critical level. At low pO_2 measurements, the oxygen may be depleted before any change is evident, and as the pO_2 of measurement is raised, enough oxygen is available for this level to be reached. Supported in part by NINCDS Grants NS 07123 and NS 08802.

50.8 SEX DIFFERENCE IN BRAIN IRON. Joanna M. Hill* (SPON: P. D. MacLean). Laboratory of Brain Evolution and Behavior, National Institute of Mental Health, Bethesda, MD 20205

Iron, stored in the form of iron-ferritin, is unevenly distributed in the brain, the highest levels occurring in the globus pallidus (GP) and substantia nigra (SN). Rat brains were analyzed for iron content to determine if a sex difference, as has been reported in liver and serum iron, exists in brain iron levels. Ovarian hormones affect the synthesis of both ceruloplasmin, an iron-mobilizing factor, and ferritin, the iron storage protein.

Brain tissue was analyzed histochemically with Perl's method for ferric iron to obtain a qualitative measure of iron as well as to localize high iron areas. A more intense Perl's reaction was obtained with the female brain; however, in both sexes, iron was evident in the globus pallidus and substantia nigra.

Quantitative measures of iron levels were made by spectrophotometry. The tissues analyzed include the serum, liver, and both high iron (GP + SN) and low iron (cortex) areas of the brains of 10 female and 10 male 14 week old rats. The results of the spectrophotometric determination of iron appear below (all Student's t-tests df=18). Units are μg of Fe/g wet weight except serum which appears as μg of Fe/ml.

	Female	Male	
GP + SN	9.2 ± 2.81	5.7 ± 1.70	p<.01
Cortex	5.7 ± .50	5.3 ± .91	NS
Liver	139.7 ± 12.35	75.9 ± 8.31	p<.01
Serum	2.8 ± .45	1.8 ± .35	p<.01

These results demonstrate a sex difference in brain iron which parallels that in the serum and liver. Ovarian hormones, through their effects on ferritin and ceruloplasmin, are implicated in the establishment and maintenance of this sex difference. The availability of iron possibly has important consequences in those aspects of cerebral respiration and neurotransmitter metabolism in which iron plays a role.

A detailed analysis of changes in brain iron during the estrous cycle and pregnancy is in progress.

50.9 AMMONIA AND METHIONINE SULFOXIMINE INTOXICATION. W. Raabe and G. Onstad*. Dept. Neurology, VA Med. Center, Univ. of Minnesota, Minneapolis, MN 55417.

Methionine sulfoximine (MSO) has been reported to protect against the neuro-behavioral signs of ammonia intoxication (Hindtfeldt, B. and Plum, F., J. Pharm. Pharmacol., 27:456, 1975). This effect is not well understood because MSO itself increases cerebral ammonia concentrations by inhibiting glutamine synthethase, the enzyme promoting the removal of ammonia from the CNS via formation of glutamine.

The ability of ammonia to inactivate neuronal Cl^- extrusion and thus to abolish action potential suppression by postsynaptic inhibition (Raabe, W. and Gumnit, R., J. Neurophysiol., 38:347, 1975) was used to determine the neuronal tolerance to i.v. ammonia loads before and after treatment with MSO (35 mg/kg i.v.). In nembutal anesthetized cats recurrent postsynaptic inhibition of pyramidal tract cells was used to suppress extracellularly recorded antidromic action potentials of pyramidal tract cells. Ammonium acetate (NH_4-Ac) was given i.v. until inhibition no longer suppressed action potential generation, i.e., "disinhibition" occurred. At that time, the cerebral cortex was frozen in situ to determine ammonia and glutamine concentrations. In untreated cats disinhibition occurred after administration of 2.6 mM/kg of NH_4-Ac. With disinhibition cerebral ammonia increased from 0.20 ± 0.02 (S.E.) µM/g to 0.92 ± 0.10 µM/g, and cerebral glutamine increased from 3.55 ± 0.20 µM/g to 6.10 ± 0.64 µM/g. Thirty minutes after MSO treatment only 1.5 mM/kg of NH_4-Ac was needed to produce disinhibition; cerebral ammonia and glutamine concentrations were 0.73 ± 0.10 µM/g and 4.85 ± 0.38 µM/g respectively. One hundred and twenty minutes after MSO treatment 0.76 mM/kg of NH_4-Ac was sufficient to produce disinhibition; cerebral ammonia and glutamine concentrations were 0.89 ± 0.14 µM/g and 3.16 ± 0.07 µM/g respectively

MSO treatment significantly decreased the ammonia loads needed to produce disinhibition. The longer MSO affected glutamine synthesis, the less ammonia had to be infused to increase cerebral ammonia concentrations sufficiently to produce disinhibition. MSO treatment did not significantly alter the ammonia concentrations required to produce disinhibition. The results show that MSO does not change the ammonia concentrations neurons can tolerate. The protective effect of MSO on ammonia intoxication remains to be clarified.

50.10 STATUS OF SARCOPLASMIC RETICULUM CALCIUM-ACTIVATED ATPase IN HIBERNATION. R. Tamburini, Jr.*, S. S. Deshpande*, E. X. Albuquerque and F. C. Kauffman. (SPON: R. F. Mayer). Dept. of Pharmacol. & Exp. Therap., Univ. of MD School of Medicine, Baltimore, MD 21201.

Hind limb muscles from both hibernating and nonhibernating ground squirrels (Citellus tridecemlineatus) were removed under chloral hydrate anesthesia (400 mg/kg; intraperitoneally). Ca-stimulated ATPase activity was determined using a slightly modified method of Froelich and Taylor (J. Biol. Chem., 250:2013, 1975). The purpose of the present study was to examine possible relationships between thyroid status and Ca-activated ATPase in the sarcoplasmic reticulum of hibernating and non-hibernating animals. In deep hibernation the basal level of ATPase activity without the addition of Ca was significantly lower than the control value seen in the muscles of non-hibernating squirrels (301 + 49 vs 642 + 93 nmol/mg protein/min). Addition of Ca to the incubation medium stimulated the enzyme activity by 137% in the muscles of nonhibernating animals whereas it increased by only 43% of the basal activity in the muscles of hibernating squirrels. The level of Ca-stimulated ATPase activity was related to the level of hibernation of the animal. In experiments where the waking process was monitored from a deep hibernating state to the completely awake state, the activity of the enzyme was lowest at a body temperature of 7 °C, increasing to 1,300 at 21 °C and reaching a value of 1,445 at 35 °C, comparable to that seen in the muscles of nonhibernating squirrels.

Since administration of thyroxine to rats is known to increase Ca-activated myosin ATPase in cardiac muscle (Limas, C., Am. J. Physiol., 235: 745, 1978) and soleus muscle (Ianuzzo, D., et al., Nature, 270: 74, 1977) it was likely that decreased thyroid activity during hibernation could be responsible for the observed decrease in Ca-stimulated ATPase. Hind limb muscles of rats treated for 7 days with daily intramuscular injection of thyroxine (Na salt, 80 µg/100g) showed a 40% increase in enzyme activity as compared to nontreated controls. Similar injections of the hormone in nonhibernating squirrels had very little effect if any in increasing the activity of Ca-stimulated ATPase. These results implicate a mechanism other than that involving thyroid modulation in maintaining lower activity of the enzyme in hibernation. Perhaps other neural factors similar to those associated with maintaining fast-twitch and slow-twitch myosin as two distinct proteins in rats (Barany, M. and Close, R.I., J. Physiol., 213: 455, 1971) could play a role. (Supported in part by USPHS Grant NS-12063, NS-14728, funds from the Paralyzed Veterans of America and Conselho Nacional de Pesquisa of Brazil.)

50.11 CHANGES IN THE REDOX STATE OF CYTOCHROME a,a_3 IN RAT CEREBRAL CORTEX DURING HYPOGLYCEMIA. R.M. Bryan, R.B. Duckrow, J.C. LaManna, M. Rosenthal, and A.L. Sylvia, Dept. of Physiology, Duke Univ. Med. Center, Durham, NC 27710 and Dept. of Neurology, Univ. of Miami Sch. of Med., Miami, FL 33101.

The effects of decreased substrate availability to the respiratory chain were studied in rat cerebral cortex by monitoring the redox state of cytochrome a,a_3 before and after insulin induced hypoglycemia. Hypoglycemia decreases the amount of substrate available to the glycolytic chain. Rats were fasted from 12 to 16 hours, anesthetized with pentobarbital (50mg/kg), paralyzed with curare, and artificially ventilated. Arterial blood was sampled for the determination of blood gas tensions, pH, and glucose concentration. Changes in the redox state of cytochrome a,a_3 and cortical blood volume were monitored from the surface of the cerebral cortex using dual-wavelength reflection spectrophotometry. The steady state redox level of cytochrome a,a_3 was determined by comparing the degree of oxidation induced by 95% O_2/5% CO_2 respiration to the total labile cytochrome a,a_3 signal, defined as the signal change from maximum oxidation to the level of reduction achieved after 30 sec. of respiration with 100% N_2. Hypoglycemia resulted in a decrease in the fraction of reduced/oxidized cytochrome a,a_3 in the steady state. An active metabolic state was induced by direct cortical stimulation and was characterized by a transient negative shift of the steady cortical potential, a transient oxidation of cytochrome a,a_3, and a transient increase in cortical blood volume. Hypoglycemia decreased the amplitude of the transient responses in both cytochrome a,a_3 and blood volume. The cytochrome a,a_3 amplitude was more severely attenuated than the blood volume amplitude. Both the "steady state" and "active" redox response of cytochrome a,a_3 to hypoglycemia could be reversed by an intravenous administration of glucose unless hypoglycemia had progressed to the point of cortical isoelectricity. Although cytochrome a,a_3 is the terminal member of the respiratory chain and responds primarily to changes in oxygen availability, its redox state is sensitive to a decrease in glycolytic flux in both the steady state and during increased metabolic activity. (Supported in part by PHS grants NS 06157, NS 14319, NS 14325, and a grant from the AHA of Greater Miami).

50.12 ETHANOL INDUCED CHANGES IN PROTEIN SYNTHESIS OF COX GLIOMA CELLS E. W. Fleming*, M. E. Woodson* and S. Tewari* (SPON: V. G. Carson) Dept. of Psychiatry and Human Behavior, Univ. of Calif., Irvine, CA 92717.

Inhibition in steps of brain protein and RNA synthesis in vivo and in vitro have been reported following chronic ethanol ingestion by rodents. To elucidate the effects of ethanol on a specific cell population derived from human brain, cultures of Cox glioma cells were grown for 10 days in the presence or absence of 100 mM ethanol. Both groups of cells showed rapid growth and mitosis. Following harvesting cell homogenates were fractionated and polyribosomes purified by magnesium precipitation and ultracentrifugation. While cell densities remained unchanged, polyribosomes had reduced RNA and protein contents following the ethanol treatment. The states of cellular synthesis of RNA and protein were analyzed by growing cells in the presence of (5-^{3}H) orotic acid and (^{14}C) leucine for 24 hours prior to harvesting. Ethanol treated cells showed reduced incorporation of the precursors into RNA and protein. The activity of the polysomes for the in vitro incorporation of (^{14}C) leucine into protein was also reduced following the ethanol treatment. Furthermore, ethanol treatment resulted in dissaggregation of polysomal chains analyzed on sucrose density gradients. In addition to ethanol, cells were grown in the presence of 0.017µgm/ml of cycloheximide (Cy) added 1 or 24 hours prior to harvesting. After 1 hour of Cy treatment of control cells, the cell densities were unchanged, polysomal protein and RNA yields decreased and in vitro protein synthetic activity increased, but all measures showed decreases after 24 hours of Cy. Cells grown in the presence of ethanol however, showed decreased polysomal protein contents after 24 hours, but increased cell densities and in vitro protein synthetic activities after 1 and 24 hours of Cy treatment. The incorporation of the ^{3}H and ^{14}C precursors into monomer and polysomal units were determined by analyzing post-mitochondrial supernatants on sucrose gradients. Cy treatment at one hour caused an increase in the incorporation into RNA and protein in the polysomal region of both groups. The results suggest that a general property of ethanol treatment is the inhibition of protein synthesis, both for brain and CNS cells in tissue culture. While cycloheximide appeared to inhibit the termination step in protein synthesis, the ethanol treatment lessened the cycloheximide effects. The significance of these results will be discussed. 50.13 MITOCHONDRIAL ISOLATION METHODS: APPLICATION TO SPINAL CORD.
N.R. Clendenon, S.T. Palayoor*, W.A. Gordon*, M.E. Nesham* and N. Allen. Neurochem. Lab, Division of Neurology, Ohio State University, Columbus, Ohio 43210.

The overall objective was directed toward finding a suitable method for isolation of mitochondria from samples of traumatized spinal cord for oxidative phosphorylation studies. A critical assessment of 3 methods was made using rat spinal cord and the data compared with results obtained for rat brain. The best procedure was applied to dog cord.

Spinal cords (7-8) were removed from Ketamine anesthetized rats by the rapid method of DeSousa and Horrocks (Dev. Neurosci. 2:115, 1979). Respiratory function was assessed with a Clarke electrode on a Gilson oxygraph at 25°C using a 1.5 ml water jacketed reaction chamber. Respiratory control rates (RCR) and P/O ratios were determined as described by Chance and Williams (J.Biol.Chem. 217: 383, 1955). Protein and cytochrome oxidase (CO) were measured for all fractions. The lysosomal enzymes, acid phosphatase (AcP) and β-glucuronidase (β-G) were assayed in fractions from at least one preparation for each isolation procedure.

In general, rat spinal cord mitochondria isolated by the Bernard(salt-wash)method (Biochim.Biophys.ACTA 548:173,1979) gave the best results in terms of RCR,P/O and respiration rates, while the Holtzman method (J.Neurochem. 30:1409,1978) using Nagarse was the least desirable. The Clark-Nicklas procedure (J.Biol.Chem. 245: 4724,1970) using a density gradient prepared with Ficoll required a longer preparation time. RCR values were approximately 50% lower in the presence of NAD-linked substrates (glutamate-malate or pyruvate-malate) when compared with the Bernard method. RCR values and State 3 respiration were generally lower than brain. Mitochondrial protein content and yield were strikingly low for all procedures. Spinal cord mitochondrial RSA values for CO were *essentially equivalent to brain preparations*. Lysosomal contamination was also similar (β-G and AcP RSA between 2 and 3).

Lumbar spinal cord (7-9cm) from Suritol anesthetized dogs maintained on N_2O:O_2(4:1) during laminectomy, was used for mitochondrial isolation by the Bernard method. Excess blood, dura and nerve roots were removed in ice cold isolation medium. Pooled data for 3 experiments gave a mitochondrial yield of 10% with a RSA for CO of 3.33. Because the amount of mitochondrial protein was very low (0.49 mg/cm cord), oxidative phosphorylation values varied greatly with State 4 respiration dropping to near zero. The Clark-Nicklas method was even less satisfactory.

Mitochondrial isolation methods when applied to dog spinal cord have proved disappointing. The limiting factor in a study of respiratory function appears to be the very large amount of material needed to isolate sufficient numbers of mitochondria from either normal or injured dog spinal cord. (Supported by NINCDS #NS-10165).

50.14 A CRITICAL ASSESSMENT OF MITOCHONDRIAL ISOLATION TECHNIQUES.
S.T. Palayoor*, N.R. Clendenon, W.A. Gordon*, M.E. Nesham* and N. Allen (SPON: J.H. Hofteig), Neurochem. Lab, Division of Neurology, Ohio State University, Columbus, Ohio 43210.

An extensive study was carried out on 4 existing methods designed to isolate rat brain mitochondria. Comparisons were made in terms of percent yields and purity in addition to good coupling and oxidation rates. For the Ozawa method (J.Biochem.59:501,1966), mitochondrial isolation is based upon differential centrifugation in isotonic mannitol with repeated rinsing of the crude mitochondrial pellet to remove the light fluffy layer. The Clark-Nicklas method (J.Biol.Chem. 245:4724,1970) utilizes a density gradient separation procedure with Ficoll to remove synaptosomes and other nonmitochondrial material plus a gentle swirling of the purified pellet with small volumes of medium lacking BSA to remove the fluffy layer. The Bernard method (Biochim.Biophys.ACTA 548: 173,1979) employs a salt wash medium to purify the crude mitochondrial pellet. Holtzman's method (J.Neurochem. 30:1409,1978) adds an equal volume of isolation medium containing Bacillus proteinase (Nagarse) to the partially disrupted tissue prior to completing the homogenization procedure. In this case, the brown pellet remains firmly attached to the bottom of the centrifuge tube during the rinsing steps.

Rats were lightly anesthetized with ether before decapitation with utilization of 2 brains per separation experiment. A minimum of 3 experiments were run for each isolation procedure. Mitochondrial respiration function was assessed with a Clarke electrode on a Gilson oxygraph at 25°C using a 1.5 ml water jacketed reaction chamber. Protein and cytochrome oxidase (CO) were measured for all fractions. The lysosomal enzymes, acid phosphatase (AcP) and β-glucuronidase (β-G) were assayed in fractions from at least one preparation for each isolation procedure.

The rate of respiration was lowest in rat brain mitochondria isolated according to the Ozawa procedure. Addition of BSA to the incubation medium significantly improved all respiratory parameters using the Clark-Nicklas method. Mitochondria prepared by the Bernard procedure showed very high respiratory control rates (RCR) with succinate, but failed to respire in the presence of NAD-linked substrates, glutamate-malate or pyruvate malate. High RCR values and respiratory rates were found with all substrates using the simpler and quicker Holtzman method. Mitochondrial recoveries based on CO as a marker were highest using the Clarke-Nicklas procedure (30%) and lowest with the Holtzman (11.8%), while the Bernard method showed the highest relative specific activity (RSA=4.69) but intermediate yield (13.8%). All preparations were somewhat contaminated with lysosomes with RSA values of 2-3 for β-G and AcP. (Supported by NINCDS #NS-10165).

51.1 MYELIN BASIC PROTEIN IMMUNOCYTOCHEMISTRY IN CHEMICALLY INDUCED DEMYELINATING LESIONS. Lidia M.N. Macedo*, Constancia del Cerro*, Robert M. Herndon. Center for Brain Research, University of Rochester, Rochester, NY 14642.

Immunocytochemical study of myelin basic protein (MBP) was performed in rat spinal cords injected previously with 2 µl of a 1% solution of lysolecithin in saline.

The animals were sacrificed by perfusion at 6,12, and 24 hours and 3,5,8,12, and 28 days. The spinal cord tissue was either cut 20 to 25 µm thick in a vibratome or embedded in epon 812 and cut 1 to 2 µm thick.

The vibratome and plastic sections were stained immunocytochemically with rabbit anti-MBP and peroxidase anti-peroxidase complex (PAP) and developed with diaminobenzidine.

After immunocytochemistry with anti-MBP, the lysolecithin lesions were easily identified by the diminished concentration of brown precipitate in the white matter. This effect was observed to start at 6 hours and to continue through the evolution of the lesion. The pale appearance of the lesion at 6 hours was due largely to edema since most of the myelin sheaths stained normally. A few of the smaller sheaths appeared to have lost staining. At 12 hours the myelin breakdown was obvious and most of the sheaths were fragmented and stained poorly. By 24 hours the myelin sheaths in the central portion of the lesion had lost most of their staining properties. In the vibratome sections, a very dark brown precipitate at the border of the lesion was observed. This was interpreted as myelin debris with a large number of antigenic sites exposed to the anti-MBP. It also suggested that the myelin breakdown was occurring more slowly at the edges of the lesion.

The phagocytized myelin debris in macrophages reacted very intensely with the antibody. In the vibratome sections this reaction was so intense that it was difficult to recognize the cell type under the brown precipitate. In plastic sections (1µm), cells with faintly stained cytoplasm appeared in the lesion at 8 and 12 days. They had the size and shape of oligodendrocytes, but EM remains necessary for definitive identification. Remyelination was apparent between 8 and 12 days after the lesion and its progression could be followed by increasing stain around axons. At 28 days the lesions remained paler than the surrounding white matter, but every axon had a thin ring of new myelin around it.

51.2 EXPRESSION OF MOSAICISM IN FEMALES HETEROZYGOUS FOR JIMPY. R. P. Skoff* and I. Nowicki Montgomery* (SPON: J. Rafols). Depts. of Anatomy and Immunology and Microbiology, Wayne State University School of Medicine, Detroit, MI 48201.

The Jimpy mouse is a sex-linked, recessive, juvenile lethal mutant that is characterized by a paucity of myelin throughout the central nervous system (CNS). The cause of the myelin deficit has not been determined although there have been numerous biochemical and morphological studies. Previous studies have been limited to affected males and there have been no investigations of female carriers of the Jimpy mutant gene. We describe here for the first time the pattern of myelination of females heterozygous for Jimpy. Myelin in the optic nerve shows a mosaic distribution which appears to be due, in part, to the effect of x-chromosome inactivation (XCI).

Mice ranging from 12 to 24 days postnatal were used in this study. More than 25 females heterozygous for Jimpy were compared to a collection of over 200 normal and 100 Jimpy littermates. Optic nerves and spinal cords, embedded in Araldite plastic, were analyzed using light and electron microscopy. Expression of the Jimpy gene in the optic nerves of heterozygous females varies considerably from animal to animal. They have a mosaic appearance where patches of tissue are identical in appearance to the hemizygote male while the remainder appears almost normal. Patches of unmyelinated fibers are always found around the periphery of the nerve but may extend into the central core. The unmyelinated areas may be all around the periphery, at opposite sides of the nerve, on one-side only or as a small isolated patch. Electron microscopic observations of the affected areas are identical in appearance to the Jimpy males. The vast majority of the axons are unmyelinated. The fibers are usually surrounded by astrocytic processes or sometimes by an incomplete wrapping of an oligodendroglial process. The number of oligodendroglial cells is reduced and they appear less differentiated than their counterparts in myelinated areas. Lipid laden microglia-like cells are present but they do not appear to be derived from oligodendrocytes. Myelinated areas of the optic nerves in the mosaics do not appear completely normal since the sheaths are often abnormally thick or thin when compared to the diameters of their axons. The intensity of the mosaicism ranges from a severe form identical in appearance to the hemizygote male to an almost normal condition. The demonstration of mosaicism in the female heterozygotes provides a unique system to study the interactions between a normal population of cells and those affected by the mutation. Supported by a Basil O'Connor grant from the March of Dimes and by U.S.P.H.S. grant NS 15338.

51.3 MYELIN SYNTHESIS FOLLOWING CHRONIC POSTNATAL METHYLZANTHINE ADMINISTRATION. G.N. Fuller and R.C. Wiggins., Dept. of Neurobiol. & Anat., Univ. of Texas Med. School, Houston, Texas 77025.

The litters of 6 pregnant Long Evans rats were adjusted to 10 pups each at birth. Five pups from each litter were given an oral dose of 1 methylzanthine(aminophylline, theophylline, or caffeine; 40 or 80 mg/Kg) daily from postnatal day 2 through weaning (20 days). The remaining 5 pups served as littermate controls. Chronic drug treatment produced no deficit in the gross body weight of experimental pups, and brain weights on the day of sacrifice were also normal. At ages 21-26 days randomly selected experimental pups were injected intraperitoneally with ^{3}H-leucine as a precursor of protein synthesis and controls received ^{14}C-leucine. Following 3 hrs incubation, the animals were killed, test and control brains were paired, and subcellular fractions prepared. For each subfraction, a $^{3}H/^{14}C$ (test/control) ratio was determined and normalized to the corresponding microsomal value for that double brain homogenate. The resultant percentage values give a measure of the relative synthesis of each drug-treated subcellular fraction.

Results for individual test/control brain pairs are shown:

Dose (mg/Kg)	40			80		
Drug	A*	T	C	A	T	C
Myelin	103	92	87	89	96	81
	102	102	89	93	93	98
				96	100	
Nuclear	100	87	96	94	92	88
	106	95	87	84	88	90
				95	95	
Synaptosomal	97	91	98	101	101	101
	97	95	100	93	98	93
				100	100	
Mitochondrial	103	99	93	99	96	99
	101	96	100	93	102	93
				96	95	
Microsomal	100	100	100	100	100	100

A*=aminophylline, T=theophylline, C=caffeine

The results show low myelin ratios for caffeine at 40 mg/Kg and for aminophylline and caffeine at 80 mg/Kg. Low ratios are also noted for the nuclear fraction. No indication of depressed synthesis is seen in the synaptosomal or mitochondrial fractions. (Supported by USPHS NS-14355 and NS-13799 to RCW).

51.4 TRYPTIC PEPTIDE MAPS OF MAJOR STRUCTURAL PROTEINS FROM MYELIN OF MICE. Marvin W. Luttges and Douglas E. Groswald*. Dept. of Aerospace Engineering Sciences, Univ. of Colorado, Boulder, CO 80309.

It is now generally recognized that there exist differing populations of myelin in the central nervous system (CNS) and peripheral nervous system (PNS) as characterized by buoyancy on sucrose gradients. Less certain, however, are the differences between the apparent microheterogeneity of the myelin proteins from these different buoyant fractions. Also in many species differing numbers of basic proteins have been reported for both CNS and PNS myelin. The major glycoprotein in PNS-myelin has been linked to two other closely electrophoretically migrating proteins as a consequence of changes in their relative concentrations during degeneration and their periodic acid schiff (PAS) sensitivity. The present study examines the relative concentration of the major structural proteins from PNS myelins which are recovered from continuous sucrose gradients, their tryptic peptide maps and the peptide maps between the basic proteins from CNS and PNS myelin from mice. PNS myelin was found to be normally distributed on continuous density gradients. The major glycoprotein accounted for approximately 40% of the recoverable protein, 15% for the basic proteins, and approximately 20% for the two major PAS-sensitive proteins. Comparisons between the mole concentrations for the different protein-species to the mole concentration of the major glycoprotein, revealed that a basic complement of protein is apparent in PNS myelins of differing buoyant densities. Tryptic peptide maps between the major glycoprotein and two PAS-sensitive proteins exhibited significant overlap. Also tryptic maps between the three major basic proteins (two slow migrating and the faster migrating one) show major similarities between themselves within their respective myelins and between the two different myelins. These studies suggest that in the PNS, protein contributions are not primarily responsible for differing myelin buoyancies, and that a similar gene in the myelin producing cells of the CNS and PNS is active in mice.

51.5 EFFECTS OF CELL DENSITY ON LIPIDS OF HUMAN GLIOMA AND FOETAL GLIA-LIKE CELLS. V.A. Liepkalns*, A.J. Yates, C. Icard*, D.K. Thompson*, and R.W. Hart*. Depts. of Pathology and Radiology, Ohio State Univ. Sch. of Med., Columbus, OH 43210.

A human glioblastoma multiforme (12-18) and human foetal glia-like cells (CH) were grown in vitro to sparse density, when few cells are in contact, and confluent density when all cells are in contact with adjacent cells. Ganglioside sialic acid, phospholipid phosphorus, and cholesterol levels were determined on both glioma and foetal cell lines at both cell densities. Distributions of sialic acid among ganglioside species and phosphorus in the major phospholipid classes were also determined. Total ganglioside sialic acid, phospholipid phosphorus and cholesterol increased in the glioma cell on a per cell number, mg protein and mg total lipid extract basis by 2 to 3-fold as cell density increased 25-fold. Ganglioside sialic acid, phospholipid phosphorus and cholesterol levels increased with cell density on a per cell and mg protein basis in the foetal cell but not on a total lipid extract basis. In both cell lines ethanolamine plasmalogen comprised a slightly greater proportion of phospholipids at all confluent densities. The proportion of sphingomyelin was higher in the glioma (9.4 $\pm$ 0.5%) than in CH (6.0 $\pm$ 0.6%) at all cell densities. Distributions of ganglioside sialic acid indicated a consistent trend towards an increased proportion of complex gangliosides in the glioma cell as density increased. The set of simpler gangliosides (GM_4 + GM_3 + GM_2) decreased with cell density from 50% of total ganglioside sialic acid to 36% during log phase to 30% at confluency. The proportions of both (GM_1 + GD_{1a}) which are in one biosynthetic pathway and the set (GD_3 + GD_2 + GD_{1b}) which are synthesized along another pathway were commensurately higher in confluent glioma cells. In the foetal glia-like cells the set of simpler gangliosides (GM_4 + GM_3 + GM_2) was about 48% of total ganglioside in both sparse and confluent preparations. The foetal cell had a 2-fold higher proportion of GM_3 (32.4 $\pm$ 2.1%) than the glioma cell (16.8 $\pm$ 1.6%) but a lower proportion of GM_1 (9.1 $\pm$ .7 vs. 18.2 $\pm$ 1.8%) at all cell densities considered. We conclude that between these two cells of glial origin, the glioma (12-18) has a greater response to increasing cell density in terms of the synthesis of more complex membrane lipid constituents.

This work was supported by grant PDT-151 from the American Cancer Society.

51.6 APPLICATION OF SENSITIVE GAS CHROMATOGRAPHY WITH NITROGEN PHOSPHOROUS DETECTOR FOR THE ESTIMATION OF SPHINGOLIPIDS. Basalingappa L. Hungund* (SPON: Dale Deutsch). Long Island Res Inst, SUNY, Stony Brook, N.Y. 11794.

The sphingolipids comprise an important lipid class which are believed to be localized predominantly in the surface membranes. Quantitative determination of these lipids is an important prerequisite for many biochemical studies. Most methods described in the literature for quantitation rely on the colorimetric and fluorimetric measurements of the long chain bases (LCB) released after hydrolysis. These techniques are sensitive but they are nonspecific and unreliable.

A simple and very sensitive gas chromatographic (gc) method is presented which utilizes the sensitivity and selectivity of recently introduced nitrogen-phosphorous (NP) detector. The sphingoid base is released from individual sphingolipid by acid hydrolysis. The free base thus released is derivatized with trifluoroacetic anhydride which is then injected onto gc column for quantitation. The method is highly sensitive (5-6 pmol) per injection, specific and can provide information on chain length and degree of unsaturation of sphingoid bases derived from individual sphingolipid.

52.1 NUCLEIC ACID SEQUENCE OF A PREDOMINANT mRNA FROM CHICK EMBRYO BRAIN. R.J. Milner*, J.G. Sutcliffe*†, T. Shinnick*†, J. Ray *†, R.A. Lerner *† and F.E. Bloom. A.V. Davis Ctr., The Salk Inst. and Scripps Clinic and Research Foundation†, San Diego, CA 92037.

The embryonic chicken brain contains several predominant mRNA species. These include mRNAs coding for tubulin and actin as shown by protein synthesis in vitro. A third predominant mRNA species codes for a protein with a molecular weight of 33,000 daltons which we have called p33. The identity of this protein is not known. Recombinant DNA techniques now provide the means to analyze eukaryotic genetic systems. Using these methods in combination with DNA sequencing techniques, it is possible, in many cases, to obtain primary structural information for a given protein more rapidly than by conventional protein sequencing. We are using this approach to characterize p33 and other gene products expressed in the nervous system.

Double stranded DNA produced from p33 mRNA by reverse transcriptase and DNA polymerase was inserted into the Hind III site of the plasmid pBR322 and cloned in E.coli. Digestion of the cloned plasmid with restriction enzymes showed that the insert contained sites for the enzymes Hpa II, Alu I, Hinf I, Mbo I and Hae III. Fragments of the insert were prepared with these enzymes, end labelled with 32p using polynucleotide kinase and sequenced by the partial chemical degradation method. Sequences of overlapping fragments were aligned to generate the complete DNA sequence of the insert. The sense strand of the insert, identified by a polyadenine sequence at its 3' terminal, corresponds to 550 bases of the p33 mRNA and includes the 3' non-coding region and approximately half of the coding region of the mRNA. The amino acid sequence of the carboxy terminal half of the p33 protein was obtained by translation of an open reading frame in the coding region. Comparison of the sequence with known amino acid sequences has not revealed any identity or significant homology. Experiments are in progress to determine the identity, function and location of this protein.

We thank D.W. Cleveland (Dept. of Biochem. UCSF) for clones used in these studies. These experiments were conducted according to NIH Recombinant DNA Research Guidelines and supported by grants from McNeil Laboratories and the Sun Oil Company.

52.2 MESSENGER RNA POPULATIONS IN VARIOUS REGIONS OF THE RAT BRAIN: PARTIAL PURIFICATION OF A DIENCEPHALON-SPECIFIC mRNA. Robert Bruce Moffett* (SPON: C. Bauer-Moffett). Dept. Molecular Biology, Roswell Park Memorial Inst., Buffalo, N. Y. 14223.

In order to delineate the genetic activity of different CNS cell types, the protein and mRNA populations of different brain regions were examined. The mRNA population of the rat cerebellum, cereberum, diencephalon, and brain stem was compared by two dimensional electrophoretic separation of their cell-free translation products. Fluorographs indicated that only a few significant differences existed among the species of abundant mRNA present in these various regions. Species of mRNA which were enriched in a particular brain region were denoted as "cell specific" products. One such mRNA was predominantly confined to the diencephalon. This mRNA was among the more abundant mRNAs present in the diencephalon and coded for a 30,000 Dalton peptide. This diencephalon "specific" mRNA was partially purified by oligo(dT)-cellulose chromatography and urea-sucrose gradient selection. These studies are preliminary to the production of cDNA and recombinant DNA probes for investigating CNS genetic activity. (NIH grant GM-07093).

52.3 NEUROCARCINOGENESIS OF ETHYLNITROSOUREA. M.J.W. Chang, A. Koestner and R.W. Hart*, Department of Veterinary Pathobiology and Department of Radiology, The Ohio State University, Columbus, Ohio 43210.

Ethylnitrosourea (ENU) is a potent single-dose perinatal neurocarcinogen in rats. The susceptibility for induction of neurogenic tumors in fetuses increases with advancing pregnancy and culminates toward the termination of the gestation period approaching a 100% tumor incidence. While newborn rats are equally susceptible, this susceptibility declines with advancing age and single-dose induction of neurogenic tumors becomes almost impossible beyond the age of 30 days. In the present study DNA was isolated from the brains of rats following i.v. exposure to radiolabeled ENU (45-180 mg/kg b. wt.) and analyzed by dilute acid hydrolysis and Sephadex G-10 column chromatography. N^7-ethylguanine, N^3-ethyladenine and O^6-ethylguanine were identified. Of these ethylated bases, O^6-ethylguanine is particularly interesting since it represents a promutagenic lesion which, if not repaired before DNA replication may result in a point mutation. Two time points were, therefore, studied: one hour and 7 days following ENU exposure to determine initial damage and repair. Three age groups of rats were compared: a) fetuses or neonates, b) 30 day old rats and c) adult rats. The persistence of brain DNA O^6-ethylguanine was similar in all three age groups (60-85% of initial O^6-EtGua/Gua). Within the 7 day period, however, the brain DNA content in neonates increased 300%, in 30 day old rats 10% and less than 1% in adults. Considering the great difference in brain tumor incidence in rats exposed to a single dose of ENU at different ages (100% in neonates and 0% in adults) and in the light of equal retention of ethylated O^6-guanine the following hypothetical conclusion has been reached: carcinogenesis by ENU and perhaps other alkylating agents is a function of both persistence of DNA adducts and rate of DNA replication in target cells. (Supported by USEPA Grant No. R-805337-02).

52.4 INTERACTION OF DELTA-9-TETRAHYDROCANNABINOL WITH BRAIN RIBOSOMAL RNA. M. K. Poddar (SPON: D. A. Urquhart). Dept. of Physiol. Biophys., College of Med. & Dent. of New Jersey, Rutgers Med. Sch. NJ 08854, USA.

Delta-9-tetrahydrocannabinol (THC), the major active component of cannabis, is lypophilic in nature. To understand the molecular mechanism of action of delta-9-THC in brain, in terms of its structure function relationship, an in vitro interaction study between the delta-9-THC molecule and the brain ribosomal RNA (r-RNA) has been made. In the present investigation the interaction between delta-9-THC and r-RNA (isolated from rat cerebral cortex and by hypothalamus) was studied based on the principle that thermal dissociation of dyes or drugs from the mixture of nucleic acid and drug depends on the nature of their interaction and also on the melting temperature (tm) of nucleic acid. The in vitro interaction of delta-9-THC at two different concentrations (9.3 and 93.0 μM) with r-RNA isolated from rat brain cortex and hypothalamus suggests that delta-9-THC binds with r-RNA (from both brain cortex and hypothalamus) maximally at low concentration (9.3 μM) whereas at higher concentration (93.0 μM) binding is comparatively less. The measurement of thermal absorbances of mixture of delta-9-THC and r-RNA indicate that the binding of delta-9-THC, at very low concentration (9.3 μM), to r-RNA may occur through intercalation between the bases of r-RNA of localized helical region; at high concentration, on the other hand, delta-9-THC may interact with r-RNA through other type of binding, instead of intercalation. These concentration dependent interaction of delta-9-THC with brain r-RNA may be explained by the fact that at lower concentration, delta-9-THC molecules may remain in the single monomeric form and because of this planar structure of the benzene ring prevails; as a result, delta-9-THC may intercalate between the bases of r-RNA segment having localized helical region. At higher concentration the delta-9-THC molecule, instead of remaining in monomeric forms, tends to exist in micelle form (Garrett and Hunt. J. Pharm. Sci. 63, 1056, 1974 and Poddar et al. Toxicol. Appld. Pharmacol. 46, 737, 1978) which may alter the configuration of the molecule and hence the interaction of delta-9-THC with r-RNA through intercalation is not possible.

52.5 ANTI-ENCEPHALITOGENIC RAT SPINAL CORD PROTEIN (RSCP): IMMUNOCHEMICAL PROPERTIES. C.F.C. MacPherson and S. Yu* Dept. of Psychiatry, Univ. of Western Ontario, London Ontario, Canada

Immunoreactive rat spinal cord proteins occur in axons of brain (RB-SCP), spinal cord (RSCP) and peripheral nerve (RSCP-PN). The importance of RB-SCP and RSCP is due to the observation that if Lewis rats are pretreated with RB-SCP or RSCP, they do not develop experimental allergic encephalitis when they are challenged with the rat myelin basic protein (MacPherson & Armstrong, Nature, 266, 459, 1977). Originally, RSCP was isolated from 0.05 M ammonium acetate extracts of rat spinal cords that had been frozen for over a year (MacPherson & Armstrong, J. Immunol. 116, 398, 1976). Subsequently, it was found that only a fraction of the total RSCP present in fresh or recently frozen rat nervous tissues could be extracted with 0.05 ammonium acetate. This report will describe the immunochemical properties of RB-SCP, RSCP and RSCP-PN obtained from acetone defatted tissues by extraction with 0.05 M sodium acetate, pH 5.0. Contaminants were removed by absorption on CM-52 cellulose at pH 5.0 and by gel-filtration on Sephadex G-50. At this stage RSCP-PN formed one band after SDS-polyacrylamide electrophoresis but RB-SCP and RSCP required a final purification step consisting of passage through a column of cyanogen bromide activated Sepharose-4B coupled to anti-RSCP IgG. RSCP's have a molecular weight of 11,000 + 1,000 daltons and an isoelectric point of about pH 4.5. The amino acid compositions of the RSCP's are similar but not identical. They contain from 32-24% of acidic amino acids, 19-13% of basic amino acids and less than 0.5% of ½ cystine.

52.6 SEROTONIN METABOLISM: CHARACTERIZATION OF SEROTONIN BINDING PROTEINS PREPARED FROM BRAIN AND PINEAL ORGAN. Yoshisuke Ozaki and Richard J. Wurtman. Lab. of Neuroendocrine Regulation, Dept. of Nutrition and Food Science, M.I.T., Cambridge, MA 02139.

It has previously been shown that mammalian brain contains cytoplasmic proteins which can bind serotonin (5HT). We are purifying such proteins from brain and pineal organ using Sephadex G25 filtration, affinity chromatography, ion exchange chromatogrpahy, polyacrylamide gel molecular sieving, and isoelectric focusing. We find that brain contains at least three distinct macromolecules that bind 5-HT, with apparent equilibrium dissociation constants (Kd) of approximately 10^{-7}, 10^{-8}, and 10^{-9} M, and apparent molecular weights of 11,000, 30,000, and 150,000 daltons. We are currently investigating the functions of these proteins (e.g., 5HT receptors; carrier molecules mediating axoplasmic flow or synaptic uptake; storage sites; enzymes). Pineal organs also contain proteins which bind 5HT with apparent affinities of 10^{-7}, 10^{-8}, and 10^{-9} M. The 5HT binding of the highest affinity pineal macromolecule (10^{-9}M) is decreased if rats are pretreated with norepinephrine (2.5 mg/Kg, SC). This could increase the amount of stored or bound 5HT available for metabolism by melatonin-forming enzymes (serotonin-N-acetyltransferase; hydroxyindole-O-methyltransferase) or monoamine oxidase.

52.7 THE Ca^{2+} IONOPHORE, A23187, INHIBITS PROTEIN SYNTHESIS IN GUINEA PIG HIPPOCAMPAL SLICES. Barbara Koons* and Peter Lipton. Dept. of Physiology, Sch. Med., Univ. of Wisconsin, Madison, WI 53706.

We are attempting to study the dependence of brain protein synthesis on cytosolic Ca^{2+} using the Ca^{2+} ionophore A23187. We are using the isolated transverse slice of the guinea pig hippocampus. Slices are incubated in a modified 95% O_2/5% CO_2 Krebs buffer at 37°C and total protein synthesis is measured as the rate of incorporation of ^{14}C-lysine into PCA-insoluble material. Statistical comparison of incorporation rates between ionophore treated and untreated slices is facilitated by a "double-label" protocol in which each slice effectively serves as its own control: slices are exposed to ^{3}H-lysine in a control period prior to exposure to the ionophore. $^{14}C/^{3}H$ in PCA precipitable material is then compared for treated and untreated tissue. Treated tissues are exposed to A23187 dissolved in DMSO; untreated tissues are exposed to DMSO.

A23187 added to the bathing medium 30 minutes prior to adding ^{14}C-lysine, produces a dose dependent inhibition of ^{14}C incorporation into proteins. Maximal inhibition occurs at 20μM ionophore. 10μM A23187 inhibits synthesis by about 25% and does not affect the uptake of ^{14}C-lysine into the PCA-soluble fraction of the cell.

Incubating slices in a Ca^{2+}-free buffer elevated basal levels of protein synthesis slightly but did not alter the % inhibition caused by A23187. Thus, an A23187-mediated influx of extracellular Ca^{2+} is probably not the basis for the inhibition of synthesis. Incubating slices in a Mg^{2+}-free buffer depressed basal levels of protein synthesis (~20%) and enhanced the inhibition of synthesis caused by A23187. This indicates that the inhibition does not result from an ionophore-mediated Mg^{2+} influx into the cell. The increased inhibition in 0 Mg^{2+} is consistent with the ability of Mg^{2+} to activate protein synthesis and to compete with Ca^{2+} for binding to the ionophore.

Incubating slices in 2.5mM EGTA for 2 hours prior to adding the ionophore reduced basal levels of protein synthesis by about 60%; however, the percent inhibition of synthesis by A23187 was the same as in slices which were not exposed to EGTA. These data suggest either i) that the ionophore-mediated inhibition of protein synthesis is independent of a rise in cytosolic Ca^{2+} or ii) that the ionophore is causing release of Ca^{2+} from intracellular stores which are unaffected by the EGTA treatment (e.g., mitochondria) and that the increased cytosolic Ca^{2+} then inhibits tissue protein synthesis. Experiments are being carried out to resolve these two possibilities.

52.8 ISOLATION OF NEUROFILAMENT PROTEINS FROM BRAIN BUFFER EXTRACTS BY IMMUNOAFFINITY CHROMATOGRAPHY. DEMONSTRATION OF IMMUNOLOGICALLY ACTIVE DEGRADATION PRODUCTS IN THE 50K RANGE. D. Dahl. Spinal Cord Injury Research Laboratory, Harvard Medical School and West Roxbury VA Medical Center, Boston, MA. 02132.

Neurofilament proteins were extracted at low ionic strength (1 mM sodium phosphate buffer) from brain and spinal cord of 4 mammalian (human, bovine, rabbit and rat) and 4 submammalian species (chicken, turtle, frog and shark). The extracts were applied to Sepharose 4B coupled to neurofilament antisera raised to degraded chicken neurofilament proteins (Dahl, D. and Bignami, A., J. Comp. Neurol., 176:645, 1977; Dahl, D, BBA, 622:9, 1980). Neurofilament polypeptides at approximately 150K and 70K were tightly attached to the column and eluted at pH 2.5. In rat and rabbit the 150K dalton protein was smaller compared to human and bovine as indicated by co-migration experiments on SDS polyacrylamide gel electrophoresis. Omission of EDTA and EGTA in the homogenization buffer resulted in the degradation of the neurofilament proteins into multiple components in the 50K range. The degraded proteins maintained their immunological activity and tightly attached to the anti-neurofilament column. Additional evidence as to the limited proteolysis of neurofilament proteins into immunologically active components was obtained in rat optic nerves undergoing Wallerian degeneration. Following enucleation of the eyes neurofilament proteins at 70K and 150K were no longer identifiable in SDS extracts of the degenerated optic nerves. However, axonal debris was still stained by immunofluorescence with neurofilament antisera in cryostat sections of the degenerated nerves. Supported by a grant from the National Science Foundation (BNS-7912962) and by the Veterans Administration.

53.1 MASS SPECTROMETRIC CHARACTERIZATION OF DERIVATIZED BIOGENIC AMINES PREPARED FOR QUANTITATIVE GAS CHROMATOGRAPHIC ANALYSIS. R. T. Coutts*, G. B. Baker and S.-F. Liu* (SPON: W. F. Dryden). Neurochem. Res. Unit, Fac. of Pharmacy and Pharm. Sci. and Dept. of Psychiatry, Univ. of Alberta, Edmonton T6G 2N8, Canada.

Various classes of biogenic amines have been detected in trace amounts in biological samples. Some can be considered to be simple derivatives of 2-phenylethylamine or analogous compounds, e.g. tryptamine, histamine; alcoholamines and phenolic amines are also encountered. The quantitative analysis of mixtures of biogenic amines presents some difficulties. They must be extracted efficiently and derivatized with a reagent which improves the sensitivity and specificity of their detection and quantitation. We have developed an analytical procedure which permits the quantitative analysis of mixtures of biogenic amines in which the amines are acetylated in aqueous solution then perfluoroacylated to give products which are readily analyzed using gas chromatography with electron-capture detection (EC-GC). An essential feature of the analytical procedure is the unequivocal identification of the derivatized products. This was accomplished mass spectrometrically.

Evidence is presented that 2-phenylethylamines are converted to N-acetyl-N-perfluoroacyl derivatives during the analytical procedure. Phenolic amines initially form N, O-diacetyl products which are, in most cases, subsequently converted to N, O-diacetyl-N-perfluoroacylated compounds. With 5-hydroxytryptamine, however, the final product is an O-acetyl-N-perfluoroacylated beta-carboline derivative (Baker, G.B. et al., J. Pharmacol. Meth., 3:173, 1980). Derivatization of histamine produces a structurally related cyclized product. Acetylation of alcoholamines results only in N-acetylation; the alcohol group remains underivatized. Subsequent perfluoroacylation of the acetylated intermediate yields an N-acetyl-N, O-di(perfluoroacyl) derivative. The product obtained from phenylethanolamine, for example, was deduced by mass spectrometry to be $PhCH(OCOC_nF_{2n+1})$-$CH_2N(COCH_3)COC_nF_{2n+1}$. This compound is not stable. On standing in solution, it decomposes to a compound which is insensitive to detection by EC-GC. Interpretation of the mass spectrum of the decomposition product revealed that it was an oxazoline derivative. A mechanism which explains its formation is suggested. Fragmentation pathways of various examples of derivatized biogenic amines, which are compatible with the recorded mass spectra, are also suggested. Many of the diagnostic ions retain the perfluoroacyl group, although a consistent fragment in most of the spectra is the result of the expulsion of a molecule of structure $CH_3CONHCOC_nF_{2n+1}$ from the molecular ion.

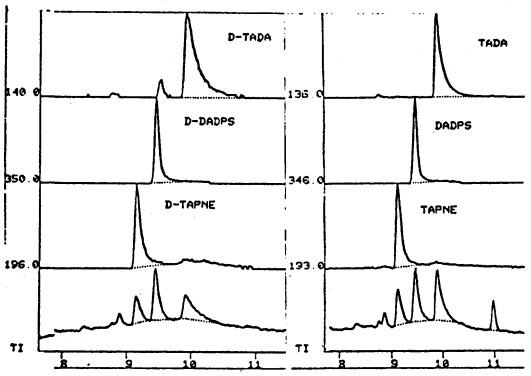
53.2 GC/MS METHOD FOR SIMULTANEOUS DETERMINATION OF PICOGRAM LEVELS OF NOREPINEPHRINE, DOPAMINE AND SEROTONIN IN BIOLOGICAL SAMPLES. Lelland C. Tolbert and George B. Brown, Neurosciences Program, University of Alabama in Birmingham, Birmingham, Alabama 35294.

A method has been developed for the simultaneous determination of norepinephrine, dopamine and serotonin in biological samples. The method involves the derivatization of the amines by acetylation with acetic anhydride followed by acylation with pentafluoroproprionic (PFP) anhydride. Dopamine is measured as the triacetyl derivative (TADA) (3-O, 4-O, N) norepinephrine as the triacetyl-mono PFP derivative (TAPNE) (as with dopamine plus the PFP addition to the β-hydroxyl position), and serotonin as the diacetyl-di-PFP derivative (DADPS). This method has the advantage of stability of the derivatives when compared to other GC/MS methods. Quantitation is achieved in the selected ion monitoring mode with reference to internal deuterated standards. Diagnostic fragments chosen for this analysis are at m/e 136 and 140 for proteo and deutero dopamine, m/e 193 and 196 for proteo and deutero norepinephrine, and m/e 346 and 350 for proteo and deutero serotonin. A representative chromatogram is given below showing the separation of the three derivatives and the specificity of the selected ions. This method also has the advantage of not requiring an extensive column purification procedure before derivatization. Because the initial reaction can occur in aqueous solutions it is also possible to directly derivatize tissue perfusates. Applications will be discussed.



53.3 PRESENCE OF CONJUGATED CATECHOLAMINES (CA) IN RAT BRAIN: A NEW METHOD OF ANALYSIS OF CA SULFATE. N.T. Buu*, L. Truong* and O. Kuchel*. (SPON: A. Barbeau). Clinical Research Institute, Montreal, Quebec H2W 1R7.

Sulfation of CA has been shown to occur readily in mammals (Rutledge & Hoehn, Nature, 244:447, 1973), but the physiological meaning of CA conjugation remains unknown. Phenolsulphotransferase (PST), the enzyme responsible for the sulfation of phenols and CA was found in rat brain (Meek & Neff, J. Neurochem., 21:1, 1973) and most recently in human brain (Renskers et al., J. Neurochem., in press, 1980). Yet despite the large concentrations of free CA in various regions of the brain no CA sulfate in brain has been reported, in contrast to the large quantities of conjugated CA found in mammalian plasma, urine and peripheral tissues, including the vesicular fraction of dog's adrenal medulla (Unger et al., Can. J. Physiol. Pharmacol., 58:22, 1980). This may be due to the lack of a sensitive method of measurement of conjugated CA in samples containing large quantities of free CA. The present paper reports an efficient method of isolating and measuring CA sulfate and the finding of CA sulfates in three different regions of rat brain.

Homogenate of brain was subjected to alumina adsorption at pH 8.6. The supernatant was acidified and transfered to Dowex 50X-8 (H^+ form) column. Eluate from Dowex column was analyzed for CA sulfate by a radioenzymatic technique in the presence and absence of a sulfatase. Values of CA sulfate from seven rat brains, expressed as means ± SEM (ng/g tissue) are as follows:

Areas	DA sulfate	NE sulfate	E sulfate
hypothalamus	77.6 ± 25.0	15.9 ± 2.7	10.2 ± 6.6
striatum	50.2 ± 20.7	4.4 ± 2.8	7.9 ± 4.1
hippocampus	25.4 ± 7.0	ND	ND

DA:dopamine, NE:norepinephrine, E:epinephrine; ND:not detectable

Concentrations of free CA are comparable to those reported in the literature. Sulfate esters of DA, NE and E account for only about 5-10 percent of the total CA in the brain. The small degree of conjugation of brain CA stands in contrast with the much higher percentage of conjugation found in the periphery (e.g. 99 percent for plasma DA). This difference in the degree of conjugation cannot be explained by the difference in PST activity alone or by a faster turnover of CA sulfates since they are not readily metabolized either by COMT or MAO. It may, however, suggest that CA sulfates are quickly evacuated from the brain. Sulfation seems to represent therefore a rapid method of removing excess of free CA from the brain to the periphery.

In summary this paper: 1) describes a rapid and sensitive new method of extracting and measuring CA sulfate; 2) reports finding of CA sulfates in three specific areas of rat brain.

53.4 AVAILABILITY OF TYROSINE AND PHENYLALANINE FOR BRAIN NOREPINEPHRINE SYNTHESIS IN PROTEIN MALNOURISHED RATS. Maravene Miller, Rachelle Hasson* and Oscar Resnick*. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545.

The availability of tyrosine (Tyr) and/or phenylalanine (Phe) for norepinephrine (NE) synthesis from birth to age 30 days was examined in regional brain areas of rats fed a normal (25% casein) or a low protein (8% casein) diet. The malnourished group, whose dams received the low protein diet 5 weeks prior to conception, showed significantly elevated NE levels at birth (Table below) and at older ages. Although the amount of brain Tyr was markedly lower at birth and at some other ages during development in the malnourished rats, these animals consistently showed marked increases in their brain Phe levels at all ages examined compared to the normal rats. Also, the plasma Phe levels of the malnourished rats were significantly higher than the normal animals from birth to 30 days, whereas their plasma Tyr levels only showed significant decreases at some ages compared to the controls. These data seem to indicate that: (1) more Tyr has been withdrawn from peripheral circulation in the deprived rats in an attempt to maintain their brain Tyr levels at near normal values, and/or (2) the increased availability of plasma Phe represents a decrease in its conversion to Tyr in the liver in order to provide enough of this essential amino acid for metabolic purposes including brain NE formation.

Day of Birth (Mean ± S.E.)

53.5 MANGANESE-INDUCED CHANGES IN BRAIN AMINES. G. Gianutsos, M. T. Murray* and M. D. Poulin* Section of Pharmacology & Toxicology, University of Connecticut, Storrs, CT 06268.

Manganese has been reported to alter brain amines, especially dopamine, when administered orally in an animal's drinking water (Bonilla et al., J. Neurochem. 22:297, 1974). In the present study, the effect of manganese on the concentrations of dopamine (DA) and GABA and on the activity of choline acetylase, a marker for cholinergic neurons, was measured. Manganese was administered in 3 different ways: I. by incorporation of 4% manganous chloride into the animal's food for up to 6 months; II. by direct unilateral intrastriatal injection of 10-20 ug of manganous chloride; and III. by subcutaneous injection of the gasoline additive methylcyclopentadienyl Mn tricarbonyl (MMT). In Exp. III, MMT was diluted in propylene glycol and injected on alternate days for 3 weeks.

Regardless of the route of exposure, manganese produced a small (15-25%) but significant decrease in striatal DA content. Decreases in DA were also noted in the olfactory tubercle and hypothalamus in Exp. I and III. Hypothalamic norepinephrine remained unchanged. On the other hand, striatal GABA concentrations were elevated in the manganese-treated mice, while GABA in the cerebellum remained unchanged. Choline acetylase also showed transient changes, tending to increase in the striata of manganese-exposed mice while remaining essentially unchanged in the hippocampus.

It is concluded that exposure to high concentrations of manganese may induce a change in DA neurons which may secondarily affect striatal GABAergic and cholinergic neurons. It is suggested that these changes may be related to the extrapyramidal symptoms associated with manganese toxicity.

53.6 EFFECTS OF SODIUM DEPLETION ON BRAIN ISO-RENIN AND CATECHOLAMINES. K.B. Brosnihan, C.M. Ferrario, R.R. Smeby,* & J.M. Saavedra. Res. Div., Cleveland Clinic, Cleveland, OH & NIMH, Bethesda, MD.

Reduction of sodium intake may alter the point of equilibrium between the renin-angiotensin and sympathetic nervous systems in the control of cardiovascular function. Recent studies from our laboratory have given support to the idea of depressed sympathetic nervous system function following severe dietary sodium depletion that caused a 15-fold increase in plasma renin activity (PRA) and was associated with elevated cerebrospinal fluid (CSF) norepinephrine (Brosnihan et al., The Physiologist 21: 13, 1978). The latter findings suggest an alteration in central noradrenergic activity; however, information regarding the concomitant change in brain renin-angiotensin is altogether lacking. Therefore, we determined the influence of sodium depletion on brain iso-renin of different brain regions and on catecholaminergic activity of the area postrema, a circumventricular area of the 4th ventricle known to be sensitive to angiotensin II.

Mongrel dogs were placed either on a normal (65 mEq Na+/day) or low (4 mEq Na+/day, supplemented with furosemide) sodium diet. Samples for PRA were taken in the conscious animal. The animals were anesthetized with sodium pentobarbital, and samples of CSF were taken from the cisternum magnum for renin determinations. Brains of animals were then perfused with cold isotonic saline. The area postrema, pyramidal tract and choroid plexus were assayed for catecholamines, PNMT, and serotonin. The brainstem, cortex, cerebellum, and spinal cord were assayed from brain iso-renin by the method of Smeby (unpublished) and for brain cathepsin D.

After sodium depletion norepinephrine concentration of the area postrema decreased from 9.17 $\pm$ 0.96 ng/mg protein to 5.23 $\pm$ 0.80 ng/mg protein ($p < 0.01$); whereas the concentration of epinephrine, dopamine, serotonin, and PNMT did not change. No alteration in catecholamines was found in the pyramidal tract during sodium depletion. As expected PRA rose from 1.3 $\pm$ 0.5 to 17.9 $\pm$ 4 ng/ml ($p < 0.01$) during sodium depletion. The concentration of brain iso-renin was significantly lower in the upper and lower brainstem of sodium depleted dogs; whereas cathepsin D concentration of all brain areas studied was unaltered by sodium depletion.

Our findings of a reduction in brain iso-renin concentration in the presence of marked elevation of PRA support the hypothesis of a negative feedback relationship between the kidney and the brain. Additionally, this study reveals for the first time an alteration in the brainstem of both iso-renin and noradrenergic activity during sodium depletion.

Supported by NHLBI grant #HL-6835.

53.7 COMPARISON OF THE EFFECTS OF TRANYLCYPROMINE AND PHENELZINE ON SEVERAL AMINES IN RAT BRAIN. G. B. Baker, J. M. Baker*, D. F. LeGatt* and R. T. Coutts*. Neurochemical Res. Unit, Dept. of Psychiatry and Fac. of Pharmacy and Pharmaceutical Sciences, Univ. of Alberta, Edmonton, Alberta, Canada T6G 2G3.

The amine hypotheses of depression propose that depression is due to a decreased functional availability of one or more amines at central synapses. Amines which have been proposed as being important in this regard include the catecholamines (primarily norepinephrine), 5-hydroxytryptamine (5-HT) and the "trace" amines 2-phenylethylamine (PEA) and tryptamine (T). Studies are presently being conducted in our laboratories in which all these amines are being assayed simultaneously in rat brain tissue. We describe in this report a study of the effects of chronic administration of the monoamine oxidase inhibitors tranylcypromine (TCP) and phenelzine (PLZ) on the brain concentrations of dopamine (DA), norepinephrine (NE), 5-HT, PEA and T. Drugs were administered ip once daily (10 mg/kg for TCP and 15 mg/kg for phenelzine) for 7 days, and rats were killed 6 h after the last dose. Brains were homogenized in ice-cold 0.1 N perchloric acid containing 10 mg % EDTA, and after centrifugation a small portion was taken for analysis of catecholamines using a radioenzymatic procedure (Martin, I. L. et al., Biochem. Pharmac., 27: 1519, 1978). The remainder of the sample was prepared for simultaneous analysis of PEA, T and 5-HT using electron-capture gas chromatography with a glass capillary column (Calverley, D. G. et al., Can. J. Neurol. Sci., in press). Briefly, this consists of isolation of the amines using di-(2-ethylhexyl) phosphoric acid, elution into HCl, acetylation in the aqueous phase with acetic anhydride and extraction into ethyl acetate. The organic phase is dried under nitrogen and the residue is reacted with pentafluoropropionic anhydride. The resultant derivatives are separated on a 10 m WCOT glass capillary column, OV-101.

Results showed that with this dosage schedule concentrations of all amines had risen significantly above controls, but there were a number of interesting differences between the effects of the two drugs. Brain concentrations of 5-HT and DA were not significantly different between the two drug-treated groups, but NE concentrations were significantly higher in the brains from TCP-treated rats ($p<0.02$). The most noticeable differences between the two drugs were their effects on the levels of PEA and T. Increases in concentrations of both amines were several times greater with TCP than with PLZ.

(The support of the Medical Research Council of Canada is gratefully acknowledged).

53.8 PHENCYCLIDINE EFFECTS ON THE SYNTHESIS/RELEASE OF SYNAPTOSOMAL DOPAMINE CONTINUOUSLY APPEARING FROM PHENYLALANINE: SENSITIVITY TO RESERPINE. S. P. Bagchi. Rockland Research Institute, Orangeburg, NY 10962.

Phencyclidine (PCP) is an abused drug and it may reactivate schizophrenic psychosis and produce treatment resistant schizophrenia like behavior. In view of the evidence implicating dopamine (DA) in schizophrenia, PCP effects on the synthesis/release of synaptosomal DA continuously appearing from ^{14}C-phenylalanine (Phe*) were examined. Influence of reserpine (Res) on the PCP actions was also tested since Res may modify the action of amfonelic acid, a nonamphetamine stimulant like PCP, on synaptosomal DA. The published methods (Brain Res. 187, 403 (1980))consisted of the incubation (10 min) of synaptosomal (P2) preparation from rat caudate nuclei in tris-salt buffer (pH 7.4) containing pargyline, sucrose, glucose and Phe* and filtration of the mixture on Millipore filter postincubation to separate synaptosomes from the medium. Separated fractions were analyzed for labelled DA and the particulate level of Phe*. Results show that PCP may stimulate the total (particulates plus medium) ^{14}C-DA synthesis at 36.4 (166% of control) and 9.1 (154%) but not at 0.91 (95%) micromolar concentration. PCP at each of these concentrations significantly increased the release (medium/total x 100) of synaptosomally formed ^{14}C-DA beyond that occurring spontaneously. A PCP congener, Ketamine, at 36.4 and 9.1 micromolar did not stimulate the synthesis and only slightly increased the release. Res (5.5 to 90 nanomolar) had an inhibitory effect on the total DA formation and a stimulatory one on the release. The PCP stimulation of DA synthesis was not only blocked by a coaddition of Res but an inhibition beyond that due to Res alone was also observed. The release index in the presence of Res plus PCP was higher than that with Res alone. After pretreating the rats with Res, PCP also showed an inhibitory effect on the total DA synthesis and stimulated the release. None of the drugs affected particulate Phe*. In summary, the results show that a) PCP may stimulate the synthesis of synaptosomal DA and its release and b) the synthesis stimulation is Res sensitive, suggesting a catecholamine storage vesicle participation in PCP action. A comparison of tetrabenazine, another amine depletor, and Res actions further suggest that the Res sensitivity may be related to, not amine depletion, but possibly an interaction of PCP with what has been termed Res receptor. (Kindly supported by the Office of Mental Health, State of New York).

53.9 CHRONIC PHENYLETHYLAMINE TREATMENT AND BRAIN CATECHOLAMINES: A POSSIBLE BIOCHEMICAL MODEL OF SCHIZOPHRENIA. F. Karoum, S. G. Speciale, Jr., L-W. Chuang,* and R. J. Wyatt. Lab. of Clinical Psychopharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032; Dept. of Psychiatry, Univ. of Texas Health Center, Dallas, Texas.

Recent reports of increased urine excretion of phenylethylamine (PEA) and of increased norepinephrine (NE) concentration and metabolism in the hypothalamus and the nucleus accumbens in the post-mortem brains of paranoid chronic schizophrenics, have prompted us to evaluate the effects of chronic PEA treatment on brain catecholamines and metabolites. PEA (100 mg/kg) was administered intragastrically twice daily to rats for 10 days. The rats were killed 2 hours after the last dose, long after any stereotypy had subsided. The brain areas analyzed were: hypothalamus, nucleus accumbens, olfactory tubercle, caudate, and frontal cortex.

Chronic PEA significantly increased NE concentration in the hypothalamus (35%) and the nucleus accumbens (95%) but not in any of the other brain areas analyzed. In the hypothalamus, 3-methoxy-4-hydroxyphenylglycol (MHPG) was also increased (44%).

Chronic phenylethylamine had no effect on dopamine (DA) concentration in any of the brain areas analyzed except in the caudate where a slight but significant increase was observed (10%). The concentration of 3,4-dihydroxyphenylacetic acid (DOPAC) was increased in the hypothalamus, nucleus accumbens, and caudate, thus suggesting increased DA turnover in these areas. DOPAC remained unchanged in the olfactory tubercle.

The changes in brain NE observed after chronic PEA treatment resemble remarkedly the post-mortem results reported first by Farley et al. (Science, 200:456, 1978) and confirmed by us. We therefore suggest that the increased NE concentration found in the hypothalamus and nucleus accumbens of paranoid chronic schizophrenics may be attributed to sustained increased brain PEA secondary to both central and peripheral causes. Increased stimulation of DA neurons in the hypothalamus, nucleus accumbens, and caudate by PEA in schizophrenia may also play a role in the etiology of the disease.

53.10 PERIPHERAL CORRELATES OF CENTRAL NORADRENERGIC ACTIVITY. J. D. Elsworth*, R. H. Roth, J. M. Stogin*, D. J. Leahy*, M. R. Moore*, D. E. Redmond, Jr. Departments of Pharmacology and Psychiatry, Yale Univ. Sch. Med., New Haven, CT 06510

One approach to the study of human brain transmitter turnover is the measurement of transmitter metabolite concentration in CSF, plasma or urine. Previous studies in rodents and primates have suggested a significant correlation among the concentrations of the norepinephrine (NE) metabolite 3-methoxy-4-hydroxyphenethylene glycol (MHPG) in plasma, CSF and two NE rich brain regions[1,2]. In addition Maas et al.[3,4] have found arterio-venous differences in MHPG content from cerebral circulation in non-human primates and man, indicating that venous plasma MHPG might reflect brain NE turnover. However, since a limited fraction of plasma MHPG is derived from brain such measurements might reflect uncontrolled peripheral sympathetic sources instead. Direct measurements in brain regions and peripheral pools under a variety of conditions might determine whether CSF and plasma MHPG content are reliable indices of central NE activity. Toward this end we have measured and correlated the quantity of MHPG in several brain areas, CSF and plasma in monkeys (Cercopithecus aethiops) before and after pharmacological manipulation of central noradrenergic systems.

Twenty-nine monkeys received one of the following treatments: saline, the α_2 agonist clonidine, the α_2 antagonist piperoxane, morphine, naloxone and/or withdrawal from morphine addiction. MHPG concentration was determined by gas chromatography-mass spectrometry using a single ion monitoring technique[3].

A significant correlation was found between plasma and CSF MHPG ($r=0.66$, $p < .001$) and between the MHPG content of hypothalamus and plasma ($r=0.55$, $p < .005$) and hypothalamus and CSF ($r= 0.63$, $p < .001$). Hippocampal MHPG also correlated with the concentration in plasma ($r=0.74$, $p < .001$) and CSF ($r=0.83$, $p < .001$).

These striking relationships further validate the technique of monitoring plasma and CSF MHPG in order to assess central NE metabolism. Similar data with other brain regions and on dopaminergic systems will also be presented. (Supported by DA 02321, MH-14092 and a grant from the Harry Frank Guggenheim Foundation)

53.11 THE EFFECT OF CYCLOHEXIMIDE AND ANISOMYCIN ON MONOAMINE SYNTHESIS IN MOUSE BRAIN SYNAPTOSOMES. M. M. Schweri* and L. A. Carr. Dept. Pharmacology and Toxicology, University of Louisville School of Medicine, Louisville, KY 40292.

Many protein synthesis inhibitors have been shown to inhibit catecholamine (CA) and 5-hydroxytryptamine (5-HT) synthesis in the brain when administered *in vivo*. In an effort to elucidate the mechanism of action of these drugs, the effect of cycloheximide (CXM) and anisomycin (ANISO) on the synthesis of dopamine (DA), norepinephrine (NE), and 5-HT in synaptosomes was measured following both *in vivo* and *in vitro* administration of these drugs.

In order to study the effects of *in vivo* administration of these drugs on CA formation, CXM (100 mg/kg) and ANISO (50 mg/kg) were administered s.c. to mice 1 hr. prior to sacrifice. Crude synaptosomal pellets (P_2) were prepared from the brains and the synaptosomes were incubated for 20 min. with ^{3}H-tyrosine (Tyr) at pH 7.4. Synaptosomal content of ^{3}H-Tyr and endogenous Tyr, and ^{3}H-DA and ^{3}H-NE in synaptosomes and medium were determined. In the *in vitro* study, CXM and ANISO were added to synaptosomes prepared from untreated mice in a concentration of 10^{-3}M. In parallel experiments, ^{3}H-tryptophan (Trp) was added as a substrate. Synaptosomal content of ^{3}H-5HT and ^{3}H-Trp was measured.

In vivo and *in vitro* administration of both CXM and ANISO caused an inhibition of ^{3}H-NE synthesis. ANISO also suppressed ^{3}H-DA synthesis under both conditions. CXM, but not ANISO, caused an elevation of synaptosomal ^{3}H-Tyr content when added *in vitro*. No effect on ^{3}H-Tyr or endogenous Tyr content was observed after *in vivo* administration of the drugs. Neither of the protein synthesis inhibitors affected endogenous Tyr following *in vitro* addition. When given *in vivo*, both protein synthesis inhibitors decreased synaptosomal ^{3}H-Trp and ^{3}H-5HT content. ANISO, but not CXM, caused similar effects when added *in vitro*.

The results indicate that these protein synthesis inhibitors do not require prior conversion to their metabolites in order to inhibit CA synthesis, as has been suggested, but may act directly on the biosynthetic enzymes. The data also suggest that CXM and ANISO may inhibit 5-HT synthesis by interfering with Trp accumulation in the nerve terminal.

53.12 ESTIMATION OF SYNTHESIS RATE AND TURNOVER OF ENDOGENOUSLY LABELED CATECHOLAMINES USING LIQUID CHROMATOGRAPHY ELECTROCHEMICAL DETECTION. Barbara A. Bennett* and David K. Sundberg* (SPON: Melvin Levitt). Dept. of Physiol. Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103.

Catecholamine turnover has been measured using steady-state methods by: (a) following the decay of tissue levels of injected labeled amines; (b) following the rate of formation of labeled amine after injection of labeled precursor; or (c) using nonsteady-state systems by following decline or accumulation of amine levels after inhibiting synthesis or degradation, respectively.

We have developed a technique for quantitating the turnover of catecholamines in various rat brain regions *in vivo*. This procedure involves the administration of 5 μCi of ^{3}H-tyrosine directly into the lateral cerebral ventricle in chronically cannulated rats. The tissues were weighed and extracted for catecholamines. Separation was by high performance reverse phase liquid chromotography and content analyzed with electrochemical detection. Eluant samples were collected for tritium monitoring.

Areas examined were the anterior hypothalamus (AH), medial basal hypothalamus (MBH), striatum, and brain stem. Both dopamine (DA) and norepinephrine (NE) were synthesized as indicated by co-migration of tritiated label with DA and NE retention times. Thirty minutes after administration of ^{3}H-tyrosine, DA synthesis was greater than NE in the MBH (1,916 fg vs 828 fg), AH (1,030 fg vs 560 fg), and striatum (7,420 fg, NE not measureable). The brain stem, on the other hand, showed greater NE (532 fg) synthesis than DA (110 fg). These levels are a conservative index of biogenic amine synthesis since specific activity of total tissue tyrosine could not be established at this time. However, they are a reliable index of amine turnover.

This method of analysis allows for pharmacological studies of synthesis inhibition and consequent changes in catecholamine turnover.

(Supported by NIH Grant HD-10900)

53.13 HYPOTHALAMIC CATECHOLAMINE TURNOVER IN VITRO MEASURED BY ELECTROCHEMICAL DETECTION. David K. Sundberg*, Laurie S. Pittman* and Barbara A. Bennett* (SPON: P. Blaise Smith). Dept. Physiol. Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103.

Catecholaminergic innervation to the hypothalamus has been implicated in the regulation of many neuroendocrine parameters. Many investigators have studied neuropeptide secretion by radioimmunoassay from isolated hypothalami in vitro and have administered exogenous catecholamines to determine their effects on release.

In the following communication we have developed a system to quantitate changes in content and the biosynthetic rate of norepinephrine (NE), L-DOPA and dopamine (DA) in vitro. Medial basal hypothalami (MBH) were incubated in Earls balance salts solution (pH 7.2, 95% O_2 5% CO_2) with 5 µCi of ^{3}H-tyrosine for different lengths of time and in the presence of various enzyme inhibitors involved in catecholamine metabolism (alpha methyl para-tyrosine, 10^{-3}M, αmpt) or catabolism (iproniazid, 10^{-4}M). Prior to, or after incubation the MBH was weighed and extracted for catecholamines using a modification of the alumina adsorption technique. The purified catecholamines were separated by high performance liquid chromatography, quantitated by electrochemical detection, and the eluant was collected for tritium monitoring. During incubation amine content fell during the first hour of incubation and approached a state of equilibrium at 2.5 hrs. NE and epinephrine content decreased by 50% when compared to non-incubated controls (3.26 ± 0.27 to 1.73 ± 0.18 ng/mg and 101 ± 12 to 46 ± 13 pg/mg, respectively). DA content, however, was reduced by 68% during incubation (1.03 ± 0.04 to 0.380 ± .05 ng/mg). Appreciable amounts of tritiated label were found to co-migrate with NE, L-DOPA and DA. During the first thirty minutes the majority of label appeared with L-DOPA (.39 ± 64 x 10^3 dpms) and particularly DA (6.45 ± 1.7 x 10^3 dpms). The newly labeled DA pool increased during incubation and plateaued at 2.5 hrs (10.7 ± .29 x 10^3 dpms), while the labeled L-DOPA pool remained essentially unchanged. The label that co-migrated with NE continuously increased (0.92 ± .10 x 10^3 dpms) but never approached that level found in the DA pool. Iproniazid reduced incorporation of ^{3}H-tyrosine into DA (61%), probably via feedback inhibition of tyrosine hydroxylase consequent to increasing amounts of the cytoplasmic amine. Direct inhibition of tyrosine hydroxylase by αmpt virtually abolished (93%) DA biosynthesis.

These studies indicate that elevated hypothalamic dopamine turnover continues in vitro using a steady-state index, while norepinephrine turnover (quantitatively the major amine) is lower. This rate of amine turnover undoubtedly affects neuroendocrine parameters as measured in vitro. (Supported by NIH grant HD-10900).

53.14 ACETAMINOPHEN AS AN INTERNAL STANDARD FOR CALIBRATING IN VIVO ELECTROCHEMICAL ELECTRODES IN RAT CAUDATE. M.E. Morgan* and C.R. Freed* (SPON: D.G. Whitlock). Depts Medicine and Pharmacology, Div. Clinical Pharmacology, U. Colorado Health Sciences Center, Denver, CO 80262.

In vivo electrochemistry has been shown to be useful for measuring relative changes in extracellular dopamine concentration in the caudate. Electrodes have been calibrated to dopamine concentrations in the beaker, but electrode responsiveness in tissue has been difficult to assess. Because acetaminophen is electrochemically active and does not interact with catecholamine neurons, we felt it would be a good compound for in vivo electrode calibration. Male Sprague Dawley rats 200 to 300 gm were anesthetized with urethane 1.0-1.5 gm/kg. A 200 micron carbon paste electrode was inserted stereotaxically in the left caudate. The electrochemical response was generated and measured with a DCV-4 cyclic voltammetry amplifier modified to provide nanoamp/volt sensitivity (Bioanalytical Systems). The amplifier output was processed by a semi-differentiator constructed by Bioanalytical Systems. Semi-differentiation has been shown to produce a more easily interpretable voltammetric readout (Lane et al. J. Electroanal.Chem. 95:117, 1979). The dopamine peak appeared at 0.42 volts. Acetaminophen electrochemical oxidation occurred at 0.55 volts. Acetaminophen was injected i.p. in doses of 25, 50, 75 and 100 mg/kg. Voltammetric scans were done every 10 minutes and maximum voltammetric response was seen approximately 0.5 hour after drug injection. Incremental doses were given at 2 hour intervals. Because the drug half-life is 1.5 hour, incremental peak heights were estimated after subtracting the extrapolated signal from the preceding dose. Results show a linear dose response relationship to acetaminophen administration. Actual electrode sensitivity was measured by killing the animals and assaying caudate acetaminophen concentrations. The ratio of the acetaminophen peak height just before sacrifice to the acetaminophen concentration assayed in the caudate is an absolute measure of electrode sensitivity. This value correlated well with the maximal current response produced by a single dose of 100 mg/kg acetaminophen (coefficient of variation 15%). Preliminary experiments with bilateral electrochemical detectors in rat caudate indicate that the acetaminophen response predicts the magnitude of the amphetamine response on each side. These data show that intraperitoneal acetaminophen can generate an electrochemical response that occurs at a potential distinct from dopamine and that is useful for predicting in vivo electrode sensitivity.

53.15 IN VIVO VOLTAMMETRY: STUDIES OF DOPAMINE RELEASE IN THE RAT STRIATUM AFTER ADMINISTRATION OF L-DOPA. F. Hefti, E. Melamed, T. Maher, and R.J. Wurtman. Lab. Neuroend. Reg., MIT, 56-245,Cambridge, MA.

We studied the time-course of dopamine (DA) release after systemic administration of L-DOPA in the rat striatum. Recordings were obtained from anesthetized animals with carbon paste microelectrodes (diameter (100 µm). Working and reference electrodes were prepared as described by Conti et al. (Life Sci. 23, 2705, 1978). Chronoamperometric measurements were made by applying a potential of 0.8V for 1 sec, with an interval of 5 min between measurements. In later experiments, the potential was scanned every 5 min from 0 to 1.0V (scan rate: 50 mV/sec); this procedure allowed us to measure DA plus DOPAC without interference from methylated catecholamine metabolites. Administration of L-DOPA (50 mg/kg) after pretreatment with carbidopa (an inhibitor of peripheral DOPA decarboxylase, DDC) produced a large rise in chronoamperometric currents, lasting for approximately 6 hours. We used different approaches to determine whether DOPA, DA, or DA metabolites (which are all oxidized at the potential chosen) were responsible for these increases. 1) Rats were killed at different times after L-DOPA administration, and their striata were analyzed biochemically for DOPA, DA, and DA metabolites. Comparison of time-courses revealed that the rise in chronoamperometric responses correlated with elevations in striatal DOPAC and HVA levels rather than with those of DOPA or DA. L-DOPA administration also raised chronoamperometric responses in the cerebellum, where only very small increases in DA levels but large elevations in DOPAC and HVA concentrations were measured biochemically. These findings suggest that DA metabolites contribute significantly to the increases in chronoamperometric responses observed after administration of L-DOPA. 2)L-DOPA given after inhibition of central DDC, a treatment that results in large increases in striatal DOPA levels (measured biochemically)without formation of DA and DA metabolites, failed to increase chronoamperometric responses, indicating that exogenous L-DOPA entering the striatum is not detected with this technique. 3) In animals pretreated with an inhibitor of monoamine oxidase, L-DOPA administration produced only a small and short-lasting increase in chronoamperometric responses, despite sustained and large increases in striatal DA concentrations. (Using the potential-scanning technique, it could be shown that the increases in electrochemical responses occur at a potential at which DA and DOPAC but not methylated catecholamine metabolites are oxidized.) Consequently, DA appears to contribute only a small fraction limited to the initial rise of the large increases in chronoamperometric responses observed after administration of L-DOPA. Our results suggest that administration of L-DOPA (after pretreatment with carbidopa) produces only a short-lasting increase in striatal DA release, despite a prolonged rise in striatal DA concentration.

53.16 IN VIVO MONITORING OF DOPAMINE (DA) RELEASE AFTER NIGRAL STIMULATION OR AMPHETAMINE USING CYCLIC VOLTAMMETRY. S.H. Butcher, C.D. Hull, R.F. Lane. Mental Retardation Research Center, School of Medicine, UCLA, Los Angeles, CA 90024 and Department of Chemistry, University of Oregon, Eugene, OR 97403.

Interest in voltammetric techniques for the in vivo, continuous measurement of endogenously released catecholamines has gained widespread interest over the last few years. Lane et al. (J. Electroanal. Chem. 95: 117, 1979) have demonstrated in the rat that d-amphetamine produces an increase in release of DA in the caudate nucleus, while producing no change in the release of serotonin.

In these experiments the effects of d-amphetamine or stimulation of the substantia nigra were examined using voltammetric techniques in the cat. Adult cats were anesthetized with sodium methohexital, a short-acting barbiturate. A four-pronged stimulating comb was stereotaxically introduced into the right substantia nigra, and a carbon paste electrode was introduced into the right and left caudate nucleus (tip diam. 100µm). Potentials are measured with respect to a reference-auxiliary electrode combination which is placed on the surface of the posterior cortex. Semiderivative voltammograms were then recorded every ten minutes until a stable baseline was reached.

After a stable baseline was achieved the substantia nigra was stimulated unilaterally for 5 min (10pps, 0.5ms duration, 10 V). The release of DA, both ipsilateral and contralateral to the stimulation was monitored immediately after stimulation, and at 10 min intervals thereafter. DA release after nigral stimulation increased 128-133% when compared with control release. However, 10 min after nigral stimulation DA release reached maximum levels, which ranged from 180-225% of control.

The increase in released DA ipsilateral to the nigral stimulation did not return to control release levels for approximately 20-30 min.

The effect of nigral stimulation on the contralateral caudate nucleus was equivocal. These effects ranged from an increased DA release (101-105% compared to control) to a decrease in DA release (80-94% of control).

Amphetamine (0.2mg i.v.) also produced an increase in release of DA (144-151%). This effect lasted for approximately 15 min. (Supp. by USPHS HD05958, NS5316).

53.17 THE DYNAMICS OF ENDOGENOUS DOPAMINE (DA) RELEASE FROM THE CAT CAUDATE NUCLEUS IN VIVO. K. G. Lloyd, B. Le Roux* and G. Bartholini*, Research Dept., Synthelabo-LERS, Paris, France.

The dynamics of the striatal DAergic synapse has been previously studied by indirect biochemical methods. The present study examines directly the "in vivo" release of endogenous DA by means of a push-pull cannula placed in the caudate nucleus through which an artificial CSF is perfused, as previously described (Experientia 31, 560, 1975). In the present study, adult cats of either sex were anesthetized, placed in a stereotaxic apparatus and the push-pull cannulae implanted (A: 15.5 ; D: + 5 ; L: + 4.5). Samples were collected over 20 min periods (200 µl/min) and the DA estimated by radioenzyme assay. All injections were by the i.v. route and 3-5 cats were used per dose per drug. The DA content of the striatal perfusate varied considerably from cat to cat, but for a given animal the release was stable for a period of at least 5 hours. Saline injection did not alter DA release. Several neuroleptics (haloperidol, pimozide, chlorpromazine) produced a large, immediate, increase in DA release which lasted for at least 3 h post-injection. Administration of pimozide (ip) daily for 10 days before the experiment greatly reduced ($p < 0.02$) the striatal release of iv pimozide injection. Amphetamine (0.5-10 mg/kg) resulted in an immediate, dose-dependent increase (to > 3000 percent of control at 10 mg/kg) in DA release. Nomifensine, (5-10 mg/kg) which inhibits DA uptake, also increased DA release, but had a slower onset of action and was less potent than amphetamine. Reserpine (2 mg/kg) produced an initial release of DA (to 300 percent of control) which was of a short duration. Gamma-hydroxybutyrate (G-OH) produced an initial small decrease in striatal DA release which was followed later (2.5 h) by a significant increase. G-OH retarded but only slightly reduced the effect of amphetamine (2.0 mg/kg) on DA release. GABA agonists (SL 76 002 or muscimol) produced a decrease in striatal DA release.SL 76 002 completely blocked the DA release induced by chlorpromazine and partially blocked that due to amphetamine. These results provide direct evidence for : (1) the enhanced striatal DA release after DA receptor blockade ; (2) the inhibition of ongoing DA neuron activity and the blockade of the neuroleptic-induced feedback activation by GABA agonists ; (3) the tolerance upon repeated neuroleptic administration to the feedback-induced release of striatal DA ; (4) the immediate effect of amphetamine on endogenous DA release "in vivo" ; (5) that nomifensine enhances the synaptic concentrations of DA : (6) that reserpine can produce an initial pulse of DA release ; and (7) G-OH initially decreases DA release, followed by a rebound augmentation. Thus, this method provides a direct "in vivo" analysis of striatal DA synaptic dynamics and can be used to define the mechanism of action of psychotropic drugs.

53.18 ELEVATION OF NIGRAL GABA CONCENTRATION BY GABACULINE: EFFECT ON STRIATAL DOPAMINE RELEASE. B.S. Glaeser, W.R. Millington, and R.J. Wurtman. Laboratory of Neuroendocrine Regulation, Dept. of Nutrition and Food Science, M.I.T., Cambridge, MA 02139.

Sprague-Dawley rats received IP injections of water or Gabaculine (100 mg/kg), an irreversable inhibitor of GABA-transaminase. Four hours later rats were sacrificed by decapitation; striatia and substantia nigrae were dissected and removed within 3.0 min. GABA was analyzed by a modified amino acid analysis method utilizing one buffer (pH = 4.53, 0.6 N Li+) with cation exchange chromatography and ninhydrin detection. Dopamine, DOPAC, and HVA were analyzed by HPLC/electrochemical techniques. Four hours after Gabaculine administration, nigral GABA levels were markedly elevated ($p \leq 0.05$) when compared with those in control animals (see table). Striatal dopamine concentrations were not altered by Gabaculine treatment; however, striatal DOPAC and HVA levels were significantly elevated ($p \leq 0.05$). In a second experiment, Gabaculine-induced elevations of GABA were not associated with significant changes in striatal acetylcholine concentrations after four hours. These data suggest that Gabaculine induced elevations of GABA levels are not associated with direct inhibition of nigrostriatal dopamine neurons. The GABA may inhibit another inhibitory neuron in the substantia nigra or striatum.

	Nigral GABA Concentrations	Striatal concentrations ng/mg tissue (X + SD) OF		
Group	nmol/mg tissue (X+SD)	DA	DOPAC	HVA
H_2O	4.87 ± 1.81 (n=8)	7.5 ± .84 (n=8)	1.32 ± .29 (n=8)	.80 ± .14 (n=8)
Gabaculine (100 mg/kg)	15.30 ± 3.42* (n=9)	7.8 ± .75 (n=10)	1.92 ± .6* (n=10)	1.19 ±.41* (n=10)

53.19 HIGH-AFFINITY GLUTAMATE TRANSPORT IN THE STRIATUM: POSSIBLE DOPAMINERGIC REGULATION. L.C. Murrin and V.J. Robertson*, Dept. of Pharmacology, Univ. of Nebraska Med. Ctr., Omaha, NE 68105.

A high-affinity glutamate transport system (K_T=10 µM) has been demonstrated in synaptosomal preparations from rat brain. In striatum there is evidence that this system is associated, at least in part, with the cortico-striatal glutamatergic pathway. High-affinity glutamate transport can be activated in synaptosomal preparations by depolarization (Mol. Pharmacol. 12:1082, 1976; Life Sci. 22:2009, 1978). The ability to alter rate of glutamate transport in response to depolarization is analogous to what has been found for high-affinity choline transport in cholinergic neurons and for tyrosine hydroxylase activity in noradrenergic and dopaminergic neurons. The cortico-striatal pathway has been shown to have dopaminergic receptors on its terminals (Nature 271:766, 1978; Eur. J. Pharm. 60:229, 1979). Thus it seems possible that rate of glutamate transport may reflect the state of activity in glutamatergic neurons and the activity of these neurons in the striatum may be modified by a dopaminergic input. We sought to examine this possibility. Rats were injected i.p. with the dopaminergic agonist, apomorphine, or the antagonist, haloperidol, and were decapitated at various times following the injection. A synaptosomal preparation (P_2) was prepared from brain regions by standard techniques. High affinity glutamate transport was measured as previously described (Mol. Pharmacol. 12:1082, 1976; Life Sci. 22:2009, 1978). Zero-sodium blanks were used throughout and were found to be essentially the same as 0°C blanks. A relatively low dose of apomorphine produced a significant increase ($p<.02$, Student's two tailed t test) in glutamate transport in the striatum. Ten and 30 minutes after 0.1 mg/kg of apomorphine, glutamate transport was 12.8 ± 1.6 pmol/2 min-mg prot (n=3) and 10.2 ± 1.0 pmol/2 min-mg prot (5) while control levels were 7.3 ± 0.5 pmol/2 min-mg prot (21). This effect was apparently dose-dependent since the alteration in glutamate transport was greatly diminished at 0.5 mg/kg and no significant alteration was seen at 1 and 10 mg/kg (10, 30 and 60 min). Haloperidol at a relatively low dose (0.1 mg/kg for 30 min) also produced a significant increase in glutamate transport while less of an effect was seen with 0.25 mg/kg for 30 min and no effect was seen with 1 and 10 mg/kg (10, 30 and 60 min). Neither drug at any of the doses or times examined produced significant alterations in glutamate transport in cortex or hippocampus. This data suggests that the dopaminergic input to the striatum may affect the high-affinity glutamate transport in that region and so may in some way modulate the glutamatergic neurons in striatum. The specificity of this effect for dopaminergic receptors and whether this is a direct or indirect effect of these drugs remains to be examined. Supported by BNS-7921105, MH-33390 and March of Dimes Foundation.

53.20 DIAZEPAM INHIBITS THE LIGHT-INDUCED INCREASE IN RETINAL DOPAMINE TURNOVER. C. W. Kamp and W. W. Morgan. Dept. Anat. Univ. Texas Health Sci. Ctr., San Antonio, TX 78284.

Light stimulates dopamine (DA) turnover in dark-adapted rat retinas, and this effect is blocked by the GABA agonist, muscimol (MU), in a dose-dependent fashion (Morgan and Kamp, 1980). Pentobarbital and phenobarbital potentiate this action of MU while picrotoxinin, a GABA antagonist, reverses the combined effect of MU and pentobarbital (Kamp and Morgan, 1980). These data suggest that light-activated DA turnover in the rat retina may offer an ideal in vivo model for testing drugs which purportedly interact with the GABA system. Here we present the effects of diazepam (DZ) on the light-induced increase in retinal DA turnover. Rats were dark adapted for 15 hr and divided into 4 groups. The first group was injected with DZ (22 mg/kg, i.p.) 90 min before sacrifice; the second received 3 equal injections of MU beginning 75 min prior to sacrifice (6.6 µmole/kg, i.v. cumulative); the third was treated with both DZ and MU, and the last group received saline or vehicle injections at all appropriate time points. All rats were exposed to light for 1 hr, and half the rats in each group were treated with α-methylparatyrosine (αMPT, 250/kg, i.p.) just before light exposure. Following sacrifice, the retinas were quickly removed and frozen. Later DA contents were assayed radioenzymatically. The decline in DA after αMPT treatment served as an estimate of DA turnover. MU alone produced no significant change in the light-mediated decline of DA. This dose of MU was also ineffective in our earlier work, but in combination with barbiturates, which were also ineffective alone, it produced a dramatic decline in DA turnover. In contrast to the barbiturates, DZ significantly reduced DA turnover in the light ($p<.05$), but this effect was not enhanced in the presence of MU. We have recently found that intraocular picrotoxinin or bicuculline methiodide enhance the light-induced increase in DA turnover (unpublished). These results indicate that there is a tonic GABAergic input to the retinal DA neurons. DZ may be potentiating the action of this endogenous GABAergic input. We are currently conducting experiments which should answer this question. Supported by DA 00755, NS 14855 and RSDA MH 00028 to WWM.

53.21 EFFECTS OF RESERPINE ON TURNOVER OF MONOAMINE OXIDASE IN MOUSE BRAIN AND LIVER. T.R. Hall*, P.B. Yurgens*, D.K. Newton*, J. Korducki* and H.R. Figueroa*. (SPON: E. Stein). Dept. of Biology, Marquette University, Milwaukee, WI 53233.

Disturbances in activity of monoamine oxidase (MAO), an enzyme important in the regulation of levels of monoamines in the central nervous system and circulation, have been implicated in a variety of affective disorders. It is important, therefore, to understand the regulation of production of this enzyme. Adult mice were injected once with the irreversible MAO inhibitor pargyline at a dose of 30 mg/kg ip., which was shown to be the minimum dose to produce maximum inhibition of MAO activity; or every 3 days with the monoamine depletor reserpine at a dose of 1 mg/kg ip., which was shown to produce greater than 75% depletion of 5-hydroxytryptamine (5HT) in the brain; or with both treatments. MAO was determined fluorometrically in hypothalamus, cerebellum, brainstem, rest of brain and liver. 5HT was determined fluorometrically in brainstem and rest of brain. In all tissues MAO activity increased in a time-dependent fashion after pargyline inhibition. The calculated half-life of the enzyme, assuming first order rate kinetics, was tissue dependent, with liver < hypothalamus < cerebellum < rest of brain < brainstem. 5HT content was elevated after pargyline, low after reserpine and showed intermediate values after both drugs for at least 2 weeks. However, 5HT levels after pargyline + reserpine were significantly depressed, compared to pargyline treatment only, in both brainstem and rest of brain. Following reserpine, turnover of MAO, as determined by the slope of the recovery curve following pargyline administration, was significantly slower in hypothalamus and cerebellum, showing a 2-3 fold increase in the time for 50% recovery of steady state activity. Reserpine alone had no significant affects on MAO activity in any tissue studied, nor did it affect the rate of recovery of MAO following pargyline in the liver. We conclude that (a) turnover of MAO varies between different brain regions and liver, (b) the content of monoamines may regulate synthesis of MAO in hypothalamus and cerebellum. Synthesis of MAO in other regions may be independent of monoamine control.

53.22 CHARGE ISOZYMES OF PHENYLETHANOLAMINE N-METHYLTRANSFERASE: MECHANISM OF ACTIVATION BY PHOSPHATE. D. Park, T. Joh, E. Baetge, K. Chiang* and D. Reis. Laboratory of Neurobiology, Dept. of Neurology, Cornell Univ. Med. College, New York, NY.

It is known that adrenal phenylethanolamine N-methyltransferase (PNMT) from different species has different biochemical characteristics, e.g., electrophoretic mobility, stability, etc. Even within the same species, several charge isozymes exist. The mechanisms governing the different biochemical characteristics of the enzyme are still unknown. In order to further elucidate the molecular mechanisms accounting for these differences, we characterized purified PNMT from both rat and bovine adrenal glands. (1) The subunit molecular weight, by SDS-PAGE, was 31,000 daltons for both forms. (2) Antibody to the rat form strongly cross-reacted to rat PNMT but poorly to the bovine form. Nevertheless, antibody to the bovine form crossreacted strongly to both forms. (3) When PNMT was synthesized in vitro by the translation of mRNA purified from bovine adrenal medulla, antibodies to either form precipitated PNMT, thereby suggesting that the basic protein structure of PNMT of both species is similar. (4) The electrophoretic mobility of the enzyme at pH 8.2 in Tris-glycine buffer in a 7.5% polyacrylamide gel was Rm = 6.3 toward the anode for the rat and 4.5 for the bovine enzyme, indicating that the rat form is more negatively charged. Since the molecular weight of both forms is similar, they are charge isozymes. (5) When phosphate buffer (0.1 M) was used for the activity assay at pH 8.6, the specific activity of pure PNMT from both species was similar (2.0 umol/mg/h for bovine and 2.1 for rat form). However, when Tris-Cl buffer was used the specific activity of the bovine form was only one-third that of the rat form (0.7 umol/mg/h for bovine). Addition of phosphate to Tris-Cl buffer in the assay mixture increased PNMT activity of only bovine origin and the increase was concentration dependent. At 100 mM phosphate, the activity increased three-fold. Since the bovine form is less negatively charged, phosphate ion, which is a polyanion, may influence the total charge of the bovine form to become more negatively charged. It is probable that the more negatively charged form has higher specific activity.

The data indicate that: (1) PNMT in bovine and rat adrenal medulla is a charge isozyme, and the rat form is more negatively charged; (2) phosphate, a polyanion, increases the specific activity of the bovine form of PNMT, probably by increasing the negative charge on the enzyme; and (3) the differences in the biochemical characteristics of PNMT isozymes are caused by post translational modification of the enzyme, probably due to carbohydrate content which changes the charge of the enzyme.

53.23 REGULATION OF TYROSINE HYDROXYLASE ACTIVITY IN WHOLE RETINA, RETINAL CELL SUSPENSIONS, AND RETINAL HOMOGENATES. P.M. Iuvone* and P.B. Marshburn* and N.H. Neff. Dept. of Pharmacology and Ophthalmology, Emory Univ. Sch. of Med., Atlanta, GA 30322; Preclinical Pharmacology Lab, NIMH, St. Elizabeths Hosp., Washington, D.C. 20032 (SPON: J. Sutin).

Dopamine (DA) is localized in a subpopulation of amacrine neurons in the retinas of most mammalian species. Photic stimulation increased the release and biosynthesis of retinal DA in vivo (Kramer, Invest. Ophthalmol. 10: 438, 1971; Iuvone et al., 1978), suggesting that these neurons are activated as a consequence of light exposure. Associated with the light-evoked stimulation of DA biosynthesis was an activation of tyrosine hydroxylase (TH). To determine if TH could be activated by depolarization of the DA-containing neurons, retinas were dissociated into cell suspensions for in vitro studies. Dissociation of the retinas disrupted most synaptic connections, and greater than 90% of the cells in suspension were present as single cells. In these suspensions, high concentrations of K^+ resulted in an activation of TH.

GABA and muscimol, injected intravitreally, inhibited the light-evoked activation of TH. Intravitreal injections of bicuculline or picrotoxin activated TH in the dark, indicating that GABA plays a role in the inhibition of the DA-neurons in darkness. Incubations of retinal cell suspensions with muscimol decreased tyrosine hydroxylase activity in a picrotoxin-sensitive manner, suggesting that the GABA receptors responsible for inhibiting the DA neurons in darkness are located on the DA neurons, rather than on other neurons that interact with the DA cells.

Incubation of retinal homogenates with cAMP, ATP and Mg^{+2} increased TH activity. Incubation of the retinal cell suspensions with 8-Br-cAMP also increased TH activity, indicating that the DA neurons contained sufficient cAMP-dependent protein kinase in the proper subcellular location to activate TH in situ.

These studies illustrate the usefulness of retinal cell suspensions in pharmacological and biochemical studies of the regulation of synaptic processes.

53.24 ACUTE AND CHRONIC EFFECTS OF β-PHENYLETHYLAMINE (PEA) ON RAT STRIATAL TYROSINE HYDROXYLASE ACTIVITY. David M. Stoff and Karen Gale. Lab of Clinical Psychopharm., St. Elizabeths Hosp., and Dept. of Pharmacol., Georgetown Univ. Schools of Medicine & Dentistry, Washington, DC 20007.

β-phenylethylamine (PEA), a naturally occurring non-catechol sympathomimetic amine, has structural and pharmacological features in common with amphetamine. In order to further characterize the actions of PEA on the nigrostriatal dopaminergic system, we investigated 1) the ability of acutely administered PEA to reverse both the catalepsy and the activation of tyrosine-hydroxylase (TH) induced by chlorpromazine, and 2) the effects of chronically administered PEA on striatal TH activity.

In the acute study, rats were pretreated with a dose of chlorpromazine (20mg/kg i.p.) which was maximally effective in causing catalepsy and activation of striatal TH, when measured between one and two hrs after injection. At 20-45 min after injection of chloropromazine, the animals were treated with various doses of either PEA, apomorphine, d-amphetamine or saline (controls). Rats were decapitated 1-1.5 hr after chlorpromazine and striatal TH was assayed (within 24 hr after killing) in the presence of a subsaturating concentration of $DMPH_4$ cofactor (0.2mM) and a saturating concentration of tyrosine. We obtained a dose-dependent reversal of both catalepsy and TH activation with all 3 drugs tested. PEA, in a dose of 150mg/kg i.p., caused approximately a 50% reduction in both the duration of catalepsy and degree of TH stimulation produced by chlorpromazine. PEA was 40 times less potent than amphetamine and 80 times less potent than apomorphine.

In the chronic study, large doses of PEA (600 mg/kg) were applied intragastrically twice daily for 14 consecutive days. This dosage regimen produced behavioral stimulation lasting for 5-7hrs per day. Rats receiving this treatment were found to have a 20% increase in V_{max} of striatal TH when compared with controls which had received daily intragastric injections of saline. The increased TH activity could be measured for up to 10 days after cessation of chronic PEA treatment. Concurrent chronic administration of haloperidol (1.0mg/kg i.p.) did not influence the stimulation of TH by chronic PEA, suggesting that the effect is not dependent upon dopamine-receptor stimulation.

Thus, we have obtained neurochemical evidence which indicates that PEA is capable of augmenting nigrostriatal dopaminergic transmission acutely: the ability of PEA to reverse the effects of dopamine receptor blockade is similar to that of known dopamine agonists. In addition, our chronic studies suggest that PEA may be able to augment DA transmission in a long-term fashion by a mechanism independent of dopamine-receptor stimulation.

53.25 STRIATAL SYNAPTOSOMAL TYROSINE HYDROXYLASE ACTIVITY: A MODEL FOR STUDY OF PRESYNAPTIC DOPAMINE RECEPTORS. Brian A. McMillen, Dept. Pharmacol., U. Texas Health Sci. Center, Dallas, Tx 75235.

The concept of an inhibitory presynaptic dopamine (DA) receptor on DA nerve endings is now well accepted. Stimulation of this receptor by DA or DA agonists causes (in vivo) decreased tyrosine hydroxylase activity (Tyr-OH) which in turn will cause decreased DA release. This autoreceptor is presumed to be on the outside of the nerve ending membrane, but evidence for this supposition is scant. If the autoreceptor is an external membrane receptor, DA re-uptake inhibitors should inhibit Tyr-OH activation due to small doses of neuroleptics by potentiating the amounts of DA released into the synapse. Furthermore, a non-diffusable DA agonist should inhibit synaptosomal Tyr-OH, in vitro. The activation of Tyr-OH by haloperidol (Halo, 0.025 mg/kg) in vivo (determined by 30 min L-DOPA accumulation after decarboxylase inhibition with NSD-1015) is inhibited by DA re-uptake blockers (amfonelic acid, nomifensine, cocaine, benztropine, etc.). Either no change or an enhancement of L-DOPA accumulation occurs when these drugs are combined with 1.0 mg/kg Halo. Thus, potentiation of DA in the synaptic cleft, by inhibiting DA re-uptake, prevents Tyr-OH enhancement by small doses of Halo. After the larger dose of Halo, DA cannot overcome the presynaptic receptor blockade and Tyr-OH is increased because of presynaptic receptor blockade and increased impulse flow. Tyr-OH, determined in synaptosomal preparations, is inhibited by apomorphine (Apo) or DA with IC_{50} values of 4.5×10^{-7}M and 2.5×10^{-6}M, respectively; and the inhibition is reversed by Halo. The potent DA uptake inhibitor, amfonelic acid, at 3×10^{-6}M did not alter the IC_{50} of DA for inhibition of synaptosomal Tyr-OH. Thus, the data indicate that the DA presynaptic receptor is indeed an external membrane receptor. Synaptosomal Tyr-OH may provide a system for study of neuroleptic affinity for presynaptic receptors using a pharmacological response (reversal of Apo inhibition of Tyr-OH) instead of ligand displacement. Comparison of neuroleptic drug interaction in this system with radio-ligand binding studies may prove useful for determining whether apparent specific binding may be at presynaptic DA receptors. Experiments on the ability of neuroleptic drugs to reverse Apo inhibition of synaptosomal Tyr-OH will be presented and the usefulness of this presynaptic DA receptor system discussed.

53.26 DIFFERENTIAL EFFECTS OF GABA-ELEVATING AGENTS ON THE NEUROLEPTIC-INDUCED ACTIVATION OF STRIATAL TYROSINE-HYDROXYLASE: EVIDENCE THAT Di-N-PROPYLACETATE AUGMENTS GABAERGIC NEUROTRANSMISSION. Mariano Casu* and Karen Gale (Spons: R.A. Gillis). Dept. of Pharmacology, Georgetown Univ. Schools of Med. & Dent., Washington, D.C. 20007.

Di-n-propylacetate (sodium valproate, DPA), in contrast to many other agents which elevate brain GABA content, appears to increase GABA selectively in a compartment that is associated with nerve-terminals (Iadarola and Gale, Eur. J. Pharmacol. 59: 125, 1979). In order to determine whether the DPA-induced increase in nerve-terminal GABA in substantia nigra (SN) could augment GABAergic transmission in SN, we examined the ability of DPA to influence nigrostriatal dopamine function.

Neuroleptic drugs, such as haloperidol, cause an allosteric activation of striatal tyrosine hydroxylase (TH) which can be measured in vitro as a decrease in the K_m of TH for cofactor ($DMPH_4$). This effect can be reversed by treatment with GABA-receptor agonists (Gale et al., JPET 206: 29, 1978). We therefore examined the ability of DPA to reverse the activation of striatal TH induced by haloperidol (0.5mg/kg i.p., 40min prior to decapitation). DPA was administered i.p., 10min after haloperidol. The data obtained (see Table below) demonstrate the ability of DPA to reverse the haloperidol-induced activation of striatal TH in doses which caused a 30-50% increase in GABA in SN. The action of DPA was completely antagonized by treatment with bicuculline (BIC) (3.5 mg/kg s.c., 5min after DPA), a GABA receptor antagonist, indicating that the effect of DPA is mediated via GABA receptors.

The effect of amino-oxyacetic acid (AOAA, injected i.p. 80min. before haloperidol) was also examined, since our previous evidence suggested that the GABA increase after this agent was largely associated with compartments of GABA other than nerve terminals. As shown below, AOAA was less effective than DPA in preventing the haloperidol-induced activation of TH, despite the fact that nigral GABA was increased by 30-100%.

K_m of Striatal TH for $DMPH_4$ (mM):

Treatments	SAL	DPA 200	DPA 300	DPA 400	DPA 400+ BIC 3.5	AOAA 20	AOAA 40	AOAA 60(mg/kg)
control	.75	.76	.75	.78	.73	.75	.70	.73
haloperidol	.30**	.29**	.43*	.76	.31**	.28**	.34**	.41*

53.27 GLUCOCORTICOID EFFECTS ON BRAIN TYROSINE HYDROXYLASE. K. A. Markey*, A. C. Towle* and P. Y. Sze. Dept. of Biobehavioral Sci., Univ. of Connecticut, Storrs, CT 06268.

An "inductive" effect of glucocorticoids on brain tyrosine hydroxylase (TH) was demonstrated in the pontine region of mouse brain during early postnatal development. Administration of corticosterone (20 mg/kg, i.p., twice daily) to 7-day-old mice for 3 days led to an increase of TH activity (by 50%) in the pons but not in the substantia nigra. Similar inductive effects on pontine TH could be produced by other glucocorticoids, including hydrocortisone, cortisone, dexamethasone and triamcinolone. Steroids such as estradiol, testosterone, 11-deoxycortisol and 21-deoxycortisol were all ineffective. Developmentally, the responsivity of pontine TH to corticosterone was limited to a brief postnatal period (approximately days 7-12). Hormone administration during postnatal days 2-5 or after day 12 failed to produce an increase of enzyme activity. Interestingly, midbrain tryptophan hydroxylase responds to exogenously administered glucocorticoids also only during the second postnatal week, as previously reported.

To examine the possible involvement of a cytoplasmic steroid receptor, the binding of ^{3}H-glucocorticoids to the receptor was determined in vitro. A 100,000 g cytosol preparation from dissected locus coeruleus region was incubated in the presence of 2×10^{-7} M ^{3}H-steroid at 0°C for 3 hrs. Corticosterone, hydrocortisone, dexamethasone and triamcinolone were all found to bind to a protein binding site with a specific binding capacity of 160-190 fmoles/mg cytosol protein (from day 10 animals). The binding of these glucocorticoids was mutually competitive, indicating binding to the same site. Cortexolone and progesterone (two steroids with "anti-glucocorticoid" actions) were found to block ^{3}H-corticosterone binding. When animals were pretreated with either cortexolone or progesterone (20 mg/kg, i.p., twice daily), the effect of corticosterone to produce the increase of TH activity was totally prevented. These data support the contention that the steroid effect on TH may be mediated by an intracellular glucocorticoid receptor.

In addition to TH, several enzymes such as liver arginase are known that respond most effectively to exogenously administered glucocorticoids only during the developmental period preceeding adrenocortical maturation. It is possible that after steroidogenesis, some enzymes have already maximally responded to endogenously available steroids. The response of TH to glucocorticoids as demonstrated in the immature animals could signify a hormone component in the regulation of the enzyme.

53.28 DIFFERENT TRENDS IN TYROSINE HYDROXYLASE ACTIVITY IN CELL BODIES AND TARGET SITES DURING DEVELOPMENT AND AGING. L. Yurkewicz, J.M. Lauder, E. Giacobini and M. Marchi*. (SPON: M. Wilson). Lab. of Neuropsychopharmacology, Dept. of Biobehavioral Sci., Univ. of CT, Storrs, CT, 06268.

Tyrosine hydroxylase (TH) activity was measured in the locus coeruleus (LC), cerebellum, cervical spinal cord, lumbar sympathetic ganglia and iris throughout most of the lifespan of the chick (8 days of incubation to 5 years after hatching) in order to compare the trends in TH activity in noradrenergic cell bodies and terminals in both the CNS and PNS. Fluorescent histochemistry and horseradish peroxidase tracing were used to characterize the LC-cerebellar projections. TH activity was detected in the cerebellum as early as 8 days of incubation, which is the earliest stage so far reported. The greatest increase in total TH activity in the LC (21-fold) and cerebellum (31-fold) occurred during the embryonic period with a greater increase in the target organ, whereas the increase in total TH activity in the cervical spinal cord was approximately the same in the embryonic (4-fold) and post-hatch (5-fold) periods. The cerebellum and cervical spinal cord displayed different trends in TH activity throughout development and aging which suggests the possibility that enzyme transport from the LC may depend upon specific characteristics of the target site during maturation. In both structures examined in the PNS, the greatest increase in total TH activity occurred during the posthatching period (1 day post-hatch to 5 yrs.) with a greater rise in the cell bodies of the lumbar sympathetic ganglia (16-fold) than in the noradrenergic terminals of the iris (13-fold). In the 3 noradrenergic target sites examined, total TH activity continued to increase long after hatching, reaching the highest levels at 7 mo. when the chicken is considered fully mature. This rise in enzyme activity may be due to continual growth of the innervating fibers up to 7 mo. as opposed to synthesis and accumulation of TH in pre-existing terminals. During adulthood and aging, cell bodies and noradrenergic target sites showed different patterns in enzyme activity, in that total TH activity declined in the LC and cerebellum after 16 mo., declined earlier in the iris after 7 mo. and continued to rise in the ganglia up to 5 yrs. During aging (16 mo. to 5 yrs.), the terminals of noradrenergic neurons seem to be more affected than the cell bodies in both the CNS and PNS, which is consistent with age-related changes in the cholinergic system (Marchi, M., Hoffman, D.W. and Giacobini, E., Dev. Neurosci., 1980. 3 in press). This phenomenon is more marked in the PNS than in the brain. Supported by the Univ. of CT Research Foundation and NIH grant, NS-13481 to J.M. Lauder.

53.29 TYROSINE HYDROXYLASE INACTIVATION FOLLOWING cAMP-MEDIATED PHOSPHORYLATION ACTIVATION. Kent Vrana* and Robert Roskoski, Jr. Dept. Biochem., LSU Medical Center, New Orleans, Louisiana 70112.

The rate of catecholamine biosynthesis is limited by the activity of tyrosine hydroxylase (TH). We have studied the regulation of this enzyme by cAMP-dependent protein kinase in rat corpus striatum homogenates. Treatment of these extracts with cAMP and Mg·ATP produces a two to ten-fold increase in enzyme activity as determined in a subsequent TH assay. After maximal activation (3 min), continued treatment under phosphorylation conditions is associated with a loss of enzyme activity. This loss is complete following 30 minutes and the inactivated TH exhibits activity which is less than or equal to the activity of homogenates incubated in the absence of cAMP and Mg·ATP. In characterizing this phenomenon, we find that after activation and inactivation of TH with a 30 minute pretreatment with cAMP and Mg·ATP, addition of cAMP alone or purified protein kinase catalytic subunit alone will reactivate and inactivate the enzyme. One interpretation of this is that inactivation of activated TH is due to the loss of protein kinase activity following hydrolysis of cAMP by phosphodiesterase. However, when cAMP levels are maintained during the 30 minute preincubation by repeated addition of cAMP or by including a phosphodiesterase inhibitor (1 mM papaverine), the enzyme is activated and inactivated, but can not be reactivated by additional cAMP or the addition of purified catalytic subunit. Inactivation following activation, then, is mediated by two mechanisms the relationship of which is presently unknown. First, the inactivation which parallels cAMP degradation and loss of protein kinase activity may be related to dephosphorylation, and is reversed by cAMP or exogenous protein kinase. Second, inactivation under conditions of phosphodiesterase inhibition, continued addition of cAMP or addition of protein kinase catalytic subunit is associated with continuous protein kinase activity. Under these conditions, however, inactivated TH can not be reactivated.

Following filtration of a striatal homogenate on a Sephadex G-100 column, the TH is activated by protein phosphorylation conditions but is not subsequently inactivated. The activated TH is therefore inactivated in the striatal homogenate by some factor(s) present in the homogenate which may be resolved by gel filtration. The regulation of tyrosine hydroxylase activity is complex and involves more than the enzyme per se and cAMP-dependent protein kinase. Additional experimentation will be required to ascertain the exact regulatory mechanisms.

This work was supported by USPHS Grant NS-15994.

53.30 REGULATION OF DOPAMINE β-HYDROXYLASE DEGRADATION BY ASCORBIC ACID. Dona L. Wong*, Steven J. Masover*, and Roland D. Ciaranello. Dept. Psych., Stanford Med. Ctr., Stanford, CA 94305.

Rat adrenal medullary dopamine β-hydroxylase (DBH) is subject to both hormonal and neuronal controls. Glucocorticoids regulate enzyme steady state levels by inhibiting the rate of protein degradation. Neuronal stimuli via the splanchnic nerve induces de novo enzyme synthesis. Both processes require an intact cholinergic receptor.

Further investigation of the hormonal control of DBH degradation indicates that glucocorticoids exert their effect via the oxidation-reduction cofactor, ascorbic acid, utilized by the enzyme in the production of norepinephrine. Tryptic proteolysis of DBH yields a biphasic degradation curve, with a 3 min half-life for fast phase degradation and a 15 min half-life for slow phase degradation. Ascorbate stabilizes the enzyme against trypsinization. At high concentrations of cofactor, slow and fast phase proteolysis merge yielding a monophasic degradation curve. Phenylethylamine, a substrate of DBH, confers minimum protection to the enzyme against proteolysis. However, when used simultaneously with ascorbic acid, this compound acts synergistically with ascorbate in preventing DBH proteolysis. Immunotitration studies suggest that native protein and protein from a 3 min tryptic digest represent a similar molecular species distinct from protein from a 15 min tryptic digest. Immunotitration of native protein and native protein, 3 min and 15 min digests executed in the presence of ascorbate indicate that ascorbate may prevent the conversion of native enzyme to a form which is less active catalytically but which still retains antigenecity.

The above data suggests that both DBH and phenylethanolamine N-methyltransferase (PNMT) are subject to similar hormonal controls. Adrenal medullary glucocorticoids regulate the steady state levels of these biogenic amine enzymes by controlling their respective cofactors. The cofactors, in turn, prevent the degradation of DBH and PNMT by binding to the enzymes and inhibiting proteolysis.

53.31 RESERPINE EFFECT ON THE AXONAL TRANSPORT OF DOPAMINE-B-HYDROXYLASE AND TYROSINE HYDROXYLASE. B. E. Levin. Dept. of Neurology & Neurosciences, VA Med. Ctr. & NJ Med. Sch., Newark, NJ 07019.

Reserpine induces the synthesis of dopamine-B-hydroxylase (DBH) and tyrosine hydroxylase (TH) enzyme protein in the locus coeruleus (LC). This is followed, after an initial delay, by increased enzyme activity in brain areas supplied by LC axons. To study the role of axonal transport in these changes, 6-hydroxydopamine (4 μg/μl in 2 μl) was injected into the decussation of LC axonal fibers in the far anterior rat hypothalamus on the left side. Axonal transport was measured by the differences in TH and DBH activities between the left hypothalamic sections, proximal to the injection site, and the comparable right, uninjected, hypothalamic sections. Both enzymes accumulated linearly, for up to 4 d proximal to the injection site. Rats were therefore injected in the left hypothalamus with 6-hydroxydopamine 24 h prior to death, preceded by reserpine (5 mg/kg, IP) from 1-22 d prior to death. Following reserpine injections, right hypothalamic (uninjected side) DBH levels were unchanged for 4 d, fell by 57% at 5 d, rose to 159% of control at 6 d and returned to control levels by 15 d post-reserpine injection. Axonal transport of DBH was uneffected by reserpine until the sixth post-injection day when it increased by 477%, with a peak increase of 593% at 7 d, and a gradual return to control levels by 22 d. Right hypothalamic TH levels began to increase on the sixth post-reserpine day, peaked at 269% of control at 8 d and returned to baseline by 15 d. Axonal transport of TH increased transiently by 108% at 2 d, was completely blocked at 5 d, increased to 389% and 493% of control at 6 d and 8 d respectively, and returned to baseline by 15 d after reserpine injections.

Therefore, the delayed increases of TH and DBH activities seen in the hypothalamus following reserpine treatment appear to be due to a delayed onset of the axonal transport of these newly synthesized enzymes from the LC.

53.32 METHAMPHETAMINE-INDUCED DEPRESSION OF BRAIN TRYPTOPHAN HYDROXYLASE: REGIONAL RECOVERY FOLLOWING ACUTE TREATMENT. C. Bakhit* and J.W. Gibb, Dept. Biochem. Pharm. & Toxicol., University of Utah, Salt Lake City, Utah 84112.

We have recently reported that acute administration of methamphetamine to rats produces large decreases in the activity of tryptophan hydroxylase (TPH) in regions that have serotonergic nerve terminals (Bakhit et al., Fed. Proc. 39:268, 1980; Hotchkiss and Gibb, In Press). In this study we report the recovery of TPH activity following acute methamphetamine treatment. Rats were administered a single injection of methamphetamine (10 mg/kg, s.c.) and sacrificed at the following time points after drug treatment: 3, 12, 36, 96 hrs and 2 weeks. To minimize the diurnal variation in enzyme activity, the experiments were designed so that groups of rats from the different time points were sacrificed on the same day between 10 a.m. and 2 p.m. Rats were sacrificed by decapitation and the following brain regions dissected: nucleus accumbens (NA), olfactory tubercle (OT), neostriatum (NS), hypothalamus (Hy), hippocampus (H), cerebral cortex (CC) and spinal cord (SC). TPH activity was measured by a modified $^{14}CO_2$ trapping method (Hotchkiss et al., Life Sci. 25:1373, 1979). Three hrs after the administration of methamphetamine, TPH activity was markedly depressed (expressed as % of control values): NA 36%, OT 50%, NS 47%, Hy 67%, H 44%, CC 42%, SC 74%. At 12 hrs enzyme activity recovered as follows: NA 61%, OT 100%, NS 74%, Hy 93%, H 62%, CC 69%, SC 85%. At 36 and 96 hrs following drug treatment, TPH activity was back to control values in all regions except the nucleus accumbens and hippocampus. When measured at 2 weeks, TPH activity had returned to control values in all regions studied. These data suggest that there is a time-dependent and differential recovery of enzyme activity in various serotonergic nerve terminal regions examined. (Supported by USPHS grants GM 07579 and DA 00869.)

53.33 SIMILAR POTENCY RATIOS OF AMPHETAMINE ISOMERS ON INHIBITION OF ^{3}H-DOPAMINE UPTAKE BY STRIATAL, OLFACTORY TUBERCLE AND FRONTAL CORTEX DOPAMINERGIC NERVE TERMINALS. R.T. Matthews and P.A. Shore. Department of Pharmacology, University of Texas Health Science Center, Dallas, Tx 75235.

Recent electrophysiological data suggest important differences between nigral (A-9) and ventral tegmental (A-10) dopamine (DA) neurons in their responses to drugs in vivo. Specifically, D-amphetamine (D-AMPH) is 5 to 6 fold more potent than L-AMPH in inhibiting A-9 impulse flow while A-10 impulse flow is inhibited equally by the AMPH isomers. It was therefore of interest to study the relative potencies of AMPH isomers on ^{3}H-DA uptake in nerve terminals of A-9 and A-10 DA neurons in the rat. A method for selective measurement of ^{3}H-DA uptake by DA nerve terminals was developed and the effects of AMPH isomers on DA uptake in striatal synaptosomes (A-9 terminals) was compared to uptake in olfactory tubercle and frontal cortex synaptosmes (A-10 terminals). Desipramine (DMI) had a biphasic dose-response effect on ^{3}H-DA (10^{-7}M) uptake in frontal cortex but only a monophasic effect at high concentrations in the other areas, suggesting substantial ^{3}H-DA uptake by norepinephrine (NE) neurons only in the frontal cortex. At a concentration of DMI chosen for maximal inhibition of NE uptake but minimal effects on DA uptake, fluoxitine (10^{-6}M), a potent serotonin reuptake inhibitor had no additional effect on DA uptake in any terminal area. In contrast, amfonelic acid, a potent DA uptake inhibitor, was additive with DMI in all areas (IC_{50} - $1\text{-}3x10^{-8}$M). In the presence of DMI and fluxotine, D-AMPH was 4 to 6 fold more potent than L-AMPH as a DA uptake inhibitor in all terminal areas. This suggests that A-9 and A-10 DA terminals are pharmacologically similar and that recently reported electrophysiological differences in AMPH isomer potencies on A-9 and A-10 neurons may be due to a NE-DA neuronal interaction.

53.34 PARANEURONS OF THE THYROID GLAND: A MODEL FOR STUDIES OF SEROTONIN STORAGE AND RELEASE. P. Bernd*, T. Tagliente*, E.A. Nunez*, M.D. Gershon and H. Tamir (SPON: E.B. Masurovsky). Department of Anatomy, Columbia University, New York, N.Y., 10032 and New York State Psychiatric Institute, Division of Neuroscience, New York, N.Y. 10032.

Parafollicular cells of the sheep thyroid gland are neural crest derivatives that have been referred to as paraneurons and contain the biogenic amine serotonin (5-HT) as well as the hormone calcitonin. These cells also contain a highly specific serotonin binding protein. The parafollicular cell, therefore, could serve as a model for studying 5-HT storage and secretion. We have devised a method to obtain an enriched and purified population of thyroid parafollicular cells. Thyroid glands of sheep were dissociated with trypsin (0.25%) and the cells were then incubated with thyroid stimulating hormone (TSH, 5 mU/ml). This hormone caused the follicular cells to extend pseudopods and become highly phagocytic. These TSH-stimulated cells were then passed through a column of Sepharose 6MB to which thyroglobulin had been coupled and fractions were collected (2 ml; 1 ml/min). The follicular cells presumably adhered to the beads and the cells that passed through the column were primarily red blood cells and parafollicular cells. The greatest number of cells was found in fraction 4, while the 5-HT concentration was highest in fraction 5 (30 fg/cell; a 10 fold enrichment over the dissociated cells). Quantitative electron microscopic evaluation of fraction 5 revealed that the ratio of parafollicular cells to follicular cells was five fold higher than the same ratio determined for the originally dissociated cells. The other fractions obtained from the column were enriched with parafollicular cells approximately two fold. Control experiments that did not include an incubation with TSH did not show an enrichment or separation of parafollicular cells from follicular cells in any of the fractions. In conclusion, cell chromatography has yielded a fraction that is greatly enriched with viable parafollicular cells. These 5-HT-rich paraneurons can now be used to study the mechanisms of 5-HT storage and release.

Supported by NIH grants NS12969, AM19743, NS12506 and GM07182.

53.35 THE UPTAKE AND FATE OF THE RADIOLABELED 5-HYDROXYTRYPTAMINE IN ISOLATED CEREBRAL MICROVESSELS. T. Abe*, W. D. Rausch*, N. Merkel*, K. Abe* and M. Spatz. Lab. of Neuropathology and Neuroanatomical Sciences, National Institutes of Health, Bethesda, MD 20205.

Only a slight amount of circulating 5-hydroxytryptamine (5-HT) was found to pass the blood-brain barrier (Axelrod and Inscoe, J. Pharmacol. Exp. Therap. 141, 161, 1963). To elucidate the mechanism responsible for these reported observations the uptake and metabolism of radiolabeled 5-HT were investigated in isolated cerebral microvessels, which were previously proven to be metabolically active and suitable for such studies (Mrsulja, Mrsulja, Fujimoto, Klatzo and Spatz, Brain Res. 111, 361, 1976).

The capillary uptake of ^{3}H 5-HT was found to be saturable since it could be inhibited by increasing the concentration of unlabeled (cold) 5-HT in the incubating medium containing the labeled substrate (estimated Km 2.3 µm). The addition of K^+ increased while the reduction of Na^+ or addition of ouabain decreased the ^{3}H 5-HT uptake in the isolated microvessels. Metabolic inhibitors (Na azide, NaFl, DNP, KCN) had little effect on either the uptake or metabolism of labeled 5-HT in the microvessels. However, hypothermia, phentolamine (1 mm), dichloroisoproterenol (1 mm) and imipramine (0.3 mm) reduced the capillary 5-HT uptake in 90, 86, 83 and 57 percent, respectively. Moreover, a cross inhibition of this uptake was seen by L-norepinephrine, DL metaraminol, L-epinephrine, L-dopa, dopamine and tryptamine but not by the amino acids of the L and A transport system. Bivalent ions (Co^{++} Mn^{++}) reduced both the uptake and metabolism of ^{14}C 5-HT. 5-HIAA was found to be the main metabolite extractable from the microvessels and from the incubating medium. The turnover rate of ^{14}C 5-HT was 1.89 nmoles/mg P/30 minutes. Anoxia markedly reduced the metabolic rate of the labeled 5-HT.

These results indicate that the capillary uptake of 5-HT takes place by a specific Na^+ and K^+ dependent carrier-mediated process (which may be shared by other amines). These features and the sensitivity of the 5-HT uptake to hypothermia and to metaraminol cross inhibition resemble the reported characteristic properties of the neuronal amines' uptake. However, the cerebral microvessels also showed the main characteristics of extraneuronal uptake, namely, the capability of metabolizing the 5-HT and releasing the deaminated metabolite. Thus, the cerebral microvessels have the capacity for 5-HT uptake and metabolism rather than for uptake and storage. Therefore, they are most likely responsible for regulating the inflow and outflow of 5-HT by inactivating the amine, which can be altered under pathological conditions.

53.36 UPTAKE OF 5-HYDROXYTRYPTAMINE AND NORADRENALINE BY SPINAL CORD SLICES IS REDUCED BUT NOT ABOLISHED BY CHRONIC SPINAL TRANSECTION. D.M. Wright* and R.S.G. Jones* (SPON: R.B. Malmo). Dept. of Anaesthesia Res., McGill Univ., Montreal, PQ. H3G 1Y6 and the Psychiatric Div., Univ. Hospital, Saskatoon, SK, S7N OW8 Canada.

It has been reported that 5-hydroxytryptamine (5-HT), but not noradrenaline (NA), evokes a significantly greater increase in the amplitude of the motoneurone field potential after chronic section of dorsal roots (Roberts & Wright, J. Physiol. (Lond.) 285 (1978) 21P). One possible explanation, the development of a motoneuronal supersensitivity to 5-HT, implicates 5-HT as a transmitter of primary afferent neurones.

To test this postulate further, monoamine uptake was measured in 200 µM slices of rat lumbar spinal cord 10 days after a 2 mm section of thorasic cord had been removed to cause the degeneration of descending monoamine pathways (*cf.* Haggendal & Dahlström, Neuropharmacology, 12 (1973) 349). Slices were placed in rapid transfer tubes for incubation in buffer (Krebs-Henseleit + 10^{-6}M Clorgyline) containing 10^{-7}M of either ^{14}C-5-HT or ^{14}C-NA. Radioactivity was determined on a Packard Tri-carb model 3320.

$^+$ Uptake expressed as (fmole.mg^{-1}.15min^{-1}; (n))

These results demonstrate the existence of active uptake systems for 5-HT and NA in the spinal cord following degeneration of descending pathways. This supports previous suggestions (Roberts & Wright, 1978,Lackovic Int.Cong.Pharm. Abs.2310; Nozaki et al., Psychopharmacology 67 (1980)25) that there are serotonergic and noradrenergic mechanisms within the spinal cord that are not supraspinal in origin.

53.37 (-)METHADONE ANTAGONISM OF BRAIN SEROTONIN DEPLETION BY p-CHLOROAMPHETAMINE IN RATS. Kenneth W. Perry*, Ray W. Fuller and Martin D. Hynes. The Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

Methadone is a potent inhibitor of the uptake of serotonin by brain synaptosomes in vitro (Ciofalo, J. Pharmacol. Exp. Ther. 189, 83, 1974), but attempts to demonstrate inhibition of serotonin uptake in vivo by methadone have generally failed (Fuller and Perry, Biochem. Pharmacol. 25, 360, 1976; Donzanti and Warwick, Eur. J. Pharmacol. 59, 107, 1979; Miranda et al., Pharmacol. Res. Commun. 11, 455, 1979). Using antagonism of p-chloroamphetamine-induced depletion of brain serotonin in rats as an index of inhibition of uptake into serotonin neurons in vivo, we have found that (-)methadone at high doses can inhibit uptake into serotonin neurons but the duration of action is short. (-)Methadone HCl at doses of 5 mg/kg i.p. given 10 min before and again 1.5 hrs after p-chloroamphetamine HCl (5 mg/kg i.p.) antagonized depletion of serotonin measured 3 hrs after p-chloroamphetamine. Serotonin concentration was 0.45 + .02 µg/g in the brains of control and methadone-treated rats. p-Chloroamphetamine lowered brain serotonin concentration to 0.17 + .01 µg/g in controls but only to 0.36 + .04 µg/g in (-)methadone-treated rats. A single dose of (-)methadone HCl given simultaneously with p-chloroamphetamine HCl (both at 5 mg/kg i.p.) protected against serotonin depletion at 1 hr and at 2 hrs, but by 4 hrs serotonin was depleted to the same extent with or without methadone co-treatment. Comparing p-chloroamphetamine antagonism and analgesic effects in a rat tail jerk assay at various s.c. doses of (-)methadone HCl indicated that inhibition of serotonin uptake by (-)methadone does not occur until doses higher than those needed for maximum analgesia are reached. A dose of 1 mg/kg (-)methadone HCl significantly prolonged rat tail jerk latency, and a dose of 2 mg/kg produced maximum effect. In contrast, no antagonism of serotonin depletion by p-chloroamphetamine HCl (5 mg/kg i.p.) occurred until a 4 mg/kg dose of (-)methadone HCl was reached. Thus inhibition of serotonin uptake probably has no role in methadone analgesia.

53.38 EFFECTS OF DRUGS ON 5-HYDROXYTRYPTAMINE, DOPAMINE AND THEIR METABOLITES IN CEREBROVENTRICULAR PERFUSATES OF UNANESTHETIZED, FREELY-MOVING RATS. J.A. Nielsen* and K.E. Moore. Dept. of Pharmacology & Toxicology, Michigan State Univ., E.Lansing, Michigan 48824.

The activity of aminergic neurons have been estimated from measurements of neurotransmitter metabolites in cerebrospinal fluid (CSF) or perfusates of the cerebroventricular system. These studies generally have been performed in anesthetized animals or have used radiolabelled precursors. To reduce problems inherent in these methods we have undertaken to characterize a procedure which would allow the measurement of endogenous biogenic amines and their metabolites in cerebroventricular perfusate of unanesthetized, freely-moving rats.

Male rats were implanted with permanent push-pull cannulas such that the tips were in the right lateral ventricles (Tilson and Sparber, J. Pharmacol. Exp. Ther. 181:387, 1972). After recovery from surgery the rats were perfused with artificial CSF at a rate of about 15 µl/minute. Perfusate samples were collected every 15 min in 0.1 M citrate-phosphate buffer (pH 3.5) and analyzed by high performance liquid chromatography utilizing a C-18 reverse phase column coupled with an electrochemical detector (Hingtgen et al., Soc. Neurosci. Abstracts 5: 559, 1979). The perfusates contain endogenous dopamine (DA), 3,4-dihydroxyphenylacetic acid (DOPAC), 3-methoxy-4-hydroxyphenylacetic acid (homovanillic acid, HVA), 5-hydroxytryptamine (5-HT) and 5-hydroxyindoleacetic acid (5-HIAA). The amounts of these compounds in perfusate are different from rat to rat but consistent for each rat over several weeks. Probenecid (250 mg/kg, ip) increased perfusate concentrations of all the acid metabolites without affecting DA or 5-HT. Tryptophan (100 mg/kg, ip) increased 5-HT and 5-HIAA but had no effect on DA or its metabolites. Pargyline (75 mg/kg, ip) decreased 5-HIAA, DOPAC and HVA while not altering 5-HT or DA. These results suggest that concentrations of endogenous amines and their metabolites in perfusates from the lateral ventricles may be used to estimate the effects of drugs on biogenic amine neuronal systems in brains of unanesthetized, freely-moving rats. (Supported by USPHS Grant NS15911.)

53.39 THE SELECTIVE RELEASE OF TRITIATED meta-TYRAMINE (m-TA) and para-TYRAMINE (p-TA) FROM RAT STRIATAL SLICES BY SOME AMINOTETRALINS (AT'S). L.E. Dyck* (Sponsor: A.A. Boulton), Psychiatric Research Division, University Hospital, Saskatoon, Saskatchewan, S7N OXO.

Cerebral dopamine (DA) systems are believed to play an important role in the mediation of drug-induced hyperactivity and stereotypy. To characterize the stereochemically effective configuration of DA at the receptor(s) responsible for eliciting such behaviors, rigid analogs of DA, such as the AT's, have been employed. For example, ADTN, 6,7-dihydroxy(diOH)AT, appears to be a highly specific and potent DA agonist. However, several other AT's, which have only one, or no, aromatic hydroxyl group, but which have a dipropyl (diPr) substituted amino group, are active as well. It is not yet clear whether the activity of these AT's is direct or indirect; therefore, several of these AT's were tested to see if they could release DA, or m- and p-TA.

The simultaneous release of m-TA-^{3}H and DA-^{14}C, or p-TA-^{3}H and DA-^{14}C, from 0.2mm slices of the anterior portion of rat striatum (10-15 mg wet wt.) was studied. The slices were preloaded by incubation for 15 min in oxygenated Krebs-Henseleit medium containing 100nM of each labelled amine at 37°C. The slices, then, were moved in succession through ten tubes containing the standard medium ± 10µM AT. Pargyline (10µM) was always present, and the AT's were in tubes 6 through 10. The percentage increases (mean ± S.E.M.) in tube 6, above the spontaneous release in tube 5, caused by the various AT's were:

	% Increase in the Release of			
Drug	p-TA-^{3}H	DA-^{14}C	m-TA-^{3}H	DA-^{14}C
ADTN	229±61	317±75	147±11	500±50
M8	281±34	377±19	164±18	327±36
5,6-diPr	90± 6	6± 9	65±14	17± 4
5OH	129±21	4± 4	124±27	42±23
6OH	104±24	35±12	103±39	40±24
7OH	181±31	20±12	62±14	43±14

ADTN and M8 released DA, as well as m- and p-TA. In contrast, the other four AT's, all of which are diPr substituted, released m- and p-TA, but did not release DA to a significant extent. diPr substituents are reported to enhance activity at post-synaptic central DA receptors and enhance the stereotypic potency of an AT; whereas they attenuate the hyperactive responses to the AT. It may be concluded from this study, that the hyperactivity induced by an AT involves DA primarily, since the diPr derivatives were not able to release DA. Stereotypy, however, may involve m- or p-TA, primarily, since the diPr derivatives released them, but did not release DA.

54.1 DIVALENT IONS AND AMINO ACID RESPONSES IN FROG SPINAL CORD. A.L. Padjen and P.A. Smith. Department of Pharmacology, McGill University, Montreal, Quebec H3G 1Y6.

In an attempt to examine the possible role of divalent ions in amino acid responses, experiments were performed on the isolated hemisected superfused spinal cord of the frog (R.pipiens) at 15°C. The DC potentials of dorsal (DR) and ventral roots (VR) were recorded using the sucrose gap technique. A series of responses to glutamate (GLU), GABA (both 1 mM), D,L-homocysteate (DLH, 50 μM) kainate (KA, 50 μM), N-methyl D,L-aspartate (NMDLA, 0.1 mM) and K^+ (8 mM) were examined in the presence of 0.1-1 μM TTX to block indirect responses. Lowering of Ca^{++} to 1 μM or less (using an EGTA-Ca buffer) caused a time dependent change in the membrane potential (2-3 mV hyperpolarization followed by a depolarization of VR and particularly DR). Initially there was a general depression of the depolarizing responses of both roots to all acidic amino acids at a time when the response to $8K^+$ was little changed or even increased. The glutamate after hyperpolarization (GLU-AHP) was more than doubled and occasionally the usually monophasic response to DLH exhibited an AHP. The GABA depolarization of DR was depressed to 50% of control while the hyperpolarization of the VR increased by 20%. Prolonged washing (>3 h) with low Ca^{++} Ringer caused a nonspecific depression of all responses. These changes were completely reversed 1 h after return to normal Ca^{++} (2 mM) Ringer. Unlike Ca^{++} removal, Co^{++} (2-5 mM) caused an immediate and lasting depolarization of both roots. (DR 2-5 mV; VR 1-3 mV). Furthermore, the responses of both roots to DLH or NMDLA were selectively antagonized (50-100%) at the time when GLU and KA responses of VR were enhanced by 10-25%. Although the response to $8K^+$ was within 10% of control on VR, but reduced on DR, the GABA responses underwent a dramatic change, a 200% increase on DR and a reversal into a depolarization on VR. Cd^{++} (50 to 200 μM) enhanced GABA responses on both roots yet nonselectively depressed all responses to acidic amino acids. D600 was only effective at doses exceeding 0.1 mM and depressed all responses except the hyperpolarizing response of VR to GABA which was enhanced by up to 400%. Qualitatively similar results were sometimes obtained with La^{+++} (0.5-1 mM). These results raise the possibility that a Ca^{++} conductance may be involved in acidic amino acid responses particularly those to DLH and NMDLA on VR and GABA on DR. Perhaps Co^{++} can substitute for Ca^{++} in these events. The possible involvement of some other mechanism such as receptor modification, modulation of agonist induced conductance change, change of membrane resistance or potential, effect on pump mechanisms, or chelating effects cannot yet be excluded.

54.2 KOJIC AMINE: A GABA AGONIST WITH DUAL ACTION. G.W. Bourne and A.L. Padjen. Dept. of Pharmacology, McGill Univ., Montreal, Quebec H3G 1Y6.

The GABA analog kojic amine (KJA) has been shown to mimic GABA in receptor binding assay and in bicuculline sensitive inhibition of cerebellar Purkinje cells and is more potent than GABA in reducing synaptic potentials in the amphibian spinal cord (Yarbrough et al.,Arch.Int.Pharm.Ther. 241:266,1979). The action of KJA was studied on the isolated hemisected superfused frog spinal cord. Synaptic, spontaneous and drug evoked responses were recorded on the ventral (VR) and dorsal roots (DR) by means of the sucrose gap technique. KJA (50-500 μM) produced a dose dependent depression of all synaptic potentials recorded (DR potentials evoked by DR or VR stimulation, and VR potentials evoked by DR stimulation). This action was completely reversible by 30 to 60 min washing. A 3 min application of 0.5 mM KJA completely abolished spontaneous activity recorded on both roots for 30 to 45 min, following an initial hyperpolarization of VR (1.5 mV) and a depolarization of DR (1.5 mV). This contrasts with the depression of spontaneous activity by GABA which does not extend beyond the time of application. Examination of direct responses to KJA (10 μM-0.5 mM; in the presence of 2 mM Mn^{2+}, 0.2 mM Ca^{2+} Ringer) revealed a dose dependent hyperpolarization of VR (2 mV with 0.5 mM). At concentrations above 0.25 mM KJA depolarized DR (2 mV with 0.5 mM), however, lower concentrations caused a 1 mV hyperpolarization of DR. Multiphasic responses were observed at intermediate concentrations (50 μM). All direct responses to KJA were characteristically slow in onset and decay, unlike the much faster and larger responses to GABA. However, at very low concentrations (10 μM-50 μM) GABA also produced a small slow hyperpolarization of dorsal roots. Bicuculline (BIC, 50-100 μM) and picrotoxin (PTX, 100 μM) both depressed the hyperpolarizing response of the VR to KJA and GABA. The depolarizing action of KJA on the DR was eliminated by both antagonists revealing a potent hyperpolarization at all agonist concentrations tested (10 μM-0.5 mM). The DR depolarization to high concentration of GABA was antagonized (BIC 50 μM) or reversed (PTX 0.1 mM, BIC 0.1 mM) by the GABA antagonists. The antagonists thus revealed a dual response of the DR to both KJA and GABA by selectively inhibiting the depolarizing component. The dorsal root ganglion, found to be reliably depolarized by GABA (1 mM) was not affected by KJA (1 mM) applied for up to 7 min. These results suggest that KJA activates both PTX-BIC sensitive and insensitive GABA receptors on primary afferents. The latter are possibly responsible for KJA depression of synaptic transmission through a presynaptic action similar to baclofen.

Supported by MRC of Canada.

54.3 STEREOSPECIFICITY OF THE GLIOTOXIC AND ANTI-NEUROTOXIC ACTIONS OF ALPHA AMINOADIPATE. T. de Gubareff,* J.W. Olney & J.F. Collins,* Dept. Psychiatry, Wash. Univ. Sch. Med., St. Louis, Mo. 63110 and Dept. Chemistry, City London Polytech., London, England.

Glutamic (Glu), aspartic (Asp) and α-aminoadipic (αAA) acids are structurally analogous dicarboxylic amino acids which differ only in the length of their carbon chains. Glu and Asp have both excitatory and neurotoxic actions on central neurons; DL-αAA has neither but we have found that it induces a gliotoxic reaction in the arcuate hypothalamic (AH) region of immature mouse brain when administered sc, and when administered together with Glu or its excitotoxic analogs it suppresses their AH neurotoxicity. We have now studied the separate isomers of αAA to determine which is responsible for the gliotoxicity and which for the anti-neurotoxic action of DL-αAA.

Four day old mice were injected sc with a 2% aqueous solution of D or L or DL-αAA at 1 or 2 mg/g body wt and sacrificed 4 hrs later for histological examination of the hypothalamus. We found that the D isomer was without discernable effect at 1 mg/g and induced mild to moderate swelling of glial processes at 2 mg/g. The L-isomer caused more dramatic gliotoxic changes accompanied by an unequivocal *neurotoxic* reaction. Both the gliotoxic and neurotoxic activities of L-αAA were clearly evident at 1 mg/g and substantially more severe at 2 mg/g. DL-αAA at 2 mg/g induced a toxic reaction affecting AH glia but not neurons.

These findings corroborate our prior observation that DL-αAA has gliotoxic but not neurotoxic activity. The new finding that L-αAA, which McLennan & Hall recently described as a neuronal excitant, has significant neurotoxicity, adds new support to the excitotoxic hypothesis (that an excitatory mechanism underlies the neurotoxicity of amino acid excitants). More importantly, the demonstration that L-αAA has significant neurotoxicity but D-αAA does not, in light of the non-neurotoxicity of DL-αAA, signifies that D-αAA is an effective antagonist of the neurotoxicity of L-αAA. Blockade of this type of neurotoxicity by a molecule (D-αAA) known to antagonize the depolarizing action of amino acid excitants, an action thought to be mediated through postsynaptic receptors on the dendrosomal surfaces of the neuron, strongly implicates these receptors and an excitatory (depolarization) mechanism in the neurotoxic activities of amino acid excitants. Conceivably the excitotoxic activity of Glu or Asp may underly the degeneration of neurons in certain human neurological disorders. If so, antagonists that specifically block the excitotoxic activities of these agents at their excitatory receptors might protect such neurons from degeneration. Supported by USPH grants NS-09156, DA-00259, RSA MH-38894 (JWO) and Huntington's Chorea and Wills Foundation grants.

54.4 DO SUBSTANTIA NIGRA PARS RETICULATA NEURONS BECOME SUPERSENSITIVE TO GABAERGIC DRUGS AFTER STRIATAL KAINIC ACID LESIONS? B.L. Waszczak and J.R. Walters. NIH, NINCDS, Bethesda, MD 20205.

Several investigators have reported that destruction of the striatonigral GABA pathway causes increases in specific ^{3}H-GABA binding in the substantia nigra (SN). These findings suggest that supersensitivity develops at GABA sites postsynaptic to the lesioned striatonigral terminals. Recent studies in this laboratory suggest that a group of cells within the SN pars reticulata, which exhibit a marked sensitivity to the inhibitory actions of GABAmimetic agents, may receive a GABAergic input from the striatonigral pathway. The following studies were undertaken, therefore, to determine if SN pars reticulata cells become supersensitive to GABAergic drugs after destruction of the striatonigral projection.

Unilateral injections of kainic acid (KA), 1 μg/0.5 μl, were made into the striata of male rats (250-300 g). Neuronal cell loss in the striatum and globus pallidus was confirmed histologically, and GAD activity in the SN on the lesioned side was reduced to 36% of that on the unlesioned side. Extracellular, single unit responses of SN pars reticulata neurons to increasing i.v. doses of muscimol (MUSC) or iontophoretically-applied GABA were compared in chloral hydrate-anesthetized control and KA-lesioned rats (14-24 days after the lesion). I.V. administration of MUSC inhibited the firing of reticulata cells from both lesioned and unlesioned rats. However, comparison of cumulative log dose-response curves for MUSC revealed no apparent changes in the sensitivity of cells from KA-treated (n=10) and control (n=9) rats. ED_{50} values for inhibition of reticulata cell firing ranged from approximately 3.5 to 5 mg/kg MUSC for both lesioned and unlesioned groups. In separate experiments in which rats received striatal KA injections of twice (2 μg/1 μl) the original dose (n=8), there were again no significant changes in the sensitivity of reticulata cells to i.v. MUSC.

Iontophoresis of GABA (0.001 M in 0.2 M NaCl) onto reticulata cells also inhibited their firing. IT_{50} values (the product of the time required to inhibit firing by 50%, T_{50}, and the ejection current, I, applied) were used as a measure of the sensitivity of reticulata cells to iontophoresed GABA. Examination of IT_{50} values obtained from 10 control rats (14 cells) and 7 KA-lesioned rats (17 cells) revealed that reticulata cells from KA-treated rats tended to be more sensitive to GABA than cells from untreated rats, but the difference in responsiveness between the two groups was of borderline significance ($.05<p<.1$). Since reticulata cells in lesioned animals did not demonstrate supersensitivity to i.v. MUSC, their increased response to iontophoresed GABA and the reorted increases in GABA binding may not be predictive of physiologically important or clinically significant changes in reticulata cell function in diseases where striatonigral GABA pathways degenerate.

54.5 EFFECTS OF pH AND TEMPERATURE ON GABA DEPOLARIZATIONS (GD) RECORDED FROM CAT DORSAL ROOT GANGLIA (DRG). Jun Nakamura*, J.P. Gallagher, and Patricia Shinnick-Gallagher. Dept. of Pharmacol. and Toxicol., Univ. Texas Med. Br., Galveston, TX 77550.

GABA depolarizes cat DRG by causing an efflux of chloride. Chloride ions move across the membrane through a selective anionic channel. We have attempted to modify this chloride efflux by altering the pH of the solution bathing the DRG. Lowering the pH from 7.4 to 6.4 resulted in a 40% increase above control amplitude of the iontophoretically induced GD. In addition to the enhanced response, its half-decay time was prolonged. The increase in amplitude occurred even though, in the low pH solution, most of the cells' resting input resistance was decreased. On the other hand, raising the pH from 7.4 to 8.9 caused a 20% reduction in the amplitude of the GABA depolarization, although the cells' input resistance was usually slightly increased. The reversal potential of the GD remained constant in either an acidic or alkaline medium. Two possible explanations for these pH effects are that the charge density of the anionic channel has been affected and/or the channel's open life-time has been changed. Two agents that may owe part of their facilitatory action to a mechanism that may be explained by that observed in acidic medium include phenobarbital and ammonium.

Cooling the DRG also altered the GD. Rapid lowering of the bath temperature from 37^0C to 27^0C produced three effects: 1) the amplitude of the GD was diminished; 2) the rise-time was lengthened; and 3) the time for ½-decay was prolonged. An explanation for this temperature effect may be inhibition of the metabolically dependent, inwardly directed chloride pump that has been proposed for these neurons. As a result, the normally high level (50 mM) of chloride in these cells cannot be maintained and the driving force for the GD is diminished. In addition, lowering the temperature may also increase the open channel life-time and thereby prolong the ½-decay time. We have attempted to mimic this depression of the GD with several putative chloride pump inhibitors (SITS, fuorsemide, ammonium ion, bumetanide and pyridoxine) but none affect the GD in a manner similar to lowering the temperature. (Support by USPHS Grant #NS 13727.)

54.6 NEUROTOXICITY OF SIMPLE ALIPHATIC DIAMINES. G. M. Strain and W. Flory*. Veterinary Physiology, Pharmacology, and Toxicology, and Dept. of Veterinary Science, LSU Sch. of Vet. Med., Baton Rouge, LA 70803.

Neurotoxicity of some members of Lathyrus pea family (neurolathyrism) has been shown to be caused by three diamine compounds: α,γ-diaminobutyric acid (DABA), β-N-oxalyl-L-α,β-diaminopropionic acid (ODAP), and γ-N-oxalyl-L-α,γ-diamobutyric acid (ODAB) (Liener, 1969, Toxic Constituents of Plant Foodstuffs, Academic Press). Intracerebroventricular (ICV) injections of these compounds produce symptoms of hyperexcitability, tremor, and convulsions with a stereotyped motor pattern. Studies of DABA and structurally related diamines by Chen et al. (Tox.Appl.Pharm.1972 23:334) showed that some, but not all, simple diamine compounds cause typical convulsions after ICV injection. In this study, diamines with the two following general structures were examined for neurotoxicity after ICV injection in the rat:

$$NH_2 - (CH_2)_n - NH_2 \qquad n \geq 2$$

$$NH_2 - (CH_2)_k - \underset{\displaystyle NH_2}{\underset{|}{CH}} - COOH \qquad k \geq 1$$

Tests of nine diamine compounds showed the general structure-activity relationship (SAR) that toxicity occurs when the carbons bound to the amino groups are separated by at least one methyl linkage, i.e., $n \geq 3$ and $k \geq 2$. Further, the toxicity decreased as the number of separating methyl groups increased. This parallels the SAR observed for compounds producing osteolathyrism, the disorder of mesenchymal tissues seen with other species of Lathyrus, where an amino group must be separated from a terminal cyanide group by one or two methyl linkages (Green, J.Neurosurg., 1960, 17:657).

ODAP has been shown to inhibit the high affinity uptake system for glutamate in rat brain and monkey spinal cord synaptosomes (Lakshmanan and Padmanaban, Nature, 1974, 249:469) and Chen et al. showed DABA to increase brain levels of glutamine and GABA, both of which have glutamate as their precursor. Thus the neurotoxic diamines may act by interacting with the glutamate transmitter system.

55.1 REDUCED LEVELS OF ACETYLCHOLINE IN THE MOTOR NERVE TERMINALS OF AGED RATS. C.T. Gibson* and D.O. Smith (SPON: D.D. Gilboe). Dept. of Physiology, Univ. of Wisconsin, Madison, WI 53706.

Synaptic depression at the phrenic nerve-diaphragm neuromuscular junction is more pronounced in aged rats. This could result from a decreased availability of the neurotransmitter, acetylcholine (ACh). To test this possibility, the ACh content in phrenic nerve terminals of aged (28 mos) and young, control (9 mos) male, Fischer 344 rats were assayed and compared.

The total amount of transmitter per nerve terminal was found to be less in the aged animals. This was determined using a radio-chemical assay for ACh, in which the choline product of ACh hydrolysis was incubated with $AT^{32}P$ to form labeled choline phosphate. Endogenous choline was initially phosphorylated using unlabeled ATP, so only the ACh associated with the tissue was labeled. From measurements of the amount of labeled choline phosphate and the number of end plates assayed, the amount of ACh per nerve terminal was estimated. The results of 9 experiments in each age group indicated averages (±S.E.) of 1.33×10^{-4} ($\pm 0.45 \times 10^{-14}$) moles/nerve terminal and 2.59×10^{-14} ($\pm 0.84 \times 10^{-14}$) moles/nerve terminal in the old and the control animals, respectively. This difference is significant statistically ($p < 0.05$). Thus, there is a reduction of about 49% in the ACh levels of phrenic nerve terminals of aged rats.

These estimates of ACh content are consistent with those obtained in other investigations. Whether the difference in total ACh content is significant physiologically, however, cannot be concluded from these data. Experiments are now in progress to determine the rates of release of ACh, the fraction of ACh released, and the levels of choline acetyltransferase and acetylcholinesterase in aged and control rats. With these additional data, the importance of lower ACh levels in aged rats should be easier to judge.

55.2 THE RELATIONSHIP OF GRADATIONS IN MOTOR AXON ACETYLCHOLINESTERASE REACTION PRODUCT DENSITIES TO REGIONAL PERCENTAGE COMPOSITIONS OF TYPE I AND TYPE II MUSCLE FIBERS. L. T. Malmgren, Otolaryngology Labs, Upstate Medical Center, Syracuse, NY 13210.

Gruber and Zenker (Brain Res., 141:325, 1978) recently reported that, in the rat, motor axons to muscles composed of predominantly fast muscle fibers (high ATPase) stain more densely for acetylcholinesterase (AChE) than motor axons supplying muscles composed of predominantly slow muscle fibers (low ATPase). In the present investigation this relationship has been further examined in the cat.

Nerves to muscles with differing percentage compositions of Type I (low ATPase) and Type II (high ATPase) muscle fibers were processed (10 μ thick cryostat sections) for the histochemical localization of AChE (Karnovsky and Roots, J. Histochem. Cytochem. 12: 219, 1964) using iso-OMPA as an inhibitor of "pseudocholinesterase." The specificity of the histochemical reaction was established using controls. Various incubation times and temperatures were used to determine the optimal incubation conditions for detection of differences in axonal reaction product densities.

After 48 h incubation at 4° C alpha motor axons in nerves to muscles containing mainly Type II muscle fibers (high ATPase), such as the caudofemoralis and the tibialis anterior, were intensely stained for acetylcholinesterase. Alpha motor axons supplying muscles consisting of predominantly Type I fibers (low ATPase), on the other hand, such as the soleus and the quadratus femoris, had no clearly detectable AChE reaction product, and did not differ from sensory axons in the dorsal spinal roots at this incubation time and temperature. These results are similar to those reported by Gruber and Zenker for the rat. However, when the incubation was extended to 72 h at 4° C some of the alpha motor axons to the quadratus femoris had faint AChE while others did not. When the nerve to the soleus was incubated under these conditions, the alpha motor axons remained essentially unstained. These differences in axonal AChE reaction product densities may be related to the finding that while the soleus muscle consists of an essentially homogeneous distribution of Type I muscle fibers, the quadratus femoris muscle includes regions where some Type II fibers are present and other regions where they are lacking. The graded AChE staining intensities characteristic of groups of alpha motor fibers supplying these muscles may reflect the regional percentage composition of muscle fiber types in the area of the motor unit.

55.3 DOES THE Ca^{++} DEPENDENT FRACTION OF K^+ INDUCED CHOLINERGIC TRANSMITTER RELEASE OCCUR FROM THE CYTOPLASMIC OR VESICULAR FRACTION OF MOUSE BRAIN? P.T.Carroll and J.M.Aspry*, Dept. of Pharmacol., Univ. of Rhode Island, Kingston, RI 02881.

Incubation of mouse forebrain minces for 30 min in lithium Krebs medium (low Na^+, high K^+, L.K.) lowers the ACh content of the crude vesicular fraction (P_3) independently of the cytoplasm (S_3) relative to normal Krebs (N.K.) incubation - Carroll & Nelson, 1978. Subsequent incubation of L.K. pretreated minces in N.K. with either ^{14}C choline or the analog ^{14}C homocholine refills the P_3 fraction with newly synthesized ^{14}C ACh or ^{14}C acetylhomocholine (^{14}C Ah), respectively. Refilling of the P_3 fraction occurs independently of the S_3 fraction since higher ratios of ^{14}C ACh or ^{14}C Ah to ACh (0.63 and 7.3) are attained there relative to the S_3 fraction (0.35 and 0.44, respectively) - Nelson et al., 1980. One can utilize the marked difference in the ratio of ^{14}C Ah to ACh in the P_3 fraction relative to the S_3 fraction to ascertain the subcellular origin of the spontaneous or K^+ induced release of cholinergic transmitter by incubating these pretreated minces a third time for 5 min in N.K. or high K^+ and comparing the ratios of ^{14}C Ah to ACh released spontaneously or by high K^+ into the medium with the S_3 and P_3 ratios of ^{14}C Ah to ACh prior to release. The results indicate that these pretreated minces release 2.0 nmol/g of ^{14}C Ah and 4.1 nmol/g of ACh spontaneously yielding a ratio of 0.49 which closely corresponds to that in the S_3 (0.44) prior to release. Neither omission of Ca^{++} nor elevation of Mg^{++} (16mM) alter the spontaneous release of ^{14}C Ah or ACh. Incubation of minces a 3rd time in high K^+ stimulates the release of ^{14}C Ah from 2 to 6 nmol/g but does not alter the release of ACh (4.1 to 4.6 nmol/g). The K^+ induced change in ^{14}C Ah (6-2) relative to ACh (4.6-4.1) released into the medium is 8.0, a value which corresponds to that present in the P_3 fraction (7.3) prior to release. In this case, omission of Ca^{++} or elevation of Mg^{++} significantly reduces the K^+ induced release of ^{14}C Ah but does not alter that of ACh. Pre-incubation of minces in L.K. relative to N.K. alters the ratio of ^{14}C Ah to ACh in the P_3 markedly but not the S_3 and also alters the ratio of ^{14}C Ah to ACh released by high K^+ markedly but does not alter the ratio of ^{14}C Ah to ACh released spontaneously. The present results confirm the prediction made by others (Carroll & Goldberg, 1976; Katz & Miledi, 1977; Gorio et al., 1978) that the spontaneous release of cholinergic transmitter occurs from the cytoplasm independently of Ca^{++} and that the depolarized release of cholinergic transmitter occurs from a vesicle-bound fraction by a Ca^{++} dependent process. (Supported by NSF grant #BNS 78-05160 A01.)

55.4 CHOLINERGIC ACTIONS OF ACETYLPYRROLIDINECHOLINE, A FALSE NEUROTRANSMITTER. Jerry J. Buccafusco and Robert S. Aronstam. Dept. of Pharmacology, Medical College of Georgia, Augusta, GA 30912.

Pyrrolidinecholine is a substrate for high affinity choline transport systems as well as cholineacetyltransferase, and the acetylated derivative, acetylpyrrolidinecholine (AcPyCh) is released by peripheral cholinergic nerve terminals as a "false neurotransmitter". Several studies have indicated that AcPyCh is less potent as an agonist than acetylcholine (ACh) in peripheral muscarinic and nicotinic systems (e.g., Collier et al., Mol. Pharmacol. 12, 340, 1976). In this study the potency of AcPyCh as an agonist for cholinergic receptors was determined.

Intraventricular injection of ACh or AcPyCh (15-120 nmoles) in anesthetized rats produced a dose-related increase in arterial blood pressure (10-30 mm Hg). The effects of both agents were mediated through stimulation of central muscarinic mechanisms insofar as they were blocked by prior injection of atropine (5 nmoles). There were no significant differences in either the magnitude or duration of the increase in blood pressure produced by the two drugs.

AcPyCh inhibited the binding of [^{3}H]3-quinuclidinyl benzilate to muscarinic ACh receptors (mAChR) in membranes prepared from rat cerebral cortex or brain stem (ED50 = 2.6 and 0.14×10^{-6} M, respectively). The binding of AcPyCh did not follow mass action kinetics: Hill coefficients, 0.67±0.02 (cortex) and 0.54±0.04 (brain stem) and Scatchard plots indicate multiple binding components with either tissue. The binding measurements fit a two receptor population model involving high and low affinity AcPyCh binding sites (K_D's = 8×10^{-8} and 7×10^{-6} M). The ratio of high to low affinity receptors was 0.43 in the cortex and 1.04 in the brain stem. Treatment of cortical membranes with 1 mM N-ethyl maleimide increased the affinity of AcPyCh 3-7 fold, apparently through a conversion of low affinity receptors to the high affinity species. In these binding properties, AcPyCh behaves as a typical mAChR agonist with an affinity similar to that of ACh.

AcPyCh inhibited the binding of [^{3}H]ACh, [^{3}H]d-tubocurarine and [^{3}H]nicotine to the nicotinic receptor (nAChR) of Torpedo electroplax with K_i values of 2.5, 3.6 and 2.2×10^{-7} M, respectively. AcPyCh also stimulated the binding of [^{3}H]phencyclidine ([^{3}H]PCP) to the ion channel associated with the nAChR (ED50 = 2.2×10^{-7} M). Preincubation of electroplax membranes "desensitized" the receptor-ion channel complex in a time- and concentration-dependent manner ($t_{\frac{1}{2}}$ = 18 sec with 10^{-6} M AcPyCh), as evidenced by a decrease in the affinity of [^{3}H]PCP binding. These findings indicate that AcPyCh is also a potent agonist of the nAChR possessing an affinity similar to that of ACh.

55.5 IS HOMOCHOLINE A COMPETITIVE ALTERNATE SUBSTRATE TO CHOLINE FOR ACETYLATION BY MEMBRANE-BOUND CHOLINE-O-ACETYLTRANSFERASE IN MOUSE FOREBRAIN? C.G. Benishin* and P.T. Carroll (SPON: R.B. Hill) Dept. of Pharmacol. & Toxicol., Univ. of Rhode Island, Kingston, RI 02881.

The choline (C) analog homocholine (H) is similar to C in many aspects of cholinergic metabolism. Both C and H are transported and acetylated by cholinergic preparations and released from the superior cervical ganglion and forebrain minces (e.g. Collier et al., 1977). Both extracellular C and H can be utilized to refill a crude vesicular fraction (P_3) of mouse forebrain, previously depleted of its acetylcholine (ACh) content, with newly synthesized ACh or acetylhomocholine (AHCh) respectively, independently of the cytoplasm(Nelson et al., 1980). However, soluble (S) choline acetyltransferase (ChAT) which is believed to be present in the cytoplasm and responsible for synthesis of releasable transmitter, does not acetylate H (e.g. Barker & Mittag, 1975). The objective of this investigation was to determine if H, like C, can be acetylated by membrane-bound (MB) ChAT which is non-ionically bound to vesicular and/or neuronal membranes.

Smith and Carroll (1980) have recently reported that two forms of ChAT exist in cholinergic nerve endings:one which is solubilized by high ionic strength washes of the P_3, and the other which remains associated with the P_3. Approximately 80% of the non-soluble ChAT activity is found in a P_4 pellet which is obtained by sucrose density gradient centrifugation. This fraction contains membrane- associated organelles, and non-hydrolyzable ACh (Carroll and Benishin, 1979). The acetylation of both C and H by this fraction is saturable. Also, NVP, a specific inhibitor of ChAT, reduces both C and H acetylation by the P_4. ACh and AHChcompetitively inhibit C acetylation by S and MB ChAT, the latter compound being more potent. To determine if H serves as an alternative substrate to C for MB ChAT, the kinetic parameters of C acetylation were determined in the absence and presence of fixed H concentrations. When combined velocity of acetylation is determined as a function of C concentration, the combined acetylation is unaltered by H at a C concentration of 42uM. According to Cha (1968), this kinetic pattern indicates that the two substrates, C and H, are competitive alternate substrates for the same catalytic site with the V_{max} of C acetylation greater than the V_{max} of H acetylation. These results suggest that MB ChAT acetylates both C and H and that acetylation of cholinergic precursors by S ChAT may not be essential for the synthesis of releasable cholinergic transmitter. (Supported in part by NSF grant #BNS 78-05160 A01)

55.6 EFFECTS OF CHRONIC ADMINISTRATION OF SOMAN ON ACETYLCHOLINE METABOLISM. Tsung-Ming Shih, David E. Lenz* and Donald M. Maxwell*. US Army Biomedical Laboratory, Aberdeen Proving Ground, MD 21010.

We have examined in rats the time course effects of the repeated subcutaneous administration of sub-lethal doses of soman (60 µg/kg), a completely irreversible inhibitor of acetylcholinesterase (AChE). The levels of AChE, acetylcholine (ACh) and choline (Ch) were determined in 4 discrete brain areas (brain stem, cerebellum, mid-brain and cerebral cortex). In addition, behavioral effects, as determined by a drinking behavior test, were monitored. It had been previously reported that rats, chronically treated with diisopropylfluorophosphate (DFP), show depressed whole brain AChE activity, elevated levels of brain ACh, and have been able to adapt to this stress as demonstrated by a behavioral test (J. Pharmacol. Exp. Ther. 192, 73, 1975). Our study was carried out to examine the generality of these results with another organophosphorus compound. In the current study animals were dosed on two schedules: (A) three times a week for 6 weeks, and (B) once a week for 6 weeks. Animals were sacrificed either 3 (A) or 7 (B) days after 2, 4 or 6 weeks of chronic dosing by heart exsanguination for AChE assay using the method of Groff et al. (Clin. Toxicol. 9, 353, 1976) or by focused head microwave irradiation for brain ACh and Ch assay using gas chromatography-mass spectrometry (Anal. Biochem. 55, 438, 1973). During the 6-week period there was no difference in drinking behavior in either treatment regimen A or B between control and dosed rats. Treatment B produced a 25-40% AChE inhibition (after 6 weeks) in brain stem, mid-brain, and cerebral cortex, but no AChE inhibition in cerebellum. The levels of ACh and Ch did not change in any of the brain areas. Treatment A caused a severe inhibition (45-75%) of AChE in all brain areas. The inhibition leveled off after 4 weeks of dosing, except in brain stem where progressive inhibition was found. Even under these conditions of severely depressed AChE activity, the levels of ACh and Ch in the 4 brain areas examined were not altered as compared with controls during the 6-week period. The differences between our observations with soman and previous results with DFP may be due to the differences in the greater specificity of soman vs. DFP for AChE. In spite of reduced AChE, brain area ACh levels remain relatively constant and adapt quickly to the sustained depression of AChE activity by soman.

55.7 EFFECT OF LEAD INGESTION BY RATS ON ACETYLCHOLINE SYNTHESIS IN VITRO. Gerald H. Sterling, Kevin O'Neill*, Mary R. McCafferty* and John J. O'Neill. Depts. of Pharmacology, Hahnemann Medical College & Hospital, Philadelphia PA 19102 and Temple Univ. Sch. Med., Philadelphia, PA 19140

The neurotoxic effects of lead are well established at high dose levels. However, the effects on the CNS of levels that do not cause overt symptoms are only now being ascertained. Several neurochemical studies have shown the inhibition of acetylcholine (ACh) release in the CNS of lead-exposed animals[1-3]. Modak et al.[4] has demonstrated significant changes in ACh, choline acetyltransferase and acetylcholinesterase after chronic lead ingestion. Our experiments were undertaken to examine the effect of chronic ingestion of low doses of lead on the synthetic pathways to the acetyl moiety of ACh. Rats were given lead acetate at 200 and 600 ppm in their drinking water for 20 days. Sodium acetate was used as a control. After the exposure period, the rats were sacrificed. Blood and brain lead levels were measured by anodic stripping voltammetry. Brain cortex slices were incubated with D-(6-^{3}H) glucose and either D-(6-^{14}C) glucose or (3-^{14}C)-β-hydroxybutyrate in Krebs-Ringer bicarbonate buffer containing 105mM potassium, 1mM choline and 0.4mM eserine sulfate. ACh and intermediates were isolated by column chromatography and the percent of ^{3}H and ^{14}C-incorporation and ^{3}H/^{14}C ratios were determined. Blood and brain levels significantly increased as the dose was changed from zero to 200 and to 600 ppm. When incubated with labeled glucose, ACh synthesis was inhibited over the 20 day period at 200 ppm lead but there did not appear to be an inhibition of glycolysis as measured by lactate production. At 600 ppm, there was a considerable decrease in citrate production as well as inhibition of ACh synthesis. The effect of lead was similar when ^{14}C-labeled β-hydroxybutyrate was substituted for the labeled-glucose. Since there was approximately the same amount of ACh inhibition whether the citrate pathway or acetoacetate pathway was measured, it appeared that lead was exerting some generalized effect, probably on energy metabolism. This study was supported in part by EPA #68-03-2381.

55.8 ACETYLCHOLINE DYNAMICS IN RAT HIPPOCAMPAL SLICES. B.E. Swartz & D.J. Jenden, Brain Research Institute and Department of Pharmacology, UCLA School of Medicine, Los Angeles, California 90024

Using GCMS analysis and stable isotope labelling, we have examined some aspects of ACh and Ch metabolism in the rat hippocampal slice preparation. Initially slices were incubated in oxygenated Krebs-Ringer bicarbonate solution (Kr; pH 7.5) with or without [$^2H_4$]Ch (10 µM) and using either glucose (10.2 mM) or pyruvate (20 mM) as substrate. Prior to incubation, ACh levels are 0.455 ± 0.063 (all values in nmol [mg protein]$^{-1}$ ± S.E.) and Ch levels are 12.120 ± 5.807 (n = 14, both). ACh rapidly increases to a plateau of 1.730 ± 0.164 at 1 hr while Ch decreases to 5.44 ± 0.623 (n = 22). ACh levels are well maintained at 5 hr (1.517 ± 0.105) whereas Ch continues to decline (2.546 ± 0.138; n = 10), although the specific activity of both ACh and Ch continues to rise (0.29 ± 0.02 and 0.32 ± 0.02 at 1 hr, respectively to 0.45 ± 0.11 and 0.55 ± 0.08 at 5 hr). The specific activities of ACh and Ch are highly correlated (r = 0.972, n = 9) in this preparation. Ch levels decline more rapidly during the first 10 min of incubation with pyruvate substituted for glucose or in the absence of [$^2H_4$]Ch. At 3 hr no differences were noted. Slices were prepared from quadrants (2.5 mm each) of left and right hippocampi. In both, ACh levels were greater in ventral (3rd or 4th) than septal (1st) quadrant. [Ll; ACh = 1.011 ± 0.62, Ch = 4.03 ± 0.290; L4; ACh = 1.820 ± 0.269, Ch = 7.302 ± 0.856; n = 6]. To examine the effects of altering exogenous Ch concentration on ACh release, slices were preincubated in Kr and transferred for 20 min to a medium containing 10 µM Tetram (an AChEI) and 10 µM [$^2H_4$]Ch or 50 µM [$^2H_4$]Ch with Tetram. K^+ levels were 5 or 25 mM. Raising exogenous Ch caused an elevation in release rates as shown below:

	[$^2H_4$-Ch]	5 mM K^+(n)	25 mM K^+(n)
Release Rate	10	10±1.2(27)	22±3.3(14)
(pmol mg^{-1}min^{-1})	50	16±1.8(15)*	19±1.2(14)

* $p < 0.01$, 50 µM vs 10 µM

Raising external K^+ eliminates this effect. We conclude that the hippocampal slice may be a useful preparation in which to study the cholinergic terminal but is a heterogenous structure whose subregions may have differentiable properties. (Supported by USPHS grants MH-17691 and MH-15345.)

55.9 MUSCARINIC CHOLINERGIC RECEPTOR BINDING AFTER CHRONIC ADMINISTRATION OF TRICYCLIC ANTIDEPRESSANTS. B.D. Bohman*, M.J. Karbowski* and A.E. Halaris. Dept. of Psychiatry, The Univ. of Chicago, Chicago, IL. 60637.

Muscarinic acetylcholine receptor binding was examined in whole mouse brain after chronic administration of tricyclic antidepressants (TADs) to determine whether tolerance to the antimuscarinic effects of these agents could be accounted for by changes in this parameter.

Tolerance was demonstrated in the following manner. Mice were injected (i.p.) for either 2 or 4 weeks with 10 mg/kg/day of imipramine (IMI) or amitriptyline (AMI). One day following the last injection, they were injected (i.p.) with 0.2 mg/kg oxotremorine along with 5 to 65 mg/kg IMI or AMI and observed over the following 15 minutes for the presence or absence of tremors. The ED_{50}'s for suppression by these TADs of oxotremorine-induced tremors increased, as compared to control animals, by about two-fold after 2 weeks and nearly three-fold after 4 weeks of pre-treatment.

Muscarinic receptor binding was also examined after 2 and 4 weeks of 10 mg/kg/day AMI or IMI. Mice were decapitated one day after the final injection. The brains were quickly homogenized in 10 volumes of ice-cold 0.32M sucrose and centrifuged at 1000g for 10 minutes. The supernatent was re-homogenized; 10 µl aliquots were then incubated for 60 minutes at 37°C with various concentrations of ^{3}H-quinuclidinyl benzilate (QNB) in 2 ml of 0.05M sodium-potassium phosphate buffer. The assay was terminated by rapid vacuum filtration, and the filters were subsequently assayed for radioactivity by liquid scintillation spectrometry. Specific binding was calculated by subtracting non-specific binding (measured in the presence of 1.0 µM atropine) from total ^{3}H-QNB binding in the absence of a receptor blocker.

Bmax was determined both at 2 and 4 weeks by measurement of specific binding in the presence of a saturating concentration (2.0 nM) of ^{3}H-QNB. At 2 weeks, Bmax and Kd were also calculated independently by Scatchard analysis. There was good agreement between the two methods of calculating Bmax. Neither IMI nor AMI produced a significant change ($p > 0.05$) in either Bmax or Kd following 2 or 4 weeks of treatment.

It appears that the development in mice of tolerance to the antimuscarinic effects of these TADs is not due to alteration of either the number or the conformation of central muscarinic receptors.

55.10 CHANGES IN REGIONAL CNS ACETYLCHOLINE AND CHOLINE LEVELS AFTER MICROWAVE SACRIFICE. J.M.Gorell*,R. Bauer*and M.Buckley* (SPON: E.P.Schoener). Depts. of Neurology & Pharmacology, Wayne State Univ. Sch. Med., Detroit, MI 48201.

During studies of brain acetylcholine(ACh) metabolism,we found unexpected changes in regional CNS ACh and choline (Ch) levels 30 min or more after "adequate" microwave (MW) sacrifice.

Adult male Swiss-Webster mice (30-36g.) were treated (9-10A.M.) with head-focussed MW(3.6kW forward, ≤ 0.1kW reflected power at 2450 MHz for 320-340 msec;Metabostat 4104,Gerling-Moore,Inc.,Sta. Clara,CA). Two groups of mice were immediately dissected at room temperature,CNS regions(cerebral cortex,CX;cerebellum,CB;brainstem,BS;striatum,S;hippocampus,H)were placed into liquid N_2 cups, weighed in turn,and homogenized in either formic acid:acetone(ACh or Ch assay;Goldberg & McCaman,1973)or Triton X100(choline acetyl transferase(ChAT) or acetylcholinesterase(AChE)assay;Fonnum,1969). Other mice were MW'ed,but CNS regions were not dissected until 30 or 120 min after treatment;these were analyzed for ACh and Ch. Mice were rejected for chemical study if the deep forebrain temperature 10-15s post-MW was < 85°C. Brain temperatures were the same in all groups;mean values ranged from 87.8-89.6°C.

	Interval Between MW and Homogenization of CNS Regions		
	Immediate	30 Min	120 Min
CX - ACh	22.1±1.2(15)	18.6±1.5(10)	25.9±2.3(11)
CB - "	5.9±0.2(15)	6.6±0.5(11)	11.6±0.8(12)***
BS - "	37.1±1.4(14)	23.4±1.8(10)***	22.4±1.6(11)***
S - "	86.5±4.0(12)	46.7±5.1 (9)***	34.1±2.9(12)***
H - "	28.5±1.1(14)	21.2±1.8(11)**	23.9±1.4(12)*
CX - Ch	27.6±2.2(13)	26.6±2.0 (7)	31.0±1.9(10)
CB - "	28.3±1.2(14)	35.3±2.7 (9)*	49.7±2.5 (8)***
BS - "	30.3±1.3(12)	34.2±3.2(10)	44.7±4.2 (9)**
S - "	36.1±1.9(11)	33.3±2.4 (9)	33.7±2.3 (9)
H - "	25.2±1.3(14)	26.6±2.1 (8)	44.5±8.4 (7)*

Values are the mean(nmol/g) ± SEM of number of mice indicated. * P < .05, ** P < .01, *** P < .001 vs. Immediate group.

Preliminary experiments suggest that too little AChE or ChAT activity persists in mouse CNS regions after MW to account for observed changes in brain ACh levels. Extracts of 5 CNS regions of 8 mice were made immediately post-MW. Measurable AChE(ie. ≥ 84 pmol/mg wet wt/h)was present in just 1 S and 1 CB region, and no ChAT activity(ie. ≥ 11 pmol/mg wet wt/h)was detected.

These changes in regional CNS ACh and Ch levels post-MW cannot be explained at present. However, our data emphasize the need to cool and quickly homogenize MW'ed CNS regions to minimize postmortem artifacts.

55.11 THE REVERSE REACTION OF BRAIN CHOLINE ACETYLTRANSFERASE: SALT EFFECTS AND PRODUCT INHIBITION, L.L. Hsu* and L.-P. Chao (SPON: H.E. Hirsch). Department of Psychiatry and Behavioral Sciences, The University of Texas Medical Branch, Galveston, Texas 77550 and Department of Neurology, the Reed Center, UCLA L.A. CA 90024.

We have recently reported a simple and sensitive assay for the reverse reaction of choline acetyltransferase (ChAc, EC 2.3.1.6) by separating and measuring the reaction product ^{14}C -acetylcoenzyme A (AcCoA) using a Dowex 50W-8 (Na^+form) cation exchange resin column. Now we report on the effects of salts and product inhibition on the reverse reaction of ChAc which has been purified to homogeneity from bovine brain (Chao and Wolfgram, J. Neurochem. 20: 1075-1081, 1973). An aliquot of brain ChAc was incubated with 5 mM ^{14}C -Acetylcholine (ACh) and 50 µM CoA with and without salt, in 90 µl of 0.05M sodium phosphate buffer (pH 7.0) at 37° C for 30 minutes. At the end of incubation, the reaction was stopped by addition of 0.5 ml of ice-cold distilled water. The reaction mixture was applied to a Dowex 50W-8 (Na^+form) resin column (2.0 x 0.7 cm) to remove the unreacted ^{14}C -ACh. The reaction product, ^{14}C -AcCoA was eluted from the Dowex column with 1.5 ml distilled H_2O and combined with the effluent for measurement of radioactivity. Reaction mixtures containing boiled enzyme served as blanks. For product inhibition studies, the activity of reverse brain ChAc was determined at various concentrations of ^{14}C -ACh and a fixed CoA concentration (5 µM) in the absence or presence of 1 mM choline or 0.1 mM AcCoA.

Our results indicated that NaCl, KCl and KBr at 0.22M greatly stimulated the reverse brain ChAc activity (to 161%, 180%, and 155% of the control respectively). On the contrary, NaF at the same concentration inhibited the reverse ChAc activity (to 70% of control). The stimulating effects of salts may be due to the monovalent cations whereas the inhibitory effects may be due to the halogen anions.

The double reciprocal kinetic plots showed that the reaction product choline inhibited the reverse ChAc activity noncompetively with respect to ACh. Furthermore, the other reaction product AcCoA exhibited a competitive inhibition with respect to ACh, unlike the product inhibition pattern reported for the reverse ChAc from human placenta. More detailed studies of salt effects and reverse ChAc kinetics are under investigations for elucidating its reaction mechanism.

55.12 EFFECT OF DIETARY CHOLINE ON THE KINETICS OF THE HIGH AFFINITY CHOLINE UPTAKE SYSTEM. K.L. Parrish, B.A. Trommer* and L. Wecker, Dept. Pharmacology, Louisiana State Univ. Med. Ctr., New Orleans, LA 70112.

Recently much interest has focused on the use of the neurotransmitter precursor choline in the treatment of various neurological and psychiatric disorders postulated to involve hypocholinergic activity. However, the effects of chronic choline availability on central cholinergic biochemical parameters have not been investigated. Therefore, this study was designed to ascertain the relationship between dietary choline availability and central cholinergic activity as assessed by kinetic characterization of the sodium-dependent high affinity choline uptake system (HACUS). Rats were randomly divided into 3 groups and maintained on: a) choline deficient diet, b) basal choline diet (0.2% choline chloride) or c) supplemented choline diet (2.0% choline chloride). After 28-32 days on the dietary regimen, the rats were decapitated and the striatum and hippocampus removed. The kinetics of the HACUS (Km and Vmax) were determined in P_2 fractions utilizing substrate concentrations of 0.1-1.43uM. Dietary choline availability had no effect on the affinity of the HACUS. In synaptosomes from rats maintained on the choline supplemented diet, no change was noted in the Vmax of the HACUS. In contrast, the Vmax of uptake in synaptosomes from rats maintained on the choline deficient diet was increased to 122% of control (basal diet) in striatum and to 141% of control in hippocampus. Although increased choline availability has been suggested to increase cholinergic activity, present results indicate that dietary (chronic) choline supplementation does not change the HACUS. However, the choline deficient diet does increase the velocity of the HACUS in both brain regions. This finding does not reflect the differential effect of dietary choline on the steady-state concentration of acetylcholine in the striatum versus the hippocampus, since dietary choline deficiency decreased the concentration of acetylcholine in the striata to 85% of control without affecting hippocampal concentrations (Life Sci.25:375, 1979). The suggestion that choline loading increases cholinergic activity has not been demonstrated in the present study. The intriguing finding whereby limited choline availability induces an increase in the Vmax of the HACUS in both brain regions requires further elucidation and is currently being investigated in our laboratory. Of particular interest is the dependence of the phenomenon on the length of time the animal is maintained on the diet. (Supported by NIMH # 33443).

55.13 BLOCKADE OF NICOTINIC CHOLINERGIC RESPONSES BY A TOXIN COMPONENT OF BUNGARUS MULTICINCTUS VENOM. M. Quik*, J.M. Trifaró*. M. Vella Lamarca*, D. Ramirez-González* and B. Collier*. (SPON: B. Esplin). Dept. Pharmacology, McGill Univ., Montreal H3G 1Y6 PQ

The use of α-bungarotoxin (α-BGT) as a ligand for the nicotinic receptor at sites other than the neuromuscular junction is currently under question. Although most reports indicate that α-BGT does not inhibit cholinergic transmission at neuronal synapses, Chiapinelli & Zigmond (1978,PNAS,75,2999) have demonstrated a block but only in chick sympathetic ganglia and only with some preparations of the toxin. Recent results of Ravdin & Berg (1979, PNAS,76,2072) indicate that other α-toxins (fraction III) in Bungarus (B.) multicinctus venom may be responsible for this action. Because of the importance of developing a ligand for neuronal nicotinic sites, the present experiments reinvestigated the effect of B. multicinctus toxins on such receptors. Venom was fractionated into its components by two commonly used procedures. METHOD A was that of Lee et al. (1972, J.Chromatogr.72,71) and Ravdin & Berg (1979). After ion exchange chromatography, an elution profile was obtained which was similar to that previously described. α-Toxin fraction II (α-BGT II), which corresponds to the commonly used α-BGT, was found to inhibit (1) nicotinic cholinergic transmission in rat sympathetic ganglia by 50% at a concentration of 1 µg/ml (2) the carbachol (1 mM) stimulated release of ^{3}H-noradrenaline from cultured bovine adrenal medullary cells by 75% at 0.5 µg/ml and (3) carbachol stimulated uptake of ^{22}Na in the same cells by 59% at 1µg/ml. Fraction III which also contains α-toxins, was without effect at these concentrations. METHOD B used to isolate α-BGT* was similar to that of Berg et al. (1972,PNAS,69,147). Crude venom was first applied to a Sephadex G-50 column and consequently to an ion exchange column. When α-BGT* was isolated in this manner, it did not inhibit the above mentioned responses. However, both α-BGT II and α-BGT* blocked neuromuscular transmission in the rat phrenic nerve-diaphragm preparation. This suggests that some component is present in the α-BGT II preparation which is responsible for the blockade of nicotinic transmission at neuronal synapses. Experiments are currently underway to identify this component.

	Nicotinic response after incubation with	
Preparation	α-BGT II	α-BGT*
Rat sympathetic ganglia	block	no effect
Bovine adrenal medullary cells		
(1) ^{3}H-NA release	block	no effect
(2) ^{22}Na uptake	block	no effect
Rat phrenic-diaphragm	block	block

55.14 DEFINITION OF THE CHOLINERGIC LESION IN EARLY THIAMINE DEFICIENCY. L.L. Barclay,* G.E. Gibson, and J.P. Blass. Cornell Univ. Medical College, Burke Rehab. Center, White Plains, NY 10605.

Impaired synthesis of acetylcholine (ACh) by thiamine-deficient brain tissue was reported in 1940, but the functional significance of the cholinergic lesion has been controversial. We recently reported that the cholinesterase inhibitor physostigmine was as effective as the vitamin itself in treating early behavioral effects of pyrithiamine-induced thiamine deficiency (Clin. Res. 28:516A, 1980). These studies have been extended.

On a quantified "string test," 44/69 pyrithiamine-treated rats performed poorly by day 5-6 (score 1.5±0.6); the other 36% performed normally (score 8.2±0.3). None lost weight or showed gross neurological abnormalities. Arecholine (2.0 mg/kg), a direct muscarinic agonist, was as effective in restoring string test performance (to 4.6±0.5) as was physostigmine (to 3.8±0.1) or thiamine (to 4.1±0.2). The effect of physostigmine was blocked by the muscarinic blocker, atropine, but not by methatropine, its peripherally acting analogue. Nicotine had no effect at three different doses. Mecamylamine, a nicotinic ganglionic blocker, did not block the effect of physostigmine.

Biochemically, by day 6-7 of pyrithiamine treatment, levels of acetylcholine were reduced by 38% ($P<0.001$) and incorporation of [$^{2}H_{4}$]choline was reduced by 34% ($P<0.01$) in animals with low string test scores compared to those with normal string test scores. Surprisingly, incorporation of [U-^{14}C]glucose into acetylcholine increased (25%, $P<0.01$) in low compared to normal string test score animals. Specific activities of both precursors were unchanged.

Thiamine deficiency induces an early central muscarinic cholinergic lesion which is functionally significant.

55.15 ACETYLCHOLINE EFFECTS IN THE LATERAL GENICULATE NUCLEUS REGION OF THE CAT. J.M.Godfraind (SPON: M.Meulders), Lab. Neurophysiol., Univ. Louvain, UCL 5449, B-1200 Brussels, Belgium.

The excitatory and the inhibitory effect of acetylcholine iontophoretically applied, respectively on the lateral geniculate nucleus (LGN) neurones and on the perigeniculate reticular (PGN-R) cells, were examined under different experimental conditions. Results are summarized in the table. These observations show that the excitability of the LGN neurones and that of the PGN-R cells - thought to play the role of inhibitory interneurones - are greatly dependant of the animal preparation.

Experimental conditions	Ach excitation	Ach inhibition
Influence of animal preparation		
1. midpontine pretrigeminal	present	present
2. chloralose 80 mg/kg i.v.	present	absent
3. urethane 1 g/kg i.v.	present	present
4. 1% fluothane in N_2O/O_2	present	present
Effect of iontophoresis of atropine and mecamylamine		
1. atropine	blocked	blocked
2. mecamylamine	blocked	not blocked
Effect of i.v. atropine or dexetimide, under urethane anaesthesia	present	blocked
Effect of iontophoresis of nicotinic blocking agents after pretreatment with i.v. atropine or dexetimide, under urethane anaesthesia		
1. mecamylamine	antagonized	not antagonized
2. DHβE	antagonized	not antagonized
3. d- tubocurarine	antagonized	not antagonized
4. hexamethonium	antagonized	not antagonized
5. decamethonium	non-specific	non-specific

55.16 CHOLINE POST MORTEM INCREASE: EFFECT OF TISSUE AGITATION, pH, AND TEMPERATURE. J.W. Kosh, R.M. Dick*, and J.J. Freeman. Div. of Pharmacology, Coll. of Pharm., Univ. S. Carolina, Columbia, S.C. 29208.

The post mortem production of choline in brain tissues is well known. In the present study we have examined the extent of post mortem choline (Ch) production in brain and other tissues of the mouse. The influence of agitation, pH, and temperature on the post mortem choline production in brain tissues was also examined. All tissue samples were assayed for acetylcholine (ACh) and Ch using gas chromatography (Kosh, et al., J. Chromatog. 163, 206-211[1979]). Brain, eye, heart, lung, liver, ileum, kidney, and skeletal muscle tissues from male albino mice (HA/ICR, 25-35g) were incubated for 15 minutes at 38°C and homogenized in formic acid-acetone prior to assay. The effect of physical agitation (oxygen or nitrogen aeration, vigorous stirring, or sonication) during incubation for 15 minutes at 38°C was determined in brain tissue homogenates. The effect of temperature and pH on the post mortem choline production was determined in brain tissue homogenized in Locke's solution adjusted to a pH of 6.6 or 9.0, followed by incubation for 15 minutes at either 0, 20, 38, 48, or 68°C. All of the tissues studied except skeletal muscle demonstrated a significant post mortem increase in choline. The brain produced the largest percent increase (700%), followed by the kidney (454%), and the lung (383%). The other tissues exhibited a 200-300% increase in choline. Several types of physical agitation significantly changed ACh and Ch values compared to control homogenates which were not agitated. Sonication had the greatest effect by increasing the Ch level from 180 nmoles g^{-1} (control)to 324 nmoles g^{-1}. Aeration with oxygen or nitrogen or mechanical stirring gave similar Ch values (303-305 nmoles g^{-1}). Sonication was the only treatment which reduced ACh levels (from 4.7 to 0.2 nmoles g^{-1}). The production of choline was more pronounced at pH 9.0 than at pH 6.6 at temperatures between 0 and 48°C. Maximal Ch production occurred at 48°C and was inhibited at 68°C at both pH's. In summary the post mortem production of choline in the mouse appears to be enzymatic, occurs in many peripheral tissues and can be stimulated by several types of physical agitation. The enzymes that catabolize phospholipids in the brain to generate choline may also be active in peripheral tissues.

55.17 STIBONIUM-CHOLINE: A POSSIBLE TOOL FOR THE LOCALIZATION OF CHOLINERGIC NEURONS. E.M. Meyer*, D. White*, R.J. Barrnett*, and J. R. Cooper. Yale University School of Medicine, New Haven, CT 06510 .

An analog of choline was synthesized in which the nitrogen was substituted with antimony by reacting trimethylstibene with iodoethanol. This compound, hereafter called Sb-choline, was purified over a weak cation exchange column (CG-50) and by organic cation exchange with tetraphenylboron. It was found to be over 99% pure via NMR, IR, and atomic analyses for C, H, and Sb. The Sb-acetylcholine analog (Sb-ACh) was further synthesized by treating Sb-choline with acetic anhydride in the presence of pyridine. Both Sb-ACh and Sb-choline stained positively with Dragendorfs reagent, and could be separated from their nitrogen containing counterparts by thin layer chromatography or CG-50 columns. Preliminary results show that Sb-choline is acetylated by a crude preparation of rat brain choline acetyltransferase at the same maximal rate as choline. It is also phosphorylated by choline kinase at the same rate as choline, which provides us with an assay for Sb-choline or after hydrolysis, Sb-ACh. As expected, Sb-choline also appeared to be a competitive inhibitor of both enzymes. After neutron activating the Sb-choline (performed by R. Litman, Lowell University Lowell, MA) to form small quantities of ^{122}Sb- and ^{124}Sb-choline, we were able to show that this compound, at concentrations from 10-100 μM, was taken up by synaptosomes at about 80% the rate of ^{3}H-choline, acetylated, and subsequently released by potassium depolarization in a calcium-dependent manner. When cortical slices were incubated with 10 μM ^{122,124}Sb-choline or ^{3}H-choline and subsequently a synaptosomal preparation was made from these slices, it was found that ^{122,124}Sb-ACh and ^{3}H-ACh were localized in both the cytoplasmic and vesicular fractions. However, K^{+}-depolarization preferentially released both compounds from the cytoplasmic pool. Our results suggest that Sb-ACh should be an excellent substrate for the in situ localization of ACh via x-ray microanalysis with which it should be possible to determine whether the transmitter is localized in or released from the cytosol, vesicles, or the terminal plasma membrane. We also plan to use this technique to map cholinergic tracts in the CNS, to which end initial experiments are in progress.

55.18 CHOLINERGIC RECEPTOR ANTAGONISM BY PURIFIED PEPTIDE TOXINS FROM CONUS GEOGRAPHICUS. O. McManus*, C. Gonzalez*, J. Musick. Dept. Physiol., Univ. Utah Col. Med., Salt Lake City, UT 84108.

Two tridecapeptide toxins (G_1 and G_{11}) have been isolated from the crude venom of the marine snail Conus Geographics, and their composition has been reported (Gray et al., Fed. Proc., 61:2171, 1977; Cruz et al., Arch. Bioch. Biophys., 190:2, 1978). Since the lethal effect of these toxins (LD_{50} = 12 μg/KG in mice) is probably due to flaccid paralysis of skeletal muscle, we have investigated the site of paralytic action by equimolar mixtures of G_1 and G_{11}. The G_1-G_{11} mixture produced a reversible blockage of the contraction of neurally stimulated mouse diaphragm muscle, but did not affect the contraction of directly stimulated muscle. Complete blockage of neurally induced contractions was seen with a G_1-G_{11} concentration of 4.6×10^{-7} within 22 minutes. The time course of onset of toxin effects on muscle contraction was dependent on toxin concentration, but was generally slower than curare, and comparable to α-Bungarotoxin (α-BT), indicating that diffusion into the muscle was a limiting factor. Blockage of neurally evoked contractions was not due to impairment of impulse conduction in motor axons because paralytic concentrations had no effect on the amplitude of compound nerve action potentials recorded from ventral roots of the bullfrog sciatic nerve (McManus and Musick, Soc. Neurosci. Abs., 5:1644, 1979). These results suggested that paralysis occurred by impairment of neuromuscular transmission. The G_1-G_{11} mixture reduced the amplitude of miniature endplate potentials in the mouse diaphragm (McManus and Musick, 1979) and in the frog sartorius. Endplate potentials were reduced in the frog sartorius, apparently by a postsynaptic action, because a 22% decrease in EPP amplitude ($p < .001$) could be observed without a significant reduction in EPP quantal content ($p > .4$). Possible antagonism of the acetylcholine receptor (AChR) was investigated by measuring the inhibition of I^{125}-αBT binding to endplate regions of the mouse diaphragm. The G_1-G_{11} mixture inhibited I^{125}-α-BT binding in a qualitatively similar fashion as did d-tubocurarine, but G_1-G_{11} concentrations tenfold less than curare produced comparable inhibition. These results suggest that part of the paralytic effect of G_1-G_{11} is due to antagonism of acetylcholine binding to its receptor, and that G_1 and/or G_{11} is a tenfold more potent antagonist of endplate acetylcholine receptor than curare. 55.19 REGULATION OF Ach RECEPTORS ON CULTURED RAT MYOTUBES BY Ca^{2+}. James McManaman* and S.H. Appel. Department of Neurology, Baylor College of Medicine, Houston, Texas 77030.

Muscle activity is known to regulate the levels of certain muscle specific proteins. In particular the number of Ach receptors has been shown to be increased by denervation, or agents that interfere with electrical excitation, and to be decreased by electrical stimulation. Similar results have been shown for myotubes in culture. As yet the factor(s) controlling the activity related changes in Ach receptor levels have not been defined. However, the involvement of Ca^{2+} in the regulation of Ach receptors is suggested by the well known changes in intracellular Ca^{2+} concentrations during muscle contraction and the involvement of Ca^{2+} in the expression of muscle specific proteins during development. We have investigated the role of Ca^{2+} in the regulation of Ach receptors on cultured myotubes by incubating myotubes in culture medium containing 1/10 the normal concentration of Ca^{2+} (Ca^{2+} deficient medium).

The number of Ach receptors on the surface of rat myotubes cultured in Ca^{2+} deficient medium was decreased to approximately 30% of control, as measured by ^{125}I-α bungarotoxin binding. In contrast the level of creatine phosphokinase was decreased only 10% and the incorporation of ^{35}S-methionine into protein was unaffected by culturing myotubes in Ca^{2+} deficient medium. The decreased number of Ach receptors was not due to a loss of myotubes since the DNA content per plate was identical to control. In addition the integrity of the myotube membrane was unaffected by incubation in Ca^{2+} deficient medium as indicated by normal resting membrane potentials and action potential amplitudes. Incubating myotubes in Ca^{2+} deficient medium did not affect the rate of degradation of Ach receptors but decreased the rate of insertion of new Ach receptors into myotube membranes, and decreased the level of intracellular Ach receptors. The rate of insertion of new Ach receptors into myotube membranes was not affected by culturing in Ca^{2+} deficient medium for the first 4 to 6 hours, thereafter the rate of insertion decreased significantly.

The decreased rate of insertion was increased to control levels by the addition of Ca^{2+} to the Ca^{2+} deficient medium. This effect was blocked by inhibitors of protein synthesis. These results are direct evidence for the involvement of Ca^{2+} in the regulation of Ach receptors and suggest that Ca^{2+} influences the synthesis of Ach receptors rather than transport of pre-existing Ach receptors to the surface. (Supported by The Muscular Dystrophy Association and a Dementia Training Grant #AG00061-01 470-G07865 from the National Institute of Aging)

55.20 CYCLIC AMP-INDUCED INCREASES IN ACETYLCHOLINE RECEPTOR REQUIRES PROTEIN AND RNA SYNTHESIS. James C. Blosser, James L. McManaman* and Stanley H. Appel. Department of Neurology, Baylor College of Medicine, Houston, Texas 77030

The synthesis and turnover of acetylcholine receptor (AchR) in muscle is regulated by both muscle activity and neurotrophic agents. However, little is known about the intracellular factors and mechanisms which ultimately mediate the changes in receptor content. Recently, we demonstrated that cAMP increases the levels and rate of insertion of AChR into plasma membrane of cultured embryonic chick myotubes (J. Biol. Chem. 255:1235 (1980)). To determine whether the effect of cAMP is due to an actual increase in synthesis of receptor the effects of inhibitors of protein and RNA synthesis have been examined. Insertion rate of AChR into external membrane is assessed by preblocking existing receptors with α-bungarotoxin and then measuring the appearance of new receptors at various times thereafter with ^{125}I-α-bungarotoxin. Intracellular cAMP levels were increased by treatment with 10^{-3}M cholera toxin. Cycloheximide at concentrations which inhibited protein synthesis by over 90% (3 μg/ml) was found to completely block the increased insertion rate of AChR induced by cholera toxin. Actinomycin D (0.03 μg/ml) also completely blocked receptor insertion in control and cholera toxin-treated cells under conditions in which [^{3}H]uridine incorporation into total RNA was inhibited by over 90%. Neither DNA content nor cAMP levels were decreased by actinomycin D suggesting that cell viability was not altered. However, because of known side effects of this agent, cells were also treated with an inhibitor of RNA polymerase II, α-amanitin. Both the control and cAMP-induced increase in AChR insertion rate were decreased by 80% without measurable effects on cAMP levels or total RNA synthesis. The extent to which the cAMP-induced increase in AChR requires de novo synthesis is being assessed by labeled amino acid incorporation into receptor. These results suggest that cAMP induces an increase in AChR through a transcriptional mechanism. (Supported by the Muscular Dystrophy Association and NSF Grant BNS-7914115)

55.21 SURFACE SPECIALIZATIONS ON CULTURED MYOTUBES FROM EMBRYONIC CHICK THIGH CONTAIN A HIGH DENSITY OF ACETYLCHOLINE RECEPTORS. Thomas G. Burrage and Thomas L. Lentz. Section of Cell Biology, Yale University School of Medicine, New Haven, CT 06510.

Surface specializations (patches) on cultured myotubes from thighs of 11 day old chick embryos incubated for 5 days were characterized by heavy metal stains and the binding of horseradish peroxidase-labeled α-bungarotoxin (HRP-α-BTX) for localization of acetylcholine receptors (AChR). The specializations consisted of slightly raised surface ridges (0.1 to 0.5 μm in width) and wider regions (2-5 μm) sometimes composed of the smaller ridges. The specialized zones were characterized by an external coating of amorphous to fine textured material, considerably more extensive than the sparse developing basement lamina occurring elsewhere on the myotube surface. On the internal surface and coextensive with the external layer, dense material was applied immediately adjacent to the plasma membrane. The extraneous coating of these patches stained with ethanolic phosphotungstic acid, bismuth iodide, and ruthenium red, and most likely contains complex carbohydrates. The specialized regions contain a high density of nicotinic AChR, as shown by the binding of HRP-α-BTX. Reaction product occurred in the plasma membrane of the patch. The larger reactive regions correspond to the "hot spots" observed at the light microscopic level. A lower density of HRP-α-BTX binding was seen occasionally in the membrane adjacent to the patch regions. This low density staining may represent diffuse receptors present in sufficient concentration to be detectable with this technique. Coated pits were often associated with patch regions. These stained with HRP-α-BTX and contained ruthenium red-staining material, indicating the pits may be involved in the transport of receptor-bearing membrane and/or extraneous coat material to the myotube surface. Caveolae of the developing sarcotubular system near surface patches were also stained with HRP-α-BTX. The specialized patch regions were widely separated on these uninnervated surfaces with only 1 to 3 usually occurring over the entire profile of the cell in section. Patches were most abundant on the basal surfaces of cells and where cells contacted the substrate or other cells. Microtubules and microfilaments occurred in close proximity to the patch regions but were found elsewhere in the cell as well. These studies show that external and internal specializations are associated with a high density of AChR in the absence of innervation. Constituents of these specializations may be involved in the localization or positioning of a high density of AChR at these sites. (Supported by NIH Grant F32 NS06144-02 and NSF Grant BNS 79-12898).

55.22 DEVELOPMENT OF ALPHA-BUNGAROTOXIN BINDING SITES IN THE CEREBRAL CORTEX OF NORMAL AND REELER MOUSE. P. F. Strang-Brown and V. Wootten*. Dept. of Anatomy, Univ. of Cincinnati College of Medicine, and Institute for Developmental Research, Children's Hospital, Cincinnati, Ohio 45267.

Biochemical studies have demonstrated changes in alpha-bungarotoxin binding during the development of the cerebral cortex in the rat and the guinea pig (Salvaterra and Moore, Biochem., Biophys. Res. Comm. 55:1311, 1973; Wade and Timiras, Brain Res. 181:381, 1980). Toxin binding in the cerebral cortex has been shown to peak between days 12 and 20 postnatal.

This study used the in vitro method of Segal et al., (Brain Res., 148:105, 1978) to show the ontogenetic changes in the morphological distribution of αBTX binding sites in the somatosensory cortex of normal and reeler mouse (strain C57BL/6J). Somatosensory cortices from animals of the following postnatal ages: 0,3,7,10,14,16,18, and 20 days were analyzed. In the cortex of normal mouse, the toxin binding increased from day 0 to a peak value on day 16. Days 18 and 20 showed similar values to day 16. In the cortex of the reeler mouse, the toxin binding showed peaks on days 3 and 20. Morphological differences in the toxin binding peaks between the normal and reeler mouse suggests an alteration in the process of receptor development and synaptogenesis in the reeler mouse.

55.23 EFFECT OF IN VITRO AND IN VIVO KETAMINE ON CHOLINE UPTAKE IN MOUSE STRIATUM. Christina VanderWende, Barbara Masley* and Marie T. Spoerlein. Rutgers Univ. Coll. of Pharmacy, Box 789, Piscataway, N.J. 08854.

A detailed study of the effect of ketamine on the cholinergic functions of different areas of the brain has not been done. Therefore, we chose to start such studies with the effect of ketamine on striatal cholinergic function using high affinity sodium dependent choline uptake (HANDCU) as a measure of this activity (Simon et al., J. Neurochem. 26: 909-922, 1976).

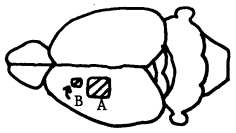
Male albino Carworth CF-1 or male albino Swiss Webster mice were used for these studies. For the in vitro experiments, ketamine was added directly into the incubation medium to give final concentrations ranging from 10^{-4} to 10^{-9} M. For the in vivo studies, ketamine was administered intraperitoneally 4 min. prior to sacrificing the animals. Animals were decapitated; the brains removed; and the striatum dissected over a bed of crushed ice. The striata were homogenized in 2.0 ml of 0.32 M sucrose and centrifuged for 10 min. at 1,000 g. The low speed supernatant was recentrifuged at 17,000 g to give the P_2 pellet. The P_2 pellet was resuspended in 1.2 ml 0.32 M sucrose and incubated with 54 uM choline and 0.49 uM ^{3}H-choline both in the presence and absence of Na^+. After incubating for 3 min. at 31°, the tubes were plunged into an ice bath, then centrifuged 15 min. at 6,000 g. The pellet was surface washed, digested with Protosol and counted in 10 ml Aquasol containing 0.5 ml acetic acid. Protein was determined by the Bio-Rad procedure.

In vitro ketamine caused a slight but significant increase in HANDCU (8-13%) at concentrations between 10^{-6} and 10^{-9}M where the increase was repeatedly greater at the lower concentration. At high concentrations (10^{-5}-10^{-4}) there was no change in HANDCU compared to controls. No explanation for these results is yet available.

In the in vivo experiments, ketamine resulted in significant increase in HANDCU at doses causing loss of the righting reflex and at toxic doses. Interestingly, higher toxic doses caused less of an increase than lower non-toxic doses.

56.1 A SECOND FORELIMB MOTOR AREA EXISTS IN RAT FRONTAL CORTEX. E.J. Neafsey. Dept. Anat. Loyola Univ. Med. Cent., Maywood, IL 60153.

Movements evoked by intracortical stimulation(2.5 msec pulses,500-5 μamps,350 Hz,300msec trains) in the frontal cortex of adult Long-Evans rats were studied. The rats were anesthetized with Ketamine (100mg/kg IP, with supplemental doses as needed). Glass insulated tungsten microelectrodes(50-150 μ exposed at tip) were inserted tangential to the cortical surface, beginning laterally and ending medially. The depth of the tip below the surface medially was 1.4-1.9mm.In each rat 15 to 20 penetrations spaced .25mm apart were made from near the frontal pole to just behind bregma. Along the 3-5mm course of each track, stimulation was delivered every .25mm. If movement occurred at 500μamp, its threshold(i.e.,current reliably evoking movement) was determined.The mean threshold was 240μamps(SD=150). For the forelimb two separate regions that produced movement were found. The first(2.5x2.5mm) was located where other workers(Hall and Lindholm,Brain Res.66:23-38,1974) have described the rat forelimb area and is labeled A in the figure below. The movements evoked included shoulder retraction, elbow flexion and extension, pronation and supination of the forearm, wrist extension, and,infrequently, digit extension. The second area (1x1mm;labeled B in figure below) was located rostrally .5 to 1.5mm from the first area. A zone of neck and/or vibrissae movements always separated the two forelimb areas. The movements evoked from the rostral area included elbow flexion, wrist extension, and digit extension and flexion. Digit movements were reliably evoked here but were uncommon in the more caudal motor region. Following HRP injection into the rat cervical enlargement, a separate cluster of labeled cortical cells has been found in the approximate location of this rostral forelimb motor area (Wise et al, Neuroscience 4:65-78,1979), providing an anatomical basis for its existence. This region appears to be concerned with control of wrist and digit movement.



56.2 CORTICAL MECHANISMS OF TWO-DIMENSIONAL AIMING ARM MOVEMENTS. I. AIMING AT DIFFERENT TARGET LOCATIONS. A.P. Georgopoulos, J.F. Kalaska* and J.T. Massey*. Dept. of Physiology, The Johns Hopkins School of Medicine, Baltimore, Md. 21205.

Arm movements aiming at targets bring the hand to final spatial coordinates that coincide with those of the target. How commands for such movements are formed in the brain using spatial (target location) information are largely unknown. We are investigating this problem using an apparatus in which a handle can be moved freely in the two (X-Y) dimensions across a plane. Monkeys were trained to move the handle and capture (within a circle attached to it) lighted targets in a reaction time task (J.T. Massey et al., Fed. Proc., 1980). This apparatus provides a high degree of spatial correspondence between movements and targets without dissociation between display and manipulandum. Of 9 targets, one is at the center and 8 around it on a circle of 8 cm radius. The animal first captures the center light and holds there for a variable length of time, then a peripheral light comes on and the animal has to move the handle to capture the target to receive a liquid reward. Since the 8 targets are arranged equidistantly around the circumference of the circle, the directions of the movements made from the center to the targets cover the whole circle with a resolution of 45°.

The cortical mechanisms of formation and execution of these aiming movements were explored using single cell recordings in motor and adjacent premotor areas of the frontal cortex in two monkeys. We studied 211 cells (isolated in 40 penetrations) that discharged in relation to spontaneous arm movements. Characteristics of responses in the task were as follows: (a) The latency (mostly within the reaction time), magnitude, direction of change (increase or decrease of discharge) and time course of the response varied with the sector of the circle within which the aiming (center-out) movement was made; for many cells the changes occurred continuously and gradually within that sector as movements of different radial directions were produced. The size of the sector was large for many cells; for some others it was narrow. Maxima and minima of activation (or inhibition) occurred at different radial directions within the sector for different cells. Therefore, the process of composition of commands for spatially oriented movements engages the activity of partially overlapping (in the directional aspect) cell populations. (b) Several movement-related cells showed a short-latency, stimulus-locked response when target lights appeared in certain locations. This may reflect a selection mechanism by which movement-related precentral populations are activated in correspondence with the location of the target, probably leading to the generation of movements aimed at that target. (Supported by USPHS Grant 5-RO-EY03167-02).

56.3 CORTICAL MECHANISMS OF TWO-DIMENSIONAL AIMING ARM MOVEMENTS. II. CHANGE OF TARGET LOCATION. J.F. Kalaska*, J.T. Massey* and A.P. Georgopoulos. Dept. of Physiology, The Johns Hopkins School of Medicine, Baltimore, Md. 21205.

Changes in the location of the target while an aiming movement is being generated (e.g., during the reaction time) result in orderly modification of the motor output (A.P. Georgopoulos et al. Fed. Proc., 1980): the hand moves towards the first target for a period of time and then changes direction and moves to the second target. The duration of the first movement is a linear function of the time for which the first target was on. We are studying this problem using an apparatus which allows free movement of a handle in the two (X-Y) dimensions of a plane. Monkeys were trained to move the handle and capture (within a circle attached to it) lighted targets in a reaction time task: they moved from the center to peripheral target lights located on a circle of 8 cm radius. The location of the target was changed from 50 to 400 msec after the appearance of the first target. Under these conditions the ensuing arm movements change direction at various times, as described above; by contrast, saccadic eye movements (monitored using implanted EOG electrodes) were all-or-none to the first target (and from there to the 2nd target). This dissociation of eye and hand movements indicates that the process which generates aiming movements differs for the two systems. For the arm, this process begins when the target appears and can be modified by subsequent changes in the spatial (target location) information.

We studied the effects of change in target location on the activity of single cells in motor and adjacent premotor areas of the frontal cortex in two monkeys. 80 cells (isolated in 40 penetrations) were studied in the above task; they discharged in relation to spontaneous arm movements. We chose target locations (and, therefore, directions of aiming movements) for which cells showed different patterns of response (see A.P. Georgopoulos et al., this Meeting). The activity of the cells was modified in an orderly fashion by the change in target location for the whole range of times used; that is, for changes in target location occurring from 50 to 400 msec after the appearance of the first target. The time from the first neuronal change (after the 1st target) to the second change (after the 2nd target) was a function of the time for which the 1st target was on. Therefore, neurons in motor and premotor areas show continuous modifiability of their discharge under conditions of changing spatial (target) information, in accordance with the motor behavioral data mentioned above. We postulate that these populations are involved in a continuous utilization and translation of this information to appropriately organized (in the spatial domain) motor output. (Supported by USPHS Grant 5-RO-EY03167-02).

56.4 CORRELATION OF TASK-RELATED CORTICAL NEURON ACTIVITY WITH EMG RESPONSES PRODUCED BY MICROSTIMULATION AT THE RECORDING SITE. E. M. Schmidt and J. S. McIntosh. Lab of Neural Control, NINCDS, NIH, Bethesda, MD 20205

The relationship between task-related activity of precentral cortical neurons and EMG responses produced by intracortical microstimulation (ICMS) at the recording site was examined in two Macaca mulatta monkeys. They were trained to perform a wrist flexion-extension task to several different target positions under different load conditions that were applied by a torque motor. Chronic EMG recording electrodes were implanted in up to six forearm muscles, along with an electrode in the mesencephalic pyramidal tract (PT) for cell identification. A microdrive base was implanted over the arm region of the contralateral precentral motor cortex. Glass coated Pt-Ir microelectrodes were used for recording and ICMS. Stimulus trains consisted of 17 pulses (0.2ms biphasic) at 400 Hz applied at specific times during the flexion-extension movements. Stimulus current was $\leq$ 20 μA. For simplicity in presentation, cortical cell firing patterns are divided into three groups depending on their correlation with muscle activity. Extensor (E) cells were more active during the extension phase of the task, flexor (F) cells were more active during flexion, while (E-F) cells either increased or decreased activity with both movements. Task related neuron activity was evaluated at 123 sites where ICMS produced either excitation or inhibition in forearm muscles. The total number of cells of each type is listed in the table along with the positively identified PT cells, which are enclosed in parentheses.

TASK RELATED CELL FIRING PATTERNS	E	F	E-F
ICMS → FLEXOR EXCITATION	18(2)	32(4)	7(2)
ICMS → EXTENSOR EXCITATION	18(9)	7(3)	4(2)
ICMS → FLEXOR INHIBITION	16(4)	10(3)	7(3)
ICMS → FLEXOR INHIB. AND EXTENSOR EXCIT.	3(3)	1(1)	

The majority of F cells are correlated with ICMS-produced flexor excitation while the majority of E cells are correlated with ICMS-produced extensor excitation and/or flexor inhibition. At sites where flexor inhibition was produced by ICMS, the majority of cells were type E. A large number of cells do not fit with the expected ICMS response pattern, suggesting an overlap of cortical outflow to different muscles. This is consistent with our previous results (see Neurosci. Abst. 5:1300,1979) where there was considerable overlap of individual forearm muscle representations in the cortex as revealed by ICMS.

56.5 STRUCTURAL AND FUNCTIONAL ANALYSES OF THE ORGANIZATION OF THE MOTOR CORTEX IN MACACA FASCICULARIS. M. Wiesendanger and B.J. Sessle. Institut de Physiologie, Univ. de Fribourg, Switzerland, and Faculty of Dentistry, Univ. of Toronto, Canada.

The details of the fine organization of the motor cortex and its anterior and posterior borders continue to be a matter of debate. We have examined these details in three monkeys with a combination of techniques including cortical microstimulation in the unanaesthetized animal, electrophysiological identification of corticospinal neurons and forelimb muscle and cutaneous afferent inputs to the pre- and postcentral cortex under barbiturate anaesthesia, and HRP labeling of corticospinal neurons by retrograde labeling from the cervical spinal cord; data was subsequently related to cortical cytoarchitecture in the same animals. Approximately 5000 intracortical loci were tested with microstimulation. "Positive" microstimulation effects (<30 μA) could only be demonstrated in areas 4 and in a posterior strip of area 6 (lateral). In area 4, microstimulation thresholds of 1-5 μA were common for evoking EMG responses and movements in distal forelimb muscles. Similar threshold values, although not as common, were also noted for proximal forelimb, trunk and hindlimb muscles. The fingers were represented nearest the central sulcus, with horseshoe-shaped bands of cortex representing progressively more proximal muscles around this central "finger core", in agreement with Kwan et al. (J. Neurophysiol. 41, 1120, 1978). Within these gross patterns, we also found multiple foci evoking a particular movement, indicating that multiple intracortical microzones may exist for each movement.

Electrophysiological identification and HRP labeling revealed that corticospinal neurons were concentrated in area 4, although scattered nests were found postcentrally and in posterior area 6. Under anaesthesia, low-threshold proprioceptive input was abundant in area 3a, but single unit responses were not recorded in area 4 from which positive microstimulation could be demonstrated. These findings indicate that the "excitable cortex" as defined by positive microstimulation effects is limited to regions showing dense concentrations of corticospinal neurons. The negative microstimulation effects from area 3a may be related to the scattering of corticospinal neurons or to the involvement of these neurons not in direct motor control but possibly in corticofugal modulation of somatosensory transmission.

56.6 MULTIPLE REPRESENTATION OF FACE, JAW AND TONGUE MOVEMENTS IN MACACA FASCICULARIS AS REVEALED BY CORTICAL MICROSTIMULATION. M. Sirisko*, G.E. Lucier, M. Wiesendanger and B.J. Sessle. Faculty of Dentistry, Univ. of Toronto, Canada M5G 1G6, and (M.W.) Institut de Physiologie, Univ. de Fribourg, Switzerland.

The cerebral cortical motor representation of the face, jaw and tongue has largely been defined by ablation and surface stimulation studies. Despite the recent use of microstimulation methods to provide greater definition of the motor representation of the forelimb in particular, little attempt has yet been made to use similar methods to examine the finer details of face, jaw and tongue motor organization. Thus, the present study was initiated in five unanaesthetized monkeys to characterize this motor organization by examining the simple twitch movements and EMG responses evoked by cortical microstimulation. Stimulus intensities were usually less than 30 μA, and intracortical sites were stimulated every 250 microns or less of microelectrode vertical depth which averaged around 3 mm in precentral cortex and 5 mm in pericentral cortex; histological reconstructions of microelectrode tracks (which were usually 1 mm apart) were subsequently made. The face, jaw and tongue motor representation occurred in the precentral cortex at sites that were more lateral than the forelimb and trunk representations (which were also mapped in the same animals), although a small overlap occurred especially between face and forelimb representations. The face representation tended to form a horseshoe around a central, laterally facing, core of tongue and jaw muscle movements. Contralateral movements predominated, but ipsilateral movements were seen at some cortical sites lateral to the contralateral representation. Thresholds of 1-5 μA were frequently effective in evoking discrete twitches limited usually to a few muscle fibres within an individual muscle. EMG responses at suprathreshold latencies of 7-20 msec were noted. In addition, we found multiple microzones of cortical tissue representing a particular face, jaw or tongue muscle movement. Even within a 2x2 mm square of tissue in which more than 60 microelectrode penetrations were made and sites tested 1.5-2 mm below the cortical surface, a particular movement could be represented more than once. Because of such multiple representation, three clearly distinct areas each representing the face, jaw or tongue were not seen. In accord with recent findings by ourselves and others for the forelimb, this study suggests that there are multiple intracortical microzones representing a particular face, jaw or tongue movement, and that each microzone might be considered part of a radial microcolumn of motor cortex.

56.7 ACTIVITY OF INDIVIDUAL NEURONS IN MONKEY SOMATOSENSORY CORTEX (SI) REFLECTS BOTH LIMB POSITION AND TENSION. Hugo Solis*, Von Ayre Jennings*, and Yvon Lamour (SPON: M. Abdelmoumene). Lab. of Neurophysiology, NIMH, Bethesda, MD 20205.

Vallbo has shown that frequencies of muscle spindle afferent discharge exhibit marked changes when a subject reverses the direction in which isometric force is being exerted, and Matthews has shown that spindle afferent inputs modify sense of limb position. Given these two observations, it seemed to us that a reversal in direction of isometric contraction might modify discharge frequencies of SI neurons in regions classically thought to subserve position sense. This hypothesis was examined by determining the interaction between limb position and muscle tension in SI neurons of a monkey performing active isometric contractions.

Single unit activity was recorded from SI in both hemispheres of a monkey (Macaca mulatta) performing supinating or pronating isometric contractions (.1 Nm) against a handle in two positions (80°, 100°) using the paradigm of Jennings et al. (this vol.). Of 203 task-related SI neurons, 56 displayed resting discharge frequencies which were greater at one or the other handle position. For a 20° shift in position (force held constant) the mean change in discharge frequency was 9.8 Hz. Each of these position sensitive cells was reciprocally related to the direction of exerted force, i.e., they were more active for one force direction and less active for the other. These changes in force (position held constant) resulted in a mean alteration in discharge frequency of 17.2 Hz. Furthermore, the position and force sensitivities of most cells were congruent: cells more active in a supinated position were also more active with supinator force and vice versa. Thus, 91% of the supination position sensitive neurons were more active with supinating force and 79% of the pronation position sensitive cells were more active during pronating force. Most neurons of this type (i.e., congruent for tension and position) were found in two discrete SI zones, one identified as area 3a (15 of 42 task-related units) and the other as area 2 (24 of 61). Other parietal fields appeared to have fewer (area 1, 4 of 44; area 5, 5 of 17) or no (area 3b, 0 of 39) cells of this type.

These results indicate that position sensitive SI neurons also reflect muscle tension, and that inputs to SI from muscle receptors or central motor systems such as the motor cortex may play a role in the mechanisms by which limb position is signaled by SI neurons.

56.8 PREMOTOR NEURONS IN THE POSTARCUATE CORTEX OF THE MONKEY. Von Ayre Jennings*, Yvon Lamour and Hugo Solis* (SPON: M. Herkenham). Lab. of Neurophysiology, NIMH, Bethesda, MD 20205.

The cortical region posterior to the arcuate sulcus has been shown by others to receive inputs from visual association cortex (area 7) and to project to precentral motor cortex (MI), suggesting that it is involved in the visual guidance of limb movement. With this in mind, we compared the activity of neurons in the region posterior to the genu of the arcuate sulcus (PAr) with MI neuronal activity during active arm movements triggered by visual cues.

Single unit activity was recorded in a monkey (Macaca mulatta) performing pronating or supinating arm movements on the basis of a visual display. The task involved two modes: isotonic displacements (20°) and isometric contractions (.1 Nm). In the isotonic mode the visual display was controlled by arm position while in the isometric mode the display was controlled by force. The task was one involving compensatory tracking, with reward being given for the display being held on center. Shifts in the monkey's arm position or force were triggered by a shift in the position of the illuminated lamp, thus requiring the monkey to make an isotonic or isometric contraction in order to return the "on" lamp to the center position.

31 PAr cells were found to form a distinct functional group. After a visual cue (VC), these neurons, termed VC cells, were characterized by a change in discharge frequency which was time-locked to VC onset. In contrast, the onset of activity in 313 extensively studied MI neurons was better correlated with movement onset than with the visual cue. Furthermore, in response to cues triggering either isotonic movements or isometric contractions, the onset of VC activity preceeded that of MI activity by an average of 67 msec. This early activity was always specific for one particular cue direction. For example, VC neurons activated by a cue for an isotonic supinating displacement were also activated by the cue for exertion of an isometric supinating force and showed decreased or no change in activity following a cue for a pronating movement or contraction.

These results provide evidence for a functionally distinct premotor zone. During a visually-triggered task, PAr neurons are characterized by directionally specific and short latency stimulus-bound activity. Since a relation to eye movements or contractions of proximal muscles was ruled out by appropriate tests, the results suggest that PAr neurons may be links in a pathway by which central motor commands reach MI following the occurrence of visual stimuli which require a motor response.

56.9 FUNCTIONAL CHARACTERISTICS AND SEGREGATION OF CUTANEOUS AND NON-CUTANEOUS NEURONS IN MONKEY PRECENTRAL MOTOR CORTEX (MI). Yvon Lamour, Von Ayre Jennings*, and Hugo Solis*. Lab. of Neurophysiology, NIMH, Bethesda, MD 20205.

The present report contrasts the behavior of MI neurons which receive cutaneous versus non-cutaneous inputs in a monkey that grasped a handle and performed pronating or supinating isotonic movements (20°) or isometric contractions (.1 Nm) in a compensatory tracking task. Reward required that the central lamp of a visual display be illuminated, and the display was controlled by force feedback in the isometric mode and position feedback in the isotonic mode. Stimuli were delivered to the handle during steady holding via a servo-controlled torque motor and consisted of changes in handle position (position pulses, 50 msec, 10° or ramp displacements, 150 msec, 20°).

Peripheral receptive fields could be determined for 154 MI neurons; 53 were classified as receiving cutaneous inputs and 101 as receiving non-cutaneous inputs. Cutaneous units had receptive fields located on the fingers, hand, or arm and were concentrated in the bank of the central sulcus (MI/c) while neurons responding to non-cutaneous inputs were concentrated in more rostral regions (MI/r). During steady holding, MI/c units showed little sensitivity to the direction of handle pulses or ramps in contrast to MI/r units which were usually directionally sensitive. Similarly, cutaneous neurons in MI/c were activated during both directions of active isotonic movement or isometric contraction but displayed little sustained activity related to steady force or position. MI/r cells, on the other hand, were usually reciprocally related to the direction of movement and isometric force and, in many cases, their activity was also related to maintained position and force. Finally, following the visual cue triggering an active displacement or contraction, the change in discharge frequency of cutaneous MI/c neurons lagged that of MI/r cells by an average of 61 msec and preceeded the first change in position or force by an average of only 42 msec.

These results confirm previous demonstrations of submodality segregation of cutaneous and non-cutaneous inputs to separate MI regions. More importantly, the results show MI/c neurons to be activated later in visually triggered motor behavior and less related to limb position and exerted force than cells in MI/r. This is consistent with the suggestion of Strick and Preston that MI consists of at least two functional motor areas. The present observations indicate that MI/r plays a role in initiation of motor activity and the maintenance of limb position and force, while MI/c is concerned with the control of movements under tactile guidance.

56.10 THE ACTIVITY OF CLOSELY SPACED MOTOR CORTICAL PYRAMIDAL TRACT PROJECTING NEURONS DURING LOCOMOTION. C. Palmer, W.B. Marks, M.J. Bak and G. Pedersen*. Lab of Neural Control, NINCDS, Bethesda, M.D. 20205.

An attempt has been made to examine the functional significance of the afferent-efferent columnar organization of the feline motor cortex in the awake, freely moving animal. In 4 cats groups of closely spaced (75μ-200μ) microelectrodes were chronically implanted in the motor cortex (Palmer et al., Neurosci. Abstr. 5:1281, 1979). Pyramidal tract (PT) neurons were identified by antidromic invasion from the medullary pyramids, obeying these criteria: constant latency, following stimulation at 100Hz, and cancellation of the antidromic response by collision with an orthodromic action potential. Muscles were chronically implanted with EMG electrodes and length gauges across the elbow joints.In one cat, 28 PT forelimb motor cortical neurons were recorded during locomotion, (latencies to pyramidal stimulation 0.94 ms to 2.94 ms) from 4 closely spaced electrodes. Two of them (A,B,)were 200μ apart. The somatosensory receptive fields were determined for each neuron with natural stimulation in the awake animal: 20 (71%) had forepaw cutaneous receptive fields, 3 (11%) had afferent input from 'deep' receptors (elbow and toe joints) and 5 (18%) had undetectable fields. Microstimulation was carried out at each electrode using 50 ms trains of .2 ms pulses at 400 Hz . Thresholds ranged from 10 to 30μamp. 23 (82%) of the PT neurons were modulated during locomotion: 11 decreased their firing rate during the end of swing and the begining of stance while the remainder increased their firing rate in relation to the movement. Of these, 9 units had bursts of activity during the flexion part of swing, 2 units had two bursts of activity during the begining and end of swing and 1 unit during the end of swing. 18 of these PT neurons were recorded at electrodes A and B thus yielding information about cortical function in relation to columnar organization. At A 10μamp stimulation gave short latency (20 ms) EMG responses in Pronator teres (PrT), in electrode B 200μaway, stimulation (10 amp) activated PrT and Extensor Carpi Radialis (ECR) while inhibiting Flexor Digitorum Profundus (FDP) with latencies of 20 to 30 ms.In locomotion PrT and ECR are active during swing while FDP is active in stance. At electrode A 8 of the 11 PT units recorded had increased activity during the swing phase of locomotion. At electrode B, with a more complex microstimulation response (ie the activation of flexor muscles and the inhibition of an antagonist) 7 of the 8 PT units had decreased activity as described above. It appears from this small sample of data that the motor modulation of PT neurons may be organized in a 'columnar' fashion.

56.11 AVERAGED MOTOR POTENTIALS ASSOCIATED WITH VOLUNTARY HAND MOVEMENTS WITHIN THE HIPPOCAMPAL FORMATION OF THE MONKEY. Joseph C. Arezzo* and Herbert G. Vaughan, Jr. Dept. of Neuroscience, Albert Einstein Coll. of Med., Bronx, N.Y. 10461.

In rodents and dogs there are characteristic alterations in the frequency on the EEG within the hippocampal formation coincident with motor behavior described as voluntary, as opposed to consummatory or reflexive. The electrical rhythms in the hippocampus of primates, including man, differ substantially from those in lower mammals and their relationship to movement is not apparent. Hippocampal involvement in motor control in the primate is, however, suggested by lesion and stimulation studies and by the recent anatomical demonstration of a direct projection from the subiculum to portions of the frontal cortex in the monkey (Rosen and Van Hoesen, 1977).

Motor potentials (MP) and multiple unit activity (MUA) associated with stereotyped self-paced wrist extension movements were recorded within the hippocampal formation of three monkeys. The rectified EMG was used to synchronize the averaging process. Potentials were recorded from a series of movable depth electrodes introduced vertically through a 10 x 20mm matrix to allow for the analysis of the intracranial field potential gradients.

MPs within the hippocampal formation consist of a large amplitude (300 uv) complex series of deflections which begin between 150 and 200 msec prior to the EMG onset and continue for a period of more than 1 sec after the movement. The field potential gradients are characteristic of an open field generator and the polarity of several components invert across the pyramidal layer of CA3. Volume conducted MPs can be traced to the dorsolateral surface of the brain where they interact with locally generated activity. There are no slow potential changes in the hippocampal MP equivalent to the N1 component (readiness potential) seen in the cortex, however the onset of antecedent phasic activity in the hippocampus precedes that seen in the precentral gyrus. MUA is recorded concurrent with the antecedent portions of the hippocampal MP and continues for approximately 150 msec after termination of contraction. The late positive MP component is not associated with changes in MUA.

The EEG recorded in the vicinity of the hippocampal formation is dominated by large amplitude low frequency activity (2-3 Hz) on which is superimposed low voltage fast activity. During a voluntary movement the low frequency rhythm is suppressed and the amplitude of the EEG is reduced. These changes precede the onset of the EMG by a variable period which can be as much as 500 msec. (Supported by grant MH 06723 from the USPHS).

56.12 SPIKE-TRIGGERED AVERAGES, ARTIFACTS, AND ARTIFICES. C.C. Boylls, Jr. Dept. Physiology, Medical School, Univ. Bristol, Bristol BS8 1TD, U.K.

The correlation technique variously known as spike-triggered or post-spike averaging is often employed to detect postsynaptic influences (upon EMG's, PSP's, or other spike trains) of the triggering-spike source (neuron or nerve fiber). It appears to be commonly accepted (e.g., ref. 1) that the method both resurrects postsynaptic effects from noisy backgrounds and allows accurate measurement of latencies. Certain authors (2) have additionally assumed that signs (facilitation, depression) and durations of effects can be correctly estimated.

In the present work it first is shown that even for simple linear, time-invariant postsynaptic processes, spike-triggered averaging per se cannot yield reliable indications of latencies, signs, or durations of effects, and can actually introduce, rather than reduce, noise in such measurements. These difficulties, which can be severe, arise from the nonuniform representation of frequencies within typical triggering spike trains. Without prior knowledge of the postsynaptic process, accurate results are assured only if the triggering train has "white noise" frequency characteristics. As demonstrated in the remainder of this study, however, it may be possible in many instances to "whiten" the frequency representation of triggering spike trains by computing the spectral densities of such trains and subsequently employing them to weight the results of spike-triggered averages (an application of the Wiener-Lee theorem). The considerable improvements so obtained in spike-triggered estimates of (linear) postsynaptic processes are illustrated. Extensions to the nonlinear situation are under inyestigation.

56.13 SOME DIENCEPHALIC PROJECTIONS OF THE FRONTAL LOBE IN CAT. E. Ramon-Moliner. Dept. of Anatomy. Sherbrooke University, School of Medicine, Sherbrooke, Quebec J1H 5N4. Canada.

In a previous communication (Abst. Soc. Neurosci. 5:119, 1979) the diencephalic projections of fibers leaving the pericruciate gyrus in the cat were determined by means of multiple injections of ^{35}S methionine in that gyrus. The present work is aimed at establishing the main differences between the projections reported at that time and the projections from those regions of the frontal cortex which do not include the pericruciate gyrus. ^{35}S methionine was injected (20-30 uC per injection) in the following sites: (1) the rostral gyrus proreus; (2) the caudal gyrus proreus; (3) the anterior extremity of the anterior suprasylvian gyrus (rostral to the gyrus coronalis); (4) the portion of the anterior suprasylvian gyrus lateral to the gyrus coronalis. All these sites shared with the pericruciate gyrus a varying degree of projection to the caudate nucleus and the thalamus. However, there were major differences with the pericruciate projections. The gyrus proreus projected to the medial portion of the head of the caudate nucleus, to medially located thalamic centers (ventralis medialis, centralis lateralis, reuniens, and dorsalis medialis). In addition, its rostral portion projected to the nucleus parafascicularis and the dorsolateral central gray matter of the mesencephalon, whereas its caudal portion projected to the lateral preoptic area, the hypothalamus and the ventral tegmental area. A projection to the rostral gyrus cinguli was also found. The anterolateral frontal lobe projected to the lateral portion of the head of the caudate nucleus although more scarcely than the pericruciate gyrus. It also projected to the claustrum and to the putamen. The thalamic projections included the lateral portion of the n. ventralis anterior, the lateral dorsalis medialis, the centralis medialis and part of the zona incerta. The cortical region lateral to the gyrus coronalis (anterior suprasylvian gyrus) projected to lateral thalamic regions: the lateral portions of the nuclei ventralis lateralis and ventralis posterolateralis. It also projected to the nucleus interstitialis. The thalamic projection of this cortical area shared with the pericruciate gyrus the presence within the lateral complex of a surprisingly well outlined ovoid field devoid of cortical afferents.

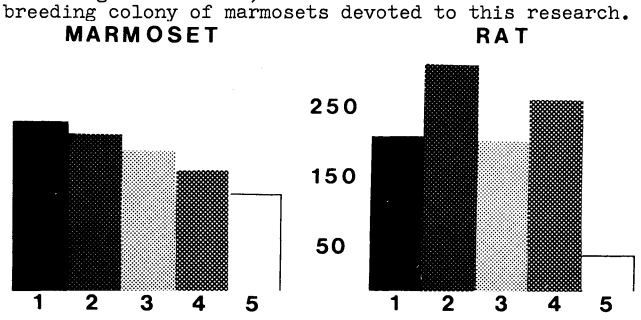
56.14 MARMOSET MOTOR CORTEX-A CYTOLOGICAL STUDY. T.J.TOBIAS. Univer. Paris VI, 45 rue St. Peres, Paris 75006 France.

In contrast to other monkeys, the marmoset possesses an agyric motor cortex. A recent study (Tobias, T.J. "Towards Analysis of Marmoset Motor Cortex" in press,) documents the existence of a single representation of distal forelimb musculature as described for Macaque by Kwan et al. (J. Physiologie 74:231, 1978.) Marmoset ability to perform an asymetrically reinforced, single digit flexion-extension, delayed alternation paradigm suggests that, in spite of relative cortical simplicity the South American simian is capable of motor behaviour comparable in complexity to tasks solved by Macaque. In brief, marmoset is ideally suited for intracellular studies of primate motor cortex. But, since Callitrichidae are endangered/vulnerable, it is preferrable to employ any other lissencephalic 300g mammal capable of independent digit movement. By comparison with the rat, however, it is clear that ethological differences between primates and rodents appear as well in motor cortex organization. Observations include: more myelin in monkey grey matter, even in layer I--which is 10% thinner than in rat; 25% thicker grey matter in monkey, containing, however, fewer cells than the rat; Marmoset possesses more large (35μ) cells in layer V, and has a much thicker layer VI, with large bundles of myelinated axons coursing superficially and laterally in both laminae. Graphs represent sum of neurons (vertical) from 3 animals within a 300μ strip from hand area in each of 5 zones (horizontal) of 500μ, beginning with Pia. These data are thus disharmonious with the concept of substituting a nonsimian, and indicate the need for a breeding colony of marmosets devoted to this research.



56.15 GABA NEURONS OF MONKEY MOTOR AND SENSORY CORTEX: AN IMMUNOCYTOCHEMICAL STUDY. C.R. Houser, J.E. Vaughn, E.G. Jones and S.H.C. Hendry. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010 and Department of Anatomy and Neurobiology, Washington University, St. Louis, MO 63110.

GABA appears to be an important inhibitory neurotransmitter in the neocortex and is believed to be used by certain local circuit neurons. A knowledge of the location and morphological characteristics of these neurons is particularly germane in higher mammals where local circuit neurons are most numerous and presumably play a significant role in cortical function. We have identified GABA neurons in the primary motor and somatosensory cortical areas of monkeys (M. fascicularis) using an immunocytochemical method for the localization of the GABA synthesizing enzyme, glutamic acid decarboxylase (GAD). Prior to immunocytochemistry, colchicine treatment was used to increase the GAD content of neuronal somata.

GAD-positive staining of somata and more proximal dendrites has been obtained for a large number of non-pyramidal neurons distributed in all cortical layers within both motor and sensory areas. The GABA somata in layer I are small (~10 μm in diameter) and show a limited amount of dendritic staining. GABA cell bodies in all other layers are morphologically heterogeneous. They range in size from small to large and exhibit a variety of proximal dendritic patterns, including apparent multipolar, bipolar and bitufted forms. A characteristic type of GABA neuron found within layers III-V is of large diameter (20-30 μm) and exhibits a multipolar dendritic pattern. The characteristics of this cell type correspond closely to those of cortical basket cells as described by previous investigators. These earlier studies have shown that basket cells form axonal arborizations around the somata of pyramidal neurons. In the present material, numerous GAD-positive puncta corresponding to GABAergic axon terminals are distributed over the somata of large and giant pyramidal cells. Thus, previous observations in conjunction with our own suggest that basket cells provide a GABAergic innervation of pyramidal cell bodies and, therefore, would be capable of exerting a powerful inhibitory control over projection neurons of motor and sensory cortex. The results of this study indicate that GABA neurons are numerous within primate sensorimotor cortex and appear to be of several morphological types. While the findings for motor and sensory areas are qualitatively similar, current efforts are directed toward determining if there are quantitative differences in the laminar distribution of GABA neurons between these two functionally distinct areas and toward a further definition of the various GABAergic cell types. 56.16 SUPRASYLVIAN GYRUS PROJECTIONS TO MOTOR AREA IN THE CAT CEREBRAL CORTEX STUDIED BY RETROGRADE TRANSPORT OF HORSERADISH PEROXIDASE R. S. Babb, K. D. Larsen, R. S. Waters and H. Asanuma. Rockefeller University, New York, N.Y. 10021

The distribution of horseradish peroxidase (HRP) labelled neurons in the anterior suprasylvian gyrus (area 5) was investigated as part of a broader study of the afferents of the motor cortex (area 4) in the cat cerebral cortex.

Nine adult cats were used in this study. In each animal two, three or four injections of 50% HRP (Sigma VI) in normal saline, each from 0.02 to 0.05 μL, were placed close together and about 1 mm deep bilaterally or unilaterally in the lateral pericruciate region of cortical area 4γ, a region from which movements of the front paw can be elicited by stimulation. After a survival time of about 44 hours the brain of each animal was perfused and processed with tetramethyl benzidine according to the method of Mesulam (J. Histochem. Cytochem. 24: 1273, 1976).

The results can be summarized as follows: (1) All the injections gave rise to cell bodies of neurons in the ipsilateral anterior suprasylvian gyrus (area 5) labelled with the blue HRP reaction product. (2) Two clearly separated regions, one in the depth of the ansate sulcus with cytoarchitecture corresponding to sub-area 5a defined by Hassler and Muhs-Clement, and the other on the surface of the suprasylvian gyrus corresponding to sub-area 5b, were both found to contain labelled cell bodies. (3) No labelled cell bodies were found in the region between these two labelled zones described above. (4) The labelled cell bodies were typically medium-sized, pyramidally-shaped and situated in lamina III in loose clusters with densities of about 16 and 7 cells per mm^2 in sub-areas 5a and 5b respectively. (5) Close to the sites of injection in the underlying white matter, compact fascicles of HRP filled fibers were observed. (6) The somata were only moderately labelled compared to darkly labelled cell bodies observed in the thalamus. (7) In addition to area 5, areas 17, 18 and 19 of visual cortex were examined and found to contain no labelled cells.

From these observations it is concluded that projections from area 5 to the ipsilateral area 4γ originate from neurons with medium-sized pyramidal-shaped cell bodies situated in lamina III. The cell bodies are loosely clustered in two groups, one situated in sub-area 5a and the other in sub-area 5b, and both groups sending axons to converge on the lateral pericruciate region of area 4γ.

56.17 ABLATION OF FELINE SENSORIMOTOR CORTEX DECREASES GLUTAMATE UPTAKE IN THE PROJECTION AREAS OF CORTICOSPINAL TRACT. A.B. Young, M.B. Bromberg, and J.B. Penney, Jr.* Dept. of Neurology, University of Michigan, Ann Arbor, MI 48109.

Despite recent advances in defining the neurotransmitters of specific pathways, the neurotransmitter(s) of the corticospinal tract is (are) still unknown. We have recently provided strong evidence in the rat that cortical inputs to ventrolateral nucleus (VL) of thalamus and red nucleus (RN) are glutamatergic (Bromberg, et al: Neurology 30: 396, 1980). Since these projections are thought to be collaterals of the corticospinal tract, we have investigated the problem further in cats.

In a series of cats, we have performed unilateral extensive ablations of pericruciate (sensorimotor cortex) under Ketamine anesthesia. Two weeks after the operation, animals are again anesthetized as above, and their brains exposed. The cats are then sacrificed by spinalization. The brains and spinal cords are put in ice cold 0.32 M sucrose and 1 mm punches taken from ventrolateral nucleus of the thalamus, caudate nucleus, red nucleus, pons, medullary reticular formation, dorsal column nuclei, and from Rexed layers IV-VIII of cervical, thoracic and lumbar spinal cord. Punches were homogenized in 0.32 M sucrose with a Potter-Elvehjem homogenizer and spun at 20,000 x g for 20 minutes. The resultant pellets were resuspended in sucrose and uptake performed as previously described (Young, et al: Brain Res. 73: 1, 1974) at a concentration of 1×10^{-7}M.

Glutamate high affinity synaptosomal uptake is decreased ipsilateral to the lesion as far as the level of the dorsal column nuclei after which uptake is decreased contralateral to the lesion. The decrease in uptake reflects a decrease in the number of glutamate transport sites not in the affinity of the site. This loss of transport sites is most likely due to loss of presynaptic glutamatergic corticospinal axon terminals. Supported by USPHS grants NS00464-01, NS00420-01 and NS15140-02, The United Cerebral Palsy Research Foundation and Michigan Memorial Phoenix Project grant 567.

57.1 SPECIES VARIATION IN THE DOPAMINE CONTENT OF CEREBRAL BLOOD VESSELS. J.F. Reinhard, Jr. and M.A. Moskowitz. Lab. of Neural and Endocrine Regulation, MIT, Cambridge, MA 02139.

A role for dopamine (DA) in the pharmacological regulation of cerebral blood flow has been shown by in vitro studies that measure the ability of this molecule to contract or relax cerebral blood vessels, or by in vivo studies which record changes in cerebral blood flow after DA administration. The notion that dopamine participates in the physiological regulation of this tissue would be supported by finding relatively large amounts of dopamine in the walls of cerebral blood vessels. Thus we have measured the content of catecholamines within large and small blood vessels from rat, cat, ferret, dog, cow, and human brains.

The middle, anterior cerebral, and basilar arteries were dissected free of the surrounding pial tissue. Microvessels were isolated using a density gradient method, and choroid plexus was isolated from the lateral ventricles. The tissues were homogenized in 0.1 M perchloric acid and the catecholamines were isolated on small alumina columns. Catecholamines were further separated and quantitated using high pressure-liquid chromatography with electrochemical detection.

Noradrenaline (NA) was detected in all of the vessel preparations studied. In cerebral vessels from rat, dog, and man, DA levels were 10-15% of the concentrations of NA. Feline and bovine vessels, however, contained relatively high levels of DA which were equal to 30 and 100% of the vessel's NA, respectively. The proportion of DA to NA in these tissues is considerably higher than we have observed for tissues receiving exclusively a noradrenergic innervation (i.e. pineal), suggesting that DA might be present outside of noradrenergic nerve terminals (e.g. in mast or endothelial cells, or in nonadrenergic nerve terminals). Thus in cat and cow brains, dopamine is contained within cerebral blood vessels where it might act to modify cerebral blood flow.

57.2 EFFECTS OF NICOTINE ON CARDIAC AND PULMONARY ARTERIES OF THE RAT. J.M. Sullivan*, N.A. Connors*, M.W. Rana*, and C.L. Lawson* (SPON: L. Massopust). Dept. of Anatomy, St. Louis University School of Medicine, St. Louis, MO 63104.

We have reported (1980 AAA Abstracts, Pp. 184-185) that nicotine increased cardiac arterial medial mass in the rat. The purpose of this study was to demonstrate the morphological effects of nicotine on pulmonary arteries as compared to the nicotinic effects on rat cardiac arteries. In general, the cardiovascular and pulmonary vascular responses to nicotine parallel those that accompany stimulation of the sympathetic nervous system. The stimulation of sympathetic ganglia and the adrenal medulla, together with the release of catecholamines from sympathetic nerve endings account for the similarity. Forty-four Sprague-Dawley rats (22 males & 22 females) were divided into four groups. Group I received 0.5 mg/kg of nicotine in one injection per day. Group II received 1.0 mg/kg in two injections per day. Group III received 1.5 mg/kg in three injections per day. Group IV received 1.0 ml of normal saline per day and served as the control. After sixty days, thirty-six animals were anesthetized with pentobarbital (50-60 mg/kg, i.p.) perfused with 10% buffered neutral formalin, and serial sections of hearts and lungs were processed for light microscopic histological studies. Sections of the hearts and lungs of the other eight animals were freeze-dried and processed for fluorescence histochemical localization of catecholamines. Cryostat sections (10 μm in thickness) were processed and examined for fluorescence. By means of the point-counting technique of Chalkley under a constant magnification of 400X, relative cross-sectional areas of intimal nuclei, media, and medial nuclei were determined for arteries in each heart and lung. The general histological stain used was H&E, however, in some cases trichrome stains were used to assure that neither adventitia nor intima was being included in measurements of arterial media. The numbers of intimal and medial nuclei were also counted in each artery. Light microscopic studies of the cardiac and pulmonary arteries were compared. Fluorescence histochemistry indicated an increase in catecholamine fluorescence. (Supported by Life Insurance Medical Research Fund #G-70-8).

57.3 EVIDENCE FOR A CENTRALLY MEDIATED SYMPATHOLYTIC ACTION OF POST-SYNAPTIC α-ADRENERGIC RECEPTOR ANTAGONISTS. Robert B. McCall and Stephen J. Humphrey.* The Upjohn Co., Kalamazoo, MI 49001.

Prazosin is a unique α-adrenergic receptor antagonist which possesses a high degree of selectivity for postsynaptic α-receptors. Unlike classic α-receptor antagonists, prazosin decreases mean arterial pressure (MAP) without causing an accompanying increase in heart rate (HR) or plasma renin activity (PRA). The present study was designed to determine if the lack of reflex increase in HR and PRA results from a central sympatholytic action of prazosin. Intravenous administration of prazosin (50 μg/kg) to anesthetized, baroreceptor denervated cats resulted in a rapid fall in MAP (-42%) and no significant change in HR. Prazosin administration was also associated with a prolonged inhibition of sympathetic nervous discharge (SND) recorded from the external carotid or splanchnic nerves. SND was significantly reduced within 5 minutes of the administration of prazosin and remained depressed throughout the 2-hour observation period. SND was maximally inhibited (-41%) 1 hour after the drug was given. Finally, prazosin significantly attenuated the pressor effect of intravenous norepinephrine. In contrast, administration of vehicle to control animals failed to alter MAP, HR, or SND. Prazosin also reduced MAP (-39%) and SND (-39%) in baroreceptor intact cats and failed to significantly alter HR. In contrast, phentolamine (1.0 mg/kg, i.v.; an α-antagonist which fails to enter the brain) decreased MAP (-30%) but increased SND (+74%) in baroreceptor intact cats. Phentolamine significantly increased HR when compared to prazosin treated animals. In a final set of experiments, the effects of WB-4101 (0.5 mg/kg, i.v.; an α-antagonist which possesses a high degree of selectivity for postsynaptic α-receptors) on MAP, HR, and SND were studied. Like prazosin, WB-4101 produced a significant decrease in MAP (-63%) and SND (-45%) in baroreceptor denervated cats. WB-4101 also produced a significant bradycardia. These data indicate that the sympatholytic action of prazosin and WB-4101 results from a centrally mediated reduction in SND as well as a peripheral blockade of α-adrenergic receptors. The relative importance of either sympatholytic component in the hypotensive action of these agents was not determined. However, the centrally mediated reduction in SND may explain the lack of tachycardia and PRA increase during the hypotension produced by prazosin. Finally, since prazosin and WB-4101 have been shown to selectively block postsynaptic α-adrenoreceptors in the central nervous system, these data suggest that central noradrenergic neurons normally facilitate transmission in central sympathetic pathways.

57.4 COMPARISON OF THE EFFECTS OF HUMAN-RAT (Ile^5 A II) AND BOVINE (Val^5 A II) ANGIOTENSINS ON PLASMA CATECHOLAMINES IN PITHED RATS. Robert C. Speth, Mahesh C. Khosla*, Michelle M. Spech*, and Carlos M. Ferrario. Research Division, Cleveland Clinic Foundation, Cleveland, OH 44106.

With a view towards finding a difference in the ability of human-rat angiotensin (Ile^5 A II) and bovine angiotensin (Val^5 A II) to release catecholamines, equipressor doses of these angiotensins were infused into two separate groups of pithed rats. A third group of pithed rats received isotonic saline vehicle only. Rats (270±15 g) were anesthetized with methoxyflurane, tracheotomized, pithed by insertion of a steel rod through the orbit and into the spinal cord and respired mechanically. The femoral artery was cannulated for blood pressure and heart rate monitoring, the femoral vein was cannulated for drug infusion and the carotid artery was cannulated for blood sampling. One hour after pithing, rats were infused with either saline, Ile^5 A II (72 ng/min) or Val^5 A II (72 ng/min) at a rate of 0.2 ml/min until blood pressure stabilized at an elevated level, at which time a sample of blood was removed from the carotid artery. Plasma catecholamines were determined by radioenzymatic assay using catechol-O-methyl transferase and ^{3}H-S adenosyl methionine. Both Ile^5 A II and Val^5 A II increased mean arterial pressure (MAP) by 84% and 80%, respectively, from the average baseline value of 55 mm Hg. Saline infusion produced an insignificant, 5% increase in the MAP. None of the infusions significantly altered heart rate from the basal value of 316 beats/min, indicating a complete loss of central nervous reflex heart rate control after pithing. Plasma dopamine concentration did not differ significantly among the three groups. Saline infused animals had a mean concentration of 175±35 pg of dopamine HCl/ml of plasma. The mean plasma epinephrine concentrations in all three groups were extremely low (< 30 pg/ml) which was below the reliable sensitivity of this assay. The mean plasma norepinephrine (NE) concentration was significantly elevated in Ile^5 A II infused rats by 81% and 58% over saline and Val^5 A II infused rats, respectively. Mean plasma NE concentration in Val^5 A II infused rats did not differ significantly from that of saline infused rats, that value being 292±37 pg/ml. These results indicate that human-rat angiotensin elevates plasma NE concentration but that bovine angiotensin does not. These differential effects on plasma NE concentration may indicate a difference in the mechanisms whereby these angiotensins produce their pressor effects.

57.5 MECHANISM BY WHICH AMPHETAMINE CAUSES MYDRIASIS IN THE RAT. Harry Klemfuss* and Lewis S. Seiden (SPON; James B. Lucot) University of Chicago, Chicago, IL 60637.

The mydriatic action of amphetamine is commonly considered one of the sympathomimetic effects of this drug. We have examined how amphetamine causes pupillary dilation in unrestrained, conscious rats by using a photographic technique. This response is not mediated by sympathetic pathways since the mydriatic effect of 1 mg/kg d-amphetamine is not altered by chronic sympathetic denervation or by subsequent adrenalectomy. Eyedrops containing physostigmine prevent the mydriasis, indicating that parasympathetic pathways are involved. To investigate the role of catecholamines in amphetamine mydriasis, we attempted to prevent it by pretreating rats with specific receptor blockers. Yohimbine, which preferentially blocks presynaptic α-noradrenergic receptors, partially antagonized the mydriasis. Blockade of both pre- and post-synaptic receptors with phenoxybenzamine eliminated the mydriasis completely, which suggests that both kinds of receptors may be involved. Dopaminergic receptors do not seem important in this response, since neither pimozide nor sulpiride, which block different subpopulations of dopamine receptors, had any effect on the mydriasis. Haloperidol caused a slight pupillary constriction at doses of 0.4 or 2 mg/kg, but only the higher dose prevented amphetamine mydriasis. Since the lower dose effectively blocks dopamine receptors while high doses of haloperidol also affect adrenergic systems, it appears that noradrenergic but not dopaminergic antagonism is responsible for haloperidol's effect. Additional evidence for the importance of α-noradrenergic receptors comes from our observation that the α-noradrenergic agonist clonidine also causes a dose-related mydriasis in conscious rats. We propose that amphetamine mydriasis in the rat is mediated primarily be central α-noradrenergic systems on parasympathetic pathways, since α-noradrenergic but not dopaminergic agents block the mydriasis, and physostigmine but not sympathectomy prevents amphetamine mydriasis. 57.6 EFFECTS OF DRUGS INTERFERING WITH METABOLISM OF OCTOPAMINE IN SPONTANEOUS HYPERTENSIVE RATS. D. Casset-Senon*, B. Delbarre, G. Delbarre . Lab. Chir. Exp., Fac. Méd., 37032 TOURS CEDEX FRANCE.

We have demonstrated that p.octopamine injected in lateral ventricle and cisterna magna of spontaneous hypertensive rats (SHR) induces dose-dependant falls of blood pressure (BP) (IRCS, Med. Sci., 1980, 8, 23).

We have investigated in SHR the cardiovascular action of octopamine precursors and the action of drugs interfering with the metabolism of this amine. The administration of pargyline (20 mg/kg i.p.) which increases brain octopamine levels, results in a significant reduction of BP in SHR. This decrease is greater after administration of tyrosine (30 mg/kg i.p.) and tyramine (5 mg/kg i.p.). Similarly drugs known to inhibit activity of phenylethanolamine N-methyltransferase (PNMT) and to increase brain octopamine level such as SKF 64139 (7,8 dichloro-1,2,3,4-tetrahydroisoquinoline hydrochloride) and DCMB (2,3-dichloro-α-methyl-benzylamine hydrochloride), decrease BP in SHR.

In unanaesthetized cats, p.octopamine (30 µg/kg), injected in lateral ventricle, decreases significantly BP. This effect is not antagonized by piperoxane (4 mg/kg i.p.), yohimbine (0.2 mg/kg i.p.) and cyproheptadine (0.2 mg/kg i.p.).

These results provide experimental evidence that octopamine may be involved in central blood pressure regulation. Moreover the receptors of octopamine seem independant of those of noradrenaline, adrenaline and serotonin.

57.7 MECHANISMS INVOLVED IN CENTRAL EFFECTS OF PROSTAGLANDIN $F_{2\alpha}$. G. Feuerstein*, C. J. Helke, J. Saavedra, D. M. Jacobowitz and I. J. Kopin. (Spon: A. M. Laties). Laboratory of Clinical Science, NIMH, Bethesda, MD 20205.

Injection of prostaglandin (PG) $F_{2\alpha}$ into the lateral ventricle (i.c.v. 10 µg/rat in 5 µl) of lightly anesthetized rats (0.7% halothane in oxygen) elicited increases of: blood pressure (BP) + 40 mmHg, heart rate (HR) + 150 beats/min, respiratory rate (RR) + 34 resp/min and rectal temperature (RT) up to 39.8°C. Intravenous injection of the same dose of $PGF_{2\alpha}$ had only a transient (2-3 min, 10-20 mmHg increase) effect on BP. The increases of BP and HR following $PGF_{2\alpha}$-i.c.v., were rapid but tapered off within the experimental period (80 min), whereas the RR and RT responses developed gradually but were sustained throughout the entire experiment. In $PGF_{2\alpha}$-i.c.v. rats, plasma norepinephrine (NE), radioenzymatically assayed, increased 4 fold - up to 930 pg/ml ($p<0.001$, $n = 10$), closely correlating with the BP and HR responses. Plasma epinephrine did not change following $PGF_{2\alpha}$-i.c.v. NE content in brainstem nuclei: A_1 and A_2 + nucleus tractus solitarius (NTS), were reduced by 45% and 31% respectively ($p<0.05$); in the A_2+NTS region there was also a 56% decrease in dopamine concentration ($p<0.05$). NE, epinephrine and dopamine levels in the dorsomedial and the ventromedial hypothalmic nuclei were not affected by $PGF_{2\alpha}$-i.c.v. In hexamethonium (10 mg/kg, i.v.) pretreated rats, BP and HR were still increased over control values by $PGF_{2\alpha}$-i.c.v., at a time when complete blockade of $PGF_{2\alpha}$-induced NE release prevailed. The RR and RT responses to $PGF_{2\alpha}$ were also attenuated by hexamethonium. The residual BP and HR responses to $PGF_{2\alpha}$-i.c.v. in the hexamethonium-treated rats persisted even in bilaterally nephrectomized (acute) rats or hypophysectomized (transpharyngeal, 3 days prior to the experiments) rats.

In conclusion, the data presented demonstrates that $PGF_{2\alpha}$, by a central action, activates the peripheral sympathetic nervous system, as well as central adrenergic pathways. Furthermore, other factors (non-renal and non-pituitary) are also involved in the central effects of $PGF_{2\alpha}$. The discrete sites for the central actions of $PGF_{2\alpha}$-i.c.v. are still unknown but may involve the brainstem nuclei, in which changes in catecholamine levels were found (A_1 and A_2 + NTS), presumably as regards to the cardiovascular responses.

57.8 STIMULATION OF R2 CHEMORECEPTORS ELICITS BILATERAL RENO-RENAL REFLEXES IN THE RAT. Paula R. Rogenes* (SPON: Robert A. Mueller). Dept. Physiol., U.N.C., Chapel Hill, N.C. 27514.

Electrical stimulation of renal afferent fibers results in either a decrease (in rabbits and dogs) or an increase (in cats) in efferent renal nerve activity (ERNA). Recent work in this laboratory has demonstrated the existence of two populations of chemoceptive receptors within the rat kidney termed renal "R1" and "R2" chemoreceptors (Recordati, et al., Circ. Res. 43:534, 1978, and 46:395, 1980). The purpose of the present study was to determine whether the R2 receptors participate in the afferent limb of a reno-renal reflex arc.

Sprague-Dawley rats were anesthetized with sodium pentobarbital. Postganglionic ERNA was recorded from a fine filament dissected from a single nerve bundle which had been cut close to the hilus of the left kidney. Multiunit ERNA was quantified with a window discriminator frequency meter. In some cases the responses of single units could be identified with the aid of a computer sorting program. R2 receptors were stimulated by backflow of nondiuretic urine into the renal pelvis of either kidney. Observations are reported only from animals in which blood pressure remained stable throughout the procedure.

ERNA was counted for three consecutive periods lasting one minute each and taken before, during, and after backflow of nondiuretic urine. An increase of multiunit ERNA over resting discharge rates was observed during backflow of urine into the contralateral as well as into the ipsilateral renal pelvis (mean increase of 21.5% and 20.9% respectively). There was no difference between ERNA before and after backflow of urine. Single unit analyses indicated that stimulation of ipsilateral and/or contralateral R2 receptors resulted in an increased firing frequency (range 50-180% over control) in some units. Other units showed no change or, less frequently, a reduction in activity during R2 receptor stimulation.

Thus, backflow of nondiuretic urine into either the ipsilateral or contralateral renal pelvis had an overall excitatory effect on ERNA in anesthetized rats. These data support the possibility that acute obstruction of the lower urinary tract results in altered ERNA bilaterally which could mediate adjustments in renal hemodynamics and excretory function. Observations of varying responses among single units give evidence that renal nerves contain a mixture of efferent fibers which may reflect functional heterogeneity. (Supported by NIH Training Grant T32 AM 07047 and NINCDS Grant NS 14899).

57.9 Kainic acid administration to mesolimbic sites: electrocorticographic and cardiovascular effects. L. S. Clark, A. Y. Deutch, and L. J. Peacock. Department of Psychology, University of Georgia, Athens, GA 30602.

We have presented data indicating that kainic acid administration to the lateral ventricle of barbiturate-anesthetized rats (4.7 nM in 1.0 ul buffered saline) elicits a rapid onset tachycardia. Because data from our own and other laboratories suggest that KA is a powerful epileptogenic agent at certain central loci, and that profound autonomic alterations accompany seizure activity, we have atttempted to 1)discern the temporal relationship between the onset of tachycardia and the appearance of epileptiform spikes following KA administration, and 2)to characterize the electrocorticographic patterns of seizure discharge resulting from administration of the neurotoxin to selected central sites.

KA administration reliably results in a short latency tachycardia following administration to the mesolimbic terminal fields nucleus accumbens septi (ACB) and nucleus interstitialis stria terminalis (NIST). Recording between a rostral skull screw and a caudal depth electrode (anterior thalamus) ipsilateral to the site of KA injection, a delay of approximately six minutes is observed between the onset of tachycardia (defined as a minimum of a 20% decrease in interbeat interval from baseline) and the first appearance of spikes. The records of both the lateral ventricle (IVT) and NIST groups show a desynchronization at approximately five minutes after the initiation of infusion (i.e., well after tachycardia onset) with spikes not appearing until approximately nine minutes. Vehicle administration also results in ECoG desynchronization; however, the electrographic activity rapidly returns to baseline appearances and does not evolve into seizure discharge. ACB injected subjects initially showed a pattern similar to that observed in animals receiving KA to the NIST and IVT; however, the tachycardia subsided at about nine minutes only to reoccur with a time course paralleling the increase in spike density and amplitude. Of these three groups the NIST animals showed the most profound spiking with spike amplitudes approaching 500 uV.

Using the same procedures, the effects of KA administration to the mesolimbic terminal field central amygdaloid nucleus or to site of origin of mesolimbic fibers, the ventral tegmental area (VTA) were as follows. No tachycardia was elicited by KA injection to either site. KA infusion to the VTA, however, did evoke spiking with a relatively long latency onset (12 minutes); amygdaloid administration was without effect. Thus, the initial tachycardia observed in response to KA administration can be differentiated from seizure-induced autonomic effects.

57.10 REGIONAL BRAIN CYCLIC NUCLEOTIDE AND HORMONAL RESPONSE IN GENETICALLY HYPERTENSIVE RATS (SHR) TO AMINERGIC AND CHOLINERGIC STIMULATION. D.R. Collins*, J.L. Meyerhoff, G.J. Kant, L.L. Pennington* and R.H. Lenox (SPON: H.C. Holloway). Dept. Med. Neurosci., Walter Reed Army Inst. Rsch., Washington, DC 20012 and Dept. of Psychiatry, Univ. of Vermont, Burlington, VT 05405

Spontaneously hypertensive rats (SHR) have been shown to be hyperactive and hyper-responsive to stressful stimuli as compared to their Wistar/Kyoto normotensive (WKY) controls. Previous work from our laboratory has demonstrated a relationship between motor activity, various stressors and the regional pattern of cyclic nucleotide response in the brain (Meyerhoff, et al.,Life Sci.,24, 1979; Lenox et al., Neuroendocrinology, In Press). We have also carefully examined in vivo regional brain cyclic nucleotide and hormone response to both aminergic and cholinergic stimulation (Bates et al., Neuroscience Abstracts, 5, 1979; Lenox et al.,Life Sci., In Press). Based upon these results, we have proceeded to examine the regional cyclic nucleotide and hormone response in SHR animals exposed to amphetamine or oxotremorine.

Female genetically hypertensive rats (SHR Okamoto/NIH/Vermont) and age-matched group of WKY normotensive controls, weighing between 250-300 gm were maintained in a light-cycled chamber. Stage of estrus was determined by vaginal smears. Animals received an intraperitoneal injection of either oxotremorine (2 mg/kg), d-amphetamine sulfate (5mg/kg) or saline 10 min. prior to sacrifice by exposure to high power microwave irradiation. Animals receiving the cholinergic agonist were pretreated (30 min.) with methylatropine (0.5mg/kg) to avoid excess peripheral cholinergic stimulation. Motor activity of all animals was measured for the 30 min. prior to sacrifice. Following sacrifice trunk blood was collected for hormone assays and 13 brain regions were dissected for radioimmunoassay of cyclic AMP and cyclic GMP.

Preliminary results in eight regions of the brain indicate similar concentrations of cyclic AMP in both SHR and WKY except for the pineal (SHR) where levels of cyclic AMP were increased twofold. This elevated pineal cyclic AMP might reflect heightened sympathetic activity observed in the SHR by other laboratories. SHR receiving oxotremorine had elevated cyclic AMP in the amygdala and both groups had striking increases in pituitary cyclic AMP confirming results previously reported by our laboratory. Regional cyclic AMP in both SHR and WKY responded similarly following amphetamine treatment. Mean serum prolactin indicate lower levels in the SHR, with both groups showing a significant reduction following amphetamine administration. These data thus far indicate that cyclic AMP and pituitary hormone response may serve to further differentiate the central nervous system of the SHR.

57.11 DIFFERENTIAL DEPLETION OF CNS CATECHOLAMINES: EFFECTS ON BLOOD PRESSURE AND DRINKING BEHAVIOR. F. J. Gordon, A. K. Johnson, & M. J. Brody* Depts. of Psychology & Pharmacology, and The Cardiovascular Center, University of Iowa, Iowa City, IA 52242.

Previous studies from this laboratory indicated that depletion of CNS catecholamines produced by lateral ventricular (LVT) injection of 6-hydroxydopamine (6-OHDA) resulted in deficits both for drinking behavior and the central regulation of arterial pressure (Gordon, et al., Brain Research, 178:161-173, 1979). The purpose of the present study was to identify which catecholamine-containing neurons (norepinephrine (NE) or dopamine (DA)) and which CNS region(s) innervated by them might participate in the pressor and drinking responses produced by central drug stimulation.

Forebrain NE was reduced in rats by injecting 4 µg 6-OHDA into the ascending noradrenergic bundles (NAB). Spinal cord NE was depleted by intracisternal (IC) injection of 50 µg 6-OHDA. Moderate depletion of forebrain DA was produced by IC injection of 200 µg 6-OHDA + pargyline i.p. (IC + P), and severe DA depletion by bilateral injection of 4 µg 6-OHDA into the substantia nigra (SN) of desipramine pretreated rats. Pressor responses to various doses of LVT angiotensin II (AII), carbachol (CARB), and hyperosmolar NaCl (HYP); and drinking responses to LVT AII and CARB were examined.

NAB 6-OHDA reduced telencephalic and hypothalamic NE by more than 80% without significantly affecting brain DA or spinal cord NE. IC 6-OHDA depleted spinal cord NE by 80% and forebrain NE by 20-25% without reducing brain DA. IC + P 6-OHDA resulted in a 61% fall in telencephalic DA, and 28% and 94% depletion of forebrain and cord NE respectively. SN 6-OHDA reduced telencephalic DA by 86% and NE by 29% without affecting NE in other CNS regions.

IC + P 6-OHDA reduced LVT AII drinking without affecting LVT CARB drinking. SN 6-OHDA attenuated drinking to both LVT AII and CARB. Pressor responses to LVT AII, CARB, and HYP were largely unaffected by these 6-OHDA treatments. Almost complete destruction of brain and/or spinal cord NE (NAB, NAB + IC, IC + P 6-OHDA) failed to alter centrally mediated drinking and pressor responses.

These data indicate that the integrity of brain DA neurons are required for the behavioral but not hypertensive responses produced by central drug stimulation. Furthermore, it appears that the pressor action of centrally injected drugs can be reduced only if CNS NE is depleted by injecting 6-OHDA LVT (Gordon, et al., 1979). This observation raises the possibility that the antihypertensive action of 6-OHDA when injected LVT may be unrelated to its specific catecholaminergic neurotoxicity. Another possibility is that catecholaminergic neurons intrinsic to the hypothalamus, which might be reached only if 6-OHDA is injected LVT, may constitute a functionally critical pool of neurons responsible for the initiation of pressor responses produced by central drug stimulation. 57.12 HARMALINE INDUCED AUTONOMIC CHANGES FROM THE CEREBELLUM IN CONSCIOUS DOGS. K. J. Dormer and E. H. Brown*, Dept. of Physiology and Biophysics, Univ. of Oklahoma Health Sciences Center, Oklahoma City, OK 73034.

Harmaline is a drug that produces motor tremor through specific activation of cells in the inferior olive which then cause repetitive firing in climbing fibers, thus activating Purkinje cells and cerebellar nuclei including the fastigial nucleus (FN). At doses above and below the tremorogenic threshold autonomic changes are also observed, including tachycardia and hypertension. In an attempt to confirm the autonomic role of the FN in response to muscle afferent activation, harmaline was given to chronically instrumented dogs to observe heart rate (HR), left ventricular pressure (LVP) and dP/dt, or HR and aortic pressure (AP) changes. Dogs were implanted with solid-state pressure transducers into the left ventricle or descending aorta, using sterile technique. After recovery from the thoracotomy, electrodes were implanted into the rostral FN which produced tachycardia and hypertension when stimulated electrically. Harmaline was injected in doses of 1.5 and 0.7 mg/kg for the LVP (n=2) and AP (n=2) dogs respectfully, and cardiovascular parameters recorded for 10 minutes following injection. Lesions were then placed in the rostral regions of FN, using a radiofrequency lesion generator (30 VRF). After 5 - 10 days recovery from lesioning, the harmaline injections and recordings were repeated. HR was increased 33% by the larger dose and negligibly by the smaller. Post lesion, the HR was not increased at all. LVP increased from 124 to 153 mmHg or 23% prelesion, and decreased by 4% after FN lesioning. Myocardial contractility as indexed by dP/dt increased by 48% before lesioning and 20% postlesioning. Of the dogs implanted for AP, only one received FN lesioning and AP increased 22% before lesioning, and decreased by 4% following lesioning. Mild tremors were also observed at the 1.5 mg/kg doses prior to lesioning but were not evident postlesioning. Thus partial removal of the FN reduces the autonomic changes associated with harmaline activation of the inferior olive and FN. This provides further evidence (see Dormer and Brown Fed. Proc. 39(3):842,1980) that muscle afferents to the cerebellum are responsible for some of the cardiovascular changes observed during exercise and that this response may be mediated by the rostral FN. This work was supported by a Young Investigators Award HL 22747.

57.13 EFFECTS OF INTRAVENTRICULAR ADMINISTRATION OF BEPRIDIL ON CARDIOVASCULAR HEMODYNAMICS OF ANESTHETIZED AND CONSCIOUS DOGS.
S. Adamski*, J. S. Francis, J. P. Buckley* and M. F. Lokhandwala, Department of Pharmacology and Institute for Cardiovascular Studies, University of Houston, Houston, Texas 77004.

The effects of intraventricular administration (IVT) of Bepridil were studied in anesthetized and conscious adult mongrel dogs (14-20 kg.). Each animal was anesthetized with sodium pentobarbital (35 mg/kg i.v.) and a stainless steel cannula was implanted into the left lateral ventricle. Animals used for the unanesthetized studies were allowed to recover for 5-7 days. The anesthetized dogs were instrumented to determine cardiac output (CO), heart rate (HR) and mean blood pressure (BP). They were injected IVT with Vehicle alone (V) or Bepridil solution (B). In these animals V produced little or no changes in HR or BP. However, B produced dose related (50-400 µg) significant ($p<.05$) increases in BP, CO and total peripheral resistance (PR) with peak responses occuring 15-20 min. after IVT injection. As the 400 µg dose of B produced the largest changes in cardiovascular dynamics its effects were investigated in conscious animals. The conscious dogs were injected IVT with (V) or Bepridil (B), while heart rate and blood pressure were measured at 5 min. intervals 15-20 min. before and up to 60 mins. after injection. In the conscious animals the V produced no significant change in resting heart rate or systolic blood pressure at any time after administration. However, B at high doses (400-800 µg) produced significant ($p<.01$) increases in systolic blood pressure (SBP) (12-40 mmHg), with a peak increase occuring at 15-20 mins. after IVT administration. Heart rate remained unchanged.

These results domonstrate that central administration of B produces an increase in blood pressure, an action which is opposite to the systemic effect of the compound.

57.14 HYPOTENSIVE EFFECTS AND PREGANGLIONIC SPLANCHNIC NERVE ACTIVITY OF E. COLI ENDOTOXIN IN THE CAT.
S. Koyama*, H. L. Santiesteban*, W. S. Ammons* and J. W. Manning. Dept. of Physiology, Emory Univ. Sch. of Med., Atlanta, GA 30322.

Within one minute after intravenous injection of 1 mg/kg E. Coli endotoxin (Difco. 0111:B4) in alpha chloralose anesthetized cats, mean blood pressure was 10% above control pressure. This was followed within 5 min. by a rapid fall to 75% of control pressure. There followed a temporary recovery of mean blood pressure to 80% of control. Finally there was a secondary decay in mean blood pressure, so that after 60 min. mean blood pressure was depressed to 55% of control pressure. The aortic pulse pressure initially decreased to 80% of control, but then recovered to 95% of control. Finally there was a secondary decay in pulse pressure. Preganglionic splanchnic nerve (PSN) activity decreased to 80% of control level before the rapid fall of mean blood pressure. There followed a temporary recovery of PSN activity coincidence with the maximal fall in mean blood pressure. During the ensuing secondary decay in mean blood pressure, PSN activity gradually decreased to 50% of control level at 60 min.after injection of E. Coli endotoxin. At 30 min. after intracisternal injection of phentolamine (500µg/kg), E.Coli endotoxin was injected intravenously. Hypotension induced by intravenous injection of endotixin was abolished by the intracisternal pretreatment with phentolamine. Pulse pressure was decreased to 85% of control at 5 min.after intravenous administration of endotoxin. There followed an increase of pulse pressure to 15% above control which persisted during experimental periods (60 min.). The changes in PSN activity with intravenously injected endotoxin was abolished by the intracisternal pretreatment with phentolamine. In conclusion, we confirmed the previous report (Fed.Proc. 39:840,1980) that the hypotensive effects of E.Coli endotoxin may be mediated by a central autonomic blood pressure regulatory circuits, by stimulation of central alpha adrenergic receptors which lead to inhibition of brain stem sympathetic pathways that participates in baroreflex adjustments.

57.15 MORPHOMETRIC CHANGES IN LUMBAR COLONIC NERVES OF RABBITS AFTER TREATMENT WITH NERVE GROWTH FACTOR - ANTISERUM.
H. Aebersold*, D.L. Kreulen, D.J. Wells* and P.J. Dyck*. Depts. of Neurology, Physiology and Biophysics and Cardiovascular Research, Rochester, MN 55901.

In late embryonic development the administration of antiserum to nerve growth factor (A-NGF) causes a degeneration of adrenergic nerves. We studied the effect of A-NGF on morphometry of lumbar colonic nerves (LCN) which originate in the inferior mesenteric ganglion (IMG) and innervate the descending colon. The unmyelinated fiber (UF) diameters in these nerves ranged from 0.1 µm to 1.4 µm. The number and density of fibers per nerve varied greatly among control animals.

A combined pre- and postnatal treatment with A-NGF was performed in two ways: 1) 5 pups were injected (0.05 ml/g body weight) one week before delivery through the exposed uterus and then for five days after birth; 2) one adult mother was immunized with NGF and then mated. Serum A-NGF levels were determined by measuring the amount required to precipitate 50% of the ^{125}I-labeled NGF in a double antibody precipitation radioimmunoassay procedure. At the age of two months the rabbits were perfused and the LCN prepared for EM evaluation.

There were no gross differences in the size of the IMG between those of the A-NGF and control animals. The mean of the median diameters of the UF of the LCN in 7 treated (no difference between the two types of treatment) animals ($\bar{x}$ = 0.39 µm ± 0.04 µm) was significantly ($p < 0.01$) smaller than the mean in 6 control animals ($\bar{x}$ = 0.51 µm ± 0.03 µm). Inspection of the fiber size distribution indicates that the frequency of small fibers was increased whereas the frequency of large fibers remained the same. There was no detectable change in overall fiber density between these two groups, which might be due to the great variability seen in control animals.

The ability of LCN stimulation to inhibit colonic motility was evaluated in vitro by measuring propulsive contractions with an intraluminal cannula and stimulating the LCN with bipolar electrodes. In three treated rabbits (2-treatment no. 1, 1-treatment no. 2) the response to LCN stimulation was not changed.

These findings show that A-NGF treatment which does not eliminate sympathetic inhibition of the colon results in a shift of the fiber size distribution to smaller diameter categories due to an increased number of small fibers.

57.16 SODIUM DEPLETION ALTERS THE CENTRAL RESPONSE TO ANGIOTENSIN II AND NALOXONE.
Julianna E. Szilagyi and Carlos M. Ferrario, Research Division, Cleveland Clinic Foundation, Cleveland, Ohio 44106

The central actions of angiotensin II (AII) at the level of the area postrema require the participation of the opiate system in the brain (Szilagyi & Ferrario, Neurosci. Abs. 5, 51, 1979). As previously reported naloxone depressed and morphine potentiated the pressor responses to AII administered via the vertebral arteries; those to intravenous infusions of the peptide were unaffected. The intricacies of this interrelationship between AII and the opiate system are not clear as yet.

Since sodium depletion in dogs is accompanied by elevated levels of circulating AII and a blunted pressor response to intravenously administered AII, the effects of morphine blockade on the central response to the peptide were examined. Fifteen male mongrel dogs (20-25 kg) were used. Five dogs were maintained on a normal sodium diet (40 mEq Na+/day) while the remaining 10 were placed on a low sodium diet (4 mEq Na+/day) for 21 days and given 40 mg furosemide (im) for 2 days prior to the experiment. All dogs were anesthetized with α-chloralose (66 mg/kg iv) after premedication with morphine (2 mg/kg im). Angiotensin II (1-20 ng/kg/min) was infused intravenously and via the vertebral arteries before and again after injection of the morphine antagonist naloxone (0.8 mg iv) and the pressor responses recorded. Dose-response curves obtained in both conditions were compared.

In normal dogs, treatment with naloxone resulted in a significant parallel shift of the vertebral AII dose-response curve to the right of control. That obtained with intravenous AII was unchanged after blockade of morphine. Animals which were maintained on a sodium depleted diet not only possessed a diminished intravenous response to AII (as previously published), but also exhibited a significantly diminished response to vertebrally infused AII so that intravenously and vertebrally elicited responses were identical, a finding reported for the first time. The vertebral dose-response curve was shifted parallel and to the right of control. Introduction of naloxone in this preparation did not alter the intravenous response and only slightly shifted the vertebral dose-response curve.

The data indicate that 1) sodium depletion abolished the greater responsiveness of the area postrema to vertebrally versus intravenously infused angiotensin II and 2) the influence of the opiate system on the response appears to be diminished in the sodium depleted state.

57.17 PRESSOR RESPONSE TO NALOXONE IN HYPOTENSIVE CATS AFTER LESION OF THE CAUDAL RAPHE NUCLEI. Paul S. Blum and James A. Spath, Jr.*, (Spon: N. Moskowitz). Dept. of Physiol., Thomas Jefferson Univ., Philadelphia, PA 19107.

Anesthetized cats were subjected to a discrete lesion of the caudal raphe nuclei, spinal transection at C1, or sham-operation. These cats then were bled to a mean arterial blood pressure (MABP) of 40 mm Hg and maintained at that pressure by adjusting volume with a servo-controlled pump. After 60 minutes, the servo system was discontinued, and 2 mg/kg naloxone was administered intravenously followed by a continuous infusion of 2 $mg \cdot kg^{-1} \cdot hr^{-1}$. The peak increase in the MABP after administration of naloxone was 0.8 ± 4 mm Hg in the sham-operated group (n=6), 17 ± 5 mm Hg in the group with caudal raphe lesion (n=4) and 21.7 ± 7 mm Hg in the group with spinal cord transection (n=3). An analysis of varience showed that there was a significant difference in the mean increase in blood pressure when the sham group was compared to the two lesioned groups ($p<0.01$). There was no significant difference in the blood pressure response comparing the two types of lesions. The increase in blood pressure was transient and MABP returned to 40 mm Hg or less in all hemorrhaged cats within 30 minutes of naloxone administration, despite continued infusion of the drug. These data indicate that naloxone administration produced a significant increase in MABP after either spinal transection or lesion of the caudal raphe nuclei in hypotensive cats but not in cats with intact neural pathways. Moreover, these results suggest that endogenous opiates, in conjunction with descending neural pathways that originate in the caudal raphe nuclei, contribute to the pathophysiology of hemorrhagic hypotension. Interruption of these central pathways allows effects of opiate receptor blockade with naloxone to be manifest. Supported by HL-20283.

57.18 EFFECTS OF ETHANOL, DIAZEPAM AND PENTOBARBITAL ON RESTRAINT STRESS AND PLASMA CATECHOLAMINES IN RATS. Kathryn H. DeTurck* and Wolfgang H. Vogel, Dept. Pharmacol., Thomas Jefferson Univ., Philadelphia, PA 19107.

Groups of 4-6 male Wistar rats, fitted with indwelling jugular catheters, were given ip injections of ethanol (500 mg/kg), valium (5 mg/kg) and pentobarbital (5 mg/kg), and were allowed to rest 15, 30 and 10 min, respectively. About half of the animals remained in the home cage as controls, while the others were then subjected to 30 minutes of immobilization. Blood samples were taken from both groups at 0 min (before restraint), at 1, 5, 15 and 30 min during restraint and at 60 min (30 min after release from restraint). Plasma norepinephrine (NE) and epinephrine (E) were determined by the radioenzymatic assay from Upjohn.

The ip injections of the 3 drugs had no significant effect on baseline NE and E concentrations, as first measured after a sufficient rest period to allow for absorption. However, when the treated rats were then taped to the workbench, the substantial elevations in plasma NE and E, characteristic of such extreme stress, were considerably reduced. Analysis of area under the curve data showed a significant ($p < 0.01$) reduction in both NE and E increases with prior administration of ethanol. These animals demonstrated less struggling and tape biting than the untreated controls, although their amount of vocalization was increased. Diazepam also caused a decrease ($p < 0.01$) in plasma NE levels, but had no significant effect on increased E levels. This corresponded with a marked decrease in all outward signs of distress, including struggling, tape biting and vocalization. The administered dose of pentobarbital had no significant effect on either NE or E increases, although peak values for both were somewhat decreased. The rats appeared as agitated as the control animals, with the incidence of tape biting somewhat increased.

57.19 ALCOHOL, DIAZEPAM, AND MORPHINE SULFATE REDUCES BOMBESIN-INDUCED ELEVATION OF GASTRIC PRESSURE AND MOTILITY IN THE RAT. W. G. Young. Dept. of Neurosciences, University of California, San Diego, La Jolla, California 92093.

Bombesin (BBS) increases gastric pressure (GP) and motility (M) in the awake rat. 9 rats, Sprague-Dawley males (300-400 g), were surgically implanted with indwelling catheters (Dow Corning Silastic tubing #602-305)(See: Deutsch, J. A. and H. S. Koopmans. Science, 179:1242, 1973) and their gastric activity was monitored by a pressure transducer. All rats demonstrated elevated GP and M when injected intraperitoneally (IP) with 2 - 16 µg/kg of synthetic BBS. The effects lasted for several hours and were significantly distinct from pre-injection resting waveforms. The BBS activity consisted of a sharp rise in GP from the resting level to 8 - 10 cm of water pressure higher after injection. This was followed by greatly enhanced contractions in M with amplitudes ranging from 36 - 40 cm of water and a frequency of about 4 per minute. Injections of the vehicle could not elicit this activity. Alcohol at 0.25 g/kg (IP) was able to reduce the BBS effects on GP and M. Morphine sulfate at 10 mg/kg (IP) had similar effects to alcohol. Diazepam (Valium, Roche Laboratories) at 5 mg/kg completely inhibited both BBS-induced GP and M. Lower doses of diazepam down to 250 µg/kg blocked the effects only partially, and a good dose-response was not obtained. BBS effects on GP and M could not be blocked with the anticholinergic methscopolamine (Pamine bromide, Upjohn Company) at 1.6 mg/kg. The present study does not determine whether these effects result from central or peripheral actions.

This research was funded by NSF grant BNS 78-01605 awarded to J. A. Deutsch, Psychology Department, UCSD, La Jolla, CA 92093. W. G. Y. is a trainee on NIAAA grant AA07129-01.

57.20 CLONIDINE-ADENYLATE CYCLASE INTERACTIONS IN SYMPATHETIC PREGANGLIONIC NEURONS. Donald N. Franz*, Robert G. Peterson*, and Parley W. Madsen*. (SPON: S.S. Stensaas). Dept. Pharmacology, Univ. Utah, Salt Lake City, Utah 84132.

Previous studies indicate that bulbospinal norepinephrine (NE) pathways to sympathetic preganglionic neurons (SPGNs) are excitatory (Life Sci. 14: 793, 1974; Psychopharmacology 62: 9, 1979). Other studies show that clonidine depresses activation of SPGNs by both segmental and bulbospinal pathways; this depression is selective, independent of central monoamine stores, and readily reversible to tolazoline (Clin. Exp. Hypertension 1: 115, 1978). Recent evidence that alpha$_2$-receptor activation by clonidine in some cellular systems suppresses adenylate cyclase (D. U'Prichard, Clonidine Symposium, FASEB, 1980) prompted the present analysis of possible interactions between clonidine and adenylate cyclase in SPGNs.

In unanesthetized, spinal cats, sympathetic discharges recorded from upper thoracic preganglionic rami were evoked by stimulating intraspinal (IS) excitatory pathways in the cervical cord or segmental spinal reflex (SR) pathways. Aminophylline (10-50 mg/kg) or isobutyl-methylxanthine (IBMX, 0.5-2 mg/kg) rapidly and markedly enhanced transmission through the IS pathways, the largest doses to averages of 175% and 240% of control values, respectively, within 10 min. Enhancement and rate of onset were dose-dependent. Spinal sympathetic reflexes (SR) were gradually enhanced after a delay of 20-30 min. Spinal somatic reflexes were not affected. These results suggest that cyclic AMP increases excitability of SPGNs in response to activation of adenylate cyclase by bulbospinal pathways. Preservation of basal levels of cyclic AMP may account for enhancement of SR.

Clonidine HCl (10-50 µg/kg) markedly depressed transmission through both pathways with the IS pathway being 5X more sensitive than the SR. The IS pathway could be depressed completely, but the SR pathway could not be depressed beyond 60%, even by much larger doses. Clonidine pretreatment prevented or markedly reduced the enhancement of transmission through either pathway by aminophylline or IBMX, depending on dose. The results suggest that adenylate cyclase activity in SPGNs is regulated by positively and negatively coupled receptors and support the proposal that clonidine inhibits SPGNs by activation of the negatively coupled receptors. (Supported by NIH grants HL-24085 and GM-07579 and the Montana Heart Association.)

57.21 CONTRASTING EFFECTS OF CLONIDINE AND 5-HTP ON SPINAL SYMPATHETIC PATHWAYS. Parley W. Madsen*, Bradford D. Hare*, Chaichan Sangdee*, and Donald N. Franz*. (SPON: L.M. Partlow). Dept. Pharmacology, Univ. Utah, Salt Lake City, Utah 84132.

Although the antihypertensive effect of clonidine is generally ascribed to actions on brainstem cardiovascular centers, we have found that it produces marked depressant effects on spinal sympathetic neurons (Clin. Exp. Hypertension, 1: 115, 1978) which are at least equal to that on higher centers (Fed. Proc., 39: 409, 1980). Similarities between the depressant effects of clonidine and 5-HT precursors on spinal sympathetic pathways originally suggested that clonidine might act on inhibitory 5-HT receptors. The weight of contrary evidence prompted further analysis of these similarities.

In unanesthetized, spinal cats, the effects of clonidine were compared with those of 5-HTP on transmission through two spinal sympathetic pathways, segmental spinal reflex (SR) pathways and descending intraspinal (IS) excitatory pathways. Evoked sympathetic discharges were recorded from upper thoracic preganglionic rami and were analyzed on-line by signal averaging.

Clonidine HCl (5-50 μg/kg) produced a parallel, dose-dependent depression of transmission through each pathway. However, the IS pathway was 5 times more sensitive to clonidine (ED50 = 6 μg/kg) than the SR pathway (ED50 = 30 μg/kg). Furthermore, whereas 50 μg/kg of clonidine depressed transmission in the IS pathway by nearly 100%, the SR pathway could not be depressed more than 60% by doses of 50-200 μg/kg. In contrast, D,L-5HTP was more effective in depressing the SR pathway than the IS pathway (ED50's = 32 and 44 mg/kg, respectively), 50 mg/kg depressing the SR by almost 100% and the IS by only 60%. Tolazine rapidly reversed the effects of clonidine on both pathways in a dose ratio of about 100:1; reversal of 5-HTP-induced depression by larger doses was slow and inconsistent. These contrasting results indicate that clonidine and 5-HTP depress the excitability of sympathetic preganglionic neurons by different mechanisms, probably involving alpha$_2$- and 5-HT receptors, respectively. Each mechanism may contribute independently to regulation of the sympathetic outflow. (Supported by NIH grants HL-24085 and GM-07579.)

57.22 **EFFECTS OF CLONIDINE ON SPONTANEOUS ACTIVITY IN A SYMPATHETIC-CHOLINERGIC SYSTEM.** Patricia J. Bernthal* and Michael C. Koss (SPON: J. I. Moore). Dept. of Pharmacology, Univ. of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma 73190.

Because of its sympathetic-cholinergic nature, we have used the electrodermal response (EDR) of the sudomotor system as a model for studying the effects of pharmacologic agents on central sympathetic outflow (Davison & Koss, Neuropharmacology, 1976, 15:197-201; Koss & Davison, Naunyn-Schmied. Arch. Pharmacol. 1976, 295:153-158). Clonidine, which is considered to inhibit tonic sympathetic activity by a central action (Haeusler, Naunyn-Schmied. Arch. Pharmacol. 1973, 278:231-246) depresses the amplitude of centrally, peripherally, or reflexly evoked EDRs, an action which is reversed or prevented by yohimbine (Koss & Davison, Eur. J. Pharmacol.,1976, 37:71-78; Bernthal & Koss, Eur. J. Pharmacol., 1979, 60:23-29). In the present study we compared the effects of clonidine and yohimbine on spontaneous EDR activity in the unanesthetized cat with those previously observed using evoked EDRs in an effort to see if earlier findings could be verified using tonic sympathetic activity.

Because spontaneous electrodermal activity is so irregular and difficult to quantify, the electrical potentials were processed over 60-sec periods through an integrator (Grass 7P10B). Cats were decerebrated under ether as previously described (Bernthal & Koss, Brain Res. Bull., 1978, 3, 437-441), and allowed to recover for approximately 90 min before any pharmacologic manipulations were begun. Some cats were subsequently spinalized at the cerivcal level (C_1). The amplitude of spontaneous EDR activity in the unanesthetized decerebrate preparation was diminished by less than 10% over a three-hour period. Clonidine (3 or 10 ug/kg, iv) rapidly depressed the amplitude of spontaneous EDR responses in unanesthetized decerebrate or decerebrate-spinal preparations, exerting a maximal effect in less than five min. Spontaneous EDR activity was depressed by approximately 50% for the 90 min observation period. Subsequent administration of yohimbine (0.5 mg/kg, iv) reversed the clonidine-induced inhibition, while prior administration of yohimbine prevented clonidine's effect. Administration of yohimbine potentiated the amplitude of spontaneous EDR activity in the unanesthetized decerebrate preparation, but not in spinalized cats. These preliminary results indicate that the effects of clonidine on spontaneous EDRs are analagous to those observed in the tonic activity of other sympathetic systems. In addition, this study provides further evidence for a spinal cord site of action for clonidine.

57.23 PARTICIPATION OF ADRENOCEPTORS IN THE MEDIAL MEDULLARY RETICULAR FORMATION IN CLONIDINE-INDUCED HYPOTENSION AND BRADYCARDIA. Yih-Huey Chen and Samuel H.H. Chan. Department of Life Sciences, Indiana State University, Terre Haute, IN 47809.

One of the proposed antihypertensive mechanisms for clonidine suggests that the imidazoline compound activates postsynaptic α-adrenoceptors located in the medulla oblongata. Previous experiments from our laboratory implicated the medial medullary reticular formation (MMRF) in rats and cats as a possible site for clonidine to exert hypotension and bradycardia (Chan and Koo, Neuropharmacol. 17:367, 1978; Chen and Chan, Neuropharmacol. in press). The present study was undertaken to further investigate the possible participation of α-adrenoceptors in the MMRF in clonidine-elicited cardiovascular suppressions.

Male Charles River rats anesthetized with pentobarbital sodium (50 mg/kg, i.p.) were used. Tracheotomy and cannulation of the left femoral artery and vein were routinely performed to facilitate ventilation, measure arterial blood pressure and heart rate, and inject drugs. Microinjection of adrenoceptor blocking agents into bilateral MMRF (1 µl in vol.) was delivered via a stereotaxically positioned 27-gauge syringe needle attached to a microinjection device. The effect of such pretreatment on the action of an intravenous administration of clonidine (10 µg/kg) was studied 30 min later.

Microinjection of phentolamine (40 µg) into bilateral MMRF appreciably blocked the hypotensive effect of clonidine, together with a significant reduction in its cardioinhibitory action. In contrast, the vasodepression produced by clonidine was not discernibly antagonized by phenoxybenzamine (50 µg), although there was a significant decrease in its elicited bradycardia. Pretreatment of the MMRF with propranolol (70 µg) did not prevent the clonidine-induced hypotension. There was, however, also a significant reduction in the clonidine-promoted cardioinhibition.

Phentolamine is an equally potent blocker for both presynaptic and postsynaptic α-adrenoceptors, phenoxybenzamine is a preferential postsynaptic α-adrenoceptor antagonist, and propranolol is a β-adrenoceptor blocking agent. Thus, the differential antagonistic effect of phentolamine, phenoxybenzamine and propranolol on clonidine-induced vasodepression may implicate that the availablity of presynaptic α-adrenoceptors in the MMRF is essential for the promotion of hypotension by clonidine. At the same time, the presence of presynaptic and postsynaptic α-adrenoceptors and β-adrenoceptors in the MMRF may be required for the imidazoline compound to exert its bradycardiac actions.

(Supported in part by the American Heart Association, Indiana Affiliate).

57.24 **ERYTHROCYTES: IN VIVO SITE OF CATECHOLAMINE TRANSPORT AND METABOLISM IN MAN & RAT.** **N. Alexander, M.T. Velasquez* and N.D. Vlachakis*. Clin. Pharm. Sect., Dept. of Med., Sch. of Med., Los Angeles, CA 90033**

Weil-Malherbe & Bone (1953) showed with flourometric assays that human blood cells contain norepinephrine (NE) and epinephrine (E). Blakeley & Nicol (1978) found that in vitro rabbit erythrocytes take up ^{3}H-NE and that its 0-methylated metabolite,^{3}H-normetanephrine (NM), accumulated inside cells within 5 minutes. We have measured, by radioenzymatic, thin-layer chromatographic methods, the concentration of NE, E, dopamine (DA), NM and octopamine (OA) in plasma and red blood cell (RBC) lysate of normal human subjects and rats. Mean ± SEM values for plasma (pg/ml) vs. RBC lysate (pg/gm of packed rbc) in 7 seated male subjects were: NE, 426±53 vs 436±51; E, 59±5 vs 164±32 ($p<.01$); DA, 87±11 vs 146±46; NM, 1725±239 vs 4070±690 ($p<.01$) and OA, 2090±340 vs 13500±1280 ($p<.001$). The NM/NE ratio in plasma vs the ratio in lysate was 4.2±.067 vs 9.4±1.1 ($p<.001$). Values for plasma vs RBC lysate from 12 rats in home cages were: NE, 463±56 vs 663±79 ($p<.05$); E, 320±79 vs 550±134; DA, 322±83 vs 1528±406 ($p<.01$); NM, 940±158 vs 3510±560 ($p<.001$); OA, 532±83 vs 3710±410 ($p<.001$). After 5 minutes of restraint, plasma NE, E, NM and OA increased significantly whereas only NE increased significantly in lysate. The NM/NE ratio in plasma and lysate from rats in home cages was 2.3±0.5 vs 5.5±0.9 ($p<.005$), respectively. These ratios were similar in the samples collected during restraint. These results show that both human and rat erythrocytes contain NE,E, DA, NM and OA in concentrations similar to or higher than those of plasma implicating erythrocytes as a functionally significant site of transport for,circulating catecholamines. Since erythrocytes also contain catechol-0-methyltransferase (COMT), the higher NM/NE ratio found in RBC lysate suggests that some NM may have been formed from NE inside red cells.

58.1 FACILITATION OF PASSIVE AVOIDANCE BEHAVIOR BY POST-TRIAL ADMINISTRATION OF NALOXONE AND ETHANOL IN MICE. E.G. Zimmermann, D.A. Gorelick and D.L. Colbern*. Depts. of Neuroscience, Psychiatry, Pharmacology and Anatomy, UCLA School of Medicine, Los Angeles, CA 90024.

Post-trial administration of ethanol (ETOH) was recently observed to facilitate retention of passive avoidance behavior in mice. Since the opiate antagonist, naloxone (NAL), has been shown to interfere with certain effects of ETOH, its effect on ETOH-facilitated avoidance behavior was examined.

Adult male Swiss-Webster mice were subjected to a one-trial, step-through passive avoidance task using a shock intensity of 0.1 mA. Immediately following the training trial, 15% ETOH (2g/kg) or saline was injected ip along with either NAL (1, 2 or 5 mg/kg) or saline. NAL alone at all dose levels, like ETOH, produced maximum facilitation of avoidance behavior (approx. 300 sec) when tested 24 hr later. Similarly, NAL plus ETOH resulted in maximum or near maximum improvement in retention at all dose levels. The conditions of the experiment precluded detection of any possible additive effects.

To explore possible additive effects of NAL and ETOH, the doses of NAL were halved. In view of NAL's short duration of action and the uncertain time-course of facilitation, the dose of NAL was repeated 30 min post-trial. Administered in this fashion, NAL again caused marked improvement in avoidance behavior except for the 1 mg/kg dose. NAL plus ETOH also caused near maximal facilitation although the highest dose of NAL attenuated the effect of ETOH ($p < 0.05$).

These results show that post-trial administration of NAL, facilitates retention of passive avoidance behavior, in agreement with a recent report by Messing, et al. (Behav. & Neural Biol. 27:266, 1079). This paradigm failed to detect any antagonism of ETOH effects by NAL except possibly at the highest dose level. The results obtained using two injections suggest that dose and duration of NAL are important variables in determining the extent to which avoidance behavior is facilitated. Further studies are underway to determine the mechanism(s) by which NAL and ETOH improve performance in this task.

58.2 EFFECTS OF ACUTE AND CHRONIC ETHANOL TREATMENT ON HABITUATION OF THE DR-VR REFLEX IN ISOLATED FROG SPINAL CORD. P. C. RINALDI,* L. Y. NISHIMURA* and R. F. THOMPSON (SPON: R. Messing). Dept. Psychobiology, Univ. of California, Irvine, California 92717.

The effects of ETOH on synaptic plasticity have been examined in very few instances. The isolated frog spinal cord preparation provides the opportunity to examine ETOH effects on habituation in a model system and to determine the particular synaptic mechanisms disrupted by it. Isolated hemisected spinal cords of Rana catesbiana were continuously perfused in buffered Ringers and maintained at 15°C±1. A dorsal and ventral root were draped across electrodes for stimulating and recording respectively. The reflex itself was found to be facilitated at low levels and depressed at the high levels of ETOH. Habituation--decrement of the polysynaptic ventral root response to repeated dorsal root stimulation --and recovery were assessed during controls in normal Ringers. Following this, ETOH was added to the perfusate and habituation repeated at varying time intervals. ETOH concentrations ranged from .025% (20mg/100ml) to 0.5% (400mg/100ml). Similar experiments were conducted with spinal cords from chronically treated frogs. These frogs were maintained for one to two weeks in their home environment with ETOH added to their living water. Frogs maintained thus had blood alcohol levels ranging from 30 to 400mg per 100ml, depending on ETOH concentration in the home water. In general, the degree of habituation appears to be reduced at most ETOH concentrations with some suggestion of biphasic effects at lower concentrations.

58.3 MODULATION OF MEMORY STORAGE BY OPIATE AGONISTS AND ANTAGONISTS. R.A. Jensen, R.B. Messing, B.J. Vasquez, J.L. Martinez, Jr., K.C. Liang*, C.B. Brewton* and J.L. McGaugh. Department of Psychobiology, University of California at Irvine, Irvine, CA 92717.

Previous research has shown that both naloxone and morphine influence memory storage processes. In these experiments, rats were trained in a one-trial inhibitory avoidance step-through task. They were shocked (0.50 or 0.75 mA; 0.5 sec) upon entering a dark compartment, and injected with drugs following the training trial. Retention was measured one day after training by obtaining the latency of each rat to reenter the dark compartment. Naloxone facilitates retention performance of rats in this task if it is peripherally administered (i.p.) after training, while morphine has amnestic effects. These results are dependent both upon schedule of drug administration and dose. Naloxone enhanced memory when administered in equally divided doses (totaling 1 mg/kg) immediately after training and again 30 min later. Morphine, on the other hand, produced memory impairment when given in a single injection (3 mg/kg) immediately after training.

We now report data indicating that the injection schedule is an important determinant of the direction of the effect of both opiate agonists and antagonists. Both naloxone (1 mg/kg) and naltrexone (0.3 mg/kg) facilitate retention performance when given in divided doses, but an impairment in performance results when naloxone is injected in a single dose 30 min following training. Moreover, if morphine (1 mg/kg) is administered in divided doses immediately and 30 min after training, it enhances retention performance in a manner similar to naloxone and naltrexone, but in contrast to its amnestic effect when it is injected in one dose immediately after training. Thus, if morphine and naloxone are given in single doses, their memory modulatory effects are different from each other; if however, morphine, naloxone, or naltrexone are given in divided doses 30 min apart, then all of the drugs enhance memory. It is therefore apparent that opiate modulation of memory storage processes is dependent upon subtle differences in drug distribution and availability through time.

58.4 THE ROLE OF OPIOID PEPTIDES IN MEMORY AND LEARNING. I. Izquierdo, D.O. Souza*, R.D. Dias*, M.L. Perry*, M. A. Carrasco*, E. Elisabetsky*, A.C. Paiva*, Dept.Bioquímica, UFRGS centro, 90000 Porto Alegre, RS, Brasil.

Beta endorphin, leu-, met-, and des-Tyr-met-enkephalin (1-10 µg/Kg ip., post-training) cause amnesia for shuttle avoidance learning and for habituation of a rearing response to a tone in rats. Naloxone (0.4-0.8 mg/Kg) has an opposite effect of its own, and antagonizes that of the opiates. At least one opioid peptide, beta-endorphin, is released from the rat brain at a rate of 30-50 ng/25 min during training (but not test) sessions of the two tasks. The release appears to result from non-associative influences of the stimuli used for training, since it is also obtained after sessions of pseudoconditioning or of footshocks alone. The amount released is compatible with the amnesic ED50 of the substance (1 µg/Kg ≅ 140 ng/rat, of which <20% reaches the brain within 120 min from injection).

These findings suggest that there is a physiologic amnesic mechanism mediated by beta-endorphin and, perhaps, by other opioid peptides as well.

In addition, shuttle avoidance and habituation learning appear to be dependent on a state caused by the beta-endorphin that is released, and this appears to normally be released in sufficient amount for that purpose. Naloxone (0.4-1.6 mg/Kg, ip.) given prior to training depresses acquisition of both tasks; beta-endorphin (2 µg/Kg) has no effect. When given prior to test sessions (in which there is no release of the peptide), naloxone has no effect, and beta-endorphin enhances retrieval. These effects occur independently of the influences of both drugs on consolidation. However, it seems possible that the state-dependency may be due to amnesic effects of beta-endorphin on adventitious and interfering forms of learning.

The role of opiates in learning and memory might be more important than, and is independent of, any that they may have in the modulation of pain. First, amnesic ED50s are 100 times lower than analgesic ED50s of opioid peptides; second, their effects on learning and memory are independent of pain; third, beta-endorphin is released both by painful and painless stimuli.

58.5 EFFECTS OF OPIATE ADMINISTRATION INTO THE AMYGDALA ON PAVLOVIAN HEART RATE CONDITIONING IN THE RABBIT. M. Gallagher, B. S. Kapp, C. L. McNall,* and J. P. Pascoe.* Dept. Psychol., Univ. of Vermont, Burlington, VT 05405.

Previous research conducted in our laboratory has demonstrated that neural systems within the central nucleus region of the amygdala contribute to the acquisition of classically conditioned heart rate responding in the rabbit (Kapp et al., Physiol. Behav., 23, 1109-1117, 1979; Gallagher et al., Pharmac. Biochem. Behav., in press.) Since opioid peptides are highly concentrated within the central nucleus, the present investigation was aimed at determining the effects of intracranial opiate administration into the central nucleus on the acquisition of conditioned heart rate responding in the rabbit. New Zealand rabbits were surgically prepared with cannulae positioned at the dorsal surface of the central nucleus. Two weeks following surgery all animals were trained using a standard Pavlovian conditioning procedure. Drug injections were delivered bilaterally in a 1.0 µl volume immediately prior to the conditioning session.

Compared to unoperated and vehicle injected control groups, central nucleus administration of the opiate agonist levorphanol (5.0 nmole) significantly impaired, whereas naloxone administration (2.5 nmole) significantly facilitated the acquisition of conditioned heart rate responding. These effects of opiate administration occurred in the absence of any significant drug effects on either baseline heart rate or on the decelerative heart rate orienting response. The effects of opiates on conditioned heart rate responding appear to be mediated by opiate receptor mechanisms because the effect obtained with levorphanol exhibited stereospecificity. Finally, data obtained from animals with cannula placements at sites around the central nucleus support the interpretation that the effects of opiates on heart rate conditioning are due to changes in opiate activity within the central nucleus region.

Recent neuroanatomical investigations have identified that the central nucleus possesses reciprocal connections with cardiovascular regulatory systems in the medulla. A role for opioid peptides in regulating these projection systems is suggested by the presence of high concentrations of opioid peptides within both the central nucleus and these medullary regions, including the nucleus solitarius and dorsal motor nucleus of the vagus. Our results support a function for an opiate sensitive system within the central nucleus of the amygdala in cardiovascular responding during Pavlovian conditioning. These results are also consistent with our earlier observations implicating an amygdala opioid peptide system in learning and memory processes (Gallagher & Kapp, Life Sci., 23, 1973-1978, 1978).

58.6 CENTRAL SCOPOLAMINE ADMINISTRATION DIFFERENTIALLY AFFECTS THE CARDIAC COMPONENT OF THE ORIENTING REFLEX AND PAVLOVIAN CONDITIONING. D. A. Powell, Shirley Buchanan, and Linda Hernandez, Neuroscience Laboratory, Wm. Jennings Bryan Dorn Veterans' Hospital, and the University of South Carolina., Columbia, South Carolina 29201

Previous experiments demonstrated that lesions which destroyed the lateral septal nucleus or dorsal hippocampus produced exaggerated Pavlovian conditioned heart rate (HR) responses in rabbits, whereas lesions of midline neocortex and ventral hippocampus attentuated conditioned HR changes. In the present experiments, these findings were extended by the intracerebral administration of the cholinergic antagonist scopolamine into these areas.

New Zealand albino rabbits were prepared with bilateral guide cannulas implanted in the (a) dorsal hippocampus, (b) lateral septum, (c) lateral ventricles, (d) caudate neucleus, or (e) neocortex overlying the septum and hippocampus. The animals were allowed to recover from surgery for one week; at this time orienting was assessed by the presentation of 20 unpaired tones (1216 Hz, 75 dB SPL, 4 sec. duration) with an intertrial interval of 45 sec. Three days later classical conditioning began. The first three days of conditioning were drug free to allow the HR CR to stabilize; three days of drug testing followed. During all 6 sessions, two tones (1216 Hz and 304 Hz/75 dB SPL, 4 sec. duration), were employed as CS+ or CS-. The CS+ was consistently paired with a paraorbital 3 mA, .5 sec., AC shock, while CS- was never paired with shock. Twenty CS+ and 20 CS- trials were randomly administered during each session with a 45 second ITI. During both orienting and conditioning, baseline HR occurring prior to the tones was compared with the HR change occurring during and after the tone in one second blocks. Prior to the beginning of the drug sessions half of the animals in each group received central injections of artificial CSF, while the remaining Ss received one of three doses, scopolamine hydrochloride dissolved in CSF solution administered in a counter balanced order over three days. These doses included 20, 40, or 80 micrograms per 1.0 µliter injection administered bilaterally over a 6 min period. The injections were made immediately prior to the beginning of an experimental session with a microburet connected to an internal cannula which was left in place for a 2 min period following the injection.

The results showed that the magnitude of the initial HR response during orienting was increased dramatically in animals in which scopolamine was injected into the dorsal hippocampus, or septum compared to control Ss with vehicle injections or Ss with scopolamine injections in cortex, caudate nucleus or ventricles. Although HR habituation was normal in drugged septal animals, it was somewhat attenuated in animals with hippocampal injections. Scopolamine attenuated the magnitude of the HR CR in septal and ventricular injected Ss compared to hippocampal injected and control Ss. The HR discrimination was abolished in ventricular injected Ss but not in the septal and hippocampal injected Ss, compared to control Ss. These findings suggest a differential effect of central cholinergic systems on the cardiac component of the orienting reflex and the cardiac component of the Pavlovian conditioned response.

58.7 SCOPOLAMINE MICROINJECTIONS INTO THE CAUDATE NUCLEUS AND INSTRUMENTAL CONDITIONING. DOSE-RESPONSE INTERACTIONS. M.P. Valle* and R.A. Prado-Alcala (SPON : J.A. Roig). Psychophysiol. Lab. Anahuac Univ. and Physiol. Dept., Natl. Univ. of Mexico, Mexico 20, D.F., Mexico.

Microinjections of cholinomimetic drugs or of anticholinergic drugs into the caudate nucleus (CN) produce improvement or impairment, respectively, of both acquisition and performance of instrumental conditioning. However, learning studies on the effects of different doses of these agents, applied to the CN, have only been done with respect to avoidance tasks.

In the present study, independent groups of Wistar rats were trained to press a lever in order to be rewarded with water (continuous reinforcement schedule), and then tested on their performance under the effects of one of several doses of scopolamine (0, 10, 15 or 30 µg), dissolved in isotonic saline, and microinjected 6 min before testing into the dorsal aspect of the anterior CN. Two control groups were also studied: non-injected and microinjected with 30 µg of scopolamine into the parietal cortex.

A highly reliable treatment effect was found. There were no significant differences between the non-injected, cortical, 0 µg and 10 µg groups. In turn, each of these groups differed from the 15 µg and 30 µg groups. As expected, a significant correlation between doses and degree of performance impairment was also found.

These data further support the notion that cholinergic activity of the caudate nucleus plays a critical role in the maintenance of instrumental performance.

A fellowship to R.A. Prado-Alcala from CONACYT-MEXICO is gratefully acknowledged.

58.8 DIFFERENT NEUROTRANSMITTER SYSTEMS OF THE AMYGDALA MEDIATE TASTE AVERSION LEARNING, RECOVERY FROM NEOPHOBIA, AND PASSIVE AVOIDANCE. M. E. Ellis* and R. P. Kesner. Dept. of Psychol., Univ. of Utah, Salt Lake City, Utah, 84112.

Many studies have implicated the limbic system, particularly the amygdala, as an important neurosubstrate for the processing of information concerning novel tastes, food toxicosis, and avoidance behavior in general. Recent research has suggested that dose-related, time-dependent pharmacological manipulations of either of two specific neurotransmitter systems of the amygdala, acetylcholine (Todd and Kesner, JCPP, 92, 1978) and norepinephrine (Ellis and Kesner, Neurosci. Absts., 4, 1978), results in retention deficits for passive avoidance training. In separate experiments the possible involvement of the cholinergic and noradrenergic systems of the amygdala in taste aversion learning and in recovery from neophobia was investigated. After adaptation to a 23 3/4 hr water deprivation schedule rats in the recovery from neophobia experiment were presented with only grape juice for a 15 min period followed 30 min later with a bilateral injection of 1 µg/µl of norepinephrine (NE) 10 µg/µl of physostigmine (PHY, an anticholinesterase) or 1 µl of special buffered saline (SBS) via stainless steel cannulas chronically implanted into the amygdala. An additional group received 1 µg NE at a 3 hr post-grape juice delay. Rats in the taste aversion experiment were presented with grape juice followed 30 min later by an injection of apomorphine (15 mg/kg, i.p.). At the onset of apomorphine-induced illness symptoms (about 5 min), the animals received a bilateral injection of 1 or 10 µg NE, 10 µg PHY or SBS via cannulas directly into the amygdala. An additional group was given 10 µg PHY at a 12 hr post-illness delay. All rats were offered grape juice again 72 hr (Test 2) following the initial taste experience (Test 1).

Recovery from neophobia was indexed by increased consumption on Test 2 compared to Test 1. In the recovery from neophobia experiment, the NE group did not increase consumption on Test 2 compared to the NE delay, PHY, or SBS groups. Taste aversion was indexed by decreased consumption of grape juice during Test 2 compared to Test 1. In the taste aversion experiment, the PHY-group did not decrease consumption on Test 2 compared to the PHY delay, NE, or SBS groups. Hence, while both the noradrenergic and cholinergic systems may be involved in passive avoidance behavior, acetylcholine appears to mediate taste aversion, but not recovery from neophobia; norepinephrine subserves processes associated with recovery from neophobia, but not taste aversion.

58.9 MICROINJECTIONS OF D-AMPHETAMINE IN THE NUCLEUS ACCUMBENS DISRUPT THE RAT'S ABILITY TO LEARN TO IGNORE AN IRRELEVANT STIMULUS. D.M. Staton* and P. R. Solomon* (SPON: R. Nixon). Dept. of Psychology, Williams College, Williamstown, MA 01267.

One of the most direct paradigms to measure an animal's ability to ignore an irrelevant stimulus is that of latent inhibition. Latent inhibition (LI) refers to the finding that nonreinforced preexposure to a stimulus retards conditioning to that stimulus when it is subsequently paired with a reinforcing or punishing event. Data from a variety of preparations indicate that this retardation of conditioning is due to the animal learning to ignore the preexposed stimulus since it does not signal a motivationally significant event.

In the present study we investigated the effects of repeated microinjections of d-amphetamine (d-amp) into either the nucleus accumbens (NA) or the caudate-putamen (CPU) on LI in the rat. We also examined the drug's effects on stereotypy and locomotor activity. Rats received 5 daily bilateral microinjections of .5µl (20µg/µl) of d-amp or the equivalent amount of saline. Half the animals in each condition received d-amp in the NA and the remaining half received the drug in the CPU. Ten minutes after the injection on Days 1 and 3, each animal was observed for a 32 minute period during which time locomotor activity and stereotypy were monitored. In agreement with previous studies, we found that d-amp in the NA increased locomotor activity while having no effect on stereotypy whereas d-amp in the CPU increased stereotypy but had no effect on locomotor activity. Saline injections had no effect on either behavior.

Testing for latent inhibition took place in a two-way avoidance paradigm immediately following the microinjection on Day 5. In Stage 1, half the animals in each of the four treatment conditions (d-amp-NA, d-amp-CPU, Sal-NA, Sal-CPU) were placed in the avoidance apparatus and received 30 tone-alone presentations. The remaining animals explored the apparatus for a corresponding amount of time. Stage 2 consisted of acquisition of the conditioned avoidance response during which the tone signaled the onset of the footshock. The results indicated that animals in both saline conditions and animals in Group d-amp-CPU demonstrated the LI effect with rats in the 30 preexposure group conditioning significantly slower than 0 preexposed controls. Animals in the d-amp-NA group, however, showed no such effect. Preexposed animals conditioned at about the same rate as nonpreexposed controls. Microinjection of d-amp in the NA but not the CPU disrupted the animal's ability to learn to ignore the irrelevant tone in Stage 1. The results are consistent with an accumulating body of literature implicating the mesolimbic system in learning to ignore irrelevant stimuli. (Supported by NIMH Grant MH-33381-01 and NSF Grant BNS 77-14871.)

58.10 APOMORPHINE REVERSES LEARNING DEFICITS IN DOPAMINE DEPLETED RAT PUPS. R. S. Wool*, D. A. Weldon, M. H. Teicher and B. A. Shaywitz. Dept. of Psychology, Hamilton College, Clinton, NY 13323 and Dept. of Ped. and Neuro., Yale Univ. Sch. Med., New Haven, CT 06510.

Neonatal rat pups that are dopamine depleted show a syndrome of transient hyperactivity and of learning deficits in both aversive and appetitive tasks. These results indicate that brain dopamine depletion is a useful model for childhood Attention Deficit Disorder (ADD). The purpose of this study was to examine the effects of the dopamine receptor agonist apomorphine on learning performance of dopamine depleted rats.

Dopamine depletion was produced by administration of desmethylimipramine (20 mg/kg, i.p.) followed by intracisternal 6-OHDA (.1 µg in 20 µL of saline) to 5 day old Long Evans rats. At 6 days of age dopamine depleted and control rats were anesthetized with ether and fitted with intratongue cannulae (Hall, Science, 1979, 205, 206). One day later animals were conditioned to presentation of licorice odor paired with intraoral Enfamil for 20 sec at each of 5 1-min conditioning cycles. On the next day, animals were tested in a rectangular apparatus with a wire screen floor; licorice extract was placed under one half of the apparatus. Learning of the classically conditioned association was measured by the percentage of a 5 min test period spent over the conditioned stimulus (not counting time spent straddling the border of the two halves of the apparatus). Prior to conditioning and testing, animals were injected with either apomorphine (.5 mg/kg, s.c.) or an equal volume of vehicle (saline).

In animals that received saline prior to both conditioning and testing, control pups spent 83% of their time over the conditioned stimulus compared to performance of only 36% by dopamine depleted animals. In control animals, apomorphine administration prior to training, testing, or both phases produced reductions in the amount of time spent over the licorice side. In dopamine depleted animals, conditioned performance was greater for pups receiving apomorphine prior to conditioning in comparison to those pups receiving saline ($\bar{X}_{Ap}$ = 63%, $\bar{X}_{Sal}$ = 35%). Apomorphine administration prior to testing did not affect performance.

These results show that the learning deficits produced by dopamine depletion can be reversed by a manipulation increasing dopamine receptor activity prior to conditioning. In addition, they demonstrate that the effects of dopamine depletion in rat pups can be generalized to a different strain of rat (Long Evans) than had been studied previously (Sprague-Dawley).

58.11 AMNESIA IS INDUCED IN CHICKS BY CERTAIN PROLINE OLIGOPEPTIDES. Joel L. Davis and Arthur Cherkin. Psychobiology Research Laboratory and GRECC, VA Medical Center, Sepulveda, CA 91343.

During a structure-function study of the amnestic potency of L-proline (L-PRO) we found L-prolyl-L-proline (L-PRO-L-PRO) to be even more potent (Van Harreveld, Cherkin and Davis, Pharm. Biochem. Behav., in press). We therefore started a systematic study of small proline peptides (see Table). We report here the amnestic properties of L-PRO-L-PRO and L-prolyl-glycyl-glycyl (L-PRO-GLY-GLY). We injected chicks intracerebrally with 10, 5 or 2 µl/hemisphere of 300mM peptide, 1 min after one-trial training to suppress the peck response to a bead. Suppression was conditioned by coating the bead with an aversive liquid (methyl anthranilate). Retention was tested 24 hr later using the uncoated bead; impaired memory is indicated by increased peck scores (mean sq. rt. of pecks in 10 sec) and reduced avoidance scores (percentage of chicks that avoid pecking for 10 sec).

The results demonstrate that L-PRO-L-PRO is amnestic at the same dose as L-PRO (6.0 µmols). At a dose of 3.0 µmols, L-PRO-L-PRO is not amnestic (nor is L-PRO). L-PRO-GLY-GLY is amnestic at doses of 6.0 or 3.0 µmols but not 1.2 µmols. Amnesia produced by L-PRO-GLY-GLY and L-PRO-L-PRO is retrograde because no effect was observed when injection was delayed for 1 or 4 hr after training.

The results with glycyl-L-proline (GLY-L-PRO), L-prolyl-glycine (L-PRO-GLY) and L-prolyl-L-leucyl-glycine-amide (L-PRO-L-LEU-GLY-NH_2) are in the direction of enhanced memory retention; we are exploring this possibility with a paradigm which is more sensitive to enhancement effects.

Peptide	Dose (µmols/chick)	N	Peck Score ($\sqrt{p}$±S.D.)	Avoidance Score (%)
L-PRO-L-PRO	3.0	20	0.60±1.17	70.0
L-PRO-L-PRO	6.0	167	2.03±1.44*	24.6*
L-PRO-GLY-GLY	1.2	30	1.10±1.50	53.3
L-PRO-GLY-GLY	3.0	30	1.71±1.50*	40.0
L-PRO-GLY-GLY	6.0	29	1.78±1.22*	20.7*
L-PRO-GLY	6.0	30	0.39±0.75	73.3
GLY-L-PRO	6.0	30	0.47±1.10	83.3*
L-PRO-L-LEU-GLY-NH_2	6.0	29	0.54±0.86	65.5
L-PRO†	6.0	304	1.59±1.49*	34.5*
D-PRO (control)†	6.0	296	0.77±1.19	56.1
No injection†	0	50	0.72±1.09	60.0

* Differ significantly from D-PRO ($p<0.01$; t-test for peck score; χ^2 test for avoidance score).

58.12 AN EVALUATION OF DRUG-INDUCED LEARNING FACILITATION ON A REPEATED ACQUISITION BASELINE. D. G. Spencer,Jr.* and G. A. Heise* (SPON: D. Schroeder). Dept of Psych., Indiana University, Bloomington, Indiana 47405.

Rats were trained on a two stimulus (panel light and tone) go-no go discrete trial discrimination task. Trials were generated by responses on one lever on a fixed interval 30 sec. schedule. Responses on another lever during the trial were counted as discriminative responses. Incorrect responding on a trial produced a correction trial next, which consisted of the same stimulus. Each session was terminated upon meeting a performance criterion and on the next session, the response requirements for the two stimuli were reversed (i.e., tone-go, panel light-no go became tone-no go, panel light-go, and vice-versa). Rats were maintained on this baseline until performance stabilized, at which point they were injected i.p. 30 min. before every third session with either normal saline, d-amphetamine (0.5 or 1.0 mg/kg), piracetam (100 or 200 mg/kg), or scopolamine (0.5 mg/kg). Scopolamine decreased overall responding and d-amphetamine increased overall responding, but neither drug significantly affected the course of discrimination acquisition. Piracetam did not change discrimination acquisition or responsivity but did facilitate go-stimulus correction trial performance and reduce inappropriate responding. It was concluded that piracetam and d-amphetamine improved performance in ways unrelated to the moment-to-moment learning process.

58.13 NEONATAL LEAD EXPOSURE TO RHESUS MONKEYS CAUSES A LONG-TERM DEFICIT ON A TASK FOR SPATIAL MEMORY. Edward D. Levin* and Robert E. Bowman. Primate Lab, Dept. of Psychology, U of Wisconsin, 22N. Charter St. Madison, WI 53706.

Lead is preferentially deposited in the hippocampus of the rat (Fjerdingstad et al 74, Br Res, V80, p350). Neonatal exposure of the rat to lead causes malformed synapses in the mossy fiber system of the hippocampus (Campbell et al 79, Neurosciences Abs. 1979, #493). Behavioral parallels have been noted in the syndrome resulting from neonatal lead exposure and from hippocampal damage in the rat (reviewed by Petit & Alfano 79, Pharm, Biochem & Behavior, V11, p165). In the monkey Bushnell & Bowman 79 (J Tox & Environ Health, V5, p1015) have found that neonatal lead exposure results in a long-lasting deficit in spatial reversal learning, a task which depends on proper hippocampal functioning in the monkey (Mahut 72, Neuropsychologia, V10, p65). Gaffan 74 (JCPP, V86, p1100) found impaired memory performance in monkeys with fornix transections. This experiment tests for deficits in spatial memory resulting from neonatal lead exposure.

Ten rhesus monkeys were given either 0.0, 0.29, or 0.88 mg/kg/day of lead acetate in their water for the first year after birth, resulting in blood lead concentrations of about 4, 50, or 80 g/dl respectively. When the monkeys were five years old they were tested on the Hamilton Search Task. This task uses six gray boxes in a row on a Wisconsin General Testing Apparatus (WGTA) tray. The monkey was allowed to open one of the self-closing boxes each trial with a 20 second ITI. All boxes were baited at the begining of each session and not rebaited thereafter. Thus for good performance they had to remember which boxes they had already opened. Each session was run until all the boxes had been opened or 50 trials had occurred. The total number of trials were counted until the monkey had a session where it opened six different boxes on the first six trials. A significant deficit was found with lead exposure (curvilinear regression of trials to criterion with neonatal blood lead r=0.650, p .05) There was no deficit seen with an easier criterion of five different boxes on the first five trials of a session. These results suggest that there is no deficit in learning to perform the task of opening different boxes per se but there is a deficit when the monkey's memory is severely tested. Lead seems to cause a deficit in spatial memory in monkeys neonatally exposed. This deficit is seen at least four years after lead exposure has ended.

58.14 LOW LEVEL CHRONIC LEAD (Pb) EXPOSURE INDUCES LEARNING DEFICITS IN YOUNG RAT PUPS. D. H. Taylor*, C. M. Brubaker* (SPON: R. Sherman), Miami Univ., Oxford, OH 45056 and R. J. Bull, Health Effects Research Lab., U.S. Environmental Protection Agency, Cincinnati, OH.

Eleven day old Sprague-Dawley (CD Strain) rat pups whose mothers were maintained on a 200 mg/l dosage of lead (Pb) acetate in their drinking water exhibited differences in a learning paradigm as compared to controls. No significant differences were noted between the control pups and the experimental pups with respect to acquisition rates but there were significant differences between the two groups with respect to extinction rates. Similar results were obtained in test of rat pups whose dams had been maintained on a 400 mg/l dosage of lead (Pb) acetate. These data indicate that low level lead (Pb) exposure can induce significant behavioral deficits in young rat pups.

58.15 FACILITATION OR DISRUPTION OF DELAYED SPATIAL ALTERATION PERFORMANCE IN RATS FOLLOWING HYPOXIA VS ANOXIA. John G. Marriott and Ronald E. Voightman*. Pharmacology Dept. Warner-Lambert Research Division, Ann Arbor, MI 48105

Although many theories of impaired cognitive function in humans have postulated important roles for hypoxia, as might occur with perinatal asphyxia and chronic cerebral insufficiency, few studies have been reported on the acute, proactive effects of hypoxia or anoxia upon complex behavior. Since the acute effects of hypoxia and anoxia may give insights into the mechanisms responsible for more permanent changes in behavior, we studied these effects upon a complex behavior, delayed spatial alternation (DSA), in highly trained rats.

Male, hooded rats of the long evans strain, which had been trained for a minimum of 3 months, were subjected to experimental hypoxia or anoxia immediately prior to testing on the DSA task. Hypoxia was induced by placing the rats in an airtight chamber for 30 min and replacing the air with a mixture of 5.11% oxygen in nitrogen at a flow rate of 7 liters/min. The animals were taken from the chamber at the end of the 30 min treatment and placed in a two-lever operant chamber for the behavioral test session which lasted 100 min. Other groups of animals were placed in an open cyclinder containing carbon dioxide gas for 10 sec to produce anoxia. These animals were revived and allowed 3 min to recover prior to being placed in the operant chamber. Performance on the task was assessed in terms of percent correct responses at each of the retention intervals tested (15, 30, 60, & 90 sec), number of trials completed, and latency to initiation of responding.

Animals treated with 10 sec of anoxia were found to be significantly impaired in all of the measures taken relative to control (untreated) performance. In contrast, animals treated with 30 min of hypoxic conditions actually improved over control values on the percent correct responses measure. Following hypoxia, animals completed fewer trials than during control session. Although the latency to begin responding was significantly delayed, the rate of responding once initiated was not different from normal. Facilitation of performance following hypoxia was apparent for the duration of the test session once the animals began responding.

These results indicate that the behavioral consequences of oxygen deprivation depend upon the nature of the treatment employed. Anoxia and hypoxia apparently have very different effects upon brain function and these effects persist for some time following treatment. These differences may provide insights into the mechanisms responsible for more permanent changes in behavior seen many hours or days following treatment.

59.1 SPROUTING AND SYNAPSE FORMATION PRODUCED BY COLCHICINE.
S. Rotshenker. Dept. of Anatomy & Embryology, Hebrew University-Hadassah Med. Sch., Jerusalem, ISRAEL.

In previous studies (Rotshenker, S.,J. Physiol.,292:535,1979; Rotshenker, S. and Reichert, F., J. Comp. Neurol., in press), we have shown that axotomy of the nerve to one cutaneous-pectoris muscle of the frog induced the intact motor neurons that innervated the intact muscle on the opposite side to sprout and form additional synapses with already innervated muscle fibers. As a consequence, muscle fibers innervated by a single motor neuron became polyneuronally innervated. It was further suggested that the axotomy initiated a signal for sprouting and synapse formation that was transferred transneuronally across the spinal cord from the injured nerve cells to the responding motor neurons. Axotomy could produce this signal by interfering with some trophic interactions between the denervated muscle and injured nerve. It was of interest to examine whether colchicine that blocks axonal transport, and thereby may interfere with such trophic interactions, will imitate axotomy in producing sprouting and synapse formation. Colchicine (0.01 M) was applied topically (5 min.) on nerves innervating left muscles at the axilla. The drug did not produce conduction block, degeneration or denervation. Left and right cutaneous-pectoris muscles were examined electrophysiologically to determine the proportion of muscle fibers innervated by two motor neurons. In intact muscles of normal frogs about 16% of the muscle fibers are polyneuronally innervated. Following colchicine application to left nerves the incidence of polyneuronal innervation increased in right intact muscles 2.5 fold to 38±4% (S.E.M.) starting about 2.5 weeks after the operation. This alteration in the pattern of motor innervation is similar in magnitude and timing to that obtained in intact right muscles following contralateral axotomy at the axilla. Sprouting and synapse formation also occurred in left muscles whose nerves were treated with colchicine. However, in left muscles new synapses were detected as early as 2 days after the operation and the incidence of polyneuronal innervation reached 29±2% (S.E.M.). No alteration in the pattern of motor innervation was detected in either left or right muscles after the application of Ringer to the nerve or colchicine at a distance of 1mm away from it.

59.2 IMPULSE ACTIVITY EVOKES COLLATERAL SPROUTING OF INTACT NERVES INTO AVAILABLE TARGET TISSUE.
B. Nixon+, P. Jackson, A. Diamond*, A. Foerster and J. Diamond. Department of Neurosciences, McMaster University, Hamilton, Ontario L8N 3Z5.

We have become interested in the possibility that the collateral sprouting of intact axons may be influenced by impulse activity in them. We showed previously (Jackson and Diamond, Soc. for Neurosci. Abstr. #2135, 1979) in adult rats that repeated testing, to determine whether collateral sprouting of nociceptive afferents had occurred into adjacent denervated skin, apparently was itself responsible for the marked recovery of function in these regions; operated animals that were not examined in the interim period showed no significant recovery 24 days after denervation, although by 40 days some recovery was apparent. We suggested that activity in the remaining nociceptive afferents, elicited by the test stimuli (skin pinching), might have evoked their sprouting into the denervated skin. In order to distinguish between impulse activity per se and other influences possibly attributable to the potentially or frankly damaging pinch stimulus, we have now examined the effects of direct electrical excitation of an intact dorsal cutaneous nerve in the rat after total denervation of skin surrounding its peripheral field; two minutes of excitation (20 Hz) suprathreshold for Group III and C fibres, on days 0, 4 and 8, resulted in a complete return of sensitivity to the denervated skin by 16 days. Section of the electrically excited nerve abolished this sensitivity. We have used silver staining to detect the presence of nerve axons in skin. No axons were found in unresponsive skin that had been denervated for 16 days; however denervated skin that had regained apparently normal sensitivity over the 16 days during which the remaining intact nerve was stimulated showed numerous axons within the dermis. We conclude that the activation of impulses in the nerve, plus the presence of adjacent denervated skin, evoked collateral sprouting of the intact high-threshold mechanosensory axons. Interestingly the low-threshold ("touch" sensitive) nerves, which do not sprout collaterals in the adult rat (Jackson and Diamond, Soc. for Neurosci. Abstr. #1515, 1978) are not induced to sprout into adjacent denervated skin when they are activated continuously by physiological stimulation for as long as 40 days.

We wonder if this dramatic effect of impulse activity on collateral sprouting of the high-threshold nerves is due to their becoming more sensitive to a sprouting influence emanating from denervated skin.

59.3 LOCALIZATION OF NEWLY FORMED PHOSPHOLIPID AND PROTEIN IN DEGENERATING AND REGENERATING MOUSE SCIATIC NERVE.
R.M. Gould, R.S. Sinatra, R.E. Madrid*, W.D. Spivack*, V.S. Weir*, and H.M. Wisniewski*, Inst. for Basic Research, Staten Island, NY 10314.

In normal sciatic nerves, autoradiographic studies have pinpointed sites of choline incorporation into phosphatidylcholine and methionine incorporation into protein in the Schwann cell cytoplasm of myelinated fibers. In contrast, tritiated myo-inositol incorporation into phosphatidylinositol was shown to be more prominent in the axon. In the present report, sites of formation of macromolecules from locally injected precursors were determined in sciatic nerves at various times after crush injury (or transection).

In one series of experiments designed to study changes in phospholipid and protein synthesis in response to injury, male mice were anesthetized, the right sciatic nerve was exposed and crushed with watchmaker's forceps #5 for 5-10 sec. The point of crush was marked with India ink or a loosely placed ligature. The wound was closed and the skin sutured. At 6 and 18 hr and 3, 7 and 14 days after crushing the nerve, tritiated precursor (choline, inositol or methionine) was injected into the nerve at points above and below the crush. The animals were sacrificed two hours later and both longitudinal and transverse sections were prepared for light microscopic autoradiography. At the earlier intervals (6 and 18 hr) axons were found to contain label suggesting either local synthesis of lipid and protein or a transfer of newly formed macromolecule into the axon. At later times (3, 7 and 14 days) only inositol lipid synthesis was present in the newly growing axons.

In a separate set of experiments designed to study changes in phosphatidylcholine metabolism in phagocytic Schwann cells, nerves were transected at the sciatic notch and one and three days later radioactive choline was injected into the distal nerve about 3-9 mm from the transection. The animals were sacrificed 20 min after injection of precursor. The pattern of phospholipid synthesis was examined in teased fiber preparations and in serial light and EM sections of individually teased fibers in order to visualize changes in the Schwann cell metabolism along an individual internode. Movement of sites of biosynthetic activity to regions along the fiber where ovoids were formed could be seen. The possible significance of altered local phospholipid and protein metabolism in Wallerian degeneration and axonal sprouting will be discussed.

59.4 ELECTROPHYSIOLOGICAL AND MORPHOLOGICAL CORRELATES OF THE REINNERVATION OF RAT MUSCLES. IMPLICATIONS ON THE ROLE OF MEMBRANE COMPONENTS SUCH AS GANGLIOSIDES IN THE MOTOR NERVE SPROUTING.
A. Gorio, G. Carmignoto* and M. Finesso*. Department of Cytopharmacology, Fidia Research Laboratories, Abano Terme, Italy.

The Extensor Digitorum Longus (EDL) muscle of the rat was denervated by crushing the sciatic nerve.

Results have led to the conclusion that the restored nerve-muscle contact occurs only at the old end-plate regions and in no instance did we observe more than one end-plate on the same muscle fibre. First sign of reinnervation is the recording of subthreshold e.p.p.'s (1-2 mV) at the site of the nerve entrance, 2 weeks after denervation. M.e.p.p.'s are very rare about 1% of the normal level and stimulation with 30mM K^+ raises the frequency to only a few per minute. However the effectiveness of K^+ stimulation is unchanged because the m.e.p.p. rate is increased 100 fold as in normally innervated muscles. The nerve and K^+ evoked releases suggest a quick recovery of the voltage dependent Ca^{++}-channel. However the m.e.p.p. frequency at rest returns normal in 2 weeks suggesting 2 different mechanisms for releasing quantal Ach. The response to hypertonic solution is further delayed and reaches normal value only 7 weeks after the crush.

Multiple innervation is apparent 3 days after recording the e.p.p. and reaches the maximum value of 70% in 2 weeks. Daily treatment of the animal with gangliosides induces a strong neurite outgrowth and the maximum level of polyinnervation is reached in about 2 days. This degree of polyinnervation is maintained and it declines to normal level parallel to the untreated muscles in spite of the continuous treatment. This suggest that gangliosides enhances a natural occurring phenomenon and when the stimulus to sprout ceases the ganglioside effect does also.

To further study the sprouting a good model is the collateral reinnervation of the Soleus muscle after resection of the L_5 root. The data clearly show that the best reinnervation process occurs when the sprouts are myelinated and so the innervation can be held.

The Soleus muscles of the animals treated with gangliosides showed a much better recovery compared to the untreated ones, showing after 30 days a full recovery which was kept even 50 days after resection of the L_5 root. This data again suggest that sprouting may be regulated by a dual phenomenon -an endogenous stimulus, perhaps coming from the muscle, and a need for membrane structures such as gangliosides.

59.5 INTERACTION OF AGE AND SEX IN SYMPATHETIC AXONAL INGROWTH INTO THE HIPPOCAMPUS. Teresa A. Milner, Joyce F. Nonaka* and Rebekah Loy. Dept. of Neurosciences, Univ. of Calif., San Diego, La Jolla, CA 92093

Although axonal sprouting in response to central nervous system damage has been described in a variety of systems, exactly what mechanisms regulate the stimulation of growth or the final distribution of terminals is unknown. One factor that influences the rate as well as the extent of intrinsic afferent reorganization in the hippocampus is the age of the animal at the time of afferent damage. Another factor that appears to influence axonal sprouting is the hormonal environment. Our findings indicate that damage to the septal afferent axons of the hippocampus elicits a post-lesion ingrowth of vascular sympathetic axons that is greater in female than in male rats. This sexual dimorphism may be due to a direct hormonal regulation of axonal growth and post-lesion terminal reorganization or to a differential organizing influence of hormonal exposure during development. To distinguish between these possibilities, as well as to examine the role of other developmental influences on axonal sprouting in this system, we have studied sympathetic axon ingrowth following damage of the septal afferent system in male and female rats of three ages. After 30 days, the brains of these animals were analyzed using either the cryostat glyoxylic acid method of fluorescence histochemistry or high affinity uptake of noradrenaline.

We find that (1) the sprouting which is reduced in adult and juvenile males relative to females, is equivalent in the two sexes after transections at postnatal day 3 (P3) and (2) the period of maximum ingrowth occurs near P3 in the male and P13 in the female.

This suggests that both the age and sex of the animal interact to determine the final extent of sympathetic sprouting. Since sexual determination probably occurs by P7, this might account for the equivalent sprouting in males and females lesioned at P3. While maximum ingrowth occurs during different developmental stages in males and females, both occur prior to adulthood. This could reflect developmental changes in the stimuli released by the damaged afferent, the growth capacity of remaining afferents, or the synaptic receptivity in the deafferented target tissue.

59.6 SYMPATHETIC AXON INGROWTH INTO HIPPOCAMPUS IN ABSENCE OF PYRAMIDAL CELLS. Gary M. Peterson and Rebekah Loy. Dept. of Neurosciences, UCSD School of Medicine, La Jolla, CA 92093.

Noradrenergic (NA)-containing axons, originating in the superior cervical ganglion, grow into the parenchyma of the hippocampal formation (HF) following disruption of the septal input (Loy, Milner and Moore, 1980). This anomolous innervation apparently arises as collateral sprouting from the normal sympathetic plexus on the longitudinal hippocampal arteries. The primary sites of innervation within the HF are adjacent to the granule cell and CA3 pyramidal cell layers. To determine the target of this anomolous innervation the pyramidal cells of CA3 were selectively destroyed by intraventricular injections of kainic acid (KA).

KA (0.8 µg in 0.8 µl saline, pH 7.4) was injected into the lateral ventricle over a period of 30 min. This produces selective loss of pyramidal cells in field CA3 (Nadler, Perry and Cotman, 1978). Five days after KA injection the fimbria was transected bilaterally. Four weeks after the transection the brains were removed and prepared for fluorescence histochemistry using the glyoxylic acid method of de la Torre and Surgeon (1976). One set of adjacent sections were stained with cresyl violet for assessment of cell loss and a second set were stained for acetylcholinesterase for the assessment of changes in the cholinergic innervation of the HF.

The plexus of coarse, intensely fluorescent catecholamine fibers which appears after fimbria transection was observed in strata lucidum, pyramidale and oriens of CA3 both in regions where pyramidal cells were intact and in regions where they had been destroyed by KA. In the fluorescent material the damaged pyramidal cells could be identified by the appearance of autofluorescent "ghosts" which were either glia or fragments of the destroyed pyramidal cells. The density of fibers did not appear to be increased or decreased in the damaged portion of the pyramidal layer as compared to adjacent areas where the cells were intact.

We conclude from these data that the sympathetic NA axons which grow into the HF following fimbria transection terminate on a cell population other than the pyramidal neurons. Previous studies in this lab have shown that within the fascia dentata these fibers form both terminal-type associations with the intracerebral arterioles and capillaries, and synaptic contacts with neuronal elements adjacent to the stratum granulosum. Whether the target in CA3 is a population of interneurons or glia cannot yet be determined. However, a model put forth by Mosko, Lynch and Cotman (1973) showing the septal input terminating on inhibitory interneurons suggests tha removal of this input might allow ingrowth of sympathetic fibers to these interneurons.

59.7 SYMPATHOHIPPOCAMPAL SPROUTING: IS ZINC THE LINK? Keith A. Crutcher and James N. Davis, Dept. of Medicine (Neurology) and Pharmacology, Duke University Medical Center and Veterans Administration Medical Center, Durham, N. C. 27705.

We have previously shown that sympathetic neurons appear in the rat hippocampal formation specifically in response to septo-hippocampal (cholinergic) denervation. Such sprouting occurs in the absence of afferent input to the superior cervical ganglion indicating that some change in the target initiates the sprouting response. The fact that both septohippocampal and sympathohippocampal fibers are distributed with a topography similar to that of granule cell axons (mossy fibers) led us to test the hypothesis that granule cells are required for sympathetic sprouting. We partially eliminated granule cells with neonatal irradiation or adult colchicine injections into the hippocampal formation. Septal lesions placed 2 months following irradiation or 2 - 4 weeks after colchicine injections resulted in sympathohippocampal sprouting only in regions where granule cells remained. The sprouts were distributed in the same areas where remaining mossy fibers could be visualized in adjacent sections stained for heavy metals (Timms method). These results support the hypothesis that granule cells, particularly the mossy fibers, are the targets of sympathohippocampal fibers. Since septohippocampal and sympathetic neurons exhibit specific transport of Nerve Growth Factor (NGF), a zinc-containing protein, and since both septo- and sympathohippocampal fibers are distributed in close association with the zinc-containing axons of granule cells (mossy fibers) it is tempting to speculate that granule cells produce a zinc-containing tropic factor. Such a factor might normally be transported by septal fibers. If so, septal lesions would result in accumulation of the hypothetical factor and subsequent sympathetic sprouting. This hypothesis, although speculative, would account for the distribution of sympathohippocampal fibers and for the specificity of the sprouting which occurs only in response to loss of septohippocampal fibers.

59.8 THE SYMPATHETIC INNERVATION OF THE HABENULA. Ron Philo* and Zehava Gottesfeld. (SPON: J.A. McConnell). Dept. of Neurobiol. & Anat., Univ. of Texas Med. Sch., Houston, Texas 77025.

The use of histofluorescence demonstrated that noradrenergic innervation of the habenula (Hb) stems from central (Fuxe, 1965) and from peripheral superior cervical ganglia (SCG) (Bjorklund et al., 1972). It has been reported recently that following partial deafferentation of the Hb by lesions in the stria medullaris (SM), sprouting of noradrenergic axon terminals was observed in these nuclei (Gottesfeld, 1980). The source of the sprouting neurons has yet to be determined. This work has been undertaken to study biochemically, first-the regional distribution of norepinephrine (NE) within the Hb, second-to assess the contribution of the SCG to noradrenergic innervation of this region and third-to determine whether or not the SCG neurons have the capacity to sprout in deafferented Hb. The experimental paradigm consisted of the following groups of male Sprague-Dawley rats (200g) :1) animals with bilateral superior cervical ganglionectomy (SCGX) were allowed to survive for 5,14 and 42 days following surgery, 2) rats with SM lesions for 25 days were then ganglionectomized and allowed to survive for an additional 10 days, 3) animals with SM lesions for 35 days and 4) sham-treated control rats for each experimental group. The rats were killed by decapitation and brain sections (300 µM thick) were cut in a cryostat at -8°C. Tissue punches were removed from the Hb region in 7 consecutive frontal sections. NE was assayed by the method of Coyle & Henry (1973). The results demonstrate regional differences in NE distribution in the Hb, with the highest NE levels in the core regions. After SCGX, NE was significantly decreased at 5, 14 and 42 days ($P<0.008$, $P<0.03$, $P<0.02$, respectively) in only one site, i.e. A4230, according to Konig and Klippel, 1963. After SM lesion for 35 days, NE levels were increased in all Hb regions, and this increase was not affected by SCGX. It is concluded that noradrenergic sprouts in the Hb observed after SM lesion, are of central origin, not from the peripheral sympathetic system.

59.9 GANGLIOSIDE MEDIATION OF IN VITRO NEURONAL MATURATION. F. Roisen and H. Bartfeld*, Dept. of Anatomy, CMDNJ-Rutgers Medical School, Piscataway, NJ 08854, and the Amyotrophic Lateral Sclerosis Research Center of St. Vincent's Hospital and Medical Center, NY, NY 10011.

Gangliosides have been suggested to be membraneous components which may play a significant role in the regulation of a variety of neuronal events including: differentiation, defense, growth, regeneration, trophic interaction and transformation. To examine the potential role of these glycosphingolipids on in vitro neuronal maturation, bovine brain gangliosides were incorporated into culture media (in the presence or absence of heat-inactivated fetal calf serum) and applied to established neuronal lines (Neuro 2a and S_{20} neuroblastoma) and primary explant cultures of chick embryonic sensory ganglia (DRG). The effects, of coded samples, of the test media on these different culture systems were evaluated morphologically and biochemically. The mean number and length of cell processes in a given unit area were repeatedly determined with high resolution light microscopy and provided a semiquantitative index of neuronal maturation. A biochemical measure of growth was obtained by determining the activity levels of ornithine decarboxylase (ODC), the rate limiting enzyme in the polyamine biosynthetic pathway.

Media containing the ganglioside mixture enhanced significantly the degree and rate of fiber formation as well as the ODC activity of Neuro 2a neuroblastomal cultures. In contrast, no significant differences were found between S_{20} neuroblastomal cells treated with either control or ganglioside supplemented media (GSM). Primary cultures of DRG exposed to GSM exhibited a significantly greater mean number of neuritic processes than that found in control cultures. The mean neuritic lengths of the control and GSM groups were not statistically different. The GSM also enhanced significantly the ODC activity of the DRG cultures in the presence or absence of serum.

These results are consistent with the notion that gangliosides can be incorporated into the axolemma where they can then function as "acceptor" molecules for growth promoting substances. The possibility of a synergistic relationship between gangliosides and nerve growth factor will be discussed.

59.10 PUTRESCINE FACILITATES BEHAVIORAL RECOVERY FROM LESIONS OF THE ENTORHINAL CORTEX IN RATS. J. Ramirez*, J. Venditto* and D. Stein (SPON: B. Fass). Brain Res. Lab., Clark University & U. Mass. Med. Center, Worcester, MA 01610

Studies have confirmed that partial deafferentation of the dentate gyrus (DG) caused by entorhinal cortex (EC) damage results in proliferation of remaining septal and hippocampal afferents (Lynch & Cotman, 1975). Additional evidence has suggested that sprouting may play a role in behavioral recovery after EC lesions (Loesche & Steward, 1977). To date, however, little is known about the specific substrates that mediate behavioral recovery and synaptic proliferation. Trophic substances such as NGF have been implicated but polyamines such as putrescine, spermidine and spermine may also be involved. Polyamines are involved in cellular growth and differentiation. They facilitate both translation and transcription by enhancing the activity of DNA replicase, DNA dependent RNA-replicase, DNA dependent RNA-polymerase and t-RNA-methyltransferase (Shaw,1979). Increased turnover of ornithine decarboxylase, the rate limiting enzyme in polyamine synthesis, has been detected in brain during development and regeneration after injury.

The present study examined whether putrescine application to a system undergoing collateral sprouting might facilitate behavioral recovery. Accordingly, rats sustained bilateral lesions of EC followed by either injection of saline or putrescine (0.2 M) bilaterally into the DG of the dorsal hippocampus. Two days after surgery the rats were tested on a Y-maze for retention of a preoperatively learned alternation task.

The results show that animals given putrescine required significantly fewer days (X=22.3) to relearn the alternation task after surgery than rats treated with saline (X=32.2). Previous research suggests that sprouting in the hippocampus may be related to behavioral recovery. Putrescine may have contributed to more rapid behavioral recovery by enhancing the biochemical processes associated with sprouting. Further studies examining the morphological consequences of polyamine treatments are presently being conducted. (Supported by NIA grant 2 RO 1 AG00295-04.)

59.11 LACK OF PLASTICITY IN SOMATOSTATIN SYSTEMS IN CAT LUMBAR SPINAL CORD. A. Tessler, M. E. Goldberger, M. Murray, B. T. Himes* and R. Artymyshyn* (SPON: I. Zimmerman). Dept. of Anatomy, The Med. Coll. of Penn., Phila., PA 19129.

Substance P (SP) and Somatostatin (SOM)-like immunoreactivities have been demonstrated in the spinal cord, transported there, presumably by one or more populations of dorsal root afferent fibers. Using the unlabeled antibody (PAP) technique we have found that the distribution of SOM reaction product in the lumbar spinal cord of the cat resembles that previously described in several species: SOM reaction product is densest in lamina II, is present in lateral lamina VII and sparse in lamina I, V and ventral horn. Thus, its distribution only partly overlaps that of SP. Unilateral complete lumbosacral dorsal rhizotomy diminishes only slightly the amount of SOM reaction product in lamina II; maximal decrease in intensity of staining and in width of the band of staining present in lamina II is apparent by about 10d. Combining deafferentation with additional surgical lesions, including ventral rhizotomy, contralateral complete lumbosacral dorsal rhizotomy, high and low lumbar transections, and hemisections above and below L6 together with commissurotomy, does not abolish SOM staining. These observations suggest that the SOM-containing cell bodies, apparent in various laminae normally or after colchicine application, are responsible for the residual but reduced SOM staining. The reduction in SOM after rhizotomy appears to be permanent. The pattern of change in SOM reaction product following dorsal rhizotomy therefore contrasts with that which we have previously described for SP. Although a decrease in dorsal horn SP reaction product is also apparent 10d after dorsal root section, SP reaction product subsequently demonstrates a partial return. This partial return of SP immunoreactivity mimics the normal distribution of SP staining, but differs in its appearance, being more granular and less globular. Interneurons are at least in part responsible for residual SOM and SP staining and for the subsequent increase in SP.
Supported in part by the Medical Research Service of the Veterans Administration and by NIH Grants NS14477 and NS13768.
Anti SOM antiserum was supplied by Dr. Seymour Reichlin, Endocrine Division, New England and Medical Center Hospital, prepared with support of USPHS Grant #RO1 AM16684.

59.12 ENDOCRINE INFLUENCES ON ADRENERGIC AXON SPROUTING IN THE RAT DENTATE GYRUS. Stephen W. Scheff, Georgia Sasvary* and Carl W. Cotman. Dept. Anat., Med. Center, Univ. Kentucky, Lexington, KY and Dept. Psychobiology, Univ. California, Irvine, CA 92717.

We previously demonstrated that chronic changes in the physiological levels of glucocorticoids can alter axon sprouting in the rat dentate gyrus of the hippocampal formation (Exp. Neurol.,68: 195-201, 1980). In the present study we investigated whether or not similar chronic glucocorticoid changes can modify the sprouting reaction of adrenergic neurons. Sprouting of adrenergic neurons innervating the rat septal and hippocampal areas was studied following a unilateral transection of the fimbria using a modified glyoxylic acid histofluorescence method for cellular localization of monoamines.

Young adult animals were adrenalectomized six to ten days prior to a unilateral transection of the fimbria which partially denervates the septal and hippocampal areas. At the time of surgery the animals were subjected to a subcutaneous implantation of a pellet containing either pure corticosterone or cholesterol depending upon group designation. Control animals were given a sham adrenalectomy followed by a fimbria transection and cholesterol implant. Animals administered pure corticosterone were maintained at circulating levels approximately twice those present in naive animals. Forty-five days after the transection the animals were killed, blood samples collected for RIA analysis of corticosterone levels and the brains processed for fluorescence microscopy. Both control animals and adrenalectomized animals receiving cholesterol, demonstrated an increase in noradrenergic innervation of the septum which was equivalent for the two groups in agreement with previous results. The response of the sympathetic catecholaminergic fibers in the hippocampus appeared extremely robust. Adrenalectomized animals maintained at high circulating levels of corticosterone showed significantly less noradrenergic sprouting in the septum and almost no indication of the sympathetic response. The chronic change in the level of glucocorticoids appears to significantly limit the reactive response of adrenergic neurons. These results support our contention that the effect of this hormone is widespread and can affect many different types of neurons.

Adrenergic axon sprouting has been shown to be greatly reduced in the senescent rat (Science 202:775-778, 1978), and it is also known that glucocorticoids are elevated in these animals. The present results support our contention that the diminished sprouting observed in aged animals may be partially due to the elevated glucocorticoid levels. (Supported by research grant AG 00538)

60.1 PURIFICATION OF THE SAXITOXIN RECEPTOR OF THE VOLTAGE SENSITIVE SODIUM CHANNEL FROM MAMMALIAN BRAIN. R. P. Hartshorne* and W. A. Catterall* (SPON: N. Nathanson). Dept. of Pharmacology, Univ. of Washington School of Med., Seattle, WA 98105.

Saxitoxin binds to a single class of binding sites on the sodium channel and blocks action potential propagation. The saxitoxin receptor solubilized from rat brain membranes by the non-ionic detergent Triton X-100 retains high affinity (K_D = .16nM) and specificity for saxitoxin. The soluble receptor is very labile ($t_{1/2}$ = 5 min at 36°) and requires phosphatidyl choline, Ca^{++}, protease inhibitors and low temperature for stability during purification. Receptor concentration is determined by measuring the specific binding of tritiated saxitoxin using a rapid gel filration technique. Gel permeation chromatography of the crude soluble receptor on Sepharose 6b indicates that the Stokes radius of the receptor -detergent-phospholipid complex is 79 Å. Centrifugation of the crude soluble receptor through sucrose gradients in H_2O and D_2O gives $S_{20,w}$=12.3, $\bar{v}$=0.82, and M_r=630,000 for the detergent-phospholipid-protein complex. Correcting for bound lipid and detergent using the partial specific volume ($\bar{v}$) measurement gives a molecular weight for the receptor protein of approximately 340,000.

The soluble saxitoxin receptor was purified by conventional methods. The first purification step was ion exchange chromatography on DEAE Sephadex at pH 6.0. The peak fractions were pooled, neutralized, applied to a wheat germ lectin-sepharose 4b column and eluted with an N-acetylglucosamine gradient. The peak fractions were pooled and centrifuged through 3-12% sucrose gradients. Analysis of the peak fractions of the sucrose gradient by SDS polyacrylamide gel electrophoresis revealed single major protein species of M_r 250,000. The concentration of this protein correlates well with saxitoxin binding activity in different fractions from the gradient. A protein of the same molecular weight is specifically labeled by a photoactivable derivative of scorpion toxin which binds at a different site on sodium channels in rat brain membranes (Beneski and Catterall, PNAS, 77, 639, 1980). Our results show that an M_r= 250,000 protein is the saxitoxin binding component of the sodium channel from rat brain and this polypeptide is located at or near the scorpion toxin receptor site.

60.2 VALPROATE AFFECTS THE MEMBRANE PROPERTIES AND CYCLIC NUCLEOTIDE LEVELS OF THE CRAYFISH GIANT AXON: THE INFLUENCE OF DILANTIN. Thomas M. Nosek. Dept. of Physiology, Medical College of Georgia Augusta, GA 30912.

This series of experiments was undertaken to compare the effects of valproate (VPA), a new and very effective antiepileptic, with those of dilantin (DPH) on the excitability properties of the crayfish medial giant axon. Electrophysiologic measurements were made on axons that were space and current clamped. Conducted action potentials were generated for the measurement of conduction velocity (CV). All axons were bathed in a control Van Herreveld's solution at 22°C for 1 hour before drugs were added directly to the bathing medium (pH was maintained at 7.4). VPA had a dose dependent (1 X 10^{-4} to 4 X 10^{-3}M) effect on membrane properties that was reversible. Within 30 minutes of application, VPA produced a depolarization of the membrane that was associated with an increase in specific membrane resistance. VPA also decreased the magnitude of the action potential (AP), $+dV/dt_{max}$, CV, and $-dV/dt_{max}$ and increased the duration of the action potential (AP-D) suggesting that it affects both the electrogenic Na^+ and K^+ channels of the axon membrane. 8 X 10^{-3}M VPA proved toxic, it rapidly and irreversibly depolarized the membrane, abolished the action potential, and decreased the resting membrane resistance. These effects are in contrast to those of a maximally effective dose of DPH (0.11 mM) which did not affect the magnitude of the resting or action potential or of the membrane resistance. It s significant effects were limited to a decrease in $+dV/dt_{max}$, CV, and threshold current and an increase in AP-D. The synergistic effects of DPH and VPA were evaluated by pretreating axons with 0.11 mM DPH for 30 minutes before VPA was added to the bathing medium. Under these conditions, a 30 minute exposure to VPA had a significant effect on only one membrane parameter; it decreased $-dV/dt_{max}$. Because elevated cellular levels of cAMP and cGMP have been correlated with the increased membrane activity associated with epilepsy, the effects of VPA and DPH, alone and in combination, on the cellular levels of these nucleotides (measured by radioimmunoassay) were elevated. 4 mM VPA significantly decreased the cellular levels of both cAMP and cGMP while 0.11 mM DPH affected neither nucleotide. Pretreatment of the axons with DPH abolished the effects of VPA on these nucleotides. These experiments demonstrate that: 1) VPA and DPH both depress axon excitability but in different ways; 2) the electrophysiologic effects of VPA are associated with a decrease in the cellular levels of cAMP and cGMP; 3) DPH has an antagonistic effect on the response of the axon to VPA. (Supported by NIH Grant #1-NS-6-2340 to the Georgia Comprehensive Epilepsy Program).

60.3 ACTIONS OF SAXITOXIN ANALOGS ON SQUID AXON MEMBRANES. C.H. Wu, T. Narahashi and Y. Shimizu*.(Spon: J.C. Houk). Dept. of Pharmacology, Northwestern Univ. Med. Sch., Chicago, IL 60611 and College of Pharmacy, Univ. of Rhode Island, Kingston, RI 92881.

Several dinoflagellate toxins which are chemically related to saxitoxin (STX) have recently become available in pure forms. Neosaxitoxin and gonyautoxin-I, -II, and -IV have been isolated from the dinoflagellate Gonyaulax tamarensis and their chemical structures recently elucidated. Although animal poisoning due to G. tamarensis resembles that of saxitoxin, the mechanism of action has not been established. We now report the pharmacological actions of these new toxins on squid axon membranes under voltage clamp conditions. In addition, comparison of their actions on sodium channels may offer us some insight into the structure-activity relationship of saxitoxin action at the molecular level.

All four toxins selectively blocked sodium currents without affecting potassium currents. Like STX, they were effective when applied externally to the axon. The blocking action was reversible upon washing with the toxin-free saline solution. The kinetics of activation and inactivation of sodium conductance did not seem to be affected. However, the effective concentration of the toxins in suppressing 50% of the maximum sodium conductance varies among the toxins. Neosaxitoxin, with an additional OH group on the 1-nitrogen atom of STX, blocked sodium channels with a K_D of 12 nM. Gonyautoxin-II, with an OSO_3^- substitution on the 11-carbon atom of STX, showed a similar potency (K_D = 14.5 nM). These results are very close to the reported value for STX binding to squid sodium channels at comparable temperature. In contrast, simulaneous substitutions of the OH group on the 1-nitrogen atom and OSO_3^- group on the 11-carbon atom seem to hinder the binding of the toxin to receptors. Gonyautoxin-I and -IV with both substitutions showed a much weaker potency, their apparent K_D being 88 nM and 58 nM, respectively. Thus, we conclude that the binding to the receptors requires an optimal steric size of the toxin molecule. The present results are also compatible with the notion that the guanidinium group around the 8-carbon atom is essential for the blocking action. (Supported by NIH grant NS 14144 to T.N. and PHS grant FD-00619 to Y.S.).

60.4 pH DEPENDENCE OF BATRACHOTOXININ-A-BENZOATE BINDING TO VOLTAGE-SENSITIVE SODIUM CHANNELS. George B. Brown. Neurosciences Program, University of Alabama in Birmingham, B'ham, AL 35294.

Batrachotoxin (BTX) and the potent analog batrachotoxinin-A-benzoate (BTX-B) act specifically at voltage-sensitive sodium channels to stabilize the open conformation of the channel, causing membrane depolarization. Bartels-Bernal et al. (Proc. Natl. Acad. Sci. USA, 74:951, 1977) have previously demonstrated a pH dependence for the action of BTX on eel electroplax. BTX was inactive at pH 6.1 and active at pH 8.5. Since the tertiary amino group of BTX may have a pKa in this range these results could be explained by a lower membrane solubility or lower binding affinity of the charged BTX species, but similar results were obtained with quaternized BTX, suggesting that a titratable residue(s) with a pKa in this range at the BTX binding site might be responsible for the observed effect. I have examined these possibilities by direct binding measurements of labeled ^{3}H-BTX-B to mouse cortex homogenates as a function of pH. A major constituent of non-specific binding in this system is due to intercalation of unprotonated BTX-B into the lipid bilayer and should therefore be a function of pH. Both non-specific and specific ^{3}H-BTX-B binding were measured between pH 6 and 9. As expected, non-specific binding is a linear function of pH in this range. Specific binding however, is a maximum at pH 8.5, decreasing to zero at pH 6.0. These data indicate that specific binding measured in this pH range may be a function of titration of a histidine residue at or near the binding site. Studies have been initiated to test this possibility. Results from selective modification of histidine in situ using dye-sensitized photo-oxidation are consistent with a role for this amino acid at the BTX-B binding site. Supported by NIH grant NS15617.

60.5 DIFFERENTIAL EFFECTS OF 4-AMINOPYRIDINE ON THE EXCITABILITY OF THE PARALLEL FIBERS OF THE CEREBELLAR CORTEX AND THE DORSAL COLUMN FIBERS OF THE SPINAL CORD. J. D. Kocsis*, R. C. Malenka and S. G. Waxman* (SPON: K. CHOW). Dept. of Neurology, Stanford Sch. of Med., and Veterans Administration Medical Center, Palo Alto, CA 94304.

We have compared the effects of 4-aminopyridine (4-AP) on two central fiber systems in the rat -- (1) the fine caliber non-myelinated parallel fibers (Pf) of the cerebellum, and (2) the large myelinated axons of the dorsal columns (d.c.) of the spinal cord. Voltage-dependent potassium conductances (g_K) have been shown in several axon systems to be blocked by external application of 4-AP. Following anesthesia with urethane, field potentials were elicited through local stimulation (glass-coated tungsten microelectrodes), and recorded with glass microelectrodes (3.0 M NaCl). Extracellular DC slow potentials (SP) were also monitored. Agar pools were built around the exposed tissue to allow continuous superfusion of the surface with warmed oxygenated normal Ringer solution (NS) into which 4-AP or other agents could be added. Since the Pfs are embedded in a dense neuropil containing postsynaptic elements, the cerebellar surface was superfused with NS containing Mn^{2+} or Mg^{2+} to block synaptic transmission. A triphasic Pf volley remained after these ions were added to the NS.

Double stimulation experiments indicate that for Pfs superfused in NS or with NS plus Mn^{2+} or Mg^{2+}, conduction velocity is reduced during the relative refractory period (RRP) and is increased during the supernormal period (SNP). 4-AP (0.1 mM) added to the NS-Mg^{2+} solution (1) increased the duration of the Pf volley, (2) increased the duration of the absolute and RRPs, and (3) reduced the SNP. No changes in excitability for the myelinated d.c. fibers after 4-AP application were observed even with higher 4-AP (2.0 mM) concentrations. Superfusion of d.c. fibers with 20 mM K^+ reversibly blocked d.c. fiber conduction indicating the efficacy of the superfusion pool. Following repetitive stimulation, a negative SP was present for the Pfs in NS-Mg^{2+}, but was eliminated by 4-AP. No SP could be recorded from the dorsal columns following repetitive stimulation, but a prominent SP was present when the microelectrode was positioned deeper into synaptic zones of the spinal cord.

These results suggest that (1) g_K may be an important contributor to the recovery characteristics of central nonmyelinated axons, and that (2) central myelinated axons may lack g_K as has been reported (Chiu et al, J. Physiol. 292, 1979) for peripheral myelinated axons. (Supported in part by the NIH (R-5353 and NS-15320), the Veterans Administration, and the National Multiple Sclerosis Society (RG-1231).)

60.7 STRATEGY AND METHODS FOR "BREAKING NEURAL CODES." W. R. Klemm and C. J. Sherry. Brain Research Lab., Dept. Biology, Texas A&M Univ., College Station, TX 77843.

Summarized herein is the evidence that supports the hypothesis that neuronal action potentials (spike trains) are coded not only in terms of simple discharge rate but also are coded by certain patterns of spike intervals. Based on the nonparametric relative interval description method of Sherry (Int. J. Neurosci. 3:259, 1972), the various analyses of single-unit activity from cerebellar cortex neurons of rats seem to disclose 3 principal categories of discoveries: 1) Serial dependence of intervals does exist. This has been demonstrated with a variety of conventional statistical tests. These serial dependencies have also been shown to be independent of the (nonsequential) interval distribution variability. 2) Information theory is appropriate for evaluating spike trains. We have developed and tested methods for computing entropy for a given number of adjacent intervals, for assessing the relative entropy of any one interval in a set of intervals, for computing for a group of neurons the mean and standard deviation of entropy for specified clusters of intervals, and for transforming entropy values so that interval clusters of differing number can all be compared on the same numerical entropy scale (percent maximum entropy). In addition to the descriptive and quantitative value of such entropy measures, we have also demonstrated their utility in testing hypotheses and in making empirical correlations. 3) The nervous system seems to process spike train intervals in "bytes," not "bits," of adjacent, serially ordered intervals. Among the several lines of evidence for this conclusion is the demonstration that drug-induced (ethanol) changes in entropy of specific interval clusters seemed to involve a "linked" combination of certain interval clusters, some which increase and others which decrease in incidence. Also, by using n-dimensional Chi Square methodology, we have demonstrated that the relationships of adjacent intervals represent a Markovian process, at least of the first order, and for many neurons, of the second order (i.e. the duration of a given interval is partially determined by the duration of the immediately preceding two intervals). Finally, we showed that the relative entropy (percent maximum entropy) of interval clusters of different number does not have a Gaussian distribution but rather is distributed in rather surprising ways by the specific number and relative durations of adjacent intervals.

60.6 INHIBITION OF CALCIUM ACCUMULATION IN SYNAPTOSOMES BY PHENYTOIN. S.M. Daniels-McQueen* and J.A. Ferrendelli (SPON: J. Trotter). Div. of Clin. Neuropharm. and Depts. of Neurol. and Pharm., Washington Univ. Med. Sch., St. Louis, MO. 63110.

Although phenytoin (PHT) is one of the major anticonvulsant drugs used for the treatment of several types of epilepsy, its mechanism of action remains poorly understood. Previous studies have indicated that PHT alters conductance of both Na^+ and Ca^{2+} across cellular membranes. To better define its action on Ca^{2+} conductance, we have compared the effect of PHT with that of Mn^{2+} and tetrodotoxin (TTX) on Ca^{2+} accumulation in isolated nerve terminals (synaptosomes).

Synaptosomes were prepared with conventional techniques and Ca^{2+} accumulation was measured by radioisotope methods. In control buffer containing 132 mM NaCl, 5 mM KCl, 1.2 mM $MgCl_2$, 1.2 mM $CaCl_2$, 1.2 mM NaH_2PO_4, 10 mM glucose and 20 mM Tris, pH 7.4, synaptosomes accumulated Ca^{2+} at a rate of 2-8 μmoles/g prot/min. Increasing the $[K^+]$ in the media to 64 mM (with an equivalent reduction of $[Na^+]$) or addition of 5 μM veratridine increased Ca^{2+} accumulation 2- to 4-fold. TTX, a selective inhibitor of Na^+ conductance, blocked the response to veratridine (ID_{50}=10 nM) but had no effect on that of K^+. In contrast, Mn^{2+}, a selective inhibitor of Ca^{2+} conductance, blocked both K^+- and veratridine-induced Ca^{2+} accumulation, equivalently (ID_{50}=1 mM). PHT also inhibited K^+- and veratridine-induced Ca^{2+} accumulation. Only 35 μM PHT was needed to produce 50% inhibition of the veratridine effect; however, an equivalent inhibition of the $[K^+]$ effect required 300 μM.

The observation that PHT produces more inhibition of veratridine-induced accumulation of Ca^{2+}, an effect that is closer to that of TTX than to that of Mn^{2+}, suggests that PHT has a greater action on Na^+ conductance than on Ca^{2+} conductance in excitable tissues. Since the therapeutic blood levels of phenytoin are usually between 40 and 80 μM, the present results may also indicate that inhibition of Na^+ conductance has a greater importance than inhibition of Ca^{2+} conductance in the antiepileptic action of PHT.

Supported, in part, by USPHS Grant NS 14834.

61.1 DIFFERENCES IN THE EFFECTS OF LEAD AND CADMIUM ON SYNAPTIC TRANSMISSION. G.P. Cooper, T. E. Kober* and R. S. Manalis. Depts. of Environmental Health and Physiology, Univ. of Cincinnati Coll. of Med., Cincinnati, OH 45267.

In electrophysiological experiments we have found Pb^{+2} and Cd^{+2} to be powerful synaptic blocking agents. Both Pb^{+2} and Cd^{+2} appear to block transmission principally through an interference with the Ca-mediated release of transmitter agents from presynaptic nerve terminals. In experiments using in vitro sympathetic ganglia we have shown that lead prevents the uptake of ^{45}Ca by presynaptic nerve terminals, thus reinforcing the conclusion reached previously in electrophysiological studies. However, ^{45}Ca uptake by presynaptic nerve terminals is not appreciably affected by cadmium even at concentrations great enough to completely block synaptic transmission.

These differences may be accounted for if we assume that a two-step process is involved in Ca-mediated transmitter release, step one being the passage of Ca^{+2} through the presynaptic membrane and step two the binding of Ca^{+2} to some intracellular site. Thus Pb^{+2} would be assumed to interfere at step one and Cd^{+2} at step two.

We have also shown that Pb^{+2} increases the spontaneous release of quanta of ACh in the frog neuromuscular junction. We postulated that Pb^{+2} must cause this effect by the displacement of Ca^{+2} from intracellular sites. If, now, the two-step process of transmitter release is valid and if Cd^{+2} does indeed interfere with Ca-mediated release of transmitter intracellularly, then it may be predicted that Cd^{+2} would be a more potent blocking agent than Pb^{+2} at the neuromuscular junction but would not increase MEPP frequency.

This deduction was confirmed in preliminary experiments performed in vitro on the isolated sciatic nerve-sartorius muscle preparation of the frog (Rana Pipiens). Standard microelectrode techniques were used to monitor intracellular responses from individual end-plates. Responses were recorded while the preparation was bathed in a control Ringer solution, or in Ringer's solution containing either 100 µM $PbCl_2$ or 100 µM Cd Cl_2. Pb^{+2} produced the expected dramatic increase in MEPP frequency while the MEPP frequency in the presence of Cd^{+2} remained approximately at control level. Whether Cd^{+2} may actually decrease the MEPP frequency remains to be determined.

These experiments indicate that, though both Pb^{+2} and Cd^{+2} interfere with Ca-mediated transmitter release, their subcellualr sites and mechanisms of action may be quite different (Supported by NIEHS Grants ES01494 and ES00159).

61.2 EFFECTS OF MEMBRANE FATTY ACID MODIFICATION ON NOREPINEPHRINE RELEASE FROM PHEOCHROMOCYTOMA CLONE PC12. Thomas P. Williams*, and Richard McGee, Jr. Department of Pharmacology, Georgetown University, Schools of Med. & Dent., Washington, D.C. 20007.

The pheochromocytoma clonal cell line, PC12, exhibits many properties consistent with the functional characteristics of neuronal cells, including the ability to release norepinephrine (NE) in response to a variety of stimuli. In order to assess the effects of alterations in membrane lipid composition on neuronal cell function, we have modified the phospholipid fatty acyl composition of the cell by exposing them to fatty acids (FA) as complexes with bovine serum albumin (BSA) (FA/BSA molar ratio <4, [FA] = 25 - 125 µM). We then examined the effects of these alterations on the release of newly accumulated [^{3}H]-NE in response to exposure of the cells to carbachol (2 mM) or K^+ (50 mM).

Addition of linoleate (18:2) or arachidonate (20:4) to the culture medium for 4-9 days resulted in a concentration related increase of these FA in the phospholipids (PL) of the cells. Exposure of the cells to 18:2 (125 µM) increased the PL content of 18:2 from 8.7% to 22.8% with a concomitant decrease in oleate (18:1) from 24.8% to 12.7%. At this same concentration of 20:4, the proportion of 20:4 in the PL component was increased from 14:3% to 29.0%, again with a concomitant decrease in 18:1. Exposure of the cells to 125 M 18:1 increased the 18:1 content of the PL from 24.8% to 37.8%. Similar alterations were observed in the FA composition of the neutral lipids of the PC12 cells.

The FA modified PC12 cells were examined for their ability to release newly accumulated [^{3}H]-NE. The FA modifications caused little, if any, change in the amount of [^{3}H]-NE released in response to the general depolarizing effects of 50 mM K^+. However, carbachol-stimulated release was decreased in PC12 cells modified by supplementation with 18:2 or 20:4. Addition of 18:2 resulted in a 40% decrease from control of [^{3}H]-NE released in response to 4 minutes of stimulation with carbachol. Addition of 20:4 resulted in a decrease to less than 50% of control values. In contrast, 18:1 had little effect on carbachol-stimulated release. These results suggest that the membrane FA alterations have little effect on generalized depolarization-dependent NE release, but may have substantial effects on receptor mediated release.
Supported by NIH grant NS 14975.

61.3 LIPOSOMES CONTAINING CALCIUM CAUSE RELEASE OF ACETYLCHOLINE FROM SYNAPTOSOMES. Richard D. Crosland*, Joseph V. Martin*, and W.O. McClure (SPON: B.C. Abbott). Section of Cellular Biology, Department of Biology, University of Southern Calif., Los Angeles, CA 90007.

Iontophoretic injection of Ca^{2+} into large invertebrate neurons has demonstrated that an increase in intracellular Ca^{2+} causes the release of neurotransmitter. Iontophoretic injection of Ca^{2+} into presynaptic terminals of the mammalian neuromuscular junction is not possible due to their small size. Recent investigations (PNAS, 75: 5214, 1978) have shown, however, that liposomes containing Ca^{2+} can increase the quantal content of evoked release of acetylcholine (ACh) at the mammalian neuromuscular junction, presumably by introducing Ca^{2+} directly into the presynaptic terminals. We have extended these studies to the central nervous system by investigating the effect of Ca^{2+}-containing liposomes on the release of ACh from rat brain synaptosomes.

Small, unilaminar vesicles composed of 3% egg phosphatidylcholine were prepared in the presence of either 113 mM $CaCl_2$ or 113 mM $MgCl_2$. The liposomes were exchanged into a Ca^{2+} free, balanced saline solution containing 1 mM EGTA. Rat brain synaptosomes previously loaded with [^{3}H] choline were incubated for increasing lengths of time at 37 degrees with either Ca^{2+}- or Mg^{2+}- containing liposomes. The suspensions were pelleted, and the supernatants assayed for [^{3}H] choline, [^{3}H] ACh, and lactate dehydrogenase (LDH).

Synaptosomes incubated with Ca^{2+}- containing liposomes released increasing amounts of radioactivity with time, reaching a maximum of 40% above control at 15 min of incubation. Liposomes containing Mg^{2+}, however, caused no increased efflux of radioactivity. After 30 min of incubation there was lysis of the synaptosomes as measured by LDH activity. Tritiated ACh accounted for more than 95% of the Ca^{2+}- induced release of radioactivity, suggesting that the Ca^{2+}-induced release reflects normal physiological processes. We have demonstrated that Ca^{2+} containing liposomes can release ACh from rat brain synaptosomes, presumably by direct introduction of Ca^{2+} into the synaptosomes. These data suggest that, as in invertebrate neurons and mammalian peripheral neurons, release of neurotransmitters in the central nervous system is dependent on the intracellular Ca^{2+} concentration and not on the influx of Ca^{2+} through Ca^{2+} channels in the presynaptic membrane. In addition, liposomes may prove to be useful vehicles for delivery of other ions and membrane impermeable drugs into the synaptoplasm.

Supported by the NSF (BNS 79-14284), and the NIH (AG 01896), Nelson Research and Development Co., Irvine, California.

61.4 CALMODULIN IN SYNAPTOPLASM: POSSIBLE INVOLVEMENT IN NEUROTRANSMITTER RELEASE. Hall, M.E., Babitch, J.A., & Cantrell, S.*. Chemistry Department, Texas Christian University, Fort Worth, Texas 76129.

It has been hypothesized that actomyosin, previously isolated from brain, may be involved in the mechanism of neurotransmitter release. In support of this hypothesis, it has been shown that actin and myosin can be identified in synaptic fractions from brain, and that phalloidin, which inhibits the depolymerization of filamentous actin, inhibits neurotransmitter release from synaptosomes. If transmitter release is mediated by an actomyosin mechanism, then based on actomyosin mechanism in muscle, the Ca^{++} sensitivity of transmitter release is probably confered by either Calmodulin (CaM) as in smooth muscle, or by troponin-C (TN-C) as in skeletal muscle.

We have investigated the protein constituents of presynaptic cytoplasm (synaptoplasm) using one- and two-dimensional gel electrophoresis. We have identified CaM, on the basis of comigration with purified CaM and changes in rate of migration with and without Ca^{++}. CaM is one of several synaptoplasmic proteins that binds $^{45}Ca^{++}$. To date, we have not found a protein corresponding to skeletal TN-C. Data will be presented concerning the presence or absence of other forms of TN-C, perhaps specific to brain. (Supported by Research Grant NS-12485 from the NIH.)

61.5 THE Na^+,K^+-ATPASE: A PLAUSIBLE TRIGGER FOR VOLTAGE INDEPENDENT RELEASE OF CYTOPLASMIC NEUROTRANSMITTERS. J.V. O'Fallon[1,2],* R.W. Brosemer[2]*and J.W. Harding[1]. Veterinary and Comparative Anatomy, Pharmacology and Physiology[1], and Biochemistry and Biophysics[2], Washington State University, Pullman, WA 99164.

Neurotransmitters are released from presynaptic nerve terminals in response to depolarizations resulting from the arrival of action potentials. When an action potential reaches a nerve terminal, it initiates the momentary opening of voltage-dependent Ca^{++} channels. The influx of Ca^{++} classically induces the exocytosis of transmitters from synaptic vesicles.

Elevation of K^+ concentrations in the external environment is routinely used in vitro to mimic the depolarizing effect of an action potential. Much evidence indicates, however, that K^+-induced release is only partially Ca^{++} dependent. Partial Ca^{++} dependency can imply the existence of two pools of neurotransmitters; e.g., a vesicular pool whose release would involve exocytosis and be Ca^{++} dependent and a cytoplasmic pool whose release could involve membrane transport processes and be Ca^{++} independent.

Recently, it has been proposed that inhibition of the Na^+,K^+-ATPase triggers neurotransmitter release (Vizi, E.S., Neurosci., 3:367-384, 1978). In order to establish the universality of the Na^+,K^+-ATPase as a possible trigger, the release of eight transmitters from eight regions of mouse brain was simultaneously examined. The release induced by 20 μM ouabain, a specific inhibitor of the Na^+,K^+-ATPase, was compared to that induced by 60 mM K^+. With few exceptions, all transmitters were released by either or both agents from each brain region. Potassium was superior in releasing the biogenic amines and acetylcholine while the putative amino acid transmitters were generally releasable by both agents. Calcium dependency was proportional to the superiority of K^+ over ouabain for initiating release. Measurements of tissue depolarization indicated that 60 mM K^+ is capable of depolarizing brain tissue above the threshold necessary for initiating an action potential while 20 μM ouabain is not. The pattern of release by ouabain, coupled with its failure to depolarize brain tissue at 20 μM, strongly suggests that inhibition of the Na^+,K^+-ATPase is capable of releasing cytoplasmic neurotransmitters in a voltage-independent manner.

61.6 CHOLINERGIC AGONIST-STIMULATED PHOSPHORYLATION OF TWO SPECIFIC PROTEINS IN BOVINE CHROMAFFIN CELLS: CORRELATION WITH CATECHOLAMINE SECRETION. R. W. Holz, C. E. Rothwell* & T. Ueda. Departments of Pharmacology and Psychiatry, and the Mental Health Research Institute, University of Michigan Medical School, Ann Arbor, Michigan, 48109.

The secretion of neurotransmitters and prepackaged hormones from nerve terminals and cells is usually triggered by the influx of Ca^{++}. By unknown mechanisms the rise in intracellular Ca^{++} causes storage vesicles to fuse with the plasma membrane and release their intravesicular contents to the cell exterior (exocytosis). We have investigated the relationship between protein phosphorylation and catecholamine secretion in monolayers of dissociated bovine chromaffin cells maintained in tissue culture. Cells were preincubated for 30 minutes in [^{32}P]phosphate to allow [^{32}P]phosphate to enter cells and become incorporated into ATP and other high energy phosphate compounds which can serve as phosphate donors in protein phosphorylation reactions. Although approximately 20 proteins significantly incorporated [^{32}P]phosphate during the 30 minute preincubation, during the subsequent 2.5 minute incubation carbachol significantly and consistantly stimulated [^{32}P] phosphate incorporation into only two specific protein bands, one of 56,000 daltons and the other of 99,000 daltons. The carbachol-induced phosphorylation of the 56,000 dalton protein was strongly Ca^{++} - dependent and occurred simultaneously with or just preceeded catecholamine secretion. The phosphorylation of the 99,000 dalton protein was not as well correlated with secretion. Carbachol- and Ca^{++} - dependent phosphorylation of the 56,000 dalton protein may participate in the biochemical mechanisms underlying exocytosis.

61.7 RELEASE OF CATECHOLAMINES AND PEPTIDES FROM RAT HYPOTHALAMI: SENSITIVITY DIFFERENCES TO HIGH POTASSIUM. N. B. Thoa*, N. D. Vu*, T. Moody, T. L. O'Donohue and D. M. Jacobowitz. (SPON: R. C. Colburn). NIMH, Bethesda, Md. 20205 and Howard Univ., Washington, D.C. 20059.

Individual hypothalami were dissected from male rat brains and chopped into 225 μm slices, using a Sorvall TC-2 sectioner. The samples were placed into polypropylene centrifuge tubes containing 0.6 ml of a modified Krebs-bicarbonate buffer aerated with O_2 (95%) and CO_2 (5%). Release was observed at 37°C and 2 minute fractions were collected. Epinephrine (E), norepinephrine (NE) and dopamine (DA) were assayed using a sensitive radioenzymatic method. The peptides bombesin, α-MSH and substance P were measured by radioimmunoassay. Fractions collected prior to KCl contained the catecholamines (CA) in the following proportions: NE = 70%, DA = 25% and E = 4%. KCl (50 mM) increased NE release 5 fold, E release 10 fold and DA release 12 fold and the proportions of the CA following KCl were: 46% NE, 47% DA and 6% E. All peptides slightly increased release of CA following KCl (50 mM). At 75 mM, KCl induced about a 3 fold increase in the release of all 3 peptides. Both CA and peptides released by KCl were calcium dependent.

The preferential release of DA by KCl suggests that, in the rat hypothalamus, DA is not just a precursor of NE. The lower sensitivity of the peptide release in response to KCl suggests that peptide and CA-containing vesicles are different with respect to storage and mobilization properties in response to depolarizing stimuli.

61.8 ANALYSIS OF TRANSMITTER RELEASE: NEW EQUATIONS FOR QUANTAL RELEASE PARAMETERS. M.D. Miyamoto. Dept. of Pharmacol., E. Tenn. St. Univ., Col. of Med., Johnson City, TN 37601.

The last decade has seen a proliferation in the use of binomial release parameters. The advantage is that they may allow investigation into the subcellular release mechanism, if, e.g., p represents a Ca-dependent probability of release and n reflects the no. of releasable synaptic vesicles.

However, Brown et al. (PNAS 73: 2913, 1976) and Barton & Cohen (Nature 268: 267, 1977) have indicated that large variations in p (var p) or n (var n) may bias the estimates, with the calculations becoming meaningless. With computer stimulation, they show that the calculated p (w/o compensation for var p) is always larger than the 'true' (programmed) $\bar{p}$, and vice versa for $\bar{n}$. McLachlan (Int. Rev. Physiol. 17: 49, 1978), by contrast, indicates that the example used is an extreme one, with 1/5 of all p = 1 and 4/5 = 0, which raises the question of whether n with small p contributes much to the estimate and whether the smaller estimates for n may not, in fact, be more appropriate.

Nevertheless, the arguments by Brown et al. have drawn enough attention that use of binomial statistics has become widely criticized. The only means of resolving this impasse is to derive equations which describe the exact contribution of $\bar{p}$, var p, $\bar{n}$ and var n. Equations for $\bar{p}$ and var p (eqns. (1) & (2)) are presented here.

Previous equations used the mean and variance of m (quantal content). These are simply the 1st two moments of m (Courtney, J. Theor. Biol. 73: 285, 1978) and are estimated by μ_1 and μ_2, where $\mu_i = E(m - \mu_1')^i$, i = 1,2,3... and $\mu_1' = E(m)$. From the moment generating function, the 3rd moment for the binomial is

$$\mu_3 = \Sigma p(1-p)\ (1-2p) \text{ or } \Sigma p - 3\Sigma p^2 + 2\Sigma p^3$$

By adding and subtracting the term 3/n (Σp) and substituting the term "var p" for its definition (Kendall & Stuart, The Adv. Theory of Statistics, Hafner, N.Y., 1969), one obtains,

$$\text{var } p = \bar{p}/3 - \bar{p}^{\,2} + 2/3\ \bar{p}^{\,3} - (\mu_3\bar{p}/3\mu_1) \quad \text{eqn (1)}$$

From Kendall & Stuart,

$$\bar{p} + \text{var } p/\bar{p} = 1 - \mu_2/\mu_1$$

By substituting eqn (1) into the above formula, one gets,

$$\bar{p} = \{1 - 3/2\ (\mu_2/\mu_1) + \mu_3/2\mu_1\}^{1/3} \quad \text{eqn (2)}$$

The "cost" of the additional information for these calculations is in the use of μ_3, such that one needs a larger sample size, perhaps as many as 300 independent measurements of m. Supported in part by NS 15089 and BRDG 1-S08-RR09171

62.1 FREEZE-FRACTURE OF SYNAPSES IN AN INSECT CENTRAL NERVOUS SYSTEM. Leslie P. Tolbert and John G. Hildebrand. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Synapses in the neuropil of the olfactory lobes of the brain of the moth Manduca sexta have been examined in an effort to determine the freeze-fracture appearance of these synapses. The neuropil consists of a central loose meshwork of coarse fibers surrounded by an array of dense, compact glomeruli, where all synaptic interactions between antennal olfactory axons and intrinsic neurons of the olfactory lobe occur. Olfactory-lobe neurons include both local interneurons and projection neurons, and inhibitory as well as excitatory synaptic interactions are common (Matsumoto, Neurosci. Abstr. 5: 170, 1979).

Thin sections reveal that a typical synaptic contact involves multiple postsynaptic profiles apposed in pairs to an individual presynaptic element. The presynaptic element contains a bar-shaped membrane-associated density which is flanked by synaptic vesicles and which follows a shallow groove in the membrane. Postsynaptic elements are lined by membrane-associated densities in the region opposite to the synaptic bar and vesicles.

Freeze-fracture replicas of the synaptic neuropil are heavily laden with membrane specializations that are thought to represent synapses. The most readily identifiable presynaptic elements have a striking similarity to excitatory terminals in the vertebrate CNS (e.g. Landis and Reese, J. Comp. Neurol. 155:93, 1974): they exhibit numerous plasmalemmal deformations, presumably representing sites of exo- or endocytosis, and a concentration of large (9-13 nm) P-face particles. The clusters of particles are sometimes found without associated plasmalemmal deformations, and rows of plasmalemmal pits are sometimes found without particle specializations; it is not known whether these represent synapses. Postsynaptically, the analogy to vertebrate excitatory synapses persists: large intramembranous particles aggregate in the otherwise bare E face immediately opposite to the presynaptic cluster of vesicles. The pre- and postsynaptic specializations are only rarely of the elongated shape that would have been expected for a bar-type synapse. This raises the possibility that the identified specializations in freeze-fracture replicas represent a type of synapse different from that known to be predominant from examination of thin sections. This possibility, however, seems unlikely from a purely quantitative point of view. Instead, transmitter release may occur at focal points along the bar-shaped density observed in thin sections, and the intramembranous particle specializations may represent the "active zones". (Supported by NIH grant AI 16150-01 and NIH postdoctoral fellowship F32 NS05891-02.)

62.2 QUICK-FREEZING REVEALS DIFFERENCES IN SYNAPTIC VESICLE ARRANGEMENTS IN THE TWO ELECTRIC ORGANS OF NARCINE BRASILIENSIS. Thomas E. Phillips & Alan F. Boyne. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611 & Dept. Pharm. & Exptl. Therap., Univ. MD., Sch. Med., Baltimore, MD 21201.

Narcine brasiliensis has a rapidly fatiguing main electric organ and a rapidly facilitating accessory organ (Bennett and Grundfest, J. Gen. Physiol., 44:805, 1961). Chemical fixation reveals no striking differences in vesicle arrangements that can explain these differing physiological behaviors.

We have used quick-freezing and freeze-substitution to prepare the two organs for transmission E.M. In the main organ, 24% of the presynaptic membrane has vesicles attached to it. This vesicle subpopulation represents 15% of the total terminal vesicle pool (n=16 terminals). In the rapidly facilitating accessory organ, only 7% of the presynaptic membrane has vesicles attached; this represents 5.5% of the total vesicle pool (n=12 terminals).

These results leave open the possibility that the difference in initial stores of vesicles attached to the pre-synaptic membrane can account for the difference in physiological behavior of the two organs. Further experiments on stimulated tissue are being done to investigate this possibility.

Sanes et al. (J. Cell Biol., 78:176, 1978) have shown that the basal lamina plays a role in active zone localization within nerve terminals at the frog nmj. Although there are no apparent thickening in pre- or post-synaptic membrane in the electric organ, we have recognized a dependence of vesicle attachment on the underlying basal lamina. This observation is facilitated by the general high frequency of vesicle attachments and the occurence of distinct separations between the basal lamina and the presynaptic membrane at post-junctional folds into which the basal lamina dips: no vesicles are seen directly over the fold (n=36 cases). On those occasions when the basal lamina is seen to bridge the post-junctional fold, vesicles are found with the same probability as in other regions of the nerve terminal.

Our results are consistent with the suggestion of Sanes et al., that components associated with the basal lamina play a role in organizing the differentiation of the nerve terminal.

62.3 BASEMENT MEMBRANE (BM) COLLAGEN (TYPE IV) METABOLISM AND NEUROMUSCULAR JUNCTIONS. K. Romstedt* and B.W. Festoff. (SPON: J.L. Voogt). Dept. of Neurology, Univ. of Kansas Med. Ctr. and Neurobiology Res. Lab., VA Med. Ctr., Kansas City, MO 64128.

Recently, several genetic types of collagen (I, III and V) have been identified by immunofluorescence in cultured and developing muscle. The involvement of the extracellular matrix (ECM) in muscle development as well as in nerve-muscle interaction is receiving increasing interest. We have been concerned with the regulation of several synaptic macromolecules at the neuromuscular junction (NMJ), specifically, fibronectin, 16S acetylcholinesterase (AChE), and, recently, Type IV collagen.

The rat anterior gracilis (RAG) muscle allows easy separation of end-plate (EP+) and non-end-plate (EP-) regions as well as for denervation studies. EP+/EP- regions were dissected, homogenized in cold 0.5M acetic acid (HAc) overnight and digested with pepsin for 6 hours. The supernatant was dialyzed and then run on dodecyl sulfate gels (SDS-PAGE) in absence or presence of reductant. A large concentration of Type I collagen was found in both EP+ and EP- regions, which could be removed if extraction in cold HAc preceded pepsin digestion. In EP+ regions, 2-3 bands were detected between $\alpha_1\alpha_2$ and $\beta_{11}\beta_{12}$ bands of Type I on non-reduced gels. These did not disappear with reduction and were present but less obvious in EP- regions. Using a sensitive hydroxyproline (HyP) assay, 2-3 times the EP- content of HyP was found in EP+ regions.

To confirm these observations, ^{3}H-proline (> 100mCi/mmol; 50μ Ci per animal) was injected I.P. into 80-100gm male Sprague-Dawley rats. After 24 hours, rats were killed by cervical dislocation, RAG dissected and EP+ and EP- regions separated. Following extraction in cold HAc labelled residues were digested with pepsin. These pepsin digests were then subjected to SDS-PAGE in 0.1M Na phosphate at neutral pH. Cut dried gels were then analyzed by fluorography and autoradiography. Using this technique quantitative increase in Type IV-like bands, which did not disappear with reducing agent, was found in EP+ regions. These data indicate that (a) Type IV collagen is found in muscle, (b) it is concentrated in EP+ regions and (c) it may be a substrate for proteolytic and/or collagenolytic activity suggesting its role in plasticity and denervation changes in muscle.

62.4 IMMUNOELECTRONMICROSCOPY OF SUBSTANCE P CONTAINING SYNAPSES IN RAT SPINAL CORD. G.Nilaver*,E.A.Zimmerman,J.G.Linner*, L.Chu* and G.P.Kozlowski. Dept. of Neurology, College of P&S, Columbia Univ. New York, NY 10032, and Dept. of Neurobiology and Anatomy, The Univ. of Texas Medical School at Houston, Houston, TX 77025.

The undecapeptide substance P (SP) is found in high concentrations in areas of brain and spinal cord involved in pain perception. SP has been implicated in pain processes and has been reported to interact with the opiate peptides met- and leu-enkephalin. Previous studies (Chan-Palay and Palay,PNAS,74,1977) have reported SP labeling in synapses of rat gelatinosa to be associated with both large and small diameter synaptic vesicles. Other studies (Pickel et al, Brain Res.,122.1977) have demonstrated selective labeling only of the large dense vesicles. The present ultrastructural study of rat substantia gelatinosa immunoreacted for SP was undertaken to compare the SP containing synaptic profiles in this region with these reports, and also with those reported in other brain areas. Rat spinal cords were perfusion fixed with 2% gluteraldehyde and 3% paraformaldehyde in phosphate buffer. 50 μm thick sections through the substantia gelatinosa were cut in the longitudinal and transverse planes using a Vibratome and immunocytochemically labeled for SP using the pre-embedding method of staining. Sections were incubated in specific antiserum generated in rabbit against synthetic SP conjugated to thyroglobulin (#NSP1-4) used at a dilution of 1:1000 for 2 hours. Ultrathin sections were studied both before and after counterstaining with lead citrate and uranyl acetate. SP immunoreactivity was concentrated in lamina I and II of the substantia gelatinosa. The reaction product was localized in unmyelinated axons and axon terminals forming asymmetrical synapses with dendrites. Several of these dendrites also had other non-reactive axon terminals with similar but unlabeled synaptic structures. The majority of synapses showed immunoreactivity in the lumen of large (120 nm) dense vesicles and on the periphery of small (20-40 nm) clear vesicles. Some synapses however, showed labeling only of the large dense vesicles. Within the labeled synapses, reaction product was also noted on mitochondrial membranes. In longitudinally sectioned axons several synaptic contacts could be demonstrated along the length of the axon, with reaction product in the axoplasmic matrix and on microtubules. No positive axo-somatic contacts could be demonstrated in the substantia gelatinosa. The present ultrastructural study of SP in the rat substantia gelatinosa shows the existance of both types of synapses previously reported in this region, and is in agreement with reports of SP-ergic synapses in other brain areas.

62.5 IN VIVO STIMULATION OF THE EDINGER WESTPHAL NUCLEUS PRODUCES MORPHOLOGICAL CHANGES IN THE PRESYNAPTIC TERMINAL OF THE CHICK CILIARY GANGLION. E. Philippe and J. P. Tremblay.* (SPON. Y. Le Beux). Lab. de neurobiologie, Dépt. d'Anatomie, U. Laval, G1K 7P4.

The Edinger Westphal nucleus of one day old chicks was stimulated during one hour at 100 Hz with a monopolar electrode placed stereostaxically. The effectiveness of the stimulation was monitored by the contraction of iris. The ciliary ganglion was fixed by injecting 2% formaldehyde and 1% gluteraldehyde in the ocular cavity while the stimulation was still continued for 2 more minutes. The ganglion was then dissected out and placed O.N. in the same fixatif. Eighty microns thick longitudinal slices of the ciliary ganglion were then obtained with a Smith Falquar tissue chopper. The tissue was then postfixed in osmium, dehydrated in alcool, stained in bloc with uranyl acetate and imbedded in epon. The ultrathin sections were collected on a 150 mesh copper grid. The occulomotor nerve ending almost completely surrounds the ciliary cells in young chicks and for this reason it has been called a calyx. Eight (4 controls, 4 stimulated) longitudinal calyx sections were completely reconstructed using about 40 overlapping pictures (at 53,000X) for each. The ciliary cells whose calyx was reconstructed had to be located in square of the copper grid completely filled with epon to prevent any density modification due to shrinking of the section. The nucleus and nucleolus of the cell had to be present to insure that the section was from the central portion of the ciliary cell. This in vivo stimulation reduces significantly the density of not only the clear vesicles (control: 100.4 ± 10.0/u^2, stimulated: 31.0 ± 1.7/u^2 p=.001) but also of the dense cores (c:1.08 ± 0.53/u^2, st: 0.15 ± 0.05/u^2, p=.025). Stimulation also increases the density of the coated vesicules (c:1.06 ± 0.30/u^2, st:1.94 ± 0.12/u^2, p=.005) and the amount of vacuoles membrane (c:0.47 ± 0.09/u^2, st:0.87 ± 0.27/u^2, p=0.05). An histogram distribution of the clear vesicles also indicated an increase of the size of the clear vesicles following stimulation. These results are similar to those reported at the neuromuscular junction by Heuser (J.Cell Biol.57,315,1973) except for the lowering of dense core vesicles which has not been reported before. The amount of membrane of the different organelles (clear, coated, dense vesicles and vacuoles) was calculated following stereological corrections for the density and the size of the organelles (total organelle membrane in u^2 per calyx section = c:35.48 ± 1.38, st:14.93 ± 1.00, p=.001). We have found that the net loss of organelle membrane following stimulation is not compensated for by an equivalent increase of the plasma membrane (plasma membrane in u^2 per section = c:10.64 ± 1.14, st:12.65 ± 3.35, p=.5). These results differ therefore from those of Heuser who found that the total amount of membrane remains constant at the neuromuscular junction following in vitro stimulation. More experiments are in progress to establish if this net membrane loss is also observed after in vitro stimulation of the ciliary ganglion.

62.6 A LIGHT AND ELECTRON MICROSCOPIC STUDY OF SYMPATHETIC NEURONS INTRACELLULARLY LABELLED WITH HRP. H. Kondo*, N.J. Dun and G.D. Pappas (SPON: R.S. Schmidt). Dept. of Anat. Col. of Med. Univ. Ill. Chicago, Ill. 60612 and Dept. of Pharmacol. Loyola Univ. Med. Ctr. Maywood, Ill. 60153.

Horseradish peroxidase (HRP) was injected intracellularly by iontophoresis into single sympathetic neurons of isolated rat and rabbit superior cervical ganglia and bullfrog paravertebral ganglia. The ganglia were then processed for light and electron microscopy study. Under light microscope, the perikarya of the labelled superior cervical ganglion cells of the rat and rabbit appeared round to oval, and several long processes could be seen emanating from the soma. The majority of processes which branched extensively among the adjacent neurons were identified as dendrites. In about 30% of the neurons labelled with HRP, several varicosities, 20-70 µm in length, could be observed at the distal portion of the dendrites; some of the varicose dendrites appeared to envelop partially the soma of the adjacent neurons. The axons, on the other hand, appeared solitary and varicosities were not observed in any of the axons. Labelled bullfrog sympathetic ganglion cells were unipolar and exhibited no branching; varicosities were not observed in any of the HRP-stained axons. The ultrastructures of cytoplasmic components could be clearly observed in several rat and rabbit sympathetic neurons lightly labelled with HRP. The dendrites which measured about 1 µm in diameter contained abundant small, clear spherical vesicles 50 nm in diameter, and a few large granular vesicles of 100 nm in diameter. The dendrites made contact with perikarya and dendrites of adjacent non-labelled neurons. In these junctions, a cluster of vesicles could be seen at the contact site of the labelled neurons, and the membrane of the non-labelled neuron immediately underneath the cluster of vesicles showed a light band of electron density; the apposed plasma membranes were separated by a space of about 20 nm. Our results using HRP-labelled sympathetic neurons of the rat and rabbit show that dendrites rather than axons give rise to varicose fibers, and that dendro-dendritic and dendro-somatic synapses appear to be present in these ganglia. (Supported in part by NSF Grant BNS 77-28493 and NINCDS Grant NS 15848).

62.7 ULTRASTRUCTURE OF NEUROMUSCULAR JUNCTIONS ON A TONIC AND A PHASIC CRAYFISH MUSCLE. T. Mendelson, R.R. Hoy and M.M. Salpeter. Section of Neurobiology and Behavior, Cornell University, Ithaca, N.Y. 14850.

In crayfish, synapses on the tonic opener muscle of the walking leg have small facilitating EPSP's which produce slow, prolonged contraction, whereas synapses on the phasic fast flexor muscle of the abdomen have large, poorly facilitating EPSP's producing large graded spikes and fast, brief contractions which fatigue rapidly. Although the morphology of the neuromuscular junctions on the opener muscle has been described (Jahromi, S.S. and Atwood, H.L., J. Cell Biol. 63:559, 1974; Smith, D.O., J. Comp. Neur., 182:839, 1978) that of the fast flexor has not. This study compares the ultrastructure of the neuromuscular junctions on the fast flexor muscles with those on opener muscles.

The axon terminals on opener muscle fibers were many times larger than those on fast flexor fibers; however, the proportion of synaptically-specialized axonal membrane was three times less in opener neuromuscular junctions than in fast flexor junctions. Opener muscle terminals had many more small synapses, a profusion of large synaptic vesicles (440 A mean diameter) which often filled the entire cross section of terminal, and many small mitochondria. They were found surrounded by a thick layer of muscle sarcoplasm containing many large mitochondria.

In contrast, fast flexor terminals were much smaller, with sparsely distributed small synaptic vesicles (377 A mean diameter) and no mitochondria. They were located close to the contractile myofilaments, surrounded by a narrow band of muscle sarcoplasm with few or no mitochondria. Terminals with finestructural features associated with excitatory and inhibitory function were found on both types of muscle but presynaptically inhibitory terminals were seen only in the opener muscle.

The fact that tonic and phasic muscles have different finestructure provides a basis for correlating morphology with physiology.

(Supported by a Muscular Dystrophy postdoctoral fellowship and an NIH postdoctoral fellowship to T.M. and NIH Grant NS 09315 to M.M.S.)

62.8 DISTRIBUTION OF COLLAGENASE IN SKELETAL MUSCLE: EVIDENCE FOR END-PLATE LOCALIZATION. B.W. Festoff, K. Romstedt* and Sharon T. Piper*. Dept. of Neurology, Univ. of Kansas Med. Ctr. and Neurobiology Res. Lab., VA Med. Ctr., Kansas City, MO 64128.

This laboratory is concerned with the neural regulation of synaptic macromolecules at the neuromuscular junction (NMJ). One such molecule has been the end-plate (EP) specific form of acetylcholinesterase (AChE) which has a 16S sedimentation co-efficient in mammalian NMJ. We have confirmed its specificity in NMJ regions of muscle, identified it in motor portions of nerve and spinal cord, calculated its transport rate in sciatic nerve and found it to be neurotrophically-regulated in rat anterior gracilis (RAG) muscle. Another molecule of interest found, but not concentrated at the NMJ, is fibronectin which we found to decrease in sarcolemmal membranes after denervation. Of particular interest is that these 2 molecules may interact at the NMJ because (a) 16S AChE appears to contain a collagenous "tail" which may "anchor" it to the basal lamina at the NMJ and (b) fibronectin has a special affinity for collagen. Types I, III, IV and V collagen have been identified in muscle using specific immunofluorescence. Type IV appears concentrated at the NMJ, but quantitative data is lacking. Since collagenase has been implicated in remodeling processes such as wound healing, in embryogenesis and in smooth muscle of the resorbing uterus, we analyzed collagenase in EP+ and EP- regions of RAG using several techniques. Collagenase is felt to be closely attached to the substrate collagen so we first assessed endogenous activity by measuring release of hydroxyproline (HyP) in 6000XG pellets or homogenates previously activated by small amounts of trypsin. Using this method endogenous activity was present in muscle with twice the activity in the EP+ region. Next we extracted collagenase using the method of Woessner and Ryan (1) and assayed activity with 2 different substrates: "native" 14C-proline-labelled guinea pig skin collagen (Dr. John Jeffrey) and ^{3}H-borohydride-reduced calf skin collagen, cross-linked with formaldehyde (as per Dr. Zena Werb). Using these techniques, (a) collagenase activity was present in muscle; (b) ratios of EP+/EP- activity was 1.06 ± 0.09 (N=7); (c) using "native" substrate, fragments of collagen, typical for the action of mammalian collagenase were found on SDS gels; (d) collagenase activity at NMJ must be tightly bound to substrate since 2X the endogenous activity was found in EP+ whereas after extraction, we found equivalent amounts throughout the muscle. Experiments to determine effects of denervation and other perturbations on activity and distribution of collagenase in muscle are in progress.

63.1 EFFECTS OF TEMPERATURE ON SPONTANEOUS ACTIVITY IN GOLDFISH CEREBELLUM MAINTAINED IN VITRO. E.J. Green* and C.L. Prosser. Department of Physiology and Biophysics, and Program in Neural and Behavioral Biology, Univ. of Illinois, Urbana, IL 61801.

Central nervous system activity in poikilotherms has been shown to be sensitive to temperature and subject to modification by thermal acclimation. Synaptic function is particularly susceptible, but the mechanisms underlying temperature effects are not known. In the present study endogenous unit activity was examined at various temperatures in slices of goldfish cerebellum.

Goldfish were rendered hypothermic by placing them in 4-5°C water until hyporeflexia and loss of equilibrium occurred. The brains were rapidly removed, cooled to 7°C, and parasagittal slices (400 microns thick) were cut with a tissue chopper (Duffy and Teyler, Physiol. Behav. 14:525, 1975). Slices were placed in a recording chamber where they were continuously perfused with oxygenated ringer solution. The slices were allowed to equilibrate in the chamber for one hour prior to data collection.

Extracellular recordings were made of single unit activity in the Purkinje cell body layer. Individual firing rates, as well as the pattern of activity of individual neurons were remarkably similar to those seen in vivo (Friedlander et al., JCP 112:19, 1976). Most units showed clear increases in firing rate (FR) with increases in temperature, and several different classes of responses were noted. For some units, increases were fairly linear, for others, FR varied exponentially with temperature. For 15°C acclimated fish, Q_{10} values (15-25°C) varied widely between neurons (0-4); however there seemed to be no correlation between initial FR (at 15°C) and Q_{10} values for individual neurons.

Temperature-induced changes in the pattern of activity were evident also. Computer generated histograms revealed that slight warming caused many units to fire in progressively longer bursts, with shorter interburst and interspike intervals. With further warming, some units became nonbursters, and assumed a more random pattern of activity. Data from fish acclimated to different temperatures is presented.

Our work with this preparation demonstrates that neuronal activity due to intracerebellar circuitry is temperature sensitive and that individual neurons respond differently to changes in temperature. Temperature modulation, in conjunction with in vitro techniques, may prove useful in the investigation of information processing and synaptic function.

63.2 EFFECTS OF LOW ETHANOL CONCENTRATIONS ON HIPPOCAMPAL CA1 FIELD EXCITABILITY IN VITRO. G. A. McLean and R. J. Person. Dept. of Physiology and Biophysics, Univ. of Okla. Health Sciences Center Oklahoma City, OK 73190.

Rat hippocampal slices were prepared and maintained in vitro with exposure to carbogen atmosphere according to standard methods (Alger and Teyler, Brain Res: 110, 463). After a preliminary equilibration period, stimulating and recording electrodes were placed in the slice and standard and somal responses were observed; thereafter a further 1 hr equilibration period was allowed. Constant current stimuli of 20-150 μA (500 μsec duration) were delivered to CA3 Schaffer collaterals. Responses were recorded in the CA1 stratum pyramidale using glass microelectrodes (2 M NaCl, 1-5 Mohm) with standard extracellular recording techniques. Ethanol was introduced into sidepools of the experimental chamber in amounts calculated to give final bath concentrations of 100-400 mg ETOH/dL bath. Final ethanol levels were verified at the conclusion of experiments by enzymatic colorimetric assay of the bath.

In 10 of 13 experiments both the population (somal) spike and population EPSP responses were significantly reduced in amplitude within 20 min of the addition of ETOH; the extent of reduction was dose-dependent. In these experiments, response amplitudes recovered substantially, returning to control amplitude with ETOH concentrations below 200 mg/dL. After 1-2 additional hours there was an irreversible decline in response amplitudes at higher ETOH concentrations. In the remaining three experiments, no early, transient reversal of the ETOH-induced response depression was observed. Rather, a slow monotonic decline in amplitude was observed reaching a plateau after 1 hour which continued for another 2-3 hours. Thereafter, responses declined again as in the biphasic experiments.

It is evident that physiological concentrations of ETOH can induce reliable changes in CNS excitability. Effects seen below 200 mg/dL were transient, suggesting that both synaptic transmission and somal spike generating machinery may recover function despite the continued presence of ETOH. These results indicate at least a limited ability of the CNS to adapt to sudden challenges of ETOH at low concentrations. At higher concentrations excitability may stabilize at a lower level than normal for a limited time, then decrease precipitously. Given low to moderate levels of ETOH, these experiments tend to support in vivo results suggesting that both the behavioral and physiological effects of ETOH are proportional to the time derivative of the blood alcohol curve.

63.3 EMBRYONIC CHICK SYMPATHETIC NEURONS GROWN IN CULTURE HAVE ACTION POTENTIAL MECHANISMS FOR Na^+, Ca^{++} AND K^+ AND SEVERAL OTHER K^+ CONDUCTANCE MECHANISMS. Barbara Pope*, Alan D. Grinnell and Paul H. O'Lague (SPON: P. M. Narins.) Dept. Biology and Jerry Lewis Neuromuscular Research Center, UCLA, Los Angeles, CA. 90024.

The electrophysiological properties of sympathetic neurons dissociated from the superior cervical ganglia of embryonic chick and maintained in culture for several months have been investigated with intracellular microelectrodes. All cells tested (n=75) had overshooting action potentials ranging from 70-90mV in amplitude and from 1-2ms in duration measured at half amplitude. These potentials were shown to be dependent on the external concentrations of both Na^+ and Ca^{++} by use of the sodium channel blocker tetrodotoxin and conventional Ca^{++} channel blockers. In addition, preliminary evidence was obtained in these cells for the presence of several K^+-dependent conductances (gK^+). These include: 1) a gK^+ that is associated with the falling phase of the action potential (i.e. delayed rectification), 2) a gK^+ that is activated by Ca^{++} and gives rise to a long lasting (100-350ms) hyperpolarization following the action potential, 3) a gK^+ that resembles anomolous rectification seen in other neurons and finally 4) a gK^+ that has been reported in several invertebrate preparations which appears inactivated at the membrane resting potential but which can be activated by a conditioning hyperpolarization of -20 to -30mV below rest followed by a depolarization. Detailed pharmacological evidence for the distinct nature of these conductances will be presented. Supported by USPHS Grant NS12901 (PHO) and NS06232 (ADG), and Muscular Dystrophy Association Grants to PHO and ADG, and postdoctoral fellowships to BP from the MDA and USPHS.

63.4 THE CONTRIBUTION OF NEURONAL ACTIVITY TO 2-DEOXYGLUCOSE UPTAKE IN SPINAL CORD CELL CULTURES. Neville Brookes and David R. Burt. Dept. Pharmacol. & Exptl. Therap., Univ. of Maryland Sch. of Med. , Baltimore, MD 21201.

Primary cell cultures derived from the spinal cords (SC) and dorsal root ganglia (DRG) of fetal mice (Peacock et al., Dev. Biol. 30:137, 1973) contain mixed cell populations. We have applied the Sokoloff method to obtain estimates of the proportion of glucose utilization in these cultures that can be attributed to SC neurons and the extent to which this is influenced by neuronal activity.

[^{3}H]2-deoxyglucose ([^{3}H]2-DG) tracer was added to 3-week-old cultures in nutrient medium containing 25 mM glucose. Uptake was measured by liquid scintillation counting of distilled water lysates of the previously washed cultures. The rate of uptake was constant for the first 1.5 hr, but began to decline by 3 hr. The contribution of SC neurons to uptake was determined by utilizing the specific neurotoxic action of monosodium glutamate (MSG) and also by using tetrodotoxin (TTX) or Mg^{++} to suppress neuronal activity. DRG neurons are resistant to MSG neurotoxicity and are not spontaneously active.

In several experiments [^{3}H]2-DG uptake was decreased by 40-60% in cultures pretreated with 1 mM MSG to destroy SC neurons. Addition of 2 μM TTX or 10 mM Mg^{++} to control cultures eliminated 60-80% of the MSG-sensitive uptake, suggesting that most of the neuronal uptake is a consequence of electrical activity. Uptake in MSG-pretreated cultures was not significantly influenced by TTX or Mg^{++}.

Strychnine, which blocks spinal inhibition, was used to increase the electrical activity of SC neurons. Addition of 10 μM strychnine to control cultures increased uptake, but the effect was variable in the range 10-90%. Uptake of [^{3}H]2-DG in the presence of strychnine was as much as 3.7-fold greater than uptake in replicate MSG-pretreated cultures. We conclude that MSG-sensitive uptake of [^{3}H]2-DG provides a useful quantitative measure of integrated neuronal activity in SC cell cultures. (Supported by USPS grants MH29011 and MH29671.)

63.5 HYPOTHALAMIC THERMOSENSITIVE NEURONS IN CULTURE. F. Baldino, Jr. and H.M.Geller. Dept. of Pharmacology, CMDNJ-Rutgers Med. Sch., Piscataway, NJ 08854

The preoptic/anterior hypothalamus (POAH) has been shown to contain thermosensitive neurons which are assumed to play an integral role in the regulation of body temperature. It was the purpose of this study to utilize explant tissue cultures to define the intrinsic thermosensitive characteristics of POAH neurons. Additionally, tuberal hypothalamus was examined as a control to insure that thermosensitivity is not a universal characteristic of all cultured neurons.

POAH and tuberal hypothalamic explants from newborn rats were maintained on coverslips at 37°C for 3-4 weeks prior to experimentation. The temperature of the recording chamber was maintained with a temperature regulator between 30° and 42°C. Recording of single cell discharges was accomplished using a single barrel glass micropipette (5-10 MΩ impedance) and standard laboratory electrophysiological techniques. Firing rate (FR) was assessed on line with a computer at each temperature randomly chosen between 30°-42°C.

This in vitro analysis of 30 cells yielded at least 3 distinct types of spontaneously active POAH neurons. The majority of cells (62%) tested were relatively unaffected by varying the temperature of the bath between 30° and 42°C ($Q_{10} \leq 2$) and were classified as temperature-insensitive neurons. Others (30%) responded with an increasing FR to increasing hypothalamic temperature and were classified as warm-sensitive cells ($Q_{10} > 2$). Cold-sensitive cells (8%) or those whose FR was inversely proportional to bath temperature ($Q_{10} < 0.5$) were also present in POAH cultures. When synaptic activity was abolished by perfusing a high Mg^{++}, low Ca^{++} medium, the thermosensitivity of these neurons persisted. No warm- or cold-sensitive neurons were found in explants of tuberal hypothalamus.

The demonstration that thermosensitive-neurons exist in preoptic but not tuberal hypothalamic tissue culture suggests that the neuronal sensitivity to temperature may be a characteristic of the neuronal network within the POAH and not solely dependent on peripheral or cutaneous thermal information. Furthermore, the maintenance of thermosensitivity by these neurons when synaptic connectivity is suppressed indicates that the ability to perceive temperature may be an intrinsic property of these POAH neurons. Supported by NSF BNS 79-14003.

63.6 PROPERTIES OF GABA-ERGIC DENDRO-DENDRITIC SYNAPSES IN THE IN VITRO TURTLE OLFACTORY BULB. M.C. Nowycky, K. Mori,* G.M. Shepherd, Sec. of Neuroanatomy, Yale Univ., School of Med., New Haven, Ct. 06510.

Dendro-dendritic reciprocal synapses have been demonstrated anatomically in the olfactory bulbs of many species. Mitral cell dendrites have a presumably excitatory action on granule cell dendrites, which then inhibit the same and neighboring mitral cell dendrites. A variety of evidence suggests that the granule to mitral cell neurotransmitter is GABA. We have investigated the physiological and pharmacological properties of this synapses in the in vitro turtle olfactory bulb preparation.

Turtles were decapitated, the brains removed and the olfactory bulbs were placed in a modified Ringer solution. Intracellular recordings were obtained from mitral cells, some of which were identified with HRP injection. Lateral olfactory tract (LOT) stimulation produced in most mitral cells an antidromic spike, followed by a complex series of at least three inhibitory potentials: two early potentials I_1 and I_2, and a late slow potential, I_s (lasting for one to several seconds). Addition of the GABA antagonist bicuculline to the Ringer solution caused elimination of I_1 and I_2 within 25 minutes and a delayed elimination of I_s at 30 or more minutes. The conductance increase and current sensitivity which normally accompany I_1 and I_2 (and to a lesser extent I_s) were all eliminated by bicuculline. Under control conditions paired LOT volleys resulted in suppression of the test antidromic spike from intervals of 10 ms up to several seconds. Bicuculline eliminated the inhibition of the test spike.

Recordings with KCl electrodes were obtained in the absence and presence of bicuculline. Within minutes of penetration with a KCl electrode the initial hyperpolarizing potentials of I_1 and I_2 became depolarizing. I_s was frequently diminished or eliminated but never reversed to a depolarizing potential. Bicuculline greatly diminished the depolarizing potentials I_1 and I_2.

We conclude that I_1 and I_2 are GABA-ergic and chloride dependent, whereas the I_s component is not. Current experiments are directed toward examining substances which modulate the synaptic components of mitral cell responses, and analysing further the mechanism of the I_s response.

63.7 MULTIPLE ACTIONS OF FLURAZEPAM IN THE PICOMOLAR RANGE ON CULTURED NEURONAL EXCITABILITY. J.F. MacDonald and J.L. Barker. Playfair Neuroscience Unit, T.W.H., Toronto, Ontario, M5T 2S8 and Laboratory of Neurophysiology, NIH - NINCDS, Bethesda, MD., 20205.

Spinal neurons dissociated from foetal mouse cords were grown in tissue culture for 4 weeks or more. Conventional intracellular recordings were made from single neurons and flurazepam was applied extracellularly using pressure microperfusion. Picrotoxin (50 µM) when appropriate was included in the bathing medium (Hank's plus 25 mM HEPES). In order to supress ongoing synaptic activity magnesium levels were elevated to 10 mM ($MgCl_2$).

Three depressant effects of flurazepam on the excitability of neurons were observed:

1) a dose-dependent increase in membrane conductance likely a consequence of a direct activation of membrane chloride permeability. This response was detectable with concentrations as low as 1 pM. But sustained applications of higher concentrations (> 10 nM) led to a complete desensitization. Picrotoxin failed to block this response.

2) a depression of the cell's spike-generating capacities. Low concentrations (100 pM - 10 nM) elevated thresholds for generating spikes and/or prevented repetitive firing. Higher concentrations (> 100 nM) were ineffective on cells that were sensitive to low concentrations (100 pM).

3) a depression of picrotoxin-induced convulsive activity. The presence of this drug evoked paroxysmal depolarizing events (PDEs) on a majority of cells studied. Relatively low concentrations (10-100 pM) of flurazepam attenuated the amplitude and duration of these events. This attenuation could be correlated to the depressant effects described in 1) and 2). However, higher concentrations (>100 nM) were much less effective.

These results suggest that flurazepam has multiple, concentration dependent actions on membrane excitability. However, not all neurons were sensitive nor did each neuron necessarily demonstrate each of these actions. The "bell-shaped" feature of the dose-response relation may help to explain tolerance.

63.8 EFFECTS OF NOREPINEPHRINE IN RAT HIPPOCAMPAL SLICES. M. SEGAL* (SPON: S.R. Sampson). Isotope Department, The Weizmann Institute of Science, Rehovot, Israel.

The effects of topical application of norepinephrine (NE) on membrane properties of about 150 neurons were studied in the rat hippocampal slice preparation. NE at a concentration of 10-100 µM applied in a droplet, produced a 3-5 mV hyperpolarization associated with minimal changes in input resistance, firing threshold, spike size or EPSP's. Higher concentrations of NE (1-10 mM) produced 15-20% reductions in input resistance. Application of NE on the soma produced its maximal effects, indicating that the observed lack of marked conductance changes is not due to activation of remote receptors. The effects of NE were blocked by sotalol, a beta antagonist. The NE induced hyperpolarizations were insensitive to changes in extracellular Ca^{+2} or Cl^- concentration. In the same preparation, 5HT produced hyperpolarizations associated with 25-35% reduction in input resistance and GABA produced a slight depolarization accompanied by 80-90% reductions in input resistance. These data indicate that unlike NE, 5HT and GABA activate K^+ and Cl^- conductances, respectively. The hypothesis that NE activates a Na-K pump was supported by the observations that NE effects were markedly attenuated by ouabain and low temperature.

The possible mediation of NE effects by cyclic AMP was tested in several experiments; it was found that cyclic AMP mimicks effects of NE. Also, the action of cyclic AMP was blocked by ouabain. Furthermore, IBMX potentiated the responses to NE.

It is suggested that NE activates, via generation of cyclic AMP, a Na-K pump which in turn hyperpolarizes the recorded neurone in the hippocampus.

64.1 EFFECTS OF BUSPIRONE ON SPINAL REFLEXES IN THE CAT. G. Keith Matheson and L. A. Riblet. Indiana University, School of Medicine, Evansville, IN 47732 and Department of Biologic Research, Mead Johnson Pharmaceutical Division, Evansville, IN 47721.

Buspirone HCl is a nonbenzodiazepine antianxiety agent which has been shown to be equipotent to diazepam in a double-blind clinical study in psychoneurotic outpatients with a primary diagnosis of anxiety neurosis (Am. J. Psychiatry 136: 1184, 1979). Binding studies indicate that buspirone neither inhibits nor stimulates ^{3}H-benzodiazepine binding to neuronal tissue (Trans. Am. Soc. Neurochem. 11: 193, 1980). Also unlike the benzodiazepines, buspirone has no anticonvulsant activity, interacts minimally with CNS depressants, does not cause muscle relaxation and lacks abuse potential. Thus, buspirone has a markedly different psychopharmacologic profile from other known antianxiety agents and is characterized as being anxioselective (Taylor, D.P., et al., this volume). The present study was undertaken in order to determine the acute effects of buspirone on spinal reflex mechanisms. Random source cats of either sex were anesthetized, intubated and cannulated for intravenous drug administration and blood pressure monitoring. If blood pressure fell below 75 mm Hg experiments were terminated. A paraffin boat was formed around the lumbar region of the exposed spinal cord. The temperature within the paraffin boat and the animal's core temperature was maintained at 37°C. Bipolar Pt stimulating electrodes were attached to the dorsal roots between L_6 and S_1. Recording Pt electrodes were attached to rootlets of the ventral root at L_7 or S_1 and to the dorsal rootlets at L_7. The animal was then paralyzed with gallamine triethiodide and artifically ventilated. Fluid balance was maintained with Lactated Ringer's Solution. Buspirone increased, by 100 percent or more, the amplitude of the dorsal root reflex and the monosynaptic reflex which persisted for over three hours. It was also noted from the monosynaptic reflex elicited after a conditioning stimulus pulse that buspirone increased five-fold the effect of post-synaptic inhibition. Presynaptic inhibitory mechanisms acting on the monosynaptic reflex were not significantly changed during the first two hours following drug administration but were reduced for the remainder of the experiment. This is in contrast to the effect of buspirone on the dorsal root reflex. These findings suggest that buspirone has differential effects on the presynaptic inhibitory mechanisms which generate the dorsal root reflex and modulate the monosynaptic reflex.

64.2 PHARMACOLOGICAL EVIDENCE THAT FIRING OF HIPPOCAMPAL PYRAMIDS IS RELEASED BY DISINHIBITION. N. Ropert*, K. Krnjević and R.J. Reiffenstein* (SPON: R. Capek). Anaesthesia Research and Physiology Depts., McGill University, Montreal Canada. H3G 1Y6.

In a recent study of IPSPs recorded in hippocampal neurons, a striking loss of inhibitory efficacy was observed during repetitive stimulation at frequencies > 2/s (Ben-Ari et al., Can. J. Physiol. Pharmacol. 57, 1462,1979). It was therefore proposed that a frequency-related disinhibition could account for the increase in firing observed during tetanic stimulation. In the present experiments, we have compared the effects of repetitive stimulation with those produced by several convulsants that are known to interfere with GABA-mediated inhibition. In rats under urethane, extracellular field responses were studied with multibarrelled microelectrodes, particularly at depths of about 2.0 mm from the cortical surface, where fimbrial stimulation evokes a maximal positive wave. At a very low frequency (≤ 1/s) this stimulation usually evokes nothing but a positive wave, which corresponds to the IPSP that is readily observed with intracellular recording. If the stimulating intensity is at least 3 x threshold (for the positive wave), increasing the frequency to 2 or more Hz causes a diminution of the positive wave and particularly the appearance of a population spike (initial latency about 6 ms). With increasing duration and/or frequency of stimulation, the spike increases in amplitude, and second and even third spikes appear (at intervals of 4-5 ms), so that a striking burst is generated, evidently reflecting the synchronized repetitive discharge of many pyramidal cells. (Presumably, weaker fimbrial stimulation is ineffective in generating spikes because it does not activate sufficient orthodromic excitation by commissural fibres.) An identical pattern of diminished positive field and population spikes (single or multiple) was readily generated by the following convulsants, *during low frequency stimulation*: picrotoxin (4 mg/kg i.v.), bicuculline methochloride, Na benzyl penicillin and d-tubocurarine (applied by microiontophoresis, in doses ≤ 7 nA). The intensity of firing was graded according to the amount of drug released, and the effects were usually only slowly reversible (over 1-2 min). Since all these agents have previously been shown to antagonize GABA-mediated inhibitions, and there is good reason to believe that GABA is the inhibitory transmitter that mediates fimbrial inhibition of hippocampal pyramids, these results support the idea that the release of firing is caused by reduced efficacy of inhibitory action, which is at least partly due to a diminished effectiveness of GABA (Ben-Ari et al., 1979). It is of interest that at least two naturally-occurring agents (ACh and met-enkephalin) have a comparable disinhibitory action.

64.3 THE EFFECT OF CAFFEINE AND MORPHINE ON ADENOSINE AND ACETYLCHOLINE RELEASE FROM RAT CEREBRAL CORTEX: INVOLVEMENT OF A PURINERGIC STEP IN THE ACTION OF MORPHINE. Z.G. Jiang*, J.W. Phillis, and B.J. Chelack*. (Spon: P.V. Sulakhe). Department of Physiology, College of Medicine, University of Saskatchewan, Saskatoon, Sask., Canada S7N OWO.

Methylxanthines (caffeine and theophylline) have been reported to antagonize several actions of morphine e.g. the analgesic effects of morphine in mice, and the depressant action of morphine on rat striatal neurons. Methylxanthines antagonize the depressant effects of morphine on acetylcholine (ACh) release from the guinea-pig longitudinal muscle myenteric plexus (JPET. 197,379, 1976) and intact rat cerebral cortex (Eur. J. Pharmac. 49,309, 1978). Adenosine also inhibits ACh release from the field stimulated guinea-pig longitudinal muscle preparation and cerebral cortex by a methylxanthine sensitive mechanism (JPET. 197,379, 1976), raising the possibility that morphine may reduce ACh release by a purinergic step. Groups of male Wistar rats were anaesthetized with nitrous-oxide-methoxyflurane. The dura was removed and a cup was placed on each hemisphere. The cortical surface within each cup was then incubated for 40 min with 100µl of ^{3}H-adenosine (0.1mM; specific activity of 0.1 Ci/M ICN) in physiological saline at 37°C and subsequently refilled with 100µl saline. Thereafter the cup contents were withdrawn every 15 min and replaced with fresh saline. Methylxanthines and morphine were administered through a femoral intravenous cannula. The bulk of the labelled material (> 50%) released was in the form of adenine nucleotides, inosine accounted for (20-40%), and adenosine and hypoxanthine together accounted for about 10% of the total activity. Morphine (1 mg/kg) evoked a significant increase (44%; $0.05 > p > 0.01$) in purine efflux rates during the initial 30 minutes following its administration and smaller increases during the next 30 min. Larger doses of morphine (5mg/kg) had a more pronounced effect. Prior injection of naloxone prevented the morphine-evoked increases in purine release. Caffeine (40 mg/kg) did not alter purine efflux rates. Morphine (1 mg/kg), given 30 min following prior treatment with caffeine (20 mg/kg or 40 mg/kg), evoked an increase in purine efflux similar to that of morphine alone. These findings are consistent with the suggestion that morphine suppression of ACh release may be mediated by a purinergic step. Morphine enhances adenosine release by a naloxone-sensitive but methylxanthine- insensitive mechanism. Morphine suppresses ACh release by a naloxone- and methylxanthine- sensitive mechanism. This lack of effect of caffeine on morphine elicited purine release suggests that caffeine is not a morphine antagonist *per se*, but rather that morphine suppression of ACh release involves a purinergic step.

64.4 BENZODIAZEPINE POTENTIATION OF INHIBITION IN HIPPOCAMPAL SLICE PREPARATIONS Herbert J. Doller and Forrest F. Weight. Laboratory of Preclinical Studies, National Institute on Alcohol Abuse and Alcoholism, 12501 Washington Avenue, Rockville, MD 20852.

Benzodiazepines have been shown to potentiate inhibitory responses in various regions of the central nervous system. The potentiation is thought to be specific for GABA mediated inhibition. We investigated the effect of bath applied benzodiazepines on the inhibition of granule cells in the hippocampal slice preparation.

The hippocampus from male Hartley guinea pigs was sliced in transverse sections with a thickness of approximately 450 um The slices were placed in a trough-like chamber, superfused at a rate of 5 ml/min with a Krebs solution saturated with 95% O_2 and 5% CO_2, and maintained at 37° C. The Krebs solution contained 124 mM NaCl, 5 mM KCl, 2.4 mM $CaCl_2$, 1.3 mM $MgSO_4$, 1.24 mM NaH_2CO_2, 10 mM glucose, and 26 mM NaH_2CO_2. Field potentials from the granule cell body layer were recorded in response to stimulation (0.1 Hz) of the perforant pathway. A second stimulating electrode was placed in the granule cell body layer near the CA_3 pyramidal cells. Stimulation of this region of the granule cells preceded by 10 to 100 msec every second stimulus to the perforant pathway. Such pre-stimulation resulted in the reduction in the amplitude of the perforant pathway-evoked granule cell population spike. The addition of 20 uM diazepam to the superfusing Krebs solution resulted in a potentiation of the inhibition evoked by conditioning stimulation of the granule cell body layer. The results indicate that benzodiazepines potentiate the inhibition of granule cell field potentials in the hippocampal slice preparation.

64.5 β-LEPTINOTARSIN-d: DOES IT ACTIVATE CALCIUM CHANNELS IN SYNAPTOSOMES? Jun E. Yoshino*, Ting H. Hsiao*, and William O. McClure. Section of Cellular Biology, Univ. of Southern Calif., Los Angeles, CA, 90007 and Department of Biology, Utah State University, Logan, UT, 84322.

Leptinotarsin-d (LPTd) is a protein, present in the hemolymph of the Colorado potato beetle, L. decemlineata, which stimulates the release of [^{3}H]acetylcholine from rat brain synaptosomes (Yoshino et al., J. Neurochem. 34, 635, 1980). The toxin has been purified in excess of 200 fold (Yoshino et al., Fed. Proc. 39, 281, 1980), but is not yet homogeneous. In contrast to the results reported by Hsiao and Fraenkel (Toxicon 7, 119, 1969), the most purified preparation of LPTd was not lethal to flies. In order to differentiate the activities in the hemolymph, the protein which is lethal to flies will be designated α-LPTd, and that which stimulates only the release of neurotransmitters will be referred to as β-LPTd.

The neurochemical properties of β-LPTd were examined using synaptosomes incubated with [^{3}H]choline and immobilized on Millipore filters. The relationship between the concentration of β-LPTd and the release of radioactive material produced a sigmoid curve with a Hill coefficient of 2. When the external Ca^{2+} was lowered by the removal of $CaCl_2$ and the addition of 50 μM EGTA, the curve remained sigmoid, but the amount of radioactivity released was depressed by 60%. Since the ability of β-LPTd to stimulate release appeared to be dependent upon the presence of Ca^{2+} in the external media, the uptake of Ca^{2+} into synaptosomes stimulated by β-LPTd was examined. β-LPTd stimulated a dose dependent uptake of $^{45}Ca^{2+}$ into synaptosomes. High concentrations of Mg^{2+} inhibit K^+-induced release of neurotransmitters from synaptosomes by interfering with Ca^{2+} influx through the voltage dependent Ca^{2+} channel. Both K^+-induced release and the activity of β-LPTd were depressed to the same extent when the external concentration of Mg^{2+} was increased. Verapamil (10 μM), a putative blocker of Ca^{2+} channels, inhibited the ability of β-LPTd to stimulate release by 25%. Since the ability of β-LPTd to stimulate release was not impaired by either the presence of tetrodotoxin or lowering the external concentration of Na^+, the toxin does not appear to be utilizing a Na^+-dependent mechanism to open the voltage sensitive Ca^{2+} channels. Our results suggest 2 molecules of β-LPTd are required to stimulate release from synaptosomes, and that these 2 molecules of toxin maybe activating the Ca^{2+} channel and promoting the influx of Ca^{2+}.

Supported by NSF, BNS 79-14284, and the Nelson Research and Development Company, Irvine, CA.

64.6 EFFECTS OF PHENYTOIN ON PYRAMIDAL CELLS IN THE IN VITRO RAT HIPPOCAMPUS. N. Hershkowitz* and G. F. Ayala, Dept. Neurol., Baylor Col. Med., Houston, Tx 77030.

The effect of 35 μg/ml of phenytoin (P) on a number of membrane and synaptic properties of CA1 and CA3 pyramidal cells in the in vitro hippocampus was examined utilizing intracellular recording techniques. Each cell was used as its own control. Effects noted below would occur 15 to 30 min after the introduction of P; reversal of effect on rinse out was usually slower. No significant effect was observed on either the resting membrane potential (RMP) or input resistance (Rn) (cf table) even up to 90 min after exposure to P. However, the amplitude (Amp), rate of rise, and rate of decay of action potentials (AP), evoked by either antidromic activation or cathodal current injection, was consistently reduced (cf table). The following table summarizes combined CA1 and CA3 results in terms of means ± standard error (*indicates $p<0.05$ difference from control by paired t test):

	Rn (MOhms)	RMP (mv)	AP Amp (mv)	AP Rise (v/sec)	AP Decay (v/sec)
n	15	15	10	10	10
Control	22.2±1.4	-56.8±2.5	84.6±1.5	422.0±20.8	112.7±8.0
15-30 min in P	21.1±1.4	-56.9±1.9	77.4±2.2*	362.4±23.5*	98.8±6.2*

The effect of P was studied on IPSPs evoked in CA1 cells by either Schaffer collateral (n=8) or recurrent pathway (n=4) stimulation and in CA3 cells by mossy fiber pathway (n=5) stimulation. P did not change the duration of these events. The conductance change and reversal potential of the early IPSP, measured at its peak response, also appeared unaffected.

The effect of P on hyperexcitability in CA1 cells (n=5) induced by tetanic orthodromic Schaffer collateral stimulation (50 Hz, 10 sec) was examined. This hyperexcitability, which may last up to 1 min following tetanus, is characterized by the ability of a single orthodromic stimulation to elicit a high frequency burst of action potentials arising from an underlying depolarization. P markedly reduced the number of action potentials in the burst as well as the underlying depolarization. This effect was observed when the neuron did not exhibit a decreased ability to generate an action potential for each stimulus during the tetanus. In a few neurons, however, continued exposure to P would cause a reduction in the ability to follow tetanus. (Supported by NIH Grant NS 11535)

64.7 NEUROPHARMACOLOGY OF AFFERENT PROJECTIONS FROM THE SUBSTANTIA NIGRA AND LATERAL HABENULA TO THE ANTERIOR RAPHE IN THE RAT. W.C. Stern, A. Johnson*, J.D. Bronzino* and P.J. Morgane. D. Dix Hosp., Raleigh, NC 27611, Trinity College, Hartford, CT 06106 and Worcester Fndn. Exptl. Bio., Shrewsbury, MA 01545

The present experiments characterized the neurotransmitter(s) likely to be involved in the suppression of raphe unit activity produced by electrical stimulation of the afferent projections from the lateral habenula (LHb) and substantia nigra (SN). Wang and Aghajanian (Science 1977, 197:89-91) reported that the LHb-raphe projection was probably mediated by GABA since the GABA antagonist, picrotoxin, blocked the effects of LHb stimulation. In the first experiment, this effect was confirmed in anesthetized rats using extracellular glass microelectrodes and i.p. doses of 2-10 mg/kg of picrotoxin. Picrotoxin produced a 50% reduction in the percent of raphe cells inhibited by LHb stimulation. In other experiments recording from over 500 raphe units, we attempted to characterize the neurotransmitter mediating the inhibitory effects of the SN on the raphe (dorsalis and medianus). Dopamine and GABA, both of which are present in high concentrations in nigral neurons, do not seem to be involved since moderate-high doses (i.p.) of blockers of these transmitters (picrotoxin, haloperidol, or chlorpromazine) failed to reduce the suppressing effects of nigral stimulation on raphe activity. Similar negative findings occurred with drugs that block acetylcholine (atropine, scopolamine), opiates (naloxone), glycine (strychnine), histamine (diphenhydramine, cyproheptadine) and norepinephrine (propranolol, phenoxybenzamine).

The effects of all the above drugs on the spontaneous discharge rates of populations of raphe dorsalis and raphe medianus neurons are also being evaluated. For raphe dorsalis units, only picrotoxin produced a significant overall change in mean firing rate (38% increase), an effect consistent with the blockade of LHb-produced suppression by picrotoxin. This suggests that the spontaneous firing rate of raphe units is influenced by tonic gabergic inhibition originating in the LHb. In the raphe medianus, the drugs which significantly altered (increased) activity were cyproheptadine (5-20 mg/kg) and yohimbine (5-10 mg/kg). Since the antihistamine, diphenhydramine (10-30 mg/kg), did not increase raphe medianus discharge rates, it is more likely that cyproheptadine's effects result from its anti-serotonin activity. These results also show that the effects of various drugs on spontaneous activity are not necessarily the same in the dorsalis and medianus subdivisions of the midbrain raphe. These results support prior findings of differential inputs, outputs, and circuitry for these two raphe nuclei. (Supported by funds from Burroughs Wellcome and NSF grant BNS 77-16512.)

64.8 PENTOBARBITAL-INDUCED PROLONGATION OF SPONTANEOUS AND EVOKED IPSPs IN CA3 HIPPOCAMPAL NEURONS. F. J. Lebeda, T.H. Brown and D. Johnston. Dept. of Neurology, Baylor Coll. of Med., Houston, TX 77030 and Div. of Neurosciences, City of Hope Research Inst., Duarte, CA 91010.

A variety of convulsant and anticonvulsant agents have been proposed to interact with inhibitory synapses in the mammalian central nervous system. The in vitro hippocampal slice preparation offers accessible inhibitory pathways for investigating these postulated pharmacological effects at the cellular level. For example, the convulsant picrotoxin has been demonstrated to antagonize spontaneously occurring miniature inhibitory postsynaptic potentials (IPSPs) in the CA3 pyramidal neurons of guinea pig hippocampal slices (Brown and Johnston, SFN Abst. 6,1980). In the present study, initial experiments were performed to determine an effective concentration range of sodium pentobarbital which counteracted the 10 μM picrotoxin-induced spontaneous epileptiform discharges observed in CA3 field potential recordings. Since pentobarbital (100-500 μM) was able to block reversibly these picrotoxin-induced discharges, the spontaneous and evoked IPSPs were therefore examined at these concentrations.

With bath-applied pentobarbital (150 μM), mossy fiber stimulation produced IPSPs in which the half-decay times were prolonged from about 50 to 150 msec in CA3 neurons. Qualitatively similar results have been obtained with pentobarbital in CA1 hippocampal neurons in vivo and in vitro (Nicoll et al., Nature 258:625,1975; Alger and Nicoll, Nature 281:315,1979).

Spontaneous IPSPs were examined by utilizing a single electrode clamp circuit and the recently introduced technique of employing Cs-filled microelectrodes (2M Cs_2SO_4; Johnston and Brown, Fed. Proc. 39:2071,1980). After injecting Cs intracellularly (causing an increase in input resistance), the spontaneous IPSPs were augmented during maintained depolarizations to membrane potentials between -40 and +20 mV. After exposure to 125 μM pentobarbital, median values of spontaneous IPSP amplitudes at 0 mV were only about 30% larger, while times-to-peak and half-decay times were approximately 3-fold longer than control (increased from about 8 to 30 msec and from 30 to 90 msec respectively). These alterations are consistent with the hypothesis that part of the mechanism of action of pentobarbital involves the enhancement of inhibitory synaptic transmission. (Supported by a grant from the Epilepsy Foundation of America and by NIH Grants NS15772 and NS11535).

64.9 HISTAMINE MODULATES SYNAPTIC TRANSMISSION IN RAT SUPERIOR CERVICAL GANGLION AND AT FROG NEUROMUSCULAR JUNCTION VIA TWO PHARMACOLOGICALLY DISTINCT RECEPTORS (H_1 & H_2). R. W. Snow, C. Stein* and D. Weinreich. Dept. Pharmacol. & Exp. Therap., Univ. MD., Sch. Med., Baltimore, MD 21201.

Previous work has suggested that histamine (HA) depresses synaptic transmission at frog neuromuscular junction (NMJ) by both pre- and postjunctional mechanisms (Scuka, M., Neuropharm., 12:441, 1973), but the type of receptors (H_1 or H_2) involved was not investigated. In addition, other work has suggested that HA can either depress transmission via H_2 receptors or facilitate transmission via H_1 receptors in mammalian superior cervical ganglion (SCG) (Brimble, M.J. & Wallis, D.I., Nature, 246:156, 1973). We sought to more clearly establish the receptor types and the mechanisms mediating this synaptic modulation by HA.

In the rat SCG, the compound action potential (CAP) recorded extracellularly following sub-maximal preganglionic stimulation was facilitated by low doses of HA (10^{-7} M) and depressed by higher doses (10^{-5} M). The H_1 agonist 2-thiazolylethylamine (2-TH, 10^{-7} M to 10^{-5} M) also facilitated transmission while the H_2 agonist impromidine (IMP, 10^{-6} M to 10^{-5} M) depressed the CAP.

Using intracellular recording techniques, HA (10^{-5} M) had no effect on membrane potential, input resistance, spike threshold, the amplitude of the spike afterpotential or acetylcholine (ACh) sensitivity. However, HA or IMP (10^{-5} M) decreased the epsp amplitude and quantal content by 15-25%. In addition, 2-TH (5×10^{-7} M) increased the epsp amplitude and quantal content by 20-25%. These H_1 and H_2 agonist effects were blocked by H_1 and H_2 antagonists. We conclude that in the rat SCG, HA mediates facilitation and depression of transmission by presynaptic H_1 and H_2 receptors.

At the frog NMJ, HA (10^{-5} M) had no effect on postjunctional ACh sensitivity. Scuka (1973) has shown that higher doses of HA interact with the postjunctional ACh receptor-ionophore complex, similar to the action of atropine. We believe these postjunctional effects of HA are not mediated by HA receptors.

HA had variable effects on miniature endplate potential frequency (m-Hz), either increasing or decreasing m-Hz in different preparations. IMP (10^{-5} M) consistently decreased m-Hz, while 2-TH (10^{-6} M) consistently increased m-Hz. These results imply the presence of both H_1 and H_2 receptors in the motor nerve terminals.

64.10 GANGLIONIC DISCHARGES INDUCED BY TYRAMINE. Daryl Christ* (SPON: D.L. Avery). Dept. of Pharmacology, Univ. of Arkansas for Medical Sciences, Little Rock, AR 72205.

d-Amphetamine produces discharges in the stellate ganglion. If this effect is due to a sympathomimetic action of d-amphetamine, other sympathomimetics should also induce ganglionic discharges. The effects of tyramine were explored in the isolated stellate ganglion of the hamster using extracellular recording methods. Tyramine HCl, at concentrations between 10^{-3} and 10^{-2}M, reduced the amplitude of the postganglionic action potential from preganglionic nerve stimulation at 0.2 Hz. The ganglionic blocking action of tyramine was much weaker than the ganglionic blocking action of d-amphetamine or norepinephrine. 10^{-4}M tyramine induced asynchronous discharges in the postganglionic nerve. These discharges were considerably larger at 10^{-3}M tyramine. The discharges were not maintained during continuous exposure to tyramine but tended to subside after approximately 5 minutes exposure to tyramine. The discharges from tyramine were potentiated by 10^{-5}M pargyline, a monoamine oxidase inhibitor. Although tyramine produced discharges, it did not increase the ganglionic discharges from DMPP (10^{-4}M).

Tyramine produces discharges in the stellate ganglion which are very similar to the discharges from d-amphetamine. This indicates that the discharges from these drugs are due to sympathomimetic actions of the drugs. The potentiating action of pargyline supports this conclusion. On the other hand, the large difference in potency of tyramine and d-amphetamine for ganglionic blockade, and the difference in abilities to potentiate the actions of DMPP indicate that these effects are not due to sympathomimetic actions of the drugs. (Supported by NIH Grant NS-15528)

64.11 EFFECTS OF VANADIUM ON RAT BRAIN SYNAPTOSOMAL ATPases AND BINDING OF ^{3}H-OUABAIN AND ^{45}CALCIUM. D. Desaiah, S. K. Mishra, and R. L. Osborn*. Neurology and Research Services, Veterans Administration Medical Center, and Department of Neurology, University of Mississippi Medical Center, Jackson, MS. 39216.

Vanadium has been shown to inhibit Na^+-K^+ ATPase in heart and brain tissue homogenates. However, a comparative study on the effects of vanadium on different ATPases in one tissue preparation is lacking. We have determined the sensitivity of Na^+-K^+, Ca^{++} and Mg^{++} ATPases of purified rat brain synaptosomes to vanadium. The effects of vanadium on binding of ^{3}H-ouabain and ^{45}Calcium to rat brain synaptosomes were also studied. Preincubation of synaptosomes with varying concentrations of vanadium chloride resulted in a significant and concentration-dependent inhibition of Na^+-K^+ and Ca^{++} ATPase activities. However, Na^+-K^+ ATPase was more sensitive to vanadium than Ca^{++} ATPase. The Mg^{++} ATPase activity was unaffected by vanadium at any concentration tested. A 50% inhibition of Na^+-K^+ and Ca^{++} ATPases were obtained at 10^{-6}M and 10^{-4}M vanadium chloride respectively. Preincubation of synaptosomes with vanadium chloride resulted in a decreased binding of ^{3}H-ouabain. The inhibition of ouabain binding was significant and dose-dependent reaching a maximum inhibition of 90% at 10^{-3}M vanadium chloride. However vanadium chloride had no appreciable effect on ^{45}Calcium binding to synaptosomes. These results and other kinetic data indicate that vanadium may be a more effective inhibitor of Na^+-K^+ ATPase than other ATPases. Also the present data suggest that vanadium may not be a specific inhibitor of Na^+-K^+ ATPase like ouabain. (Supported by Medical Research Service of Veterans Administration).

65.1 PROPERTIES OF ELECTRICAL CONNECTIONS FORMED BY ISOLATED LEECH NEURONS IN CULTURE. P. A. Fuchs and D. F. Ready* Neurobiology Dept., Stanford Univ. Med. School, Stanford, California. 94305.

Single, identified neurons isolated from the leech CNS will establish electrical connections with one another in culture. We have investigated the extent to which these de novo contacts resemble the normal connections of cells within the ganglion. In ganglia from adult leeches Retzius cells are electrically coupled to their contralateral homologues, but not to pressure (P) sensory cells. P cells, as well as nociceptive (N) sensory cells, normally make electrical connections with the longitudinal (L) motoneuron, and L motoneurons are electrically coupled to their contralateral homologues.

These connections are reproduced by isolated cells in culture. Retzius cells become electrically coupled to other Retzius cells, but not to P sensory neurons. P and N sensory cells make electrical connections with L motoneurons, and L cells become electrically coupled. Thus, neurons maintained in culture interact with a variety of targets to display the pattern of connectivity they show in the animal.

The properties of the electrical junctions formed by cells in culture are similar to those of the corresponding synapses in the ganglion. The electrical connections formed by pairs of Retzius cells or pairs of L motoneurons is non-rectifying, while P and N sensory cells make rectifying connections with L motoneurons. For the most part, the sites and structures underlying these various forms of electrical coupling between leech neurons are unknown. Using isolated pairs of nerve cells in culture it is possible to examine such interactions in detail and to begin to define the mechanisms involved in different forms of electrical connectivity between neurons.

65.2 DEVELOPMENT OF RAT NEUROMUSCULAR JUNCTIONS IN ORGAN CULTURE. L. Ziskind-Conhaim and M.J. Dennis*. Dept. of Physiology, University of California Medical School, San Francisco, CA 94143

Explants of d15-d18 embryonic rat intercostal muscles together with their thoracic spinal cord segments were maintained in organ culture for up to 6 days. Muscle fibers continued to grow and differentiate after explantation although not as extensively as during the same interval in utero. The small tufts of nerve sprouts which were observed at d15 began to branch and extend along the center of the muscles after 1-2 days in culture.

Acetylcholine receptors, as detected by autoradiography, were uniformly distributed along the fibers at d15 and began to cluster in the mid-region of the fibers one day after explantation. Furthermore, receptor clusters were associated with acetylcholinesterase, indicating that the cholinergic receptors accumulated at the endplates of the muscle fibers. The time course of receptor aggregation was identical to that seen in vivo and the formation of the clusters was dependent on the presence of nerve terminals.

The resting membrane potential of the explanted muscle fibers varied between -70 mV and -85 mV and the properties of spontaneous and evoked synaptic potentials were comparable to those recorded in embryonic fibers in vivo (Dennis, Ziskind-Conhaim and Harris. Develop. Biol., in press). The number of functional synaptic contacts on individual muscle fibers increased during the culturing period at a rate similar to that observed in vivo. Our observations establish the developing rat intercostal muscles in organ culture as a favorable preparation in addressing questions which could not be easily studied in the embryos.

65.3 DEGREE OF SPECIFICITY MAINTAINED BY SPROUTING AND REGENERATING MOTOR NERVES TO CAT TIBIALIS ANTERIOR MUSCLE. J. Ungar-Sargon* and M. E. Goldberger. Dept. Anatomy, The Medical College of Pennsylvania, Philadelphia, PA 19129.

Cats were allowed to survive up to 2 years following a unilateral spared (L7) nerve preparation (lumbosacral spinal nerves cut sparing L7) in order to permit collateral sprouting by L7 and then regeneration by L5, L6, S1, S2. Reflexes were tested sequentially. Initially the tibialis anterior (T.A.) myotatic reflex was present but extremely weak on the operated side indicating that only some fibers to T.A. were carried in the L7 nerve and others had been cut. Later (1 week) the reflex recovered and became exaggerated suggesting collateral sprouting of L7 fibers into the muscle. Two years later the motor innervation to T.A. was examined by using retrograde transport of HRP injected into the T.A. muscle of both legs. In the normal cat, labeled cells innervating T.A. are found in a narrow range of L6 (caudal) and L7. Thelabeled cells are symmetrical in their rostrocaudal extent on the two sides and are found in a discrete nucleus also symmetrical bilaterally in the lateral-ventral horn consistent with the localization found by Romanes. T-test showed there is no significant difference in size on the two sides. On the operated side in the segment of the spared nerve, the discrete nucleus is still observed; cells of other nuclei are only occasionally labeled. The labeled cells on the operated side are up to twice as large as the labeled cells on the control side in the spared nerve segment. In segments of the cut but regenerated nerves, the cross sectional organization of the motor representation of T.A. appears to be disrupted. Labeled motor neurons are not found in a particular nucleus; moreover, their location is not necessarily similar to the position of the T.A. nucleus. Some appear to lie in the medial motor nucleus. The normal rostro-caudal extent is also changed. Labeled cells are found in L5, L6 and S1 as well as L7. The cells outside of the spared nerve segment are not consistently enlarged. Apparently a normal representation is maintained by cells undergoing collateral sprouting. For the most part, the normal topography suggests that specificity is retained by collateral sprouting and motor neurons which sprout into the partly denervated muscle already maintained connections there (or lie among cells that do). This is not the case for regenerating motor neurons which project to a muscle they do not innervate normally.

65.4 INNERVATION OF THE CILIARY GANGLION IN ADULT AND NEONATAL RABBITS. David A. Johnson* and Dale Purves. Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO. 63110.

An important feature of the postnatal development of synaptic connections in mammalian autonomic ganglia is the elimination of some of the synapses initially formed. Neither of the ganglia studied to date (submandibular ganglion of the rat; hamster superior cervical ganglion) is ideally suited to further exploration of synapse elimination. The rules which govern this phenomenon might be studied to best advantage in a ganglion which is a) anatomically well defined, b) comprised of a small number of neurons, c) comprised of ganglion cells each of which is innervated by only a few preganglionic axons in maturity, d) innervated by a small number of preganglionic neurons whose location is well defined, and e) amenable to physiological modification of ganglion cell activity. The ciliary ganglion of the albino rabbit meets these criteria.

The number of neurons in the ganglion, as well as the preganglionic population, is indeed small. Cell counts show that the ganglion is comprised of about 500 neurons (range 366-593, n=15). Moreover, the average number of cells in ganglia of one day-old animals is not significantly different from the number of cells in adult ganglia. Horseradish peroxidase applied to the proximal cut end of the preganglionic stalk labeled fewer than 300 neurons in the ipsilateral brainstem just ventral to the fourth ventricle at the level of the oculomotor nucleus (n=3). Since we have not ruled out some uptake by damaged oculomotor axons, this figure is a maximum estimate of the number of preganglionic cells.

Intracellular recordings from ganglion cells during graded stimulation of the preganglionic nerve in vitro show that adult neurons (older than 10 weeks) are innervated by an average of 2.2 different axons (range 1-6). In contrast, neonatal neurons (from animals 1-7 days old) are innervated by more than 5 different axons on average; only occasional cells in newborns receive inputs from one or two axons, compared to 64% of neurons in adult ganglia. The average number of inputs to ganglion cells declines gradually during the first few postnatal weeks, reaching the adult level by about 9-10 weeks of age.

A possible reason why some ciliary ganglion cells remain innervated by up to 6 different axons in maturity while others lose their multiple innervation is considered in an accompanying abstract (R.I. Hume and D. Purves, this volume).

Supported by NIH grant NS-11699 and a grant from the Muscular Dystrophy Association.

65.5 RELATION OF MULTIPLE INNERVATION TO THE GEOMETRY OF RABBIT CILIARY GANGLION CELLS. Richard I. Hume and Dale Purves. Department of Physiology and Biophysics, Washington University School of Medicine, St. Louis, MO. 63110.

Neurons in the rat submandibular ganglion, which generally receive innervation from only one preganglionic axon, have few if any processes; on the other hand, neurons in the guinea-pig superior cervical ganglion, which receive several different inputs have a complex dendritic arborization. This suggests a correlation between multiple innervation of autonomic ganglion cells and the number of dendrites they possess (see Lichtman and Purves, 1980). We have examined this possibility directly by determining both the number of inputs and the geometry of individual cells in the ciliary ganglion of adult albino rabbits.

We impaled 100 ganglion cells (1-3 cells per ganglion) with micropipettes filled with 5% horseradish peroxidase (w/v) in buffered 0.2 M potassium acetate. The number of axons making synapses upon each ganglion cell was determined by counting increments in the postsynaptic response during graded stimulation of the preganglionic nerve. HRP was then pressure-injected into the cells for 2-20 minutes. One to three hours later the ganglia were processed according to a modification of the Hanker-Yates procedure. Cells marked in this way were viewed in whole mount and drawn with the aid of a camera lucida.

There was a strong correlation between the complexity of the geometry of individual neurons and the number of inputs they received. Most cells (20/29) receiving one input lacked dendrites altogether; conversely, all those cells with 5 or 6 different inputs (n=9) had extensive dendritic arbors (5.5 primary dendrites, on average). In general, cells with 2-4 inputs (n=62) had an arborization of intermediate complexity (2.4 primary dendrites).

On average, neonatal ciliary ganglion cells are innervated by a greater number of axons than adult ganglion cells (see D.A. Johnson and D. Purves, this volume). That mature cells receive a number of inputs that varies according to the number of dendrites they possess suggests that the geometry of each neuron may be important in determining the outcome of synapse elimination in early postnatal life.

65.6 CENTRAL REGULATION OF THE MORPHOLOGICAL AND BIOCHEMICAL MATURATION OF SYMPATHETIC GANGLIA. R.W. Hamill, J.M. Lawrence, P. Cochard, G. Raisman and I.B. Black. Div. Develop. Neurology, Cornell Univ. Med. Coll., New York, N.Y. 10021; Natl. Inst. for Medical Research, London, Eng. NW7 1AA; Institut D'Embryologie Du CNRS 94130 Nogent Sur Marne - France.

The effects of interruption of descending central pathways on the morphological and biochemical ontogeny of peripheral sympathetic ganglia were examined in the sixth lumbar (L-6) sympathetic rat ganglia. Previous studies defined the normal maturation of presynaptic choline acetyltransferase (CAT) activity, postsynaptic tyrosine hydroxylase (T-OH) activity, and total protein in the L-6 ganglion. More recent studies indicated that neonatal spinal cord transection prevented the normal ontogeny of presynaptic CAT, postsynaptic T-OH and ganglion protein but the morphological substrate of these biochemical abnormalities remain to be defined. In the present investigations ganglion synapse numbers and adrenergic neuron numbers were examined in transected and sham-operated littermate controls 6 weeks after surgery at 10 days of age and correlative biochemical studies were performed.

Spinal transection resulted in a reduction in synapse number in ganglion cell bodies (53.5% reduction) and neuronal processes (55.8% reduction). This abnormality in synapse number was associated with a reduction of CAT activity to 56% of control. Although T-OH activity also failed to develop normally and was 25% of control, there was no associated alteration in adrenergic neuron number.

These studies suggest that descending central pathways regulate the maturation of presynaptic cholinergic terminals (and hence synapse number) in sympathetic ganglion and that CAT activity serves as an accurate marker for these terminals. Additionally, the ontogeny of ganglion T-OH activity is altered by central lesions and this effect is not secondary to a decrease in adrenergic neuron number.

66.1 COLLATERAL INPUT TO THE NEOSTRIATUM FROM DESCENDING AXONS OF THE RAT SOMATIC SENSORY-MOTOR CORTEX. John P. Donoghue and S.T. Kitai, Dept. of Anatomy, Michigan State University, East Lansing, Michigan 48824.

Using the technique of intracellular injection of horseradish peroxidase (HRP) it was demonstrated that single neurons in the rat somatic sensory-motor (SSM) cortex project both to the brainstem and to the neostriatum. Brainstem projecting neurons were identified during intracellular recording by antidromic activation from the cerebral peduncle or by tracing HRP labeled axons into the internal capsule after histological processing. A total of 17 HRP-injected cells, all in layer V, were identified in this manner. Five of these neurons gave a collateral branch to the striatum.

Branched cells are typical layer V pyramidal neurons with spiny dendrites. Their cell bodies, measuring 22-26μm, are among the largest in rat SSM cortex. Similar to other layer V cells, the main axon issues several fine intracortical axon collaterals that terminate mainly in layers VI and V, but also ramify near the apical dendrite in the upper cortical layers. The main axon, measuring 2.0-2.5μm in diameter, does not branch in the white matter. About 300μm after entering the striatum a single axon collateral, approximately 0.5μm in diameter arises from the main axon of these cells. Although the HRP reaction product faded in most cases after a few hundred μm, one collateral was followed 1.3mm within the striatum. Typical of other striatal collaterals this axon projects laterally and anteriorly with relatively little arborization. This branched striatal and brainstem projecting cell was antidromically activated from the peduncle at a latency of 0.6 msec, which was the shortest latency found for any of the layer V neurons recorded. All branched cells were excited by peripheral somatic sensory (electrical) stimulation.

Thus, the results demonstrate that some large, rapidly conducting layer V pyramidal cells of rat SSM cortex that project into the brainstem give a fine axon collateral to the neostriatum Further, these cells respond to somatic sensory inputs and would relay this information to lower centers and also to the striatum. The large size of these cells suggests that they may project to the lower brainstem or even to the spinal cord. Supported by NIH Grants NS 14866 and NS 06249.

66.2 INVOLVEMENT OF A CORTICO-STRIATAL AXON REFLEX IN THE RESPONSES OF STRIATAL NEURONS TO SUBSTANTIA NIGRA STIMULATION IN THE RAT. C. J. Wilson*, H. T. Chang & S. T. Kitai, Dept. of Anatomy, Michigan State University, E. Lansing, MI 48824.

Stimulation of substantia nigra has been previously shown to elicit an extracellular field potential in rat striatum and a complex pattern of excitation and inhibition in rat striatal neurons. The early response appears in intracellular recordings as a depolarization beginning as early as 2 msec after nigral stimulation and often containing more than one component. The earliest component of the excitatory response has been interpreted as a monosynaptic nigral induced EPSP. The present evidence, however, suggests that this EPSP and the associated field response arise from inadvertent stimulation of cortical efferents projecting both to brainstem and striatum.

Intracellular recordings were obtained from rat striatal neurons using bevelled glass microelectrodes containing 4% horseradish peroxidase (HRP) in Tris buffer (pH 7.6) and .5M potassium chloride or potassium acetate. Neurons were identified by microscopic examination after iontophoretic application of HRP through the recording electrode and subsequent histochemical processing. Most identified spiny neurons responded to stimulation of substantia nigra with short latency (2-6 msec) monosynaptic EPSP. In many cases, this depolarizing response exhibited more than one distinct component. Stimulation of the rostro-ventral pons more than 2 mm caudal to substantia nigra, however, resulted in a nearly identical response in these same neurons. When both sites were stimulated simultaneously the two responses failed to summate, suggesting that they may be mediated by the same population of axons. Since both of these areas contain a high density of cortical efferent fibers, the experiments were repeated in rats subjected 3-4 days earlier to large ipsilateral aspirations of frontal cortex. After this treatment, the short latency EPSP and the field response to both nigral and pontine stimulation were severely attenuated or absent. In the decorticate rats, nigral stimulation elicited long latency (8 to 16 msec) low amplitude depolarizations which could not be elicited from the pontine stimulation site. Despite its long latency, this depolarization appeared monosynaptic by virtue of its constant latency upon variation of stimulus intensity or frequency. This response to nigral stimulation may represent the activation of slowly conducting dopaminergic nigro-striatal axons. (Supported by USPHS grant NS 14866).

66.3 EXCITATORY POSTSYNAPTIC POTENTIALS RECORDED IN NEURONS OF THE RAT CAUDATE-PUTAMEN FROM STIMULATION OF THE DORSAL RAPHE NUCLEUS ARE SEROTONERGIC. M.R. Park, J.A. Gonzales-Vegas*, J.W. Lighthall and S.T. Kitai, Dept. of Anatomy, Michigan State University, East Lansing, Michigan 48824.

Stimulation of dorsal raphe nucleus (DR) has previously been shown (VanderMaelen, et al., Brain Res., 175:356, 1979) to produce monosynaptic EPSPs in neurons of the rat caudate-putamen (CP). It has not been determined, however, whether these excitatory responses are due to the known serotonergic DR-CP projection. In order to answer this question, intracellular recording of the responses to DR stimulation was performed in male hooded rats (275-350 g) in which the levels of serotonin (5-HT) were first depleted then restored (as: Wang & Aghajanian, Neuropharm. 17: 819, 1978). In the period 48 to 12 hours before the beginning of the recording session, the animals were injected with 2 or 3 divided doses of p-chlorophenylalanine methyl ester (PCPA), total dose 375 mg/kg, in order to deplete 5-HT. Later, during the acute recording session, the immediate precursor of 5-HT, 5-hydroxytryptophan (5-HTP) was injected (7.5-15 mg/kg) in order to raise the level of 5-HT available as neurotransmitter. In all, recordings from 83 neurons in the 5-HT depleted state can be compared with 77 post-5-HTP recordings. In addition, 5 untreated animals (55 neurons) provide a comparison to normal responsiveness. Internal control was possible in those cases where a neuron could be recorded from both before and as the 5-HTP became effective. In these cases the EPSP evoked from DR stimulation was observed to increase in amplitude (e.g. from 0.8 to 19 mV in one case and 0.9 to 9 mV in another). The effect of systemic injection of 5-HTP was not immediate but required up to 30 minutes to develop. Responses to DR stimulation were not entirely absent in the PCPA treated animals prior to the injection of 5-HTP. Low amplitude (ca. 1mV) long latency responses were observed, conceivably due to residual 5-HT in the DR terminals. In addition, EPSPs of short latency (3-5 msec), relatively large amplitude (>5mV) and fast rise time were observed in 20% of the neurons encountered in PCPA treated pre-5-HTP injected animals. These fast responses are distinct from the bulk of DR evoked responses, as recorded either after 5-HTP injection or in non-PCPA treated animals, in that they are not reduced in amplitude (shunted) by a preceeding DR, substantia nigra, or cortex stimulation (interstimulus interval 20 msec) and are resistant to shunting by recurrent inhibition. The observed recovery of EPSP amplitude following 5-HTP injection strongly suggests that 5-HT is an excitatory neurotransmitter in CP. There also exists a short latency non-serotonergic excitation following DR stimulation which is not necessarily due to a mid-brain projection to CP. (Supported by NIH Grant BRSG 05772-04 and USPHS Grant NS 14866).

66.4 EVIDENCE FOR INHIBITION IN RAT NEOSTRIATAL BRAIN SLICES. J.W. Lighthall, M.R. Park, S.T. Kitai. Dept. of Anatomy, Mich. State Univ., East Lansing, Michigan 48824.

On the basis of both extracellular field responses and intracellular recording, inhibition could be observed in brain slices of rat caudate-putamen (CP). Slices, cut parasagittally, 350-400μm thick, where taken from a rectangular core of brain measuring 2 by 5 mm and containing both the right and left CP. The slices were maintained in artifical media at 37°C. Glass micropipettes were used for recording. Intrastriatal bipolar stimulation (0.05-0.30 msec, 10-90 V, delivered at 1 Hz) elicits a field potential lasting 1-8 msec. With low stimulation intensity, the field potential, which consists of two negative components N-1 and N-2, exhibited characteristics similar to those previously described in CP brain slice (Misgeld, U., et al., Brain Res. 34: 575, 1979). The amplitudes of both N-1 (latency 0.5-2.0 msec) and N-2 (latency 1.5-5.0 msec) vary within the range 0.5-1.0 mV. Stimulus intensity and/or duration could be adjusted to evoke a maximum N-2 response measuring 2.0-5.0 mV in amplitude. The amplitude of the N-2 response also increased as the recording pipette was advanced toward the cell and was maximum prior to pentration. Double shock at low stimulus intensity, given at a 5 msec interstimulus interval (ISI), and delivered at 0.75 Hz, either produced a slight potentiation of, or did not change the amplitude of, the N-2 portion of the test response. Increasing the frequency of stimulation from 0.75 Hz to 5 Hz resulted in a reduction of the N-2 portion of the second response. This phenomenon was observed at ISIs up to 50 msec. When stimulation levels were adjusted to evoke a maximum N-2 response, double shock resulted in total reduction of the test N-2 component at a 5 msec ISI. This reduction occured at stimulus frequencies of 1 Hz or less. The N-2 response returned to control levels at ISIs of 20 to 30 msec.

Intracellular records indicate the N-2 response to be a mass response of synaptically induced action potentials. Immediately before penetration, the N-2 component is superimposed on a positive potential. The positive potential gradually increases in amplitude (0.5-1.0 mV) and duration (1.0-6.0 msec) as the microelectrode is advanced toward the cell. Upon penetration, EPSPs were observed, often triggering APs whose latencies correspond with those of the N-2 component. Double shock stimulation delivered at 1Hz resulted in failure of the test spike to be triggered from the EPSP. Intracellular injection of HRP (Sigma type VI, 2M in tris buffer, pH 7.6, and 0.5M K-acetate) identified the recorded cells as CP spiny neurons.

(This work was supported by USPHS Grant 14866).

66.5 EFFECT OF PERIPHERAL NERVE STIMULATION ON THE ACTIVITY OF DOPAMINERGIC NEURONS: INVOLVEMENT OF NON-DOPAMINERGIC NIGRAL NEURONS AND STRIATONIGRAL PATHWAYS. D. W. Hommer* and B. S. Bunney (SPON: M. Bowers). Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, CT 06510

Biochemical (Nieoullon et al., Nature 269: 340-342, 1977) and electrophysiological (Chiodo et al., Brain Res., in press, 1980) studies have demonstrated an effect of sensory stimulation (light flashes, hind paw stimulation, tail pressure and cervical probing) on dopaminergic (DA) cell function in the substantia nigra. In unpublished experiments we have observed that noxious stimuli (toe pinch) also can induce changes in DA activity. To investigate these effects further we have used extracellular single unit recording techniques to study the effects of sciatic nerve stimulation on the activity of nigral DA and non-DA neurons in chloral hydrate anesthetized male albino rats. The sciatic nerve was stimulated with single 50 u sec duration, 40-80 uA square wave pulses. Unit responses to stimulation were analyzed using post stimulus time histograms. Two populations of DA neurons could be distinguished. A minority of DA cells responded to stimulation with a single period of inhibition. Sixty percent of the DA neurons tested responded to stimulation with an initial inhibitory period followed by one or more oscillations between excitation and inhibition. These oscillations were blocked by i.v. administered haloperidol (0.1 mg/kg) or by cutting the striato-nigral pathways (without damaging DA axons). The initial inhibitory period was decreased by haloperidol but was increased by the lesion. A population of identified non-DA zona reticulata neuron, which has been shown to exert an inhibitory influence on DA neurons (Grace and Bunney, Eur. J. Pharmacol. 59: 211-218, 1979) was found to respond to stimulation with an initial excitation. The latency for this stimulus-induced excitation was similar to the latency of the initial inhibition of DA neurons.

These results suggest that sensory stimuli may induce an initial inhibition of DA neurons, at least in part, through excitation of an inhibitory non-DA zona reticulata neuron. The ability of haloperidol to decrease the initial inhibition suggests that dopamine release, perhaps at dendrodendritic synapses, may also play a role in the DA neuron's response to peripheral stimuli. The subsequent oscillations in DA neuron activity appear to be mediated through reciprocal striato-nigral, nigro-striatal pathways, since lesioning these pathways abolishes the oscillations. The fact that not all DA neurons demonstrated oscillations in their activity after stimulation suggests that not all zona compacta DA neurons receive innervation from striato-nigral feedback pathways. (Supported by NIMH grants MH-28849, MH-25642, MH-14276 and the State of Connecticut.)

66.6 LIGHT MICROSCOPY OF ISOLATED CAUDATE. L. A. Marco and R. B. Chronister. Departments of Psychiatry and Pharmacology, Jefferson Medical College, Thomas Jefferson University, Philadelphia, PA 19107 and VA Medical Center, Coatesville, PA 19320; Department of Anatomy, College of Medicine, University of South Alabama, Mobile, AL 36688.

Recent electrophysiological recordings indicate that the surgically isolated caudate nucleus of rats and cats in situ has retained an appreciable amount of internal circuitry and that most of its neurons are highly responsive to iontophorized acetylcholine (Marco et al., Soc. Neurosci. Abstr. 5:75, 1979). To determine 1) the extent of the isolation, and 2) the status of caudate neurons, the brains examined physiologically were fixed in either 10% formalin or 10% formalin/80% alcohol and embedded in either paraffin (10-20 μ sections) or celloidin (40 μ sections). In every brain so far examined 14-60 days post-isolation, the isolation was complete in both rats and cats. Numerous areas which project to the caudate had degenerating neurons; paramount among these were the substantia nigra and the dorsal raphe. This degeneration was brought about by section of the medial forebrain bundle. Two parasagittal sections, one separating the caudate from the septal area and accumbens and the other immediately lateral to the caudate, isolated the nucleus further. Isolation was completed by removal of the overlying cortex and a coronal transection through the rostral pole of the caudate. Examination of the caudate revealed that indeed the intrinsic neuronal circuitry of the caudate was to a large extent intact. The medium sized neurons and the large neurons did not show any consistent patterns of chromatolysis. The 40 μ sections showed a number of degenerated neurons. These had a uniform distribution and seemed to be exclusively the medium sized neurons and not the large ones. On the other hand, phosphotungstic-acid hematoxylin stains revealed that a glial reaction was in process. Furthermore, silver impregnations of the paraffin sections revealed that degenerating fibers with associated terminals were present. These observations suggest that although most of the somata of the intrinsic neurons are still fairly normal, the input systems are degenerating with a concomitant glial cell and glitter cell clean-up. Critical staining (toluidine blue) of the 10 μ paraffin sections revealed that dendritic alterations were present. Main dendrites were no longer linear with a smooth appearance but twisted and irregular in contour. This type of dendrite is suggestive of major de-afferentation. Golgi impregnations are underway to determine the extent of this de-afferentation and concomitant post-synaptic spine/dendrite changes. 66.7 INCREASED NEUROANATOMICAL RESOLUTION USING PEROXIDASE-LABELLED LECTIN TRANSPORT: DEMONSTRATION OF A PALLIDOSTRIATAL PATHWAY Wm.A. Staines*, H. Kimura*, H.C. Fibiger and E.G. McGeer
Division of Neurological Sciences, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

The characteristics of a conjugate of horseradish peroxidase with wheat germ agglutinin (WGA-HRP) as a neuroanatomical tracer were determined in the CNS. The main technical finding was the high degree of control over the injection site allowed by this technique.

Adsorptive tracers, such as WGA, have a high affinity for the sugar moieties of membrane glycoproteins and/or glycolipids. It has been suggested that this allows for uptake by a process of adsorptive endocytosis, rather than fluid phase endocytosis as is the case for HRP. The usefulness of WGAas a retrograde/anterograde tracer has been shown using a number of different methods for marking the lectin[1]. The most convenient marking technique so far developed is the direct chemical conjugation of the lectin to HRP (WGA-HRP)[2]. This conjugate has been shown to be transported from the periphery with a sensitivity much higher than that of free HRP. It was reasoned that the lectin character of the conjugate should not only enhance sensitivity but also limit diffusion from the injection site and thus confer an important improvement over free HRP for studies in the CNS.

Apparent injection site diameters could be controlled by changes in either the volume or concentration of the WGA-HRP solution. The concentration dependence of the injection site size indicates saturable binding of the conjugate to the striatal neuropil. Upon injection of dilute solutions of WGA-HRP into the striatum of the rat, injection site diameters on the order of 500 μm could be easily and reproducibly obtained. The retrograde labelling of cell bodies in the substantia nigra was correspondingly very restricted. Using both the diaminobenzidine and the tetramethylbenzidine protocols for the visualization of peroxidase activity, anterograde transport was in evidence, but could be abolished if the WGA-HRP was co-injected with kainic acid.

After discrete striatal injections of WGA-HRP, in addition to a highly localized labelling of known striatal afferents, a pallidostriatal pathway was demonstrated at both light and electron microscopic levels.

66.8 PRECISE LOCATION OF NIGROTECTAL NEURONS IN THE MONKEY, CAT AND RAT. R.M. Beckstead, S.B. Edwards and A. Frankfurter. Dept. of Anatomy, University of Virginia Sch. of Med., Charlottesville, Va. 22908.

Although the projection from the substantia nigra's pars reticulata (SNR) to the deeper layers of the superior colliculus has been mapped in the monkey by anterograde methods, the precise location of the nigrotectal cells within SNR has not been documented. Moreover, retrograde cell-labeling studies in the cat and rat indicate some species differences in the location of nigral neurons that send axons to the superior colliculus. In the present study, the intranigral location of nigrotectal neurons was compared in the monkey, cat and rat using the horseradish peroxidase (HRP) retrograde cell-labeling technique. The histochemical reaction employed was that of Mesulam in which the chromogen is tetramethylbenzidine. In each species, it was possible to obtain a number of cases in which the HRP deposit involved essentially the entire extent of the superior colliculus of one side with only minimal involvement of adjacent brainstem structures.

In the monkey, labeled nigrotectal cells were particularly numerous in the extreme rostrolateral portion of SNR. A progressively decreasing number of cells spread medially from this region of high concentration in a ventral stratum of SNR immediately dorsal to the pes pedunculi. No labeled cells were found in the caudal one-half or so of SNR, nor in its extreme medial part. A substantial number of HRP-positive cells were present in the contralateral SNR in a similar distribution. In the cat, labeled cells were less selectively localized in SNR's mediolateral expanse, being distributed more or less randomly in its middle portion with a scattering of cells in both medial and lateral parts of SNR. As in the monkey, all cell-labeling was confined to the rostral half of SNR. Although some cell-labeling occurred in the contralateral SNR, it was less substantial than in the monkey. In the rat, the HRP-positive cells were especially concentrated throughout the mediolateral extent of a ventral stratum of SNR immediately dorsal to the pes pedunculi. Although some labeled cells were located more dorsally in SNR, they were far fewer in number and consistently less heavily labeled with HRP reaction product. As in the cat and monkey, the cell-labeling in SNR did not invade its caudal half. Only one or two HRP-positive cells could be detected in the contralateral SNR of the rat.

Thus, these three common laboratory mammals exhibit some differences in the precise location of the nigrotectal neurons and in the degree of bilaterality of the nigrotectal projection. Common to all three species, however, is the confinement of the nigrotectal cells to the rostral part of SNR. Supported by NIH Grant 5 S07 RR05431-18.

67.1 HETEROGENEITY OF EXCITATORY AMINO ACID RECEPTOR-IONOPHORE COMPLEXES IN THE RAT STRIATUM. A. Luini*, O. Goldberg* and V.I. Teichberg. Depts. of Neurobiology and Organic Chemistry, The Weizmann Institute of Science, Rehovot, Israel.

We have developed a new biochemical method allowing quantitative studies of the interactions of excitatory amino acids with their respective receptor-ionophore complexes in brain. After loading rat striatum slices with either $^{22}Na^+$, $^{42}K^+$, $^{86}Rb^+$ or $^{36}Cl^-$, we measure the rate of efflux of the tracer ion into a non radioactive physiological medium. The addition of excitatory amino acids to this medium increases the rate of $^{22}Na^+$ efflux in a dose dependent manner. This effect is not modified by 10^{-7}M TTX, a high Mg^{++}/Ca^{++} ratio, 1 mM theophylline and low temperature and is still observed in a Na^+-free medium indicating that the amino acid induced increase in $^{22}Na^+$ efflux rate is due to the opening of receptor linked ionophores. The order of potency of excitatory amino acids measured in this system is the following: N-methyl-D-aspartate (NMDA) > DL-homocysteate > quisqualate (QA) > kainate (KA) > D-glutamate > L-glutamate(L-Glu) > L-aspartate. The K_m values for L-glutamate and kainate are 1.2mM and 0.15 mM respectively. NMDA, in the striatum is about 50 fold more potent than L-glu. We have also studied the effects of various antagonists on the above-mentioned agonists. 2-amino-5-phosphonovalerate at 0.2 mM was found to block NMDA >> L-Glu but did not block QA or KA. γ-D-glutamylglycine at 0.2mM blocks NMDA >> KA > L-Glu and not QA. DL-aminosuberate at 1 mM blocks only NMDA but not KA, QA or L-Glu. DL-aminoadipate at 3mM blocks NMDA >> KA > Glu > QA. Kainic acid lactone, a derivative of kainate newly synthesized in our laboratory, used at 3mM blocks NMDA > KA but did not affect L-Glu or QA. On the basis of these results one can conclude that there exist at least four types of excitatory amino acid receptors in the striatum. Further evidence for difference between L-Glu and KA receptors is the finding that L-Glu increases the efflux rates of both $^{22}Na^+$ and $^{42}K^+$ where KA, while increasing $^{22}Na^+$ efflux rate, does almost not affect $^{42}K^+$ efflux rate. Our results raise the question of the nature of the excitatory neurotransmitters in the striatum.

67.2 GABA Analogues: High Correlation Between Channel Duration on Cultured Mouse Spinal Neurons and 1/IC50 Values at Low Affinity GABA Receptor Sites on Frozen Rat Brain Synaptic Membranes. Jeffery L. Barker and David A. Mathers* Laboratory of Neurophysiology, NINCDS, NIH, Bethesda, Md. 20205

Intracellular recordings from voltage-clamped mouse spinal neurons in tissue culture were used to study the effects of γ-aminobutyric acid (GABA) analogues on membrane excitability.Thirteen agonists tested depressed excitability in a dose-dependent, reversible manner through an increase in Cl^- ion conductance like GABA.Fluctuation analysis of membrane current responses provided estimates of the elementary events underlying these responses,all of which were associated with an increase in variance.Estimates of the single channel conductance activated by each analogue did not differ significantly from one another.Power density spectra of the agonist responses could be fit by single Lorentzian equations,from which estimates of agonist-induced single channel durations were calculated.These estimates all differed significantly from that for GABA, their ratios relative to GABA (=1) being 0.1 (taurine, GuAC, BABA, IAA), 0.3 (3APS, DAV, BGP,P4S), 0.5(THIP, isoguvacine, GABOB), 0.8(TAC), and 2.5 (muscimol).The results indicate that these analogues activate channels of the same conductance but of different durations.

We cannot be certain that all of the analogues are agonists at GABA receptors.Investigators using frozen rat brain synaptic membranes as a source of GABA receptor sites have shown that GABA binds to low and high affinity sites.Competitive binding assays have revealed that many structural analogues can displace GABA from the low affinity site.We have found that single channel conductance is not significantly correlated with the reciprocal of the analogue concentration displacing 50% of the bound GABA(IC50). However, single channel duration is correlated with 1/IC50 values for those analogues used in both binding and electrophysiological studies.For three independent binding studies the correlation coefficients were 0.95(n=10 analogues),0.97(n=7),0.97(n=5), all highly significant ($p<0.001$).The close correlations strongly suggest that the biochemical and biophysical assays involve a common parameter important to GABA receptor activation of Cl^- ion channels and that the low affinity site described in the binding studies is related to post-synaptic GABA receptors coupled to Cl^- ion channels. Although the method of assay used in binding studies does not provide a reliable estimate of the affinity of each analogue for the GABA receptor, the data suggest that agonist affinity may be the rate-limiting step in determining channel kinetics at GABA receptors.

67.3 CHARACTERIZATION OF ENDOGENOUS INHIBITORS OF Na^+ INDEPENDENT ^{3}H-GABA BINDING TO SYNAPTIC MEMBRANES (SM). S. Mazzari* and A. Guidotti. Lab. Preclin. Pharmacol., NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Endogenous inhibitors of ^{3}H-GABA binding different from GABA were extracted from SM, washed twice with Triton X-100. When this extract was applied to a Biogel P-2 column, two major peaks endowed with inhibitory activity of ^{3}H-GABA binding were obtained. The first one was not retained by the column, while the second corresponded to a molecular weight of 400-800 dalton. The first peak, reapplied to a Sephadex G-50 column was eluted in position similar to that of ribonuclease A (a marker for 14,000 dalton). This peak (GABA-modulin) can be characterized as:

1) inhibiting high affinity ^{3}H-GABA binding non competitively
2) preventing GABA-stimulated ^{3}H-diazepam binding
3) inhibiting ^{3}H-diazepam binding competitively
4) being trypsin and pronase sensitive and 5) not dyalizable.

When GABA-modulin was incubated at 4°C for 24 hr and then reapplied to a Biogel P-2 column, a decreased activity of the GABA-modulin peak was observed. This decreased activity was associated with the appearance of a small molecular weight material (400-800 dalton) which binds GABA and inhibits ^{3}H-GABA binding noncompetitively. Furthermore, the 400-800 dalton material inhibits competitively ^{3}H-diazepam binding, prevents GABA-stimulated ^{3}H-diazepam binding and is dyalizable. These two molecular forms of endogenous inhibitors of ^{3}H-GABA binding can be obtained either from fresh or microwaved rat brains after the endogenous GABA is removed from the extracts using fast purification procedure according to Penefsky et al. (J. Biol. Chem. 252:2891, 1977).

67.4 ENHANCEMENT OF [^{3}H]GABA BINDING BY THE NOVEL ANXIOLYTIC ICI 136,753 AND BENZODIAZEPINES. B. A. Meiners* and A. I. Salama* (Spon. J. B. Malick), Biomedical Research Dept., ICI Americas Inc., Wilmington, DE 19897

ICI 136,753, an anxiolytic pyrazolopyridine, enhances specific [^{3}H]GABA binding to frozen and thawed, Triton X100 treated rat brain synaptic membrane fragments. The maximal enhancement in chloride-free Tris-citrate buffer was 20-30% over control and half maximal values are achieved at 10μM ICI 136,753. The enhancement of [^{3}H]GABA binding thus requires higher concentrations than the enhancement of [^{3}H]flunitrazepam binding by ICI 136,753 (EC_{50} 1 μM) (Salama and Meiners, 1980).

Two other pyrazolopyridines, cartazolate and SQ20,009, were also found to enhance GABA binding. When compared to ICI 136,763 cartazolate gives a larger maximal enhancement with about the same EC_{50}.

The benzodiazepines, flunitrazepam, diazepam and chlordiazepoxide, were found to enhance GABA binding in this preparation. The maximal enhancement for the three compounds was about 16%. This enhancement is lower than seen for cartazolate in chloride-free buffer. The rank order of potency for enhancement of GABA binding by the three benzodiazepines was the same as that for their displacement of [^{3}H]flunitrazepam binding. The range was from 10^{-6} to 10^{-9}M.

The binding isotherm for GABA in the presence and absence of ICI 136,753 (20 μM) gave a curvilinear Scatchard plot. In the presence of the drug there was a parallel shift of the points to the right. This is consistent with an increase in the number of both high and low affinity binding sites with little, if any, change in the affinities. In contrast, the changes in the GABA binding isotherm caused by chlordiazepoxide appeared to reflect affinity changes.

The effects of ICI 136,753 and flunitrazepam on [^{3}H] GABA binding were additive even at high concentrations of flunitrazepam (10^{-5}M) where additional flunitrazepam had no additional effect.

It has been suggested that the benzodiazepines exert their anxiolytic effect by altering GABA binding. Given the enhancement by ICI 136,753 of GABA binding, it is reasonable to suggest that the pyrizolopyridine anxiolytics such as ICI 136,753 may also be exerting their effects by altering GABA binding. ICI 136,753 appears to bind to a site distinct from the [^{3}H]GABA binding sites and the high affinity [^{3}H]benzodiazepine binding site. The site to which ICI 136,753 binds is, however, linked to both the [^{3}H]GABA and [^{3}H]benzodiazepine sites.

67.5 Enhancement of Benzodiazepine Binding by the Novel Anxiolytic ICI 136,753

A.I. Salama* and B.A. Meiners* (Sponsor, M.E. Goldberg
Biomedical Research Dept., ICI Americas Inc.,
Wilmington, DE 19897

ICI 136,753 is one of a series of pyrazolo (3,4) pyridines possessing some cyclic AMP phosphodiesterase inhibitory activity. It has also been shown to restore behavior suppressed by punishment in animal conflict procedures. Unlike the benzodiazepines, ICI 136,753 enhances the specific binding of ^{3}H-flunitrazepam in fresh rat brain P_2 fraction suspended in Tris-HCl buffer. The maximal effect was about 40% with an EC_{50} about 1μM. Scatchard plot analysis revealed that a change in the binding affinity is the cause for the enhanced binding. ICI 136,753 at 10^{-5}M changes the K_D of ^{3}H-Diazepam from 8.1 nM to 4.5 nM with no significant change in the number of binding sites. The enhancement of ^{3}H-flunitrazepam binding caused by GABA (1-5 μM) could be blocked by the GABA antagonist bicuculline at a concentration (10 μM) which reduced the binding slightly. Similarly, this same concentration of bicuculline also prevented the enhancing effects of ICI 136,753 (0.5-5 μM). This suggests that the effects of ICI 136,753 are mediated through a GABAergic component. At a concentration of GABA (100 μM) where maximal enhancement is obtained on ^{3}H-flunitrazepam binding, addition of 5 μM ICI 136,753 caused a further enhancement of this binding. The effects of GABA and ICI 136,753 were compared in a preparation which had been frozen and thawed. In this situation, the enhancement due to GABA was greater than in the fresh P_2 fraction, while ICI 136,753 produced a concentration dependent (0.5-50 μM) displacement of ^{3}H-flunitrazepam binding (10-30%).

Thus it is concluded that the anxiolytic effects of ICI 136,753 seem to be manifested by a mechanism different from that of the benzodiazepines. The enhancing effect seen with ICI 136,753 may involve GABAergic mechanisms, at a site which is different and perhaps allosteric to the GABA binding site.

67.6 THE INTERACTIONS OF 5HT AND QUIPAZINE ON NEUROBLASTOMA.

C.E. Morris* and I. Spector* (SPON: D. Gilbert). N.I.H., Bethesda, Md. 20205.

Cells of the neuroblastoma line NIE-115 respond to 5HT (applied by pressure injection) at $5X10^{-6}$M or higher by a depolarization. Desensitization of the response occurs. We were interested in the effects of quipazine [2-(1-piperazinyl) quinoline maleate] on these cells since the drug's strong stimulatory effect on smooth muscle is thought to be mediated by 5HT receptors (cf. Hong et al. (1969) Eur. J. Pharm 6:274). At 10^{-5}M, quipazine applied for 1-2 sec had no effect but 10^{-4}M produces depolarizations of up to 10 mV (but usually less than 5mV), and 10^{-3}M quipazine causes depolarizations of up to 20 mV which repolarize slowly (several minutes) or not at all. If 5HT and quipazine act as agonists on the same receptor, they should exhibit simple cross-desensitization. However, quipazine (at 10^{-3}M) in the bath does not just reversibly diminish the depolarizing response of 10^{-5}M 5HT, but causes the residual 5HT-induced depolarization to be prolonged like a quipazine depolarization. Furthermore, the response of cells to 10^{-3}M quipazine is virtually unaltered by the presence of 10^{-3}M 5HT in the bath. The actions of 5HT and quipazine on NIE-115 cells may not, therefore, be confined to a single receptor, but further study is required to clarify the mechanisms involved in their interactions.

68.1 INTERSTIMULUS INTERVAL EFFECTS ON CLASSICALLY CONDITIONED FLEXION REFLEX FACILITATION IN SPINAL CAT. R.G. Durkovic, Dept. Physiol., Upstate Med. Ctr., Syracuse, N.Y. 13210.

In the unanesthetized, decerebrate, spinal cat repeated trials of paired stimuli delivered to two hindlimb cutaneous nerves produces an increase in the anterior tibial muscle response to the first (conditioned) stimulus (Durkovic, Physiol. & Behav. 14:297, 1975). Control treatment animals which receive the same stimuli in an unpaired sequence do not exhibit reflex facilitation.

The present study was carried out to investigate the effects of the interval between conditioned stimulus (CS) and unconditioned stimulus (US) onset on the reflex response. Experiments were conducted on ten groups of animals, each with a different interstimulus interval (ISI). CS alone trials were interspersed among 30 conditioning trials to assess response alterations in all groups.

With simultaneous CS-US onset and with CS onset before US onset (forward conditioning) an inverted U shaped function was obtained with maximum flexion reflex facilitation at +0.5 and +1.0 sec. and little or no facilitation in groups with ISIs of 0.0, +0.25, +3.0 and +30.0 secs. With US onset before CS onset (backward conditioning) increases in reflex response to the CS were also produced with maximum facilitation at -0.25 sec and a drop off of facilitation with larger backward ISIs (-0.5, -1.0 and -3.0 secs).

These data suggest the following:

(i) Classically conditioned flexion reflex facilitation is brought about by the application of two stimuli paired closely together in time.

(ii) This classical conditioning effect can be obtained with both "forward" and "backward" conditioning paradigms.

(iii) There appears to be a mechanism at the spinal level which effectively blocks the classically conditioned response at ISIs near zero. This holds even though maximum overlap of CS and US occurs with such ISIs.

The results of the simultaneous and forward conditioning groups are in agreement with the vast majority of classical conditioning studies in whole animals. The finding of backward conditioning is also consistent with a substantial number of studies reporting successful backward conditioning in intact animals including man.

These results reinforce the concept that spinal conditioning can be viewed as an appropriate model for the study of neural mechanisms of classical conditioning.

Supported by NSF Grant BNS 77-23845.

68.2 THE FIXATION OF CENTRALLY AND PERIPHERALLY INDUCED REFLEX ALTERATIONS. J. E. Steinmetz*, M. M. Patterson and J. Cervenka*. Dept. of Psych., Ohio Univ., Athens, OH 45701.

Over the past 50 years a body of research has appeared focusing specifically on retention or memory-like processes in the spinal reflex arcs. These studies have found that postural alterations in the limbs caused by various CNS lesions are maintained after spinal section if a temporal interval between lesion and section called spinal fixation time (SFT) is allowed. To replicate these earlier studies, unilateral lesions were placed in the anterior cerebellum of 30 rats to produce flexion-extention asymmetry in the hindlimbs. Fifteen of the rats were allowed a SFT of 20 min while the remaining animals had a SFT of 50 min. At the end of the fixation times, the degree of asymmetry was measured by suspending weights from the flexed leg until the hindlimbs were level. A spinal transection at T-7 was then performed and asymmetry was again measured. No differences in the amount of asymmetry was found between groups prior to the transection. However, the 50 min SFT group showed a persistent although reduced asymmetry after spinal section while the 20 min SFT group failed to show any asymmetry retention. The temporal parameters involved in spinal fixation of a cerebellar lesion induced asymmetry were more closely examined by varying fixation times from 25 to 45 min in five groups of rats. The data indicate that only an SFT of 45 min results in a consistent retention of asymmetry. Another study explored the possibility of demonstrating the fixation phenomenon through a peripherally induced asymmetry. Hindlimb flexion was produced in 10 male rats who received either 20 or 45 min of unilateral DC hindlimb stimulation. The asymmetry was measured by suspending weights from the flexed limb, a spinal section was performed at T-7 and the asymmetry again assessed. No differences in asymmetry were found before spinal section but differences were noted after the section. The 45 min stimulation group demonstrated a significantly greater amount of asymmetry retention than did the 20 min group. To assess the local effects of DC stimulation on the retention of the peripherally induced asymmetry, the dorsal and ventral spinal roots between T-12 and L-6 were cut in 20 rats. Upon completion of the rhizotomies, the animals were stimulated for either 10, 20, 30, 40 or 50 min after which the resulting asymmetry was measured. The stimulation failed to produce a consistent display of asymmetry in any of the animals. This series of studies suggest that a cerebellar lesion-induced postural alteration can be retained after spinal section if a minimum of 45 min is allowed between the lesion and a cord section. Likewise, a peripherally-induced asymmetry can be retained after spinal section and appears not to be a result of local stimulation effects.

68.3 SUCCESSFUL OBJECT DISCRIMINATION LEARNING AFTER COMBINED AMYGDALOID-HIPPOCAMPAL LESIONS IN MONKEYS DESPITE 24-HOUR INTERTRIAL INTERVALS. B. L. Malamut*, R. C. Saunders* and M. Mishkin. Lab. of Neuropsychology, NIMH, Bethesda, MD 20205

Combined ablation of amygdala and hippocampus in monkeys produces severe impairments on tests of both one-trial object recognition memory (Mishkin, Nature 273:297,1978) and one-trial object-reward associative memory (Spiegler & Mishkin, Neurosci. Abstr. 5: 323, 1979). Although the operated animals' rate of forgetting after a single acquisition trial in the associative memory test is unknown, their rate of forgetting in the recognition memory test seems to be extremely rapid, with performance approaching chance after an unfilled interval of only 2 minutes. Despite this rapid forgetting, animals with the combined lesions have no difficulty learning object discriminations,at least in the standard situation where trials are repeated 3-4 times per minute. In an attempt to resolve this discrepancy between rapid forgetting and successful learning,we tested whether object discrimination learning would be prevented in animals with limbic lesions if intertrial intervals exceeded the putative memory span.

Rhesus monkeys were trained preoperatively in a simultaneous visual discrimination paradigm in which a set of 20 pairs of junk objects were presented only once every 24 hours. The positive and negative objects within each pair, as well as the order of the pairs, remained constant across sessions. When the monkeys reached criterion of 90 correct in 100 trials, they were trained on a second set of 20 new object pairs in the same manner as before. The animals learned each of the sets in an average of 10 sessions, i.e. 10 trials. On completion of both tests, half of the animals received bilateral amygdaloid-hippocampal ablations and half remained as unoperated controls. Postoperatively, all animals were retrained with the same object pairs as before, one set at a time, followed by a third set of 20 new object pairs. Whereas the controls showed nearly perfect retention of the 2 sets learned preoperatively, the operated monkeys showed no retention, a result implying retrograde amnesia. However, they did relearn these sets in approximately twice the number of trials as before, and, in addition, they learned the new set in about the same number of trials as the control animals. In view of this surprisingly successful learning, we subsequently tested these animals in one-trial visual recognition and found the same rapid forgetting as in the original study. Thus, although animals with combined limbic lesions have an extremely short memory span on some tests, they can retain and accumulate information gained from single discrimination learning trials separated by 24-hour intervals. This paradoxical success implies the existence of an important memory mechanism outside the limbic structures of the temporal lobe.

68.4 IMPAIRED SERIAL ORDER PERFORMANCE AFTER TRANSECTION OF SUBICULUM-ANTERIOR THALAMIC FIBERS IN THE RAT. C.J. Rogers*, R.E. Davis, M. Karukan*, R. Smith*, C. Ahrens*, and C. VanHartesveldt. (spon: C. VanHartesveldt). Psychology Dept., Univ. of Fla., Gainesville, Florida 32611.

Recently, we demonstrated that animals with selective transections of the subiculum-anterior thalamus component of the postcommissural fornix learn operant response sequences in a manner different from undamaged animals. These transected animals readily adopt rigid response sequences which they maintain under a broad range of stimulus conditions. In this experiment, we investigated the effects of procedures designed to disrupt the formation of rigid response sequences in animals with these transections. These included changes in the intertrial intervals (0,10, 30,60 secs) and interresponse intervals (0,10,20 secs).

Initially, male, Long-Evans hooded rats were given CRF training in an operant chamber with 4 closely placed levers extending from one wall. Once stable performance was achieved, animals were required to press all 4 levers in any order to complete a trial. Ten trials were given each day. Only the first press on each bar was reinforced. The intertrial interval (ITI) was maintained at 10 secs (days 1-14), 30 secs (days 15-21), 60 secs (days 22-28), and 1 sec (days 23-35). Animals with transections of the subiculum-anterior thalamus connections (AT) were similar to controls at all ITI levels except 60 secs. At this level AT animals demonstrated increased perseverative responding relative to normal animals. In addition, AT animals exhibited significantly more lever pressing than did control animals during all ITI's.

To further interfere with the formation of rigid response sequences, we instituted inter-response delays of 4, 10, and 20 secs. During the inter-response delay period, animals were allowed access to the levers but responses were not reinforced. Onset of a house light signaled the inter-response interval (IRI) while a tone and house light compound stimulus signaled onset of the ITI. All animals exhibited similar increases in error rates during performance of the response sequence. Also both groups demonstrated similar numbers of responses during the IRI delay periods. However, AT animals failed to discriminate between IRI and ITI delays in a manner similar to controls. AT animals exhibited similar response rates during ITI and IRI delays while undamaged animals demonstrated lower rates during ITI delays than during IRI delays.

Taken together, these results suggest that when the formation of rigid response sequences are prevented, the performance of AT animals is impaired. AT animals fail to adopt alternative response strategies whereas normal animals exhibit more flexible behavior.

68.5 MEDIAL SEPTAL LESIONS AND THE ENTORHINAL THETA RHYTHM: CORRELATING THETA LOSS WITH RADIAL ARM MAZE LEARNING.
J. N. P. Rawlins*, S. J. Mitchell, D. S. Olton, Dept of Psychology, The Johns Hopkins University, Baltimore Md 21218, and O. Steward, Dept. of Neurosurg., Univ. Va. Sch. Med., Charlottsville Va. 22901. (SPON: E. Blass)

A regular slow wave theta rhythm can be recorded from the hippocampus (HPC) and medial entorhinal cortex (MEC) of freely moving rats. Lesions of the medial septal area (MSA) abolish theta in HPC and deplete acetylcholinesterase (AChE) in hippocampus and entorhinal cortex. In this experiment MSA lesions are shown to have equivalent effects on HPC and MEC theta, and can abolish both. AChE depletion is related to theta loss at these sites.

Adult rats were trained to walk in a treadmill and then had an electrode implanted in MSA and pairs of recording electrodes implanted in the right dorsal HPC and bilaterally in MEC. After recovery from surgery recordings were made between a frontal bone screw and each one of the recording electrodes in turn while the rat walked. Recording sessions took place over a 2-3 week period. A small lesion was then made in MSA using the implanted electrode. Subsequently recordings were made as before, and compared for amplitude and regularity to the activity seen earlier; thus the degree of theta retention was assessed. Recordings were continued over periods of up to 14 weeks, during which the rats were trained to obtain food in an 8-arm radial maze baited with one food pellet at the end of each arm.

In each recording the peak to peak amplitude of 20 consecutive theta waves was measured. The theta retention on the day after the lesion ranged from 0%-66% (median 0%) in HPC and from 0%-89% (median 4%) in MEC; one week later the retention was 0%-74% (median 49%) in HPC and 0%-94% (median 41%) in MEC. No further significant recovery was seen, and the extent of theta retention in HPC was well matched by that in MEC.

The rats were ranked for theta retention, and also for choice accuracy during the first ten sessions of maze learning. A Spearman's rank correlation test yielded a positive, but not significant, coefficient of 0.63 between rankings on these two measures. The rats showed a slight impairment in acquisition of the maze task, but were able to attain a criterion level of performance in spite of their loss of theta activity.

Since the degree of theta retention in HPC and MEC covaried well, MEC theta might depend on pacing by HPC theta activity. A further series of lesion experiments is exploring this possibility.

68.6 ASSOCIATIVE AND RECOGNITION MEMORY IMPAIRMENTS IN MONKEYS AFTER HIPPOCAMPAL RESECTIONS. M. Moss*, H. Mahut and S. Zola-Morgan* (SPON: D.Rosene) Dept. of Psych., Northeastern U. Boston, MA 02115

Deficits of memory have been seen in monkeys with combined bilateral removals of hippocampus and amygdala, but impairments following selective resections of the hippocampus have been inconsistent. Accordingly, we re-examined the effects of selective hippocampal removals on memory in three separate experiments. In the first, behavioral effects of hippocampal resections were compared to those of either fornix, entorhinal or anterior inferotemporal lesions on a visual concurrent discrimination task. This task involves the presentation of eight pairs of objects in an intermingled fashion until animals learn to discriminate every pair, and, thus, it tests the animals' ability to learn associations between reward and given stimulus objects in the presence of proactive and retroactive interpair interference. The second experiment was based on the clinical finding that medial temporal lobe damage in patients produces a modality non-specific impairment of memory. Accordingly, the performance of monkeys with hippocampal resections was compared to that of monkeys with anterior inferotemporal ablations on the concurrent task in the tactual modality. In the third experiment, the performance of monkeys with either hippocampal or fornix lesions was compared on a non-matching-to-sample task (cf. Mishkin, 1978). This task was administered under eight conditions: with delays between presentation of the sample and choice of either 10, 30, 70 or 130 sec, or with the number of object samples shown prior to pairing each one with a new object numbering 1, 3, 5 or 10 (lists). Both versions of this task require an ability to recognize whether or not a given object had been seen before, rather than whether it had been rewarded before.

In the first experiment, monkeys with either hippocampal, entorhinal or inferotemporal ablations, but not those with fornix sections, were significantly impaired. In the second experiment, both types of lesions resulted in an impairment on the concurrent task in the visual modality, however, in the tactual mode, monkeys with inferotemporal ablations were no longer impaired, whereas four of the six monkeys in the hippocampal group were still markedly impaired. In the third experiment, monkeys with hippocampal resections, but not those with fornix sections, were significantly impaired at all delays and with all list lengths.

Taken together, the results reveal that 1) Selective resections of hippocampus are sufficient to produce memory impairments in non-human primates and 2) These impairments are general since they are found both on tasks which tax discrimination learning ability in the presence of interference as well as on those which demand only recognition of familiar objects after varying time intervals.

69.1 THE INTRACELLULAR DYNAMICS OF A VERTEBRATE CONE. G.A. Carpenter Dept. of Math., Northeastern University, Boston, MA 02115 and S. Grossberg, Dept. of Math., Boston Univ., Boston, MA 02215.

A quantitative model of the intracellular dynamics within a vertebrate cone is described and used to explain parametric data from the turtle cone. The model differs qualitatively from the one suggested by Baylor, Hodgkin, and Lamb in its description of the rules whereby the intracellular transmitter acts. These rules can be derived from simple hypotheses about optimal transduction, and are similar to the transmitter rules that operate in nonvisual neural systems. Thus the cone transmitter is suggested to be a special case of a general principle of neural design.

69.2 CHEMICALLY MIMICKING THE EFFECT OF LIGHT ON THE cGMP CONCENTRATION OF THE VERTEBRATE PHOTORECEPTOR. Edward P. Meyertholen, Meegan J. Wilson, and Sanford E. Ostroy. Department of Biological Sciences, Purdue University, West Lafayette, Indiana 47907.

The major decreases in cGMP concentration which are initiated by light in the vertebrate rod photoreceptor exhibit many of the characteristics required of the phototransduction process. We have critically tested the role of this process by using a chemical procedure which mimics the effect of light on the cGMP concentration of the photoreceptor cell in the excised vertebrate retina. This procedure alters the intracellular level of cGMP in the dark, without requiring injection or extrinsic artificial inhibitors. The chemically induced decreases in cGMP concentration were 80-100% of the change normally observed on illumination; under these conditions the light-induced changes were completely eliminated or reduced to 20% of normal. Electrophysiological experiments done under comparable conditions exhibited a compression of the Light Intensity-Signal Amplitude relationship, but unlike continuous light, no significant changes in sensitivity were observed. The data suggest that light-induced changes in cGMP concentration are not responsible for the phototransduction or light adaptation processes of the vertebrate photoreceptor. (Supported in part by USPHS GRANT EY00413 and GM07211).

69.3 EFFECT OF TEMPERATURE ON SENSITIVITY AND KINETICS OF THE ROD PHOTOCURRENT. G. Matthews, K.-W. Yau* and D. A. Baylor*. Dept. of Neurobiol., Stanford Univ. Med. Sch., Stanford, CA 94305

The time-scale of the light response of vertebrate photoreceptors is strongly dependent on temperature (Penn & Hagins, 1972; Baylor et al., 1974). We have further examined this effect by measuring the photocurrent of single toad rod outer segments drawn into a suction electrode connected to a current-to-voltage transducer. Temperature was controlled by circulating heated or cooled water through channels in the walls of the chamber containing small pieces of toad retina. Temperature in the chamber was measured by a calibrated thermistor mounted within 0.5 mm of the tip of the suction electrode. Photocurrents were faster at higher temperatures. To quantify this effect, the reciprocal time-to-peak, $1/t_p$, of the average response to dim flashes was measured as a function of temperature. In 16 experiments of this type, the Q_{10} was 2.57 between 20° and 30°C, corresponding to an activation energy of 16.7 kcal mole^{-1}. In cones, corresponding values were 1.8 and 10 kcal mole^{-1}(Baylor, et al., 1974). The average dim flash response at 20°C was usually fitted by the expression for the impulse response of a series of four low-pass filters with equal time constant (Baylor, et al., 1979). The characteristic time constant of a cell was usually about 500 msec at 20°C. In most cases, the dim flash response at different temperatures was fitted by the same expression as at 20°C, but with different time constants. This implies that the four delay stages were roughly equally sensitive to temperature changes. In a few cases in which high temperature reduced the time constant to about 250 msec or less, the number of delay stages increased reversibly to five. This suggests that when the time constants of the four delays are reduced sufficiently, a fifth, relatively temperature-insensitive delay with a time constant of about 200 msec is revealed.

Sensitivity, defined as the flash sensitivity in darkness or the half-saturating light intensity, declined with increasing temperature, as did the average amplitude of the single photon response. The reduction in sensitivity could be accounted for quantitatively by the observed decrease in single photon response amplitude. This indicates that the quantum efficiency of isomerization of rhodopsin was unaffected by temperature in the range 15°-35°C.

Baylor, D.A., Hodgkin, A.L. & Lamb, T.D. (1974) J. Physiol., 242, 685-727. Baylor, D.A., Lamb, T.D. & Yau, K.-W. (1979) J. Physiol., 288, 589-611. Penn, R.D. & Hagins, W.A. (1972) Biophys. J., 12, 1073-1094.

69.4 $[Ca^{+2}]_i$ MODULATES SODIUM CONDUCTANCE IN ROD OUTER SEGMENTS. B. Oakley II and L. H. Pinto. Dept. of Biological Sciences, Purdue University, W. Lafayette, Indiana 47907.

It has been suggested that light causes calcium ions to be released from the intracellular disks in vertebrate rod outer segments, and that the resulting increase in intracellular free calcium concentration, $[Ca^{+2}]_i$, decreases the sodium conductance, g_{Na}, of the plasma membrane of the outer segment. We tested the hypothesis that $[Ca^{+2}]_i$ modulates g_{Na} in the isolated, superfused retina of the toad, Bufo marinus. While the input conductance of an impaled outer segment was monitored, EGTA was injected into the cell in order to reduce $[Ca^{+2}]_i$.

Rod outer segments were impaled with double-barrel micropipettes; one barrel was used to measure membrane voltage and the other was used both to pass current and to pressure-inject EGTA. Since the injection of EGTA produces a membrane depolarization, the membrane was (point) voltage clamped to its dark resting potential to prevent changes in voltage-sensitive conductances. The input conductance was assessed by measuring the incremental membrane current required to produce a small (10 mV), hyperpolarization of the membrane.

During voltage clamp, the injection of EGTA evoked an inward membrane current of ≈250 pA and an increase in input conductance. In 21 cells, the input conductance averaged 8.7 nS, and increased by 38% during the injection of EGTA. The EGTA-evoked increase in input conductance was not an artifact due to any limitations of the point clamp, since it was present even after voltage-sensitive conductances were abolished by bathing the retina with TEA^+, Cs^+, Co^{+2}, and 4-AP (3 cells). The observed effects were specific to EGTA; in control experiments, injection of K^+ acetate$^-$ did not detectably alter membrane current (5 cells). Superfusion with low Na^+ Ringer's solution (choline$^+$ substituted for Na^+) caused a membrane hyperpolarization. When the cell was clamped to its new resting voltage, the EGTA-evoked changes in membrane current and input conductance were greatly attenuated (11 cells). Thus, the EGTA-evoked changes in input conductance observed in normal perfusate were due primarily to changes in g_{Na}. Injection of a Ca^{+2}/EGTA buffer having equimolar Ca^{+2} and EGTA did not produce a detectable change in membrane current (3 cells). It is unlikely, therefore, that EGTA produced its effects by chelating a trace metal for which it has a high affinity. Since EGTA chelates Ca^{+2} with an affinity ≈6 orders of magnitude greater than it chelates Mg^{+2}, we conclude that a decrease in $[Ca^{+2}]_i$ increases g_{Na} in rod outer segments. (Supported by EY01221 and EY07008).

69.5 EFFECT OF ADAPTATION ON PHOTORECEPTOR RESPONSE DUALITY IN LIMULUS. Lolin T. Wang* and Gerald S. Wasserman. Sensory Coding Lab., Dept. of Psychological Sciences, Purdue University, West Lafayette, IN 47906.

Intracellular recordings were obtained from the photoreceptors (retinular cells) of excised mature Limulus lateral eyes. At low intensities two types of discrete waves are seen in dark adapted (DA) cells: Small slow potential fluctuations (SPF's)-previously described by Fuortes and Yeandle (1964)- and large fast potential fluctuations (LPF's)-previously described by Dowling (1968). At high intensities, the receptor response is more continuous. Light adapted cells (LA) also exhibit continuous responses, even when low intensity stimuli are used.

A second indicator of adaptation-dependent duality was obtained from measurements of the intensity-response function of the later portions of the response. In DA, this function is inflected-the response grows with intensity up to an intermediate intensity, then levels off and ultimately grows again. In LA, this inflection disappears and the intensity-response function has only one segment.

A third indicator of response duality was given by examining the late components of the response (Wulff and Fahy, 1979). At least three late components could be seen in the DA state. The time course of these late components seems relatively stereotyped. The wavelength dependence of the various components (Adolph, 1968) is being investigated.

These data indicate that there are two mechanisms governing the receptor response in Limulus. A high sensitivity mechanism which yields discontinuous responses made up of distinct components in dark adaptation and a low sensitivity mechanism which yields continuous responses in light adaptation. Some of these data are similar to those obtained by Dowling (1968) from juvenile eyes and some are similar to data obtained by Kaplan and Barlow (1975) from intact eyes. But since these data were obtained from adult excised eyes, they indicate that adaptation is the main variable affecting duality, not age or intactness of the eye.

69.6 INCREASED SUSCEPTIBILITY TO CONSTANT LIGHT-INDUCED RETINAL DEGENERATION IN DIABETIC RATS. D. D. Johnson and W. K. O'Steen, Dept. of Anatomy, Bowman Gray Sch. of Med. of Wake Forest Univ., Winston-Salem, NC 27103.

Albino rat retinal photoreceptors degenerate rapidly following exposure to continuous low-intensity fluorescent illumination. Albino rats were rendered diabetic with streptozotocin to determine if the severity of photoreceptor damage was significantly influenced during diabetogenesis. Young adult female rats were injected intravenously with streptozotocin (65 mg/kg) dissolved in buffered saline, while the control animals received only the vehicle solution. Immediately following the injections, rats were exposed to continuous, low-intensity fluorescent lighting (110 ft-c.) for 9 or 19 days. Additional animals injected with streptozotocin or saline were maintained in a cyclic photoperiod. On day 3 after injection blood glucose assays indicated that the average blood glucose value for the streptozotocin-injected rats was 418 + 22 mg%, as compared to 95 + 6 mg% for the saline-injected group. Both streptozotocin and saline-injected animals had a severe destruction and reduction in numbers of photoreceptor cells following the 9 and 19 day exposure periods, as compared to identically-treated animals housed in a cyclic photoperiod. Measurements of the retina (ONL, outer nuclear layer; and RT, entire retina) showed a 64% and 84% reduction in ONL thickness in the streptozotocin-treated rats exposed to 9 and 19 days of constant light, respectively (both $p<0.001$), and a 42% and 82% reduction in the ONL of saline-injected animals exposed to 9 and 19 days of constant light, respectively (both $p<0.001$), as compared to the cyclic light controls. The RT was also significantly reduced in both the constant light exposed streptozotocin and saline groups as compared to the cyclic light controls (all $p<0.001$). The ONL thickness of the saline and streptozotocin-treated animals kept in cyclic light were nearly identical, as were the RT measurements. When streptozotocin-induced diabetic rats and nondiabetic animals were exposed to constant light, the diabetic animals were more susceptible to retinal damage as judged by ONL and RT measurements. The ONL in the 9 and 19 day streptozotocin groups was reduced in thickness 34% ($p<0.001$) and 31% ($p<0.001$) as compared to the control animals. Similarly, the RT in the 9 and 19 day diabetic groups was reduced 16% ($p<0.01$) and 11% ($p<0.02$) as compared to the control animals. These results indicate that streptozotocin-induced diabetic animals are more susceptible to constant-light induced retinal degeneration, a process which occurs by an as yet undetermined mechanism. (Supported by NIH Grant #EY 02359)

69.7 PHOTORECEPTOR DEVELOPMENT IN THE ZEBRAFISH. T.A. Branchek* and G. Streisinger. Inst. Molecular Biol. and Dept. of Biol., U. of Oregon, Eugene, OR 97403.

The zebrafish, Brachydanio rerio, is highly vision dependent and undergoes rapid embryological development. We have studied its retinal differentiation at the light microscopic level. Of specific interest is the timing of the appearance of rods and cones. Reports in the literature indicate that cones appear before rods (at least in some fish species). This study provides a specific characterization of the anatomical substrate for visual function in young zebrafish and is also of interest from a comparative point of view.

Light microscopic analysis of Epon embedded material shows that at two days (d2) post-fertilization, the layering pattern characteristic of the adult retina is already established. By d4, cone-like outer segments (OS) appear, and they are arranged in a mosaic pattern. Higher resolution electron microscopic analysis is in progress to determine if rods are present at this stage. Appearance of photoreceptors at d4 correlates well with the behavioral repertoire of the zebrafish: vision-dependent feeding behavior begins on this day as does the onset of coordinate eye movements.

In d8 specimens, we observe presumptive rods which have short, bent OS scleral to the cone OS. At this same time, we note the beginning of pigment migration. In other species, pigment migration has been associated with the presence of functional rods.

Cone OS reach their adult dimensions by d12. Rod OS growth continues until d24 when approximate adult length is attained. The four cone types distinguishable in the adult retina are readily identified at d24.

Physiological experiments are in progress to determine the state of functional maturation of rods and cones in this retina at selected ages. In combination with the anatomical data, this work will provide a correlated analysis of the structural and functional development of rods and cones in this vertebrate retina.

70.1 ATTENTIONAL UNITY FOLLOWING BRAIN BISECTION IN MAN. Jeffrey D. Holtzman*, John J. Sidtis*, Bruce T. Volpe*, Michael S. Gazzaniga (SPON: Steven A. Hillyard). Division of Cognitive Neuroscience, Department of Neurology, Cornell University Medical College, New York, New York 10021.

Patients who have undergone a complete midline section of the corpus collosum are unable to perform interfield comparisons of lateralized visual information on a variety of perceptual tasks. Accurate performance would require perceptual access to both visual half-fields, and, at least for certain perceptual tasks, such bilateral representation appears to be unavailable to these patients. Despite this, perceptual-motor performance outside the psychology laboratory is remarkably unimpaired. These patients can carry out directed and coordinated motor activity within the environment: walk, run, avoid physical obstacles, even, in one case, operate a motorcycle.

In two such patients we asked whether the selective allocation of visual attention, an important aspect of directed motor behavior, has access to a unified perceptual representation of the visual world. The paradigm we employed was a modification of one originally used by Posner and his colleagues. Essentially, performance at a detection task under conditions in which a target stimulus was preceded in time by a cue to its spatial location was compared with performance under conditions in which no spatial cue or a misleading cue preceded the target. In general, detection latencies were shortest when attention was directed to the cued location via the valid spatial cue.

In our paradigm, a 3X3 grid appeared on each side of a central fixation point. In the Within-Field condition, the valid spatial cue and the target stimulus were presented with a one second delay to the same cell within the same grid; the invalid prime to a diffferent cell within the same grid. In the Between-Field condition, they appeared in homologous cells in different grids or in different cells in different grids, respectively. Performance was facilitated when a valid spatial cue preceded the target stimulus, not only in the Within-Field condition, but also in the Between-Field condition. These data suggest that the mechanisms which control the allocation of visual attention in these patients have access to a unified representation of the visual environment. Since each grid square subtended only 5 deg of visual angle, the specificity of the spatial priming effect is impressive. It remains to be determined whether or not cortical-cortical (anterior commissure) connections or cortical-subcortical (e.g., parietal-pulvinar) connections mediate this effect.(Aided by USPHS Grant NS15053 and the Alfred P. Sloan Foundation.)

70.2 INTERHEMISPHERIC COGNITIVE INTERACTION FOLLOWING PARTIAL COMMISSUROTOMY. John J. Sidtis*, Bruce T. Volpe*, Jeffrey D. Holtzman*, M.S. Gazzaniga Division of Cognitive Neuroscience, Department of Neurology, Cornell University Medical College, NY,NY

Because of the recent modifications in the surgical technique of commissurotomy, the effects of partial as well as complete callosal section can now be examined in the same patient. The present observations are made on a 26 yr old right handed male, case J.W., who underwent mid-line section of the corpus callosum in two stages. The posterior half of the corpus callosum including the splenium was sectioned first, with the remaining anterior portion sectioned in a second operation approximately 10 wks later. Following the initial posterior section, the primary visual, auditory and somatosensory systems of the right hemisphere were disconnected from the expressive language system of the left hemisphere.

Unlike the completely sectioned patient, J.W. did not deny having "seen" anything following left visual field stimulation. When asked to verbally identify what was presented, however, the patient was unable to do so although he still claimed to be able to "see" the stimulus in his mind. After several such instances, the investigators instituted an interactive probe with the patient that took the form of a game of 20 questions. Such questions began with "Is it an object or a living thing?" and would include questions about form, function and class. At the first interoperative testing, J.W.'s left visual field picture naming was slightly but significantly, better than chance ($p < .02$), by virtue of the 20 questions interaction. His naming of left visual field information improved throughout the interoperative period and by the sixth week, J.W. had adopted a self-generated inferential strategy based on his description of a mental image. Following complete callosal section, left visual field naming fell to chance ($p > .10$). The inference strategy was no longer attempted and the patient denied any experience following left field stimulation.

In the interoperative period, rather than having direct access to sensory information from the right hemisphere, the expressive language system appeared to be acting on a somewhat diffuse activation of stimulus related to semantic information that reflected an end stage result of semantic or gnostic processing within the right hemisphere. The availability of this activation was mediated largely, if not solely, by the anterior portion of the corpus callosum.

70.3 ELECTROPHYSIOLOGICAL INDICES OF CONSONANT INVARIANT CUES FROM SCALP RECORDED POTENTIALS OF PRESCHOOL AGE CHILDREN DURING SPEECH PERCEPTION. D.L.Molfese, R.J.Erwin*, and M.E.Deen*. Dept. of Psychology, Southern Illinois Univ., Carbondale, IL 62901.

Investigators have been unable to identify the acoustic invariant in stop consonants - the cue that enables a listener to identify particular consonant sounds independent of context. Consonant transition frequencies change as a function of the sounds that precede or follow these transitions. Nevertheless, consonant identification remains unchanged (Liberman, A., et al., Psychol. Rev., 74:431, 1967). The initial consonants of the syllables /di/ and /du/ are perceived as /d/ even though the acoustic cues differ for the two consonants. The present study reports for the first time the identification of neuroelectrical responses recorded from the scalps of preschool children which reflect the encoding of consonant invariant as well as consonant context deoendent cues. Auditory evoked responses (AERs) were recorded from the left and right hemisphere temporal (T_3, T_4, T_5, T_6) and parietal (P_3, P_4) regions of 12 right handed 4-year-old children in response to computer synthesized consonant-vowel syllables /bi, bæ, bɔ, gi, gæ, gɔ/.Amplified AERs for each sound were averaged independently at 8 ms intervals over a 600 ms period follwoing stimulus onset (for 75 points). These averages were then formed into a correlation matrix and subsequently submitted to a principal components analysis. Eleven factors (80% total variance) were isolated and then rotated using the normalized varimax criterion to improve factor distinctiveness. Factor scores were computed for each factor for each averaged AER. Independent analyses of variance with repeated measures for Consonant (2) X Vowel (3) X Formant Structure (2) X Hemisphere (2) X Sites (3) were performed on the factor scores to determine if any factors varied systematically as a function of the experimental manipulations. Factor 3 accounted for 10% of total variance and indicated that the right hemisphere differentiated between consonants independent of context, $F(1,11)=19.18$, $p < .005$. Factor 5 (8% total variance) discriminated between the vowels independent of initial consonant sounds, $F(2,22)=8.10$, $p < .005$. Factor 8 (5% total variance) discriminated between consonats as a function of the vowel sounds, $F(4,44)=6.58$, $p < .001$. These findings suggest that speech perception involves multidimensional processes which involve a variety of lateralized and bilateral hemispheric processes, some of which are sensitive to context independent and some of which are sensitive to context dependent speech cues.

70.4 A SEARCH FOR MORPHOLOGICAL ASYMMETRIES IN AREAS 9 AND 39 IN HUMAN MALE CEREBRAL CORTEX. Marian C. Diamond, Ruth E. Johnson and Amir Dehghan, Department of Physiology-Anatomy, University of California, Berkeley, CA 94720.

Recent studies on morphological asymmetries in the male, rat cerebral cortex have provided intriguing results. An earlier publication (1975) showed that the right cortex was thicker than the left in 15 male, Long-Evans rats per age group in 15 separate age groups in a study beginning at 6 days of age and terminating at 650 days of age. In a more recent study (1980) on 21 standard colony, 90-day-old, S_1, male rats, the right hemisphere was again thicker than the left, and Areas 17 and 39 reached differences which were statistically significant. Additional results with 92 S_1 male rats from various environmental conditions also showed Area 39 (along with some other areas) to be significantly thicker on the right than on the left.

With this information as a guideline, a sample of Area 39 was removed from the right and left hemispheres of 15 human male brains, ranging in age from 45 to 67 years. Since Area 9 in the rat showed the right hemisphere to be greater than the left but not significantly so, a sample of Area 9 was removed from both hemispheres in the human brains to compare with the findings in Area 39 from the same brains.

In order to study neuronal and glial populations, 20 micra, frozen sections were cut and stained with Kluver-Barrera stain. Beginning at the crest of the gyrus, two red lines were drawn 2 mm apart, beginning at the pial surface and extending to the underlying white matter. Another line was marked perpendicular to these two at the junction between the grey and white matter. These lines served as guides to count cells, differentiating neurons, astrocytes and oligodendrocytes. A comparison of neuron-glia ratios, cell numbers and number of microscopic fields/hemisphere will be presented.

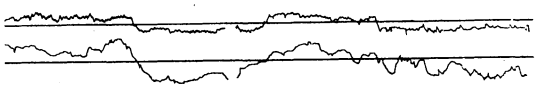
We are interested in area 39 in human brains in particular because the right-left differences shown in the male rat at 90 days of age were not seen in the female at this age and also because Area 39 is a most elaborate sensory integrating area. The question we eventually hope to answer is: Is there really a sex difference between hemispheres in this area and does it exist in human brains?

70.5 CEREBRAL HEMISPHERIC ACTIVITY AND AUTONOMIC NERVOUS FUNCTION
∇¶Deborah A. Werntz*,∇ Reginald Bickford,§ Floyd E. Bloom and ¶§David Shannahoff Singh Khalsa*(Spon. A. Traynor).∇ EEG Lab. UC San Diego Sch. Med. Dept. Neurosience, La Jolla CA 92093. §The Salk Institute, La Jolla CA, ¶ Kundalini Research Institute.

The nasal cycle is an ultradian rhythm with 75-200 min. periodicity in which air flow through the nares predominates unilaterally. This activity is presumed to be regulated via peripheral vasomotor activity with unilateral sympathetic dominance in one nostril coordinated with unilateral parasympathetic dominance in the other. We have compiled experimental evidence which directly correlates the nasal cycle with an alternation of cerebral hemispheric activity exhibited by the integration of EEG amplitudes. The nasal cycle was measured with thermistors to determine the relative air flow through each nostril. This information was recorded simultaneously with the primary EEG, at various montages, and then both were subjected to a continuous integration over time yielding data as seen in Fig.1. This study consisted of 43 males and females, right and left handed, recorded for a minimun time of 85 min. and a maximum of 190 min., with a mean of 2 hours. 22 subjects exhibited a nasal cycle during their recording period and a shift in hemispheric activity was observed to correlate in phase. The remaining subjects did not exhibit nasal cycles. Dominant right nostril air flow is associated ($p<10^{-6}$) with relatively greater left hemisphere amplitude and vice versa Fig.1.

Our data confirm the existence of the nasal cycle as an easily measurable indicator or 'window' of the basic organization of autonomic nervous function. This cycle may be viewed within the context of other ultradian rhythms, to support the concept of a single oscillator system. Dominance of right nostril air flow is correlated with a dominance of sympathetic activity greater on the right side of paired body structures, and left cerebral hemisphere EEG 'activity'. Conversely, left nostril dominance is a relative predominance of sympathetic activity on the left side and relatively greater EEG amplitude in the right hemisphere. Such phenomena could include the basic physiology of other known cyclic phenomena.

Fig.1



Top Tracing: Points above midline indicate a dominance of right nostril air flow; points below midline left nostril air flow. Bottom Tracing: Points above midline indicate greater integrated EEG amplitude (0-30 Hz.) in the left hemisphere; points below greater right hemisphere amplitude. Total time 185 min.

70.6 INTRAHEMISPHERIC AND THALAMIC CONNECTIVITY OF THE POSTERIOR PARIETAL CORTEX IN THE RACCOON. Sharleen T. Sakai Dept. of Psychology and Neuroscience Program, Michigan State University, East Lansing, MI 48824.

The purpose of this study was to investigate the intrahemispheric projections of the posterior parietal cortex with particular regard for the interconnectivity of this region with MI in the raccoon. In addition, the thalamic projections of the posterior parietal area was investigated.

The neural connectivity was determined using the horseradish peroxidase (HRP) tracing technique. Electrophoretic/pressure injections of 30-50% HRP were made into electrophysiologically identified areas of MI or the posterior parietal cortex in chloralose anesthetized raccoons. Following a survival period of 24-72 hours, the animals were transcardially perfused with a buffered aldehyde mixture. The brains were processed for HRP histochemistry using tetramethyl benzidine and diaminobenzidine as the chromogens on adjacent sections.

Following an injection into the MI forepaw area, labelled cell bodies were observed in the posterior parietal cortex in a region caudal to the SI arm area. Evoked potentials were recorded in this area of the posterior parietal cortex following stimulation of the contralateral forepaw. An HRP injection of this region resulted in labelled cells throughout a wide extent of MI forepaw area. The cells of origin were arranged in clusters. Within a cluster, retrogradely labelled neurons were found primarily in layers III and V, although some cells were observed in layer VI. In addition, HRP anterograde dust was observed overlying a cluster of retrogradely labelled neurons. The HRP dust was heaviest in layer I but occasionally was found to extend throughout all cortical layers. Following the posterior parietal cortical injections, labelled cell bodies were also observed rostral to MI in a region corresponding to MII. In addition, labelled neurons were also observed just lateral to SII.

The thalamic afferents of the posterior parietal area were arranged in a dense patch-like configuration. HRP anterograde dust was observed overlying and extending beyond the distribution of labelled thalamic cell bodies. The primary thalamic projection was observed arising from the dorsal cap region of VL throughout much of its rostrocaudal extent. Labelled cells were also observed in VA and dorsal LP. CL also contained HRP positive neurons.

The interrelationship of the posterior parietal cortex and motor structures observed in the present study suggests the posterior parietal cortex maybe involved with the integration of sensory and motor information.

(Supported by NSF grant no BNS 78-00879).

71.1 ON THE USE OF THE LIPOPHILIC CATION TETRAPHENYLPHOSPHONIUM (TPP^+) AS A MONITOR OF MEMBRANE POTENTIAL IN MITOCHONDRIA CONTAINING PARTICLES. S. Rochel*, A.J. Blume and F.L. Margolis. Department of Physiological Chemistry and Pharmacology, Roche Institute of Molecular Biology, Nutley, NJ 07110.

Several laboratories have used TPP^+ and other lipophilic cations to monitor transmembrane potential in prokaryote and eukaryote systems. Possible problems in calculation of $[TPP^+]$ due to mitochondrial contributions have been noted. However, details of the influence of TPP^+ interaction with mitochondria in eukaryotic systems have generally not been carefully evaluated. We have monitored the membrane potential ($\Delta\Psi$) of rodent olfactory bulb synaptosomes with TPP^+, which distributes across membranes according to the Nernst equation (Lichtshtein, Kaback & Blume, PNAS 76:650-654 [1979] and Ramos et al., PNAS 76:4783-4787 [1979]). Intrasynaptosomal mitochondria also exhibit a negative $\Delta\Psi$ and would therefore be expected to accumulate TPP^+ in a cascade fashion as a function of cytoplasmic $[TPP^+]$. Thus, the effects of TPP^+ on mitochondrial function were studied. We observed that when the effect of external potassium concentration on the synaptosomal potential was monitored in the range from 0 to 90 mM K^+, the calculated $\Delta\Psi$ was 25 mV lower in the presence of oligomycin/Argon (Ar) than in its absence. This indicated that there is accumulation of TPP^+ into mitochondria. It is represented by the difference in accumulation of TPP^+ in the absence and in the presence of the mitochondrial inhibitor oligomycin/Ar which eliminates the mitochondrial potential. This difference was used to calculate an apparent mitochondrial potential of -106 mV and a plasma $\Delta\Psi$ of -65 mV. In addition, the mitochondrial accumulation of TPP^+ decreased as a function of increasing TPP^+ concentration in the medium in the range from 0.1 µM to 200 µM TPP^+, while no such change in accumulation of TPP^+ was observed under oligomycin/Ar, where the only potential maintained is that of the plasma membrane. This suggests that TPP^+ interfered selectively with maintenance of mitochondrial $\Delta\Psi$ under aerobic conditions. Finally, TPP^+ exhibited toxicity in vivo at levels comparable to those used in vitro. As a result of the in vivo experiments, precaution with regard to exposure to the compound is recommended. In conclusion, TPP^+ accumulation is an accurate monitor of the response of synaptosomal $\Delta\Psi$ to the presence of drugs such as veratridine or tetrodotoxin, as well as to alterations of external K^+ concentrations (Rochel & Margolis, Soc. Neurosci. Abstr. 5:745 [1979]) when intrasynaptosomal mitochondrial $\Delta\Psi$ is eliminated by oligomycin/Ar. Our results suggest that TPP^+ at high concentrations (100 µM) may be used for both synaptosomal plasma membrane $\Delta\Psi$ measurements and elimination of mitochondrial $\Delta\Psi$.

71.2 EVIDENCE THAT HIGH FREQUENCY STIMULATION INFLUENCES THE PHOSPHORYLATION OF PYRUVATE DEHYDROGENASE AND THAT THE ACTIVITY OF THIS ENZYME IS LINKED TO MITOCHONDRIAL CALCIUM SEQUESTRATION. Browning, M., Baudry, M.*, Bennett, W.*, Kelly, P., and Lynch,G. Psychobiology Dept., Univ. of California, Irvine, Calif. 92717

Brief bursts of high frequency stimulation of the Schaffer-commissural axons of the rat hippocampal slice induce long-lasting potentiation of the stimulated synapses and a marked change in the endogenous phosphorylation of a 40,000 dalton (40K) brain protein. Since only potentiating stimulation was effective in producing the effect on the 40K protein, we hypothesized that this polypeptide might play some role in producing or triggering LTP. Subsequent experiments (Finn, Browning, and Lynch, Neurosci. Lett., 1980, in press) indicated that trifluoperazine which interferes with the induction of LTP, also blocks the endogenous- and clamodulin-stimulated phosphorylation of the 40K protein. Given the potential importance of this phosphoprotein to synaptic potentiation, we have been interested in establishing its identity and determining the significance of its phosphorylation

The 40K phosphoprotein is enriched in the mitochondrial fraction and since the α-subunit of pyruvate dehydrogenase (α-PDH) is the only mitochondrial phosphoprotein known to be close to that molecular weight, we compared the two proteins. We concluded that the 40K protein was α-PDH on the basis of partial and total proteolytic fingerprint comparisons as well as comparisons of ionic and pharmacological manipulations of the two proteins. We next used Dichloroacetate (DCA) which inhibits PDH kinase. to assess the effects of changes in the phosphorylation of PDH on various mitochondrial functions. (It is known from the work of Linn et al., (1969), Proc. Nat. Acad. Sci., U.S.A., 64, 227-234 that PDH is inhibited by phosphorylation.) DCA stimulated pyruvate-supported calcium accumulation by brain mitochondria and was half-maximally effective at a concentration (0.5mM) which was reasonably close to that at which it inhibited phosphorylation of PDH (0.16mM) and increased pyruvate dehydrogenase activity (0.3mM). DCA had no effect on calcium uptake supported by succinate or ATP, a result which indicates that the drug is acting selectively on the PDH step of mitochondrial metabolism. It appears then that calcium sequestration by mitochondria is tightly linked to the phosphorylation of PDH. Since the available evidence strongly suggests that α-PDH and the 40K material are the same protein, it follows that repetitive stimulation of the type which produces LTP, influences the phosphorylation of PDH and hence perturbs calcium buffering by the mitochondria. A perturbation in intracellular calcium levels could then act on any of several calcium sensitive processes related to the organization of the pre- and post-synaptic elements to produce an enduring change in the efficacy of the transmission process.

71.3 EXTRACELLULAR ALTERNATING CURRENTS CHANGE FIRING RATE IN APLYSIA PACEMAKER NEURONS. A. R. Sheppard*, E. French* and W. R. Adey (SPON: T. J. Willey). VA Hospital, Loma Linda, CA 92357 and Dept. of Physiol., Loma Linda Univ., Loma Linda, CA 92350

Electrical coupling of a neuron to an external current is weak because: 1) most current is shunted around the cell by the highly conductive extracellular medium, and 2) there is no net polarization of a spherical cell. Yet, Terzuolo and Bullock (PNAS, 42:687, 1956) observed modulation of the firing rate (FR) in crayfish stretch receptors by direct currents at extracellular gradients of about 10 mV/cm, and Wachtel (DOE CONF-781016, 1979) reports a frequency dependent change in FR of Aplysia pacemaker neurons at current densities as low as 2 µA/cm .

We report several phenomena affecting the FR of beating pacemaker neurons of the abdominal ganglion of Aplysia californica during exposure to sinusoidal, low frequency currents passed between two Ag-AgCl electrodes immersed in the artificial seawater medium (17C) that surrounds the ganglion.

Electric fields of 0.01 to 0.2 Hz (slow compared to cell FR) at about 20 mV/cm (peak) produce prompt changes in FR, although the correspondence between current maxima and either acceleration or slowing of the FR may differ from cell to cell, and sometimes the correspondence reverses upon a change in frequency for a given cell. The dual phases of the current/rate relation suggest that transduction of the extracellular field occurs at localized sites, and is not due to a net cellular polarization.

Secondly, smaller electric fields (1-4 mV/cm) at frequencies near the endogenous FR (~1 Hz), and at 60 Hz, were applied for 10 or 20 minutes. At all frequencies, the effects, when apparent, occurred after considerable delay. We observed altered FR, increased variability in FR, a field-related hyperpolarizing shift in previously stable neurons, and paroxysmal activity. In particular, the hyperpolarizing potential resembles the one associated with the slow K^+ current in bursters, and in the absence of prompt changes in FR, suggests a coupling of the external field to selected membrane functions.

We estimate that only 5 ppm of the extracellular current crosses the membrane of a 150 µm radius cell (membrane resistance, $9 \cdot 10^4$ Ωcm^2). For a cell in a 4 mV/cm field, bathed in a medium of 19 Ωcm resistivity, the trans-hemisphere current is only $\sim 10^{-12}$A. The localized membrane potential change at a pole of the cell is about 90 µV, while any net potential change is far less, as it depends upon assymetries in cell shape or conductance, and the effects of axonal loading. (Funding: DOE DEAI101-79ET29078, FDA RO1-FD00963, and Southern California Edison Company.)

71.4 VOLTAGE AND CURRENT TRANSFER ALONG DENDRITES OF LOBSTER STRETCH RECEPTOR NEURONS. William H. Calvin and Dennis A. Turner* (SPON: A. A. Ward, Jr.). Department of Neurological Surgery, University of Washington School of Medicine, Seattle WA 98195.

Membrane leakiness in the dendritic tree affects the transfer of voltage and current to the impulse trigger zone at the axon's initial segment. Unlike the losses along an infinite cable, current loss may be minor in a dendritic tree even though voltage is markedly attenuated (see Graubard & Calvin 1979, in The Neurosciences Fourth Study Program). A typical sensory neuron, SN_1 in *Panuliris interruptus*, was investigated by 1) cobalt staining and anatomical reconstruction out to 2 µm diameter distal processes; and 2) intrasomatic measurement of input resistance (yielding 1.09 megohm using the spike height method) in a similar group of neurons. An average SN_1 neuron had an 80 µm soma diameter, a surface area of 7.7×10^4 μm^2, and about eight major dendrites. A simple resistive-only reconstruction of the electrotonic properties was done using the original exact method of Rall (1959; *not* assuming $d^{3/2}$ conservation). Not knowing the anatomy distal to the 2 µm points, one brackets the possible range of R_m by alternately assuming a sealed end or an infinite extension distally. This causes an uncertainity in the computed R_m value (that value which will yield 1.09 megohm intrasomatic input resistance) of 800 to 3600 $ohm \cdot cm^2$. However, voltage and current transfer from a single distal tip input to the soma are little affected by this large range of R_m: voltage transfer averaged 22% for both extremes, while current transfer was 89-83%. The large voltage loss is thus not primarily caused by current loss along the path; it is primarily created by the central loading of the major dendrite by the other dendrites without simultaneous inputs. For inputs simultaneously on all major dendrites, we adapted the method of Rinzel & Rall (1973, which assumed $d^{3/2}$ conservation) and obtained changes from the single-input case qualitatively similar to theirs.

It is clear that R_m alone cannot characterize the electrotonic properties of a dendritic tree; geometry, particularly branching pattern, is usually a far more important variable. One must also ask whether voltage or current is the relevant variable for the neuron's operation. While voltage is relevant when the neuron is silent but approaching the (voltage) threshold for the first impulse, current is considered (Calvin, 1975) to be what elevates firing rate, once rhythmic firing is in progress. The low-loss aspects of SN_1 for current are, however, in contrast to the moderate current losses of spinal motoneurons (Barrett & Crill 1974) and hippocampal pyramidal neurons (Turner & Schwartzkroin 1980). Dendritic trees are often rather good funnels for current; the more branching, however, the greater the loss. [NIH grants].

71.5 REVERSIBLE BLOCKAGE OF ACTION POTENTIALS BY APHANTOXIN. T. Hoshi, W. Watson, J.J. Sasner. (SPON: H. Levitan). Zoology Dept. University of New Hampshire, Durham, NH 03824.

Toxic blue-green algae (Aphanizomenon flos-aquae) bloom in eutrophic, freshwater lakes and ponds in New England. Preliminary studies on frog nerve and muscle preparations indicate that lethal effects are due to the toxin's ability to block the generation of action potentials (Sasner and Ikawa, 1975).

In this investigation, semipurified aphantoxin (M.W.<500 daltons) was applied to partially desheathed nerve cords of crayfish to test its effects on the membrane properties of the medial and lateral giant fibers. At a concentration of 4 µg/ml, aphantoxin reversibly blocked the generation of action potentials in 20 seconds. The time required for this effect was dose-dependent, with a minimum effective concentration of 0.4 µg/ml. Complete recovery following a 4 µg/ml application was obtained after 10 minutes of washing with toxin-free saline solution at a flow rate of 4.5 ml/min. No significant change in resting potential or resting membrane resistance was observed during repeated application of the toxin. The toxin decreased the rate of depolarization much faster than the rate of repolarization.

It is suggested that aphantoxin blocks voltage-sensitive sodium channels much like saxitoxin (STX) and tetrodotoxin (TTX). Aphantoxins' effects are more readily reversible than either STX or TTX and therefore may prove to be a more useful tool for some neurophysiological investigations.

71.6 INACTIVATING FAST POTASSIUM CONDUCTANCE IN VAGAL MOTONEURONS IN GUINEA PIGS: AN IN VITRO STUDY. Y. Yarom*, M. Sugimori* and R. Llinás (SPON: R. A. McCrea). Dept. Physiology & Biophysics, New York Univ. Med. Ctr., 550 First Ave., New York 10016.

A fast voltage-dependent potassium conductance, normally inactive at rest membrane potential level and which may be de-inactivated by hyperpolarizing, is present in mammalian vagal motoneurons. This conductance is observed when the membrane is depolarized from a hyperpolarized level and is in every way similar to that reported in invertebrates by Hagiwara et al. (J. Physiol. 155: 410, 1961) and Connor and Stevens (J. Physiol. 213: 21, 1971). Intracellular recordings from these cells were obtained in brain stem slices from 300 gm. animals. Steady-state measurement of membrane resistance indicates stable properties if taken at rest (-65 mV) and at 10 mV depolarization or hyperpolarization from rest. It was noted, however, that following a hyperpolarizing pulse the potential at the break of the current pulse did not return to the resting level with the expected passive time constant but, rather, remained at a hyperpolarized level having a time course of approximately 30 msec. Measurement of slope conductance following break of the hyperpolarized pulse indicates a large conductance change concomitant with the duration of the after-hyperpolarization. Biphasic current pulse injections demonstrate that this after-hyperpolarization has an equilibrium potential similar to that produced by the after-hyperpolarization following an action potential or the potassium activation which follows calcium electroresponsiveness in this cell. It is, therefore, concluded that the I_A current present in invertebrates is also represented in mammalian CNS neurons. The significance of this current in determining the repetitive firing properties of this neuron will be discussed. (Supported by USPHS grant NS-13742 from NINCDS)

72.1 EFFECTS OF OVARIAN STEROIDS ON SEROTONIN METABOLISM WITHIN DISCRETE BRAIN REGIONS OF OVARIECTOMIZED RATS. Ric. I. Cone, Gary A. Davis* and Robert W. Goy. Wis. Reg. Primate Res. Ctr. and Neurosciences Training Program, Univ. Wisconsin, Madison, WI

Brain serotonin (5-HT) metabolism within the dorsal raphe nucleus (DR) was elevated in ovariectomized (ovx) rats following ovarian steroid replacement compared to metabolism in controls given oil (O) as vehicle. Females received either estradiol (E, 20 µg/kg) and progesterone (P, 2 mg/kg) sc 48 hrs apart or O + O. The animals also received either the monoamine oxidase (MAO) inhibitor, pargyline (75 mg/kg, i.p.) or vehicle (saline) at designated times 10-40 min prior to sacrifice. Decapitation occurred 5 hrs following the second steroid injection and 4-6 hrs into the dark phase of a 14:10 light/dark cycle. Basal 5-HT (5-HT_b) levels and the rate of 5-HT accumulation (5-HT_r) following MAO inhibition were estimated by radioenzymatic assay in select anatomically-defined regions punched from frozen brain tissue. Values within DR listed in the table are based on results from several experiments.

	O + O	E + P
5-HT_b*	37.1 ± 0.7 (30)	42.2 ± 0.7 (29)
5-HT_r†	36.2 ± 1.6 (44)	44.6 ± 2.5 (48)

* ng 5-HT/mg protein ± S.E. (N)

† ng 5-HT/mg protein per half-hour ± S.E. regression (N)

Within the DR, 5-HT_b levels and 5-HT_r rates were 13.8% ($p < .001$) and 23.2% ($p < .025$) higher in E+P treated females compared with O+O treated controls. Differences in 5-HT_b were found within the median raphe nucleus, but these were inconsistent from experiment to experiment. No differences were found in tissue immediately adjacent to these nuclear regions or within other brain regions including the ventral medial nucleus and suprachiasmatic nucleus of the hypothalamus.

It is not clear whether the effects on 5-HT metabolism reported here resulted from the presence of E, P or sequential E+P. In an earlier study, females given either E+O or E+P were found to have significantly higher 5-HT_b levels than controls in grossly dissected tissue from the brainstem raphe area. In addition, plasma levels of corticosterone and progesterone were significantly higher in these animals than in the control group. This suggests that with respect to the effects reported here, adrenal release of P following a low dose of E may have been sufficient to eliminate any distinctions between treatment with E+O versus E+P. Consequently, examining the endocrine specificity of this increase in 5-HT metabolism within DR would require appropriate controls for the effects of E on adrenal activity. Research supported by grants #RR00167 and #MH21312.

72.2 THE EFFECT OF CHRONIC, APERIODIC CORTISOL LEVELS ON THE DIURNAL FLUCTUATION OF SEROTONIN AND DOPAMINE ASSOCIATED BEHAVIORS IN THE GUINEA PIG.
P.CARVEY*, P.NAUSIEDA, W.WEINER, C.GOETZ* AND H.KLAWANS*
Rush-Presbyterian-St.Luke's Medical Center, Chicago, IL 60612

Chronic corticosteroid (CS) therapy, Cushing's syndrome, and, in a significant percentage of cases, long term levodopa therapy, are associated with elevated, non-fluctuating levels of CS. These clinical states are frequently associated with thought disorders, disruption of sleep architecture, fragmentation of the sleep-wake cycle, and myoclonus. Interest in the mechanisms involved in these side effects prompted us to study the effect of chronic, elevated, aperiodic CS levels upon two behavioral models of central monoaminergic activity.

Stereotypic chewing behavior (SB) induced by the direct dopamine (DA) receptor agonist, apomorphine, is a quantitative measure of striatal DA activity. Myoclonic jumping behavior (MJB) induced by the serotonin (5HT) precursor 5-Hydroxytryptophan, is a quantitative measure of brainstem 5HT activity. Prior to chronic CS treatment, the sensitivity to a fixed dose of each test drug was monitored at five time points over a 24 hour period in 110 guinea pigs. The behavioral response to each test drug varied independently, demonstrating statistically distinct circadian variations. We then delivered cortisol succinate (12.5mg/kg/day) to one-half of the animals in such a fashion that daily intake was continuous and aperiodic. Both behaviors were again assessed over 24 hrs in control and experimental animals on days 14 and 28 of treatment. 48 hrs after the final behavioral assessment, animals were sacrificed at their respective time-points and tissue samples were removed and immediately frozen.

Results indicated that elevated, aperiodic CS levels affect both absolute activity within and periodicity of central monoaminergic systems. 14 days of continuous, aperiodic CS treatment abolished rhythmicity and decreased behavioral sensitivity to 5HT precursors, but had no effect on apomorphine behavioral sensitivity or rhythmicity. After 28 days of CS treatment, enhanced sensitivity to 5HT appears to develop and dopaminergic sensitivity and rhymicity are diminished. It is possible that the initial pertubation of sensitivity and periodicity within the 5HT system may have been responsible for subsequent, similar changes in the DA system. These data, when applied to clinical observations of psychomotor toxicity in states of chronic aperiodic hypercortisolemia suggest that manifestation of these side effects may depend upon similar CS mediated alterations of central monoaminergic activity. The mechanism of such putative neuroendocrine interactions is currently being assessed in binding and transmitter level analysis of discrete brain regions.

72.3 BINDING OF ^{3}H-DIHYDROERGOCRYPTINE TO AN α-ADRENERGIC RECEPTOR IN THE BOVINE STALK-MEDIAN EMINENCE. H.T. Chen* and R.I. Weiner. Reproductive Endocrinology Center, Univ. Calif. Med. Sch., San Francisco, CA 94143

Dopaminergic and noradrenergic terminals, implicated in neuroendocrine regulation, densely innervate the external and internal layers of the median eminence, respectively. A high affinity, saturable binding site for ^{3}H-dihydroergocryptine (DHE) was reported in the stalk median eminence (SME) of the sheep (Endocrinology 103:302, 1978). DHE is a potent dopamine agonist and α-adrenergic antagonist and has been used extensively as a radioligand to study both receptors. In the present study, we have further characterized ^{3}H-DHE binding to the SME of the steer. Particulate fractions of the SME were incubated in concentrations of ^{3}H-DHE from 0.1 - 20nM in Tris buffer (pH 7.4) at either 22°C for 90 min. or 37°C for 60 min. Bound ^{3}H-DHE was separated from free by filtration on glass fiber filters. Specific binding defined by 10^{-5}M phentolamine was high affinity (K_d = 1.78 ± 0.22nM) saturable (Bmax = 481 ± 39 fmol/mg protein) and stereoselective. The K_d (2.8 ± 0.1nM) calculated from the ratio of the rate constants K_2/K_1 (K_1 = 1.47 ± 0.15 x $10^7 M^{-1}$ min^{-1} and K_2 = 0.04 ± 0.002 min^{-1}) at 37°C was in good agreement with the K_d determined in equilibrium experiments.

Agonist	Ki(nM)	n	Antagonist	Ki(nM)	n
L-epinephrine	292±67	4	phentolamine	3.0±0.8	3
apomorphine	792±248	2	yohimbine	38±7	3
L-norepinephrine	801±142	4	D-butaclamol	105±19	3
dopamine	6110±1210	3	spiperone	744±34	2
D-norepinephrine	15700±3560	2	prazosin	798±190	3
isoproterenol	71300±19000	4	chlorpromazine	849	1
serotonin	75600	1	propranolol	22300	1
			L-butaclamol	61100	1

The rank order of potency of agonists and antagonists to displace ^{3}H-DHE binding was consistent with an α-adrenergic site. The affinity of dopaminergic agonists to displace DHE was shifted approximately 10 fold to the right relative to their potency at known dopamine receptors while the affinity of dopaminergic antagonists was shifted 100 fold. The rank order of potency of the α-antagonists (phentolamine > yohimbine > prazosin) is consistent with an α-2 receptor. α-adrenergic receptors in the SME may play a role in the neuroendocrine regulation of anterior pituitary hormone secretion. Further studies are needed to determine if these sites are localized on neuronal elements or tanycytes in the SME.
(Supported by NIH Grant HD-08924 and the Rockefeller Foundation.)

72.4 QUANTITATION OF NORADRENERGIC INPUT TO MAGNOCELLULAR PERIKARYA IN THE RAT SUPRAOPTIC NUCLEUS. H. Khachaturian and J.R. Sladek, Jr. Department of Anatomy and Center for Brain Research, Univ. Rochester School of Med. and Dentistry, Rochester, N.Y. 14642.

Noradrenergic mechanisms have been implicated in the central control of neurohypophyseal hormone release. The supraoptic nucleus (SON) receives a dense noradrenergic input originating from monoamine cell groups located in the brain stem. Many fluorescent, norepinephrine-containing varicosities are arranged pericellularly to magnocellular neurons. That these varicosities might represent functional noradrenergic "contacts" has been suggested by quantitative electron microscopy, and direct microiontophoretic applications of norepinephrine onto antidromically identified neurosecretory neurons of the SON.

The present study is aimed at the direct quantitation of the number of fluorescent varicosities juxtaposed to SON neurons, through serial reconstructions of magnocellular neurons. Hypothalami from adult male, Fischer 344 rats of 3 months of age were processed for formaldehyde-induced fluorescence of catecholamines. 4µm paraffin sections were cut on a microtome and the rostral, middle and caudal regions of the SON were photographically reconstructed. Magnocellular neurons were traced through serial sections; the total number of fluorescent varicosities in juxtaposition to the entire perikaryal surface was determined for 120 magnocellular neurons. The results are shown below:

SON region	Zone	Mean(hits/cell)	Range(hits/cell)	N(#cells)
Rostral	Dorsal	3.8	1-9	10
	Ventral	13.3	7-23	13
Middle	Dorsal	4.4	0-9	22
	Ventral	14.5	6-29	53
Caudal	Dorsal	4.7	4-6	4
	Ventral	17.7	10-25	18

Magnocellular neurons in the ventral SON were more heavily "contacted" than those in the dorsal regions of the nucleus. The mean number of varicosities per perikaryon was 15.0 (range 6-29, n=84) for neurons situated ventrally, and 4.3 (range 0-9, n=36) for those located more dorsally. The majority of neurons in the caudal SON belong to the more heavily "contacted" group, while at middle and rostral levels of the nucleus a more uniform dorsoventral separation was seen. It is known that vasopressin neurons predominate in the caudal and ventral parts of the SON. This taken with the present findings suggests that perikarya of vasopressin neurons may receive a richer noradrenergic input than those of oxytocin neurons in the rat SON. Supported by USPHS Grants GM 07230, AG 00847, AG 01456, and NS 15816.

72.5 AGING OF ENDOCRINOLOGICALLY-IMPORTANT CENTRAL NEURONS. John R. Sladek, Jr. and Gloria E. Hoffman, Dept. of Anatomy and Center for Brain Research, University of Rochester School of Medicine and Dentistry, Rochester, N.Y. 14642.

Several neuroendocrine mechanisms are compromised with age; these include the hypothalamo-pituitary gonadal axis, prolactin secretion, growth hormone release, and others. In order to better define a possible mechanism for these functional alterations a combined analysis of specific peptidergic neurons and functionally interactive dopaminergic neurons was undertaken in the aged rat. Male rats (Fischer 344) of 3, 12, 20, and 30 months of age were examined for formaldehyde-induced histofluorescence of monoamines and PAP immunochemistry of neuropeptides. Antisera generated against LHRH (Nilaver-Silvermann#3) and somatostatin (Stewart#9) were employed. Major declines were noted in the immunochemical staining of LHRH and somatostatin fibers throughout all rostral to caudal levels of the median eminence. In general the density of fibers was decreased although in some instances, especially for somatostatin fibers, exceptionally large profiles were noted which appeared reminiscent of Herring bodies of the neurohypophyseal system. These age-related changes were first noted in the 12 month old animals and were most severe in the 30 month old animals. Dopamine histofluorescence in the external zone of the median eminence also appeared depressed in the aged animals. However, perikarya of origin of this system within the arcuate-periventricular region appeared to contain an increased amount of fluorescence in aged rats. For 30 month old rats this increase was determined microspectrofluorometrically to be about 50-65% greater than 3 month old rats; the dopamine fluorescence of the external zone was 30-40% less than controls.

Two other unusual fluorescence parameters were noted; first what appeared as a hyperinnervation of neurons located in the lateral arcuate nucleus was seen in aged animals and secondly, a thin rim of supraependymal catecholamine fluorescence was seen overlying the region of the arcuate nucleus in the third ventricle.

Whether decreased staining and intensity of dopamine, LHRH, and somatostatin in the median eminence is the result of some change in synthesis and/or release, or alternately some modification of axonal transport of synthesized neurochemicals is unknown. Nevertheless these findings may point to a central locus of altered endocrine function in the senescent rat. Supported by USPHS Grants AG 00847, AG 01456, NS 15816, NS 13725, and RCDA NS 00321.

72.6 CATECHOLAMINE INNERVATION OF THE SUPRAOPTIC NUCLEUS OF THE BRATTLEBORO RAT. J. Schöler* and J.R. Sladek, Jr. (SPON. I. Shoulson) Dept. Anatomy and Center for Brain Res., Univ. Rochester Sch. of Med. and Dentistry, Rochester, N.Y. 14642.

The Brattleboro rat carries a congenital diabetes insipidus due to an inability to synthesize vasopressin as opposed to a neuronal cell loss. Magnocellular hypothalamic nuclei of normal rats receive a dense noradrenergic innervation from the medullary and pontine brain stem which favors the perikaryal innervation of vasopressin neurons. Oxytocin neurons are sparcely innervated. Considering the possibility that the presence of vasopressin may be essential to the maintenance of these innervation patterns, this phenomenon was examined in the Brattleboro rat which is deficient in the target neuron peptide, but not the target neuron. Normal, adult male Long Evans rats and their genetically deficient counterparts were examined for formaldehyde-induced histofluorescence and rat neurophysin immunocytochemistry utilizing a combined demonstration technique. Comparator bridge microscopy was employed to identify peptide-specific target neurons. Alternate section analysis of fluorescence and neurophysin immunocytochemistry revealed the following. The ventral portion of the supraoptic nucleus, which has been shown to contain a majority of vasopressin neurons, appeared to contain a dense pattern of catecholamine varicosities in the normal rat. In the Brattleboro rat however, this same region of the nucleus contained a less dense pattern such that it often appeared devoid of catecholamine varicosities. In contrast, neurons in the more dorsal portion of the nucleus in the Brattleboro rat appeared more heavily rimmed by catecholamine varicosities; comparator bridge microscopy revealed that these neurons stained positively for rat neurophysin and are presumed to be oxytocin-containing. This division is not strict and when neurophysin-containing neurons were found in the more ventral regions of the supraoptic nucleus, they, too appeared to be rimmed in a pericellular manner. Additionally, a zone ventral to the magnocellular perikarya, shown by McNeill & Sladek (JCN 1980 in press) to contain neuritic profiles of magnocellular neurons and a maximally dense catecholamine varicosity pattern appeared to contain a decreased varicosity pattern in the Brattleboro rat. These data suggest an alteration in the innervation patterns of oxytocin and vasopressin neurons in the Brattleboro rat in comparison to normal animals. Supported by USPHS Grants MH 14577, AG 00847, AG 01456 and NS 15816.

73.1 THE MOLLUSCAN CARDIOACTIVE NEUROPEPTIDE FMRFamide IS A NEUROSECRETORY PRODUCT. G.T. Nagle, D.A. Price and M.J. Greenberg. Dept. of Biological Sciences, Florida State Univ., Tallahassee, FL 32306.

FMRFamide (phenylalanyl-methionyl-arginyl-phenylalanine amide) is a cardioactive peptide found in the ganglia of the clam Macrocallista nimbosa (Price & Greenberg, Science 197: 670, 1977). But is FMRFamide a neurosecretory product?

Homogenates of Macrocallista ganglia were subjected to differential centrifugation, and the resulting fractions were osmotically shocked and purified by cation exchange chromatography (CM-25 Sephadex). The fractions were assayed for FMRFamide on the radula protractor muscle of the whelk, Busycon contrarium. This assay can detect less than one picomole of peptide when the muscle is isolated in a microbath (< 150 µl).

The majority of FMRFamide activity occurred in the high-speed (100,000g) microsomal fraction. If radiolabelled FMRFamide was added to the ganglion homogenate, it appeared primarily in the high-speed supernatant; only about 1-5% was associated with the microsomal pellet. The FMRFamide storage granules must now be characterized more specifically. To this end, we are now purifying the microsomal fraction by sucrose density gradient centrifugation for electron microscopy.

Isolated Macrocallista ganglia were depolarized by incubation in high potassium medium (100mM K^+ replacing part of the sodium). FMRFamide activity was extracted from the bathing medium into butanol, purified by cation exchange chromatography, and assayed. The concentration of FMRFamide in the depolarizing medium was significantly increased over controls (incubation in artificial seawater: 10mM K^+). Ten-fold reduction of the calcium concentration blocked the potassium-induced release.

The occurrence of FMRFamide in the microsomal fraction of ganglion homogenates, its release from ganglia by high potassium depolarization, and the blockade of the potassium-induced release by low calcium all suggest that FMRFamide is a neurosecretory product in Macrocallista.

73.2 CONTROL OF THE PTTH NEUROSECRETORY CELLS IN THE TOBACCO HORNWORM, MANDUCA SEXTA. Grant M. Carrow*, Ronald L. Calabrese and Carroll M. Williams*. (Spon: Joel L. Cohen). The Biological Laboratories, Harvard University, Cambridge, MA 02138.

The cell bodies of the neurosecretory cells which are the major source of prothoracicotropic hormone (PTTH) in M. sexta have been localized to bilateral clusters in the brain (Gibbs and Riddiford, 1977, JEB 66:255; Agui et al., 1979, PNAS 76:5694). We report here on studies aimed at determining the sites and control of PTTH release by these neurons.

PTTH activity was measured using an in vitro assay involving the PTTH-stimulated secretion of α-ecdysone by prothoracic glands (PG). One PG of each pair was incubated in Grace's medium (GIBCO) with an extract of PTTH while the other was incubated in PTTH-free medium. PTTH was quantified by comparing the rates of α-ecdysone secretion by each member of the pair; the response was dose dependent. α-ecdysone activity was measured by radioimmunoassay using a rabbit anti-α-ecdysone antiserum provided by Timothy Kingan (Oregon State Univ.). PG from 3-day-old 5th instar larvae exposed to brain extracts from wandering larvae in vitro (0.5 brain equivalents or more) responded with a greater than 10-fold increase in the rate of α-ecdysone secretion.

We have measured PTTH release from intact and surgically interrupted brain-retrocerebral complexes (brain, corpora cardiaca, and corpora allata) in vitro of animals at various stages of development. Results indicate that the corpora allata (CA) contain the primary sites for release of PTTH. Isolated CA from feeding 5th instar larvae released PTTH spontaneously, indicating that the hormone may be stored in the CA throughout the feeding period. However, intact brain-retrocerebral complexes from early 5th instar larvae did not release PTTH, while those from later in the 5th instar did. Additional experiments employing a sucrose gap around the nerves between the brain and the CA suggest that electrical activity in the neurons may be involved in hormone release. The morphology, electrical properties and control of these neurons are presently being investigated with anatomical, pharmacological, and electrophysiological procedures.

Supported by grants from NIH.

73.3 ADENYLATE CYCLASE STIMULATION BY COINCUBATION OF ALBUMEN GLAND AND BRAIN EXTRACTS OF HELIX POMATIA. Jeffrey L. Ram & Esther M. Goudsmit. Dept. of Physiology, Wayne State Univ., Detroit, Mi. 48201 & Biology Dept., Oakland Univ., Rochester, Mi. 48063.

Albumen glands of reproductively active Helix pomatia synthesize galactogen (a galactose homopolymer) in preparation for laying eggs, which contain galactogen. Albumen glands from hibernating Helix do not ordinarily synthesize galactogen, but may be made to do so in organ culture by exposure to Helix brains or extracts thereof. The substance(s) in brain that cause(s) galactogen synthesis is brain-specific, heat-stable, and protease-labile. It is released from brain in high [K^+] media by a Ca^{++}-dependent mechanism (Goudsmit, Br. Res. 151: 418, 1978) and thus has the properties expected of a polypeptide neurohormone. Activation of galactogen synthesis in organ-cultured albumen glands from hibernating Helix also occurs in response to 10^{-3} M dibutyryl cAMP and is enhanced by 10^{-3} M theophylline (Goudsmit, Soc. Neurosci. Abs. 4: 194, 1978). To test the hypothesis that the stimulatory effect of brain substance(s) on albumen gland galactogen synthesis is mediated through activation of an albumen gland adenylate cyclase, we have begun to characterize this enzyme and to look for effects of brain substance(s) on it.

Albumen gland pellet fraction (38,000 x g x 30 min resuspended in 2 mM tris-maleate, pH 8.0) was incubated in a medium containing 5 mM $MgCl_2$, 25 mM tris-maleate (pH 8.0), 0.6 mM EGTA, 1 mM isobutylmethylxanthine, 20 mM creatine phosphate, 80 U/ml creatine phosphokinase, 1 mM cAMP, and 1 mM α^{32}P-ATP in a final volume of 100 µl. Synthesis of ^{32}P-cAMP was measured by the method of Salomon et al., Anal. Bioc. 58: 541, 1974. Activity was linear with time (0-20 min) and with amount of albumen gland protein (0-100 µg protein/100 µl incubation vol.). Average activity (hibernating glands) was 5.6 ± 1.4 (S.E.M.) pmole/min/mg protein (N=4 glands). Albumen gland adenylate cyclase is stimulated 80-fold by 10 mM NaF, 3-fold by 10^{-5} M GTP, and 6-fold by 10^{-5} M GppNHp. A brain extract (supernatant from 8000 x g x 4 min centrifugation of brain homogenate) added to the incubation medium to give 10 µg brain protein (≈.01 brain)/100 µl caused a doubling of adenylate cyclase activity (2.0 ± .3[S.E.M.]-fold increase, N=4 brain extracts). Under these conditions, .01 brain itself has no detectable adenylate cyclase activity (N=2).

These data are consistent with the hypothesis that Helix brain contains factor(s) which stimulate albumen gland adenylate cyclase. Further experiments to compare biochemical properties of these factor(s) to galactogen synthesis activating factor(s) of brain are in progress.

73.4 PHARMACOLOGICAL ANALYSIS OF THE INSECT PROCTOLIN RECEPTOR: STRUCTURE-FUNCTION RELATIONSHIPS OF AGONISTS AND ANTAGONISTS. R. E. Sullivan and R. Newcomb*. Békésy Laboratory of Neurobiology, University of Hawaii, Honolulu, HI 96822.

Recent investigations have revealed that proctolin (Arg-Tyr-Leu-Pro-Thr) or proctolin-like activity is found in semipurified tissue extracts from a number of arthropods (Brown, B.E., J. Insect Physiol., 23:861, 1977, and Sullivan, R.E., J. Exp. Zool., 210(3):543, 1979). Although it was originally suggested that proctolin was a neuromuscular transmitter in the cockroach hindgut (Brown, B.E., Life Sci., 17:1241, 1975), more recent pharmacological investigations suggest a hormonal function affecting peripheral and myocardial neuromuscular events in insects (Piek, T., and Mantel, P., J. Insect Physiol., 23:321, 1977, and Miller, T., Am. Zool., 19:77, 1979) and crustaceans (Lingle, C., Ph.D. Thesis, Univ. Ore., 1979).

Having considered the possible structural and pharmacological relationships between proctolin and a crustacean cardioexcitatory peptide (Sullivan, R.E., op. cit., 1979), we undertook a study of the pharmacology of proctolin analogues. Using solid-phase techniques we have synthesized and purified numerous deletion, addition, and substitution analogues of proctolin and assayed for agonistic and antagonistic activites on the cockroach hindgut. Active analogues (effecting contractures at ≤ 10^{-6} M) to be discussed include: tryptophan and phenylalanine substituted for tyrosine, the N-terminal addition of glycine, C-terminal addition of glycine and C-terminal substitution with alanine. Glutamate and glycine substituted-N-termini were without effect. Also without effect at 10^{-6}- 10^{-5} M were Arg-Tyr-Pro-Thr, Tyr-Leu-Thr, Arg-Tyr-Leu-Pro, Tyr-Leu-Pro-Thr, Leu-Pro-Thr, Arg-Tyr, and the cysteine addition to the C-terminus. In high concentrations (>10^{-7} M), none of the inactive peptides appear to antagonize the response to proctolin (10^{-8} - 10^{-7} M).

In our hands proctolin elicits both an increase in spontaneous contractions and a contracture from cockroach hindgut. It is worth noting that C-terminus additions and substitution appeared to qualitatively enhance only the spontaneous contractions. This observation led us to reinvestigate the antagonist role (see Brown op. cit., 1975) of octopamine and tyramine on this preparation. We found that the phenolamines selectively block the proctolin induced spontaneous contractions but not the contracture, suggesting the possibility of two proctolin receptors on the insect hindgut. Further work is in progress.

73.5 EFFECT OF THYROTROPIN RELEASING HORMONE ON THE CYCLIC AMP CONTENT IN PARIETAL GANGLIA OF THE POND SNAIL LYMNAEA EMARGINATA. Y. Grimm-Jørgensen, Dept. of Anatomy, Univ. of Connecticut Health Center, Farmington, CT 06032.

The tripeptide thyrotropin releasing hormone (TRH) is found in the nervous system of various gastropods. The physiological role of this peptide in molluscs is poorly understood. In an attempt to determine whether TRH may serve as a neurotransmitter or neuromodulator in gastropod nervous tissue, we have studied the effect of TRH on the cAMP content of various ganglia of the pond snail Lymnaea emarginata. We have reported that TRH (10^{-8}M) causes a decrease in the cAMP content of in vitro incubated cerebral ganglia, while it causes a significant increase in the concentration of this nucleotide in pooled left and right parietal ganglia (Grimm-Jørgensen, Y., Life Sci. 26: 1211,1980). The TRH-induced increase in cAMP content in parietal ganglia was further assessed. It was found that TRH causes an increase in the cAMP content of the large right as well as the small left parietal ganglion.

Because neurotransmitters cause a transient effect on the electrical activity and a transient increase in cAMP content of gastropod neurons, while the effect of neuromodulatory peptides on these parameters is more prolonged, the time course of the TRH-induced cAMP increase was assessed in right parietal ganglia. The cAMP concentration in in vitro incubated ganglia was highest at 20 min after the addition of the peptide and remained at this level for up to 30 min, the longest incubation time measured. This long-lasting effect of TRH was not abolished when the ganglia were exposed to the peptide in medium containing a high concentration of Mg^{++} (20 mM) and a low concentration of Ca^{++} (2 mM), indicating that synaptic activity is not required for the observed TRH effect.

It is concluded that the observed effect of TRH on the cAMP content of parietal ganglia of Lymnaea emarginata is compatible with the hypothesis that the peptide acts as a neuromodulator on some neuron(s) and that it is unlikely that TRH causes the release of an endogenous molecule which in turn promotes cAMP accumulation. 73.6 PEPTIDE HORMONE STIMULATED PROTEIN PHOSPHORYLATION CHANGES IN INSECT CNS AND MUSCLE. Susan K. Welch*, Lawrence M. Schwartz* and James W. Truman. (SPON: J. Loeser). Dept. of Zool. NJ-15, University of Washington, Seattle, Wa. 98195.

The eclosion hormone is a peptide which triggers the stereotyped behaviors of ecdysis and eclosion in silkmoths. When the peptide is added to the isolated silkmoth CNS, the motor program corresponding to these behaviors is evoked (Truman,J.W., 1978, J. Exp. Biol. 74, 151-173). The behavioral effects of eclosion hormone apparently are mediated by an increase in cyclic GMP levels in the nervous system of the moth (Truman,J.W., Mumby,S., and Welch, S.K., J. Exp.Biol. 84, 201-212).

Alterations in the phosphorylation of proteins by cyclic nucleotide-dependent protein kinases have been implicated in the action of peptide hormones in nervous and other tissues. To determine if such protein phosphorylation changes occur in moth CNS in response to eclosion hormone, cell-free homogenates of silkmoth brains were incubated with $[\gamma\text{-}^{32}P]$-ATP in the presence and absence of hormone. The homogenates were subjected to SDS-polyacrylamide gel electrophoresis and autoradiography. A physiological dose of purified eclosion hormone selectively stimulated the phosphorylations of several proteins from the silkmoth brain. A low concentration of cyclic GMP also stimulated the phosphorylation of several brain proteins, although these proteins were not the same as those whose phosphorylation was stimulated by the hormone. Both the hormone and cyclic GMP dependent phosphorylations were Ca^{++} dependent.

The eclosion hormone also acts on the intersegmental muscles of the silkmoth to trigger their degeneration following adult eclosion. An early step in this hormone-mediated cell death is a 20-fold increase in cyclic GMP levels in the affected muscles (Schwartz, L.M. and Truman,J.W., this volume). When cell-free homogenates of silkmoth muscle were incubated with $[\gamma\text{-}^{32}P]$-ATP in the presence and absence of eclosion hormone or cyclic GMP, a 25 to 30-fold stimulation of phosphorylation of several proteins was observed. Experiments are underway to determine if any of the proteins whose phosphorylation is stimulated by eclosion hormone are common to both muscle and brain. We are also focusing on demonstrating these hormone-stimulated phosphorylation changes in intact animals and in brains and muscles in culture.

74.1 INTRACELLULAR POTENTIAL OF MEDIAL BULBAR RETICULAR FORMATION NEURONS DURING NATURALLY OCCURRING STATES OF SLEEP AND WAKEFULNESS. M. Chase, S. Enomoto*, T. Murakami*, Y. Nakamura*, and M. Taira*. Departments of Physiology and Anatomy and the Brain Research Institute, Univ. of California, Los Angeles, CA 90024.

Since 1976 we have been studying a model of motor control which describes putative neuronal mechanisms and circuitry responsible for the suppression of somatomotor activity during active sleep (AS)(1). The key element in the model is the activation of cells in the nucleus reticularis gigantocellularis (NRG) by neurons of the nucleus reticularis pontis oralis. We have proposed that cells of the NRG serve as "premotor" inhibitory neurons which initiate, directly or through interneurons, the hyperpolarization of motoneurons during AS that we have described (2,3). In order to extend our explorations of this model, we recorded intracellularly from neurons of the NRG in the chronic cat preparation during sleep and wakefulness. The experimental paradigm which was utilized for chronic intracellular recording has been previously described (2).

Seventy neurons of the NRG were recorded from intracellularly; all neurons exhibited a membrane potential greater than -40 mV. During the transition either from wakefulness (W) to quiet sleep (QS), or from QS to W, no definite change in membrane potential level was detected. In contrast, compared to QS, the membrane potential level invariably depolarized by 3 to 14 mV (8.9±3.5) coincident with the onset of AS. This pattern contrasts with that of alpha motoneurons of the brain stem and spinal cord, which hyperpolarize during AS compared to W or QS (2,3).

Six reticular neurons, which exhibited spontaneous spike activity in QS, increased their discharge frequency coincident with the onset of AS. The tonic nature of the increased discharge pattern and decrease in polarization closely paralleled the tonic decrease in EMG activity. This pattern is different from that of other putative AS related cells which fire in bursts during AS in head-restrained cats or appear to fire, again in bursts, during W and AS in freely moving animals.

In summary, the data presented in this abstract indicate an active, functional role for NRG neurons in the process of somatic atonia during active sleep. Supported by grants from the USPHS (NS 09999) and the NSF-INT (77-22299).

74.2 PONTINE TEGMENTAL LESIONS RELEASE SIMILAR BEHAVIORS IN BOTH WAKEFULNESS AND PARADOXICAL SLEEP. J. C. Hendricks*, A. R. Morrison, G. L. Mann*. Lab. of Anatomy, Sch. of Vet. Med. University of Pennsylvania, Philadelphia, PA 19104.

Small bilateral pontine lesions disrupt the normal atonia of paradoxical sleep (PS) in cats, which permits the expression of complex motor activity in that state (Henley and Morrison, Acta Neurobiol. Exp. 34:215-232, 1974). In the present study, the behavior seen in PS differed with lesion site and was paralled by alteration in activity in wakefulness (W).

Four different syndromes were identified. Group I (n=9) showed what could be called "PS without atonia without behavior". Abnormally vigorous proximal limb movements occurred; but the head was not raised; and coordinated behavior was not seen. No specific pontine lesion was correlated with the Group I syndrome. Group II (n=10) showed coordinated behavior involving the head, neck and forelimbs with movements resembling orienting, staring, searching and attempts to rise and walk. The smallest (1 mm diam.) lesion needed to produce such behavior was symmetrical, centered at P=3.0, H=2.0, V=-3.0. Group III (n=6) exhibited periods of violent behavior resembling directed attack interspersed with tonic periods of quiet staring or searching movements. Attack behavior resulted from damage extending rostroventrally into the midbrain at P=2.0, H=2.5, V=-4.0 (4/6) or unilateral damage (2/6) to the descending projection of the central nucleus of the amygdala (Hopkins and Holstege, Exp. Brain Res. 32:529-547, 1978). In Group IV (n=5) hindlimb activity was seen as the animals walked in PS. Walking resulted from larger lesions centered at P=3.0, H=2.5, V=-4.0.

During W, cats exhibiting PS without atonia also demonstrate a significant increase in locomotion on an open-field test as well as increased orienting and exploratory behavior (Morrison et al., Soc. Neurosci. Abstr. 5:697, 1979). Five of the six cats which attacked in PS (Group III) also attacked both the experimenters and other cats during W. Both the W and PS attacks were predatory rather than defensive in nature.

The attack (Smith & Flynn, Brain Res. 164:103-119, 1979) and locomotor (Mori et al., J. Neurophysiol. 40:284-295, 1977) systems are anatomically closely related to each other and to the lesion sites of Groups II-IV. Thus, these lesions damaged neurons which must normally modulate coordinated behaviors such as attack and locomotion as well as promote dramatic motoneuronal inhibition in normal PS. Parallel lesion effects observed in W and PS indicate a remarkable similarity in motor control in the two states.

Supported by NIH grants NS 13110 and GM 07170.

74.3 PGO BURST NEURONS: CORRELATIONS WITH EYE MOVEMENT POTENTIALS AND RESERPINE WAVES. John P. Nelson, Robert W. McCarley and J. Allan Hobson. Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School, Boston, MA 02115.

PGO burst neurons are a class of midbrain cells which fire in stereotyped bursts of 4-6 spikes 12 msec before onset of pontogeniculo-occipital waves (PGO waves) during desynchronized, rapid eye movement sleep (REM sleep). We have shown previously that cells on one side of the midbrain fire in correlation to larger PGO waves in the lateral geniculate body (LGB) of the same side. They therefore transmit eye movement information to the visual system during REM sleep. Similar but less stereotyped waves occur in visual cortex and LGB during wakefulness (W) at the offset of saccades and also occur upon sudden noises or other startling stimuli. These waves have been called eye movement potentials (EMP). We have been unable to detect consistant changes in their waveforms with saccades in various directions.

Of 35 burst cells we have studied to date, and which could be followed from REM sleep into W, 4 cells showed clear relationship to EMP occurence. The burst cells lose their bursting pattern in W and fire single spikes in association with eye movements; they tend to be silent otherwise except for single spikes elicited by sudden stimuli (taps on the cage). Most cells did not fire before each EMP, nor was every spike followed by an EMP. One cell fired at latency (to peak of EMP) of 158±45 msec before 82% of 76 EMP's in one 8 minute period of alert W. The spike usually occurred near onset of a saccade. Another cell fired before fewer EMP's and at shorter latency (63±17 msec). This cell could be antidromically activated at fixed latency from two sites in the contralateral LGB (10 and 15 msec). Collision with spontaneous bursts could be demonstrated from both sites in REM sleep. In two cases the cell fired bursts of 4 spikes during spontaneous saccades. In one instance while testing for antidromic activation in W, a stimulus fell during a saccade and elicited a 4 spike burst followed by a large EMP suggesting that the excitability of the cell was raised during the saccade. EMP-like waves can be evoked in one LGB by stimulation of the other, possibly by antidromic activation of burst cells. When stimuli occur during saccades the resulting wave is larger than usual, which suggests that the population excitability is raised.

One cell recorded after 75 mg/kg reserpine IP fired bursts before many reserpine waves, which is evidence that such waves are also generated through burst cell activity. PGO burst cells seem to be a final path in generation of PGO waves, EMP's and reserpine waves. They transmit eye movement information to the visual system in REM sleep, and fire in association with saccades in W.

This research was supported by NIH grant 2 RO1 MH 13923-13.

74.4 THE PONTINE RETICULAR FORMATION: AN INTRACELLULAR RECORDING STUDY OF INPUTS FROM MIDBRAIN, BULBAR, AND CONTRA-LATERAL PONTINE RETICULAR FORMATION IN THE UNANESTHETIZED CAT. Robert W. McCarley and Keihachiro Ito*. Laboratory of Neurophysiology, Department of Psychiatry, Harvard Medical School, 74 Fenwood Road, Boston, MA 02115

The medial pontine reticular formation (gigantocellular tegmental field, FTG) is important for control of somatic and oculo-motor events during waking; its neurons are further notable for the dramatic modulation of their discharge rate over the sleep-waking cycle. Anatomical studies have demonstrated projections to FTG from medial reticular areas in midbrain (MRF), bulb (BRF) and contralateral pons (cFTG), but electrophysiological studies are needed for information about the synaptic sign and time course of these inputs. This report describes the short-latency synaptic effects on caudal FTG neurons (intracellular recordings from over 100 neurons, AP -7.5 to -3.5) of low current < 70uA) square wave stimulation (200uS duration) of ipsilateral BRF and MRF and contralateral FTG (cFTG). The head restrained, unanesthetized chronic cat preparation avoids artefacts resulting from the effects of anesthetic and paralytic agents on reticular neurons. Subsequent reports will discuss sleep-waking cycle alterations of membrane and stimulation effects.Our data support the following tentative generalizations: (1) Depolarizing (excitatory) effects predominate among short-latency, probably monosynaptic PSPs (latency < 1.2mS, following of 200 Hz stimuli). Over 90% of these PSPs were depolarizing, whether evoked from BRF, cFTG, or MRF. (2) These probably monosynaptic PSPs were elicited in a high proportion of the caudal FTG neuron population by stimulation of BRF (3/4 of neurons) and cFTG (3/5) but were less common with MRF stimulation (3/10). (3) FTG neurons projecting to a reticular area also may receive input from this same area, as indicated by the presence of monosynaptic depolarizing PSPs in the same neuron at times when the previously elicited antidromic response was absent due to collision or change of stimulation parameters. (4) Hyperpolarizing PSPs play a less prominent role than depolarizing ones. Hyperpolarizing PSPs were usually of longer latency (1.2-1.8 mS) than the monosynaptic time range,were of short duration (range: 2-5 mS) and were, in this unanesthetized preparation, usually followed by large, complex depolarizing PSPs. Chloride diffusion experiments suggest that the hyperpolarizing PSPs represent IPSPs. We conclude that reticulo-reticular connections are predominantly excitatory, and thus could provide the synaptic substrate for reticular self-excitation we have postulated to exist on the basis of extracellular recordings.

Supported by NSF Grant BNS 78-24498.

74.5 A NEW LOOK AT SPINAL PROJECTIONS FROM BULBAR AREAS OF THE RETICULAR FORMATION. EVIDENCE FOR CONNECTIONAL HETEROGENEITY IN THE NORTH AMERICAN OPOSSUM. G.F. Martin, T. Cabana*, A.O. Humbertson, L.C. Laxson* and W.M. Panneton. Dept. Anat., Sch. Med., The Ohio State Univ., Columbus, Ohio, 43210.

Retrograde and orthograde transport techniques show that the nucleus reticularis gigantocellularis pars ventralis and the nucleus reticularis gigantocellularis project the entire length of the spinal cord. Double labelling methods show that some neurons in each area innervate both cervical and lumbar levels. There is evidence, however, that neurons in the lateral part of the nucleus reticularis gigantocellularis pars ventralis and the dorsal extreme of the nucleus reticularis gigantocellularis project to only cervical and thoracic levels. The autoradiographic method shows that the above nuclei supply direct innervation to autonomic and somatic motor columns as well as to laminae V-VIII and X. The nucleus reticularis gigantocellularis pars ventralis provides additional projections to lamina I and the outer portion of lamina II. Several areas of the medullary reticular formation project mainly and in some cases, exclusively, to cervical and thoracic levels. These areas include the nucleus reticularis parvocellularis, the nucleus reticularis lateralis, the nucleus retrofacialis, the nucleus ambiguus, the nucleus lateralis reticularis, caudal parts of the nuclei reticularis medullae oblongata dorsalis and ventralis and the nucleus supraspinalis. Neurons in the lateral medulla, particularly rostrally (the nucleus reticularis lateralis and neurons related to the nucleus lateralis reticularis) innervate sympathetic nuclei. These data suggest that spinal projections from bulbar areas of the reticular formation are more complicated than previously supposed and are in conformity with the evolving concept of reticular heterogeneity. Supported by U.S.P.H.S. Grant NS-07410.

74.6 BRAINSTEM UNITS RELATED TO MOVEMENTS OF THE PINNA. J.M. Siegel, R.L. Wheeler*, S.M. Breedlove* and D. J. McGinty. VA Medical Center, Sepulveda, California and Departments of Psychiatry and Psychology, UCLA, Los Angeles, California 90024.

Sherrington first demonstrated that structures caudal to the inferior colliculus were sufficient to control a variety of complex protective reflex movements of the pinna. However, the specific regions in the lower brainstem that might be involved in the regulation of these movements have not been further localized. The present study reports the discovery of a group of neuronal units in the cat's medial pontomedullary reticular formation that discharge in relation to pinna movement.

A total of 19 cells whose discharge was correlated with "spontaneous" movements of the pinna were observed. All cells were related to movements of the ipsilateral pinna. Detailed observation of the topography of the pinna movement correlated with unit activity was made in 13 of the cells. Of these, four related to caudal, five to ventro-caudal and four to rostral movements of the pinna. Rapid pinna rotation in the appropriate direction was accompanied by a burst of unit discharge. Five cells exhibited tonic discharge if the pinna was maintained in the displaced position but the remaining units discharged only during the movement. Pinna movement cells did not discharge during eye, head, neck or limb movements.

All cells were tested for response to somatic stimulation. When such stimulation elicited pinna movement, discharge occurred as in the case of spontaneous movements. In the absence of detectable ear movements, 16 of the 19 tested cells had no somatic field. None of the cells responded to passive movement of the pinna by the experimenter or electrical stimulation of pinna musculature. None responded to auditory or visual stimulation.

All of the units were observed during polygraphically identified slow wave and REM sleep states. All but three of the cells (84%) were silent throughout sleep. This contrasts with the sleep modulation of activity in adjacent non-pinna movement cells only 25% of which are of this type.

We have conducted behavioral analyses on a total of 300 medial reticular formation cells located between stereotaxic coordinates A3 and P13, L0.8 and 3.0. Those related to pinna movement were all localized to the area between P2 and P8 and especially between P4 and P8 in the gigantocellular tegmental field. None of the pinna movement units were histologically localized to the facial nerve or nucleus.

74.7 AFFERENTS TO THE CENTRAL SUPERIOR RAPHE NUCLEUS IN THE CAT. R. Maciewicz*, S. Ronner, E. Taber-Pierce, and W. Foote. Depts. of Neurology, Neurosurgery, and Psychiatry, Mass. Gen. Hosp., Boston, MA 02114.

The afferents to the central superior raphe nucleus (CS) in the cat were studied using retrograde transport and electrophysiological methods. Following aspiration of the posterior cerebellar vermis, HRP was iontophoresed into CS through micropipettes advanced into the brain stem under direct visual control. After a two day survival period the animals were perfused with mixed aldehydes and frozen sections from the brains were reacted to demonstrate HRP with either diaminobenzidine or tetramethylbenzidine as substrate. Retrogradely labeled neurons were localized to the dorsal tegmental region of the pons (DT), the lateral habenula (both medial and lateral parts), and the interpeduncular nucleus (IP). Within the pons, labeled cells were restricted to the DT just caudal to CS. Cells were found scattered throughout this area and were not restricted to the dorsal tegmental nucleus. Labeled cells were only rarely encountered within the adjacent locus ceruleus. Within IP, labeled cells were primarily segregated to the lateral parts of the nucleus. In cases with lateralized injections of HRP into CS this projection appears predominantly ipsilateral. A few scattered cells were also found within the substantia nigra and hypothalamus, but in contrast to the known inputs to the dorsal raphe nucleus, no labeling was seen in the medulla or other raphe nuclei. To confirm these anatomical observations, single cell recordings were made from CS in anesthetized cats. Stimulating electrodes were placed in the habenula, IP, and DT of the pons. With IP stimulation both antidromic and orthodromic excitatory effects were seen in a population of CS neurons. Similarly, DT stimulation elicited excitatory responses with monosynaptic latency (1-2msec.) in some CS neurons. The demonstration of such short latency inputs from the interpeduncular nucleus and the dorsal tegmental area to CS is in agreement with the retrograde transport evidence for direct projections from these nuclei to CS.

75.1 Physiological and histochemical properties of motor units in reinnervated triceps surae muscles in the cat. T. Gordon, R.B. Stein & M.J. Gillespie. *Department of Physiology, University of Alberta, Edmonton, Alberta T6G 2H7.*

When a peripheral nerve supplying fast and slow motor units is cut and allowed to reinnervate, nerve fibres return to muscle fibres that formerly belonged to different motor nerves. As a result, the muscle fibres in early reinnervated motor units are heterogenerous in their properties, and our preliminary data showed that there was no relationship between twitch tension or contractile speed of these units with motor nerve size, as there was in that muscle before reinnervation (Gordon & Stein, 1980, in "Plasticity of Muscle", Pette, ed. Springer: Berlin, pp. 283). We have now shown with chronic recording of motor unit properties that reinnervated muscle once more obeys the size principle in terms of its motor unit properties after 3 to 5 months, i.e., twitch tension and contractile speed of reinnervated motor units become directly correlated with nerve size. The fatigue characteristics of the motor units were studied in acute experiments in which motor units were classified as slow (S), fast fatigue resistant (FR) or fast fatigueable (FF) according to the classification of Burke *et al.* (1974, J. Physiol. 234: 723). The order of mean twitch and tetanic tension remained: FF greater than FR greater than S, and the nerves that supply fast units were significantly larger than those innervating the slow, as in the normal. Also, the relative proportion of unit types in the mixed medial gastrocnemius muscle was not different from control muscles. Thus, the order of tension developed by the three unit types and their contractile speed provided further evidence for the return of the size relationships shown with chronic recording of reinnervated unit properties. The MG muscle showed no apparent preference for reinnervation by slow or fast nerves. However, soleus motor units reinnervated by LGS or MG nerves were homogeneous in their histochemical properties, showing negative staining for alkaline ATPase and positive for NADH, as in control muscles. Thus, there may be limits to the degree nerve fibres can modify muscle properties following reinnervation.

75.2 HOMOGENEITY OF ENZYME ACTIVITIES IN SINGLE DISSECTED FIBRES OF THE MOTOR UNIT. P. Nemeth*, Dirk Pette* and G. Vrbova*† (SPON: W.F.H.M. Mommaerts). Faculty of Biology, Univ. of Konstanz, Germany, †Univ. College London, England.

Biochemical analyses of single dissected muscle fibres have shown that fibre populations are heterogeneous in their content of metabolic enzymes, even among fibre groups whose histochemical characteristic are identical (Spamer and Pette, 1977, 1979); Lowry et al., 1978). It has been suggested that this heterogeneity is due to differences in the neural input to the muscle fibres. If so, it would be expected that metabolic characteristics of a motor unit be identical, as suggested by qualitative histochemistry (Edström and Kugelberg, 1968). In the present investigation, malate dehydrogenase and fructose 1,6-diphosphatase was measured in single dissected fibres of motor units. The enzyme activities were compared to those in randomly selected fibres of the same muscles. The methodology combined the microchemical techniques (Lowry and Passonneau, 1972) with the glycogen depletion means of detecting the fibres of a motor unit (Kugelberg and Edström, 1968), and is described in detail elsewhere (Nemeth, Pette and Vrbova, 1980). The malate dehydrogenase activity in single fibres of the general population of 6 extensor digitorum longus muscles of the rat ranged between 20 and 226 u/g fresh weight, showing up to tenfold differences in a single muscle. Enzyme levels of the six motor units ranged between 31 and 106 u/g fresh weight, but differed only slightly, 0.7 to 4.2%, between fibres of the same motor unit. This appears to be negligible compared to the large variations existing within the fibre population. The experimental error was judged as the SD in enzyme activity of multiple determinations on pieces of single fibres. This error ranged between 2.2 and 6.5%. Fructose 1,6-diphosphatase activities measured in fibres of one motor unit ranged between 0.75 and 0.80 u/g fresh weight, showing only a 2.2% deviation. The experimental error of multiple determinations on pieces of single fibres was 5.1%. Thus, the activities of both of these enzymes are identical in fibres belonging to the same motor unit, well within the range of experimental error. It is suggested by this study that the motor unit represents a metabolically pure population of fibres. The high resolution of microchemical techniques has revealed how precisely the nerve can control the metabolic enzyme properties of the various fibres that it supplies.

75.3 GENESIS OF THE NEURONS IN THE MOTOR CORTEX AND VA-VL THALAMIC COMPLEX IN RHESUS MONKEY. J.J. Dekker and P. Rakic, Sec. of Neuroanatomy, Yale Univ. School of Med., New Haven, Ct. 06510.

The sequence of genesis of neurons comprising the VA-VL complex of the thalamus and cortical areas 4 and 6 of Brodmann were determined in autoradiograms from juvenile monkeys that were exposed to a pulse of ^{3}H-thymidine on selected embryonic (E) days of the 165 day gestational period in this species. The time of origin of cells in the VA-VL thalamic complex was analysed in coronal sections cut through three levels of the rostral thalamus. Heavily labeled neurons, representing cells that had undergone final cell division at the time of ^{3}H-thymidine injection, were present only in cases exposed to the isotope over a five day period from E38 to E43. The peak of genesis was at E43 (labeling index-labeled neurons/total neurons, 44%). There was a lateral to medial spatiotemporal gradient of genesis such that the majority of neurons born at E38 eventually become situated in the lateral parts of VA and VL, whereas most of those born at E43 become situated more medially. This is consistent with an outside-to-inside pattern of neurogenesis. No pronounced caudal to rostral gradient was present and both nuclei are generated as a unitary structure.

The time of origin of the motor cortical areas that receive imput from the VA-VL thalamic complex was determined in coronal sections through the frontal cortex. Detailed analysis was performed in the upper and lower half of area 6 and in 5 different regions of area 4: the upper (trunk) and lower (face) half of the anterior part of area 4, and the upper (hindlimb), middle (forelimb) and lower (tongue) one third of the posterior part of area 4. Heavily labeled cells were present in animals injected over a forty day period from E40 and E80. As in other cortical areas of primate and nonprimate species, there was an inside-to-outside gradient such that cells generated at early stages are eventually situated in the deep layers and those generated at later stages in more superficial layers. Most neurons in lamina 6 were born between E40 and E60, those of lamina 5 (including Betz cells) and 4 between E45 and E70, those of lamina 3 between E62 and E80, and lamina 2 neurons around E80.

Thus, the neurons of the cortical motor areas in monkeys are generated slightly earlier than the more posterior cortical areas such as the visual cortex but later than its major ascending input neurons in the VA-VL thalamic complex. Contrary to expectation, the timing and pattern of neuronal genesis in regions of both areas 4 and 6 are remarkably similar regardless of whether they issue projections to the brainstem, the cervical or the lumbar spinal cord. Likewise, both deep and superficial cells in lamina 5 are born at about the same time, despite the fact that their targets in the brain stem and spinal cord are generated at different times. Supported by NS 14841.

75.4 ORIGIN OF HIGH-FREQUENCY TREMOR IN EARLY-POSTNATALLY X-IRRADIATED RATS. J. Gruner* and R. Llinás (SPON: K. Walton). Dept. Physiol. & Biophys., New York Univ. Med. Ctr., New York, NY 10016

Early postnatal cerebellar x-irradiation of rats, which destroys 90-95% of the granule cells and most stellate and basket cells (Altman and Anderson, J. Comp. Neurol. 149: 123, 1973) also produces ataxia and head and limb tremor. Investigation of the tremor showed it be in synchrony with high-frequency (18 Hz) EMG bursting. Hindlimb tremor was not blocked by deafferentation as determined by recording EMGs before and after section of dorsal roots L2-T13 bilaterally. Descending influences are necessary for sustained hindlimb tremor. Indeed, tremor was blocked bilaterally by transection of the spinal cord and unilaterally by hemisection at the T10 level. The characteristics of the descending signals and their distribution in the cord have yet to be determined. EMGs of irradiated rats during tremor were similar in many respects to those seen during harmaline-induced tremor (de Montigny & Lamarre, Brain Res. 53: 81, 1973; Llinás and Volkind, Exp. Brain Res. 18: 69, 1973). For instance, ipsilateral extensors were usually in phase and tended to be out of phase with flexors. Also, bursting in extensor muscles such as vastus lateralis and gastrocnemius was more pronounced than in the flexors tibialis anterior or iliacus. The semitendinosus (knee flexor, hip extensor) showed strong tremor. However, some differences between post-irradiation and harmaline tremor were evident. Thus, harmaline tremor frequency was 8-12 Hz, and when harmaline was injected into irradiated rats, the tremor frequency dropped from about 18 to 10 Hz. Chemical lesion of the inferior olive by 3AP (Llinas et al, Science 190: 1230, 1975) blocked irradiation tremor. These experiments indicate that the inferior olive is necessary for generating cerebellar-irradiation tremor. Since the cerebellum is likely to be a locus for the generation of post-irradiation tremor, chronic extracellular unit recordings were undertaken in irradiated rats. In a number of animals rhythmic synchronization of Purkinje cell unit activity was observed in the anterior lobe vermis. The synchronization was very near the frequency of ipsilateral EMG bursting, though the phase relations did not remain constant for long periods. It appears that reorganization of cerebellar circuits following the irradiation treatment leads to synchronized oscillatory activity of cerebellar, brainstem, and spinal circuits, possibly involving the olivocerebellar inputs to cerebellar cortical and nuclear structures. (Supported by USPHS grants NS05880 and NS13742 from NINCDS).

75.5 INFANT LESION EFFECT: RESULT OF NEONATAL AND ADULT HEMISECTION IN CATS. B. S. Bregman and M. E. Goldberger. Dept. of Anatomy, The Med. Coll. of Penn., Phila., PA 19129.

Adult Operates (A.O.) and Neonatal Operates (N.O.) show remarkable recovery/development of motor function following spinal hemisection (L1, dorsal columns spared). Postural reflexes (tactile placing, proprioceptive placing, monopedal hopping) and conditioned locomotion on "difficult" runways were examined in adult cats: neonatally operated (day of birth), adult operated, and unoperated. Hindlimb tactile placing is abolished ipsilaterally in A.O.'s but not in N.O.'s, and represents a sparing of function. Other postural reflexes in this limb reveal enhanced function; proprioceptive placing and hopping (all directions) recover in both groups, but have a lower threshold in N.O.'s. Quantitative study of lateral hopping shows that normals have no significant (t-test, p=0.01) interlimb difference in hops/meter. N.O.'s show a deficit ipsilaterally but are superior to A.O.'s. Contralaterally, A.O.'s show no deficit, while N.O.'s show significant impairment. Thus, in N.O.'s some motor behavior ipsilateral to hemisection is superior but contralateral deficits are more pronounced. After recovery (A.O.'s) or maturity (N.O.'s) the cats were trained/tested for accurate limb placement during locomotion on difficult (parallel bars, grids, 2" wide) runways with a 12" wide runway as control. Time to cross difficult runways is increased in both groups because they make more errors than controls (i.e. misplacements). Cinematographic analysis shows that on the parallel 1" bars and grid N.O.'s attempt bar placement at each step, whereas the A.O.'s frequently cross with minimal use of the ipsilateral hindlimb, thereby reducing the number of potential errors but increasing speed. The step cycle in the ipsilateral hindlimb in N.O.'s is altered compared with control and A.O.'s. There is a 2:1 increase in stance:swing ratio, increasing total step cycle duration. Maximum angle at ankle joint prior to initiation of swing is normal in N.O.'s but is increased in A.O.'s. Thus, the enhanced postural reflexes in N.O.'s may be useful in locomotion.

These results suggest that there is no monolithic response to neonatal CNS damage. Following neonatal lesion, some aspects of motor function are enhanced (sparing of tactile placing, enhanced recovery of proprioceptive placing and hopping). However, the N.O.'s also show more bilateral deficits. In locomotion, differences in performance are apparent, but there is no simple relationship indicating a uniform advantage for either group.

75.6 NEURAL DEVELOPMENT IN CHILDREN. P. Bawa, Dept. of Kinesiology, Simon Fraser Univ., Burnaby, B.C. Canada.

There is no neurophysiological literature available on the post-natal development of the human nervous system. The following experiments were done to investigate the development of the reflex pathways and reaction times in children between the ages of 3 and 13 years.

Torque motor-imposed angular displacements of the adult human wrist result in reflex EMG responses recorded from the muscles stretched. The response can be separated into two components, (1) the short latency reflex (SLR, 25-50msec) and (2) longer-latency reflex (LLR, 50-90 msec). The SLR has been suggested to result from a spinal reflex pathway and LLR at least partially from supraspinal pathway.

Ten boys and eighteen girls were tested for these reflex components. The subject held the handle attached to the shaft of the torque motor at a specified position shown on the oscilloscope. Surface EMG was recorded with a pair of silver disc electrodes from wrist flexors. Square torque pulses applied to the torque motor extended the wrist and stretched the wrist flexor muscles. Those children who could follow instructions were asked to compensate for the imposed displacement by bringing the handle back. In children below 6 years, SLR component lasted up to 40msec whereas LLR component lasted from 50msec to 200msec. The duration of LLR was 100-150msec in these children as compared to about 40msec in adults. Children above 8 years of age had adult-like LLR. However, reaction times were longer in children below 10 years. Shortening of reaction times took place after the reflex components had developed.

The long duration of LLR in young children could be attributed to larger range in conduction velocities of the undeveloped axons involved in the reflex pathway and/or to longer processing times at various synapses.

This work was supported by BCHCRF. The author is thankful to Dr. R.B. Stein for his torque motor and Dr. R.G. Lee for the use of his computer.

75.7 ELECTROMYOGRAPHIC STUDIES ON THE MUSCLE RELAXANT EFFECTS OF PHENYTOIN IN THE DECEREBRATE CAT. A. Raines and S.K.Swope*. Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, D.C. 20007

Previous studies in our laboratory indicate that phenytoin (PH) in doses usually employed for anticonvulsant effects, depresses muscle spindle function (Anderson and Raines, J. Pharmacol. 1974) and diminishes clinical behavioral muscle extensor hypertonus and gamma motoneuron discharges in the decerebrate cat (Hershkowitz et al., Neuroscience Abs. 1978).

The present studies were designed to evaluate PH influences on the electromyogram (EMG) of the triceps brachii of the cat. Adult cats of either sex were anesthetized with halothane and decerebrated by a mid-collicular transection. Decerebrate rigidity ensued briefly after discontinuation of halothane.

Stainless steel implantable electrodes were sutured to the exposed muscle and the forelimb was briskly displaced 90° and 180° from the full extension position, thus stretching the triceps brachii muscle. The stretch was held for 10 sec and the EMG frequency determined by means of a mini-computer at 0-1 sec as an index of phasic stretch reflex and at 7-8 sec as an index of tonic stretch reflex.

PH in doses of 10 and 20 mg/kg (i.v.; 1 mg/kg/min) depressed spontaneous background EMG in 7 of 7 cats by 71 and 96% (means) respectively. The phasic response at 90° was reduced by 28 and 58%, and at 180° by 23 and 47% by these two PH doses. The tonic response was reduced by 59 and 81% at 90° and by 54 and 94% at 180°. Afterdischarge was suppressed by 71 and 96% by 10 and 20 mg/kg PH.

These data suggest that whereas the spontaneous background EMG activity, the tonic stretch evoked activity and the afterdischarge are exceedingly sensitive to depression by PH, phasically induced muscle responses are relatively resistant.

These data lend further support to the hypothesis that PH possesses muscle relaxant properties in an animal model exhibiting muscle hypertonus secondary to an upper motor neuron lesion and provides further evidence for putative utility in spastic man (Cohan et al., Arch. Neurol. 1980).

76.1 DIFFERENTIAL DISTRIBUTION OF HOST RETINAL AND CORTICAL AFFERENTS WITHIN TECTAL TRANSPLANTS IN RATS. A. R. Harvey* and R. D. Lund. (SPON: J. S. Lund). Dept. of Anatomy, Medical University of S. C., Charleston, S.C. 29403.

We have previously shown that both host retina and cortex project to tectal transplants. We wished to determine how these separate afferents distribute and interrelate within the transplants. Tecta were dissected from fetal rats (14 to 16 days gestation) and injected over the left superior colliculus of newborn rats. After at least one month survival, experiments were undertaken to define the host input to the transplants. In some animals, the left visual cortex was removed and the right eye injected with tritiated proline. In others, one eye was injected with tritiated proline and the other eye was removed. Brains were processed for neurofibrillar, Fink-Heimer and Nissl stains as well as for autoradiography. Most of the transplants connected to the left superior colliculus, although a number connected to the right or to both colliculi.

Retinal afferents project to discrete areas within the transplants. These regions are commonly located close to the surface of the transplants and are characterized by their lack of heavy fiber staining and by the presence within them of many small, relatively close-packed cells. In some cases, particularly when the transplants connect with both superior colliculi, there is a projection to the fiber-free areas from both eyes. In this circumstance, the afferents from each eye often project adjacent to one another, but there is little overlap between them. After a cortical lesion, fine degeneration is distributed throughout most of the fibrous regions of the transplant, but is sparse or absent in areas which receive retinal input.

Thus, despite the abnormal location of the tissue and the unusual paths taken by the host afferents, the differential distribution of the inputs found in the normal, intact superior colliculus is preserved within the tectal transplants. We are currently using electro-physiological techniques to examine whether this separation of afferents can also be recognized functionally at the single cell level.

76.2 THE UNCROSSED RETINOTECTAL PATHWAYS IN GOLDEN HAMSTERS-AN ORTHOGRADE HRP STUDY. L. S. Jen*, H. H. Woo*, and K.-F. So*. (SPON: P. W. F. Poon) Department of Anatomy, University of Hong Kong, Hong Kong.

Previous studies using degeneration and autoradiographic techniques have shown that the uncrossed retinotectal pathway in normal hamsters is restricted primarily in the anterior third of the stratum opticum of the superior colliculus. If one eye is removed on the day of birth, the uncrossed retinotectal projections from the other eye will expand and occupy all superficial laminae in the rostral half of the colliculus. The implication of these results is that the uncrossed retinotectal projection from an eye can enlarge its terminal field to cover a larger area after early removal of the opposite eye. This phenomenon is further investigated in the present study with a more sensitive pathway tracing technique, namely the orthograde HRP method.

Three milligrams of horseradish peroxidase (Sigma type VI) dissolved in 5 µl of saline were injected into one eye of normal adult hamsters and hamsters with one eye enucleated at birth. After perfusion, the brains were stored in sucrose-buffer for several hours. Frozen sections cut coronally and sagittally were collected and processed for HRP reaction with TMB as the chromogen, and the uncrossed retinotectal projections were examined.

The results indicate that in normal hamsters the uncrossed retinotectal axons and their terminals are distributed in both stratum opticum and stratum griseum superficiale in most areas of the superior colliculus. The distribution area of the uncrossed retinotectal pathway in unilaterally enucleated animals is basically similar except the density of the uncrossed projection is considerably higher than that observed in normal animals. These results contrast with previous observations that the uncrossed retinotectal projection is normally limited in the rostral colliculus, but expands to occupy a wider area in response to eye enucleation in neonatal stage. Since it is shown in preliminary studies that the uncrossed retinotectal pathway in developing hamsters covers most areas of the superior colliculus as in the normal adults. This leads us to suggest that enucleation of the contralateral eye at birth results in enlargement of terminal field of the uncrossed retinotectal projection from the remaining eye by increasing its density without an extensive increase in distribution area.

(Supported by a research grant from the University of Hong Kong and a research grant from the Wing Lung Bank Medical Research Fund).

76.3 DIFFERENT GRADIENTS OF NEUROGENESIS IN RHESUS MONKEY SUPERIOR (SC) AND INFERIOR (IC) COLLICULUS. M.L. Cooper and P.Rakic. Sec. of Neuroanatomy, Yale Univ. School of Med., New Haven, Ct. 06510

We analyzed the spatiotemporal patterns of neurogenesis in the SC and IC by plotting the positions of heavily labeled neurons in autoradiograms from a series of monkeys that had been exposed to ^{3}H-thymidine at various embryonic (E) days and sacrificed either shortly thereafter or at 2-3 months postnatally. All tectal neurons are generated in the ventricular and subventricular zones around the Sylvian aqueduct within the first third of the 165 day gestation period. Cells in the SC undergo final mitosis from E30 to E56, with peak proliferation from E38 to E43. Neurogenesis in the central nucleus (CN) of the IC also occurs between E30 and E56, and peaks around E43. A weak rostrocaudal gradient within the tectum as a whole is indicated by the later onset of robust proliferation in the IC than in the SC.

There is a weak ventral-dorsal gradient of genesis in the SC, in that all laminae except the stratum griseum superficiale are labeled before E36, whereas labeled cells tend to lie more dorsally late in neurogenesis. However, most cells in all laminae are generated in the same period. No mediolateral or rostrocaudal gradients were evident, although proliferation appeared to subside earlier rostrally. In general, SC gradients are rather weak, particularly in comparison to those evident in frog, chick and rat. There are distinct rostrocaudal, lateromedial and ventrodorsal gradients of genesis in the CN which appear in general to be more pronounced than those in the SC. We compared quantitatively the strengths of these various gradients, both within and between the SC and CN by dividing each nucleus into thirds along each axis (anterior-posterior, lateral-medial, ventral-dorsal) and determining the density of labeled cells within each third. For a weak gradient, cells generated at the same time should be more diffusely spread throughout the nucleus than for a strong gradient. Thus, using diffuseness of labeling as a criterion for gradient strength, we compared (with a Wilcoxon test) the spread of labeled cells along pairs of axes for each injection day. This analysis revealed that neurogenesis along all three axes of the SC proceeds with about equal strength, whereas in the CN the lateral-medial gradient is statistically significantly stronger than the anterior-posterior gradient. Further, the lateral-medial and ventral-dorsal IC gradients are significantly stronger than all three SC gradients. Thus, our analysis of gradient strengths reveals significant differences in proliferative patterns between the SC and IC, suggesting that there is a mosaicism in the generative zone of the midbrain tectum, with nearby regions which give rise to the SC and IC having their own distinct developmental programs controlling the spatial patterns of neuronal proliferation.(Supported by EY-02593)

76.4 EXPANSION OF THE IPSILATERAL VISUAL CORTICOTECTAL PROJECTION IN HAMSTERS SUBJECTED TO PARTIAL POSTERIOR NEOCORTICAL ABLATIONS IN INFANCY. R. W. Rhoades. College of Medicine and Dentistry of New Jersey, N.J.S.O.M., Piscataway, NJ 08854.

Partial retinal lesions, in goldfish, anurans and neonatal rodents can result in expansion of the projection of the remaining retina in the damaged eye so that it encompasses the entire optic tectum or superior colliculus. Like the retina, the visual cortex also projects topographically to the superior colliculus and the present experiments have used autoradiographic and electrophysiological methods to demonstrate that partial cortical damage in neonatal hamsters results in an expansion of the projection of the remaining visual cortex in the damaged hemisphere to the ipsilateral superior colliculus.

A strip of posterior cortex extending from the midline to the rhinal fissure was removed under methoxyfluorane anesthesia on the 7th-10th postnatal day. Three to 10 months later the visual representation in the damaged hemisphere was delineated using standard single unit recording and receptive field mapping techniques. In animals in which visual responses could be recorded from the cortical remnant and an unequivocal visual scotoma was also noted, an electrophoretic deposit of [^{3}H]-leucine and [^{3}H]-proline was made into the approximate center of the visually responsive cortex and the resulting label in the ipsilateral superior colliculus was charted. Identical experiments were carried out in normal hamsters.

In the normals superficial layer collicular label was topographically matched with the site of the cortical amino acid deposit. In the brain damaged hamsters such labelling was seen in all portions of the colliculus. Experiments in which electrical stimulation of the visually responsive portion of the cortical remnant was combined with single unit recording in the ipsilateral colliculus showed that the topography of the collicular visual field representation in the neonatally brain damaged animals was normal and that the expanded corticotectal projection made functional synapses throughout the tectum on this side.

An additional series of electrophysiological and anatomical experiments demonstrated further that the aberrant, crossed corticocollicular pathway which has been previously shown to result from lesions similar to those carried out in this study (Mustari, M.J. and Lund, R.D., Brain Res., 112:37, 1976; Rhoades, R.W. and Chalupa, L.M., J. Neurophysiol., 41:1466, 1978) was intermingled with the expanded ipsilateral cortical projection and that some tectal cells in these animals could be activated by stimulation of either cortex.

Supported by RR-09085 and NS16001 from N.I.H., MH32897-01 from N.I.M.H. and grants from N.J.O.E.F. and the C.M.D.N.J. Foundation.

76.5 FIBER-TO-FIBER INTERACTIONS IN DUALLY INNERVATED TECTUM IN XENOPUS WITH RIGHT DOUBLE NASAL AND LEFT DOUBLE TEMPORAL EYES Charles Straznicky, Department of Human Morph., Sch. Med., Flinders Uni. of South Australia, Bedford Park S.A. 5042, Australia.

Compound eye projections, eyes made by the embryonic fusion of two nasal (NN), two temporal (TT) and two ventral (VV) retinal halves are abnormal in adult Xenopus in that each hemiretina projects across the whole extent of the contralateral tectum (Gaze et al., 1963, J. Physiol. 165, 484-499; Straznicky et al., 1974, JEEM 31, 123-137). Yet, during development the optic fiber outgrowth from such eyes to the tectum is selective, involving the innervation of the corresponding tectal half only (Straznicky et al., 1979 Neurosci. Abstr. 5, 181).

In order to determine whether the expansion of the compound eye projection can be prevented we introduced a second set of optic fibers to the tectum soon after metamorphosis. Compound nasal (NN) eyes on the right and compound temporal (TT) eyes on the left side of Xenopus embryos were formed and tha animals reared to metamorphosis and beyond. Two weeks after metamorphosis the right or in other animals the left optic nerve was sectioned (ONC) in order to induce bilateral tectal innervation from one eye. Three to five months after ONC ^{3}H-proline was administered either into the right NN or left TT eye. Visual projections from the eye with intact optic nerve to the contralateral and from the eye with regenerated optic nerve to both contralateral and ipsilateral (monocularly and dually innervated) tecta were mapped electrophysiologically.

The restored contralateral compound eye projections, as shown autoradiographically and electrophysiologically, confirmed previous findings in that it covered the whole extent of the tectum. In contrast, in the dually innervated tecta the rostral part was innervated exclusively by the appropriate temporal retinal halves from TT and the caudal part by the appropriate nasal retinal fibers from NN eyes. Partially superimposed projections from NN and TT eyes were found in the middle of the tectum.

These observations suggest that during regeneration nasal and temporal fibers preferentially select the corresponding tectal termination. The presence of nasal and temporal retinal fibers in the dually innervated tecta prevents the spreading of the hemiretinal projections across the whole extent of the tectum. The segregation of the hemiretinal projections indicate fiber-to-fiber interactions between the two sets of optic fibers from NN and TT eyes.

76.6 RETINAL SPECIALIZATION AND GROWTH IN THE CICHLID FISH, HAPLOCHROMIS BURTONI. Russell D. Fernald and Pamela R. Johns*. Dept. of Biol., Univ. of Oregon, Eugene, OR 97403. *Neurobiology, Harvard Medical School, Boston, MA 02115.

Behavioral experiments suggest that the African cichlid fish, Haplochromis burtoni, preferentially use a restricted retinal region while viewing behaviorally interesting stimuli. This fish has a highly evolved social system with behavioral interactions mediated by bright chromatic and spatial patterns on the fishes' bodies. We have determined the density of the different retinal cell types across the retina. The ventrotemporal retinal region has a significantly higher concentration of all cell types except rods. In young fish (8-11 weeks) three times as many ganglion cells and twice as many cone nuclei are found in that region compared with the nasal retina. This density differential is maintained in older animals although it is not as great. In order to compare differently sized animals, we use a cartographer's projection of the nearly hemispherical retinal surface onto a plane. In this way the retinal representations can be scaled and direct comparisons made.

The retina continues to enlarge throughout the life of the animal. To study this, we compare the two eyes from the same fish, one removed when the animal is small and the other after a period of growth. Labelled ^{3}H-thymidine is injected and one eye excised after incorporation. The fish is then placed in a social situation known to enhance growth rate. When the desired size is attained, the second eye is removed and compared with the first using radioautography. The thymidine-labelled cells mark the boundary between retinal tissue present in the small eye and that added later with growth. In this way we can distinguish the change in retinal dimensions due to accretion of cells from that due to expansion of existing tissue.

(Supported by USPH grant EY-02284.)

76.7 THE DEVELOPMENT AND MODULATION OF AVIAN MUSCARINIC RECEPTORS. Suzanne B. Por* and Stephen C. Bondy* (SPON: Clifford L. Mitchell). Laboratory of Behavioral and Neurological Toxicology, National Institute of Environmental Health Sciences, P.O. Box 12233, Research Triangle Park, North Carolina 27709.

The maturation of the cholinergic muscarinic receptors has been studied in the optic lobe of the chick using ^{3}H-quinuclidinyl benzilate (QNB) as a receptor ligand. The developmental profile showed these receptors to be present in the chick embryo as early as 8 days incubation. Rapid accretion of receptor binding occurred between days 12-14 of incubation, a period of maximal synaptogenesis within the optic lobe. A subsequent phase of increased binding occurred around hatch.

Removal of the optic vesicle of 3 day old embryos, prior to major development of tectal receptors caused only a 14% reduction of QNB binding in the non-innervated optic lobes at 19 days incubation. Thus, the appearance of most of the tectal muscarinic receptors is independant of innervation by the retinal ganglion cells.

Unilateral enucleation of 2 day old chicks arrested normal increases of weight, protein, and cholinergic receptors in the denervated optic lobe contralateral to the excised eye. The overall amount of binding expressed on a protein basis was not significantly changed in 22 day old birds. However, Scatchard analysis revealed that denervated optic lobes possessed significantly more receptors (B_{max} = 0.80±0.03 pmoles/mg protein) than corresponding control lobes (B_{max} = 0.58±0.02 pmoles/mg protein); whereas the binding affinity of these receptors was reduced. The K_D of deafferented lobes was (0.79±0.06) x 10^{-9}M and control value was (0.63±0.03) x 10^{-9}M. These data imply that compensatory changes in density may accompany altered dissociation constants of receptors.

77.1 IN VITRO SYNTHESIS AND MEMBRANE INTEGRATION OF THE SUBUNITS OF TORPEDO ACETYLCHOLINE RECEPTOR. D.J. Anderson*and G. Blobel* (SPON: N. Kalderon). Rockefeller Univ., New York, N.Y. 10021

We have synthesized the four subunits of T. californica Acetylcholine Receptor (AChR) in vitro, in order to define the primary translation products of AChR mRNA(s) and tostudy the membrane insertion of this oligomeric integral membrane protein. Our results indicate that the subunits of AChR are synthesized as independent polypeptides which are co-translationally inserted into rough endoplasmic reticulum membranes, by a mechanism analagous to that first described for viral transmembrane glycoproteins.

A wheat germ cell-free protein synthesizing system was programmed with total cellular RNA extracted from electroplax tissue by conventional procedures (SDS/Phenol/Chloroform.) [^{35}S]methionine -labelled AChR polypeptides were purified from the total translation products by immunoprecipitation after SDS denaturation. We used subunit-specific antibodies prepared in rats immunized with AChR polypeptides isolated from Torpedo by affinity chromatography and preparative gel electrophoresis. The sera were characterized by immunoprecipitation of [^{125}I]-labelled purified AChR from the mature tissue (authentic AChR.) Glycosylation and membrane insertion of the in vitro synthesized subunits were studied by performing translations in a system supplemented with dog pancreas rough microsomal membranes. Translation products were analyzed by SDS polyacrylamide gel electrophoresis.

When translated in the absence of membranes, Torpedo mRNA codes for four separate AChR polypeptides, of which α, $\gamma$and δ are slightly smaller (by 1,000-3,000 Daltons) than their authentic counterparts. The lower molecular weight of these products is due to their lack of carbohydrate residues. (Glycosylation of these proteins is not expected without membranes which catalyze the linkage of oligosaccharide moieties.) Furthermore, each subunit is translated optimally at a different Mg^{++} concentration. Since eukaryotic mRNA's have a single 5' terminal initiation site, and since initiation is Mg^{++}-dependent, this result suggests that the four AChR subunits may be encoded in separate mRNA molecules.

If membranes are present during the translation, the α, γ and δ subunits synthesized therein are of slightly greater mass, exhibiting an M_r close to that of their corresponding mature chain. This is presumably due to the attachment of Asn-linked core oligosaccharides. These glycosylated forms of the AChR subunits are only partially degraded by Trypsin digestion under conditions which totally digest the non-glycosylated precursors. The β chain is also incompletely cleaved by this proteolytic digestion at the cytoplasmic surface of the membrane. These data indicate that all four AChR subunits synthesized in vitro have undergone membrane insertion and, in this system, span the lipid bilayer.

77.2 MONOCLONAL ANTIBODIES AGAINST AChR AND COMPLEMENT-DEPENDENT LYSIS OF AChR-CONTAINING VESICLES. B. A. Pollok*, D. S. Dwyer, R. J. Bradley, G. E. Kemp* and J. F. Kearney*. Dept. of Microbiology & Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

Monoclonal antibodies (MAbs) against the acetylcholine receptor (AChR) were produced by injecting BALB/c and C57BL mice with purified receptor from Narcine brasiliensis. Spleen cells were removed from immunized animals and fused with the non-producing myeloma X63-Ag8.653. The resulting hybridomas were tested for anti-AChR activity by both ELISA and immunoprecipitation assays. Thus far, only two clones have been produced which cross-react with AChR from rat muscle. These were both subclass IgG1 antibodies. Isoelectric focusing of the MAbs allowed determination of the heterogeneity of antibodies produced by separate clones and indicated that different heavy chains (e.g. μ and γ3) may share the same light chain. The MAbs and heat-inactivated sera from patients with myasthenia gravis were then tested for their ability to induce complement dependent lysis of membrane vesicles containing AChR. Homogenized electric organs from electric fish (N. brasiliensis) spontaneously formed vesicles which were then radiolabelled with ^{3}H-glucose. All monospecific clones were capable of causing 35-70% lysis of the vesicles, indicating that single antigenic determinants on the receptors are close enough in the membrane to allow for IgG-induced complement fixation to occur. Mixtures of certain MAbs created a synergistic effect for complement dependent lysis by allowing crosslinking of antigenic determinants and enhanced proximity of IgG molecules. A wide variance in the ability of myasthenic sera to cause lysis of the AChR-containing vesicles was observed, with 0-70% of the maximum releasable label liberated. Heat-treated myasthenic serum alone was incapable of initiating lysis. In addition, an excess of solubilized AChR inhibited the lytic action of MG sera. It appears that anti-AChR antibodies in myasthenic sera or in the form of MAbs can potentiate complement mediated membrane damage in vitro.

77.3 SELECTIVE SUPPRESSION OF CHOLINOCEPTIVE FUNCTION IN RAT BRAIN BY INTACT IgG AND F(ab')$_2$ PREPARATIONS OF MONOCLONAL ANTIBODY AGAINST THY-1 GLYCOPROTEIN, M. L. Cameron*, J. Roberts*, N. Schupf and C. A. Williams. Div. Nat. Sci. SUNY-Purchase and Dept. Psychol. Manhattanville College, Purchase, N.Y. 10577.

In rat and mouse the Thy-1 glycoprotein (Theta antigen) reaches adult levels on neuronal cell surfaces at about 3 weeks or age (A.N. Barclay, 1979). Experiments in other tissues suggest that Thy-1 participates in developmental events. Dulbecco et al. (1979) have reported that some but not all monoclonal antibodies against the Thy-1.1 determinant (MC antiThy-1.1) block dome formation in cultures of a rat mammary carcinoma cell line. We have reported that injection via implanted cannulae of a MC antiThy-1.1 into rat perifornical hypothalamus selectively suppresses carbachol (CC, 0.8 µg) induced drinking but is without effect on norepinephrine (NE, 6 µg) induced eating. (Williams et al. Nature 283, 82, 1980).

The objectives of the present study were to determine whether complement mediated cytotoxicity could be responsible for the "anticholinergic" effect and whether different MC antiThy-1.1 antibodies may differ quantitatively in their biological activity.

Three intact MC antiThy-1.1 immunoglobulins (IgG): T32B11 (subclass 2A), T31G10 (subclass 2B) and MRC OX-7 (subclass 1), supplied by A.F. Williams, were compared. The non-complement fixing divalent peptic fragment F(ab')$_2$ of MRC OX-7 was also tested. All preparations significantly suppressed carbachol induced drinking in an approximately linear relationship to the log dose in picomoles (pmol). T31G10 was the most active with 50% suppression at a dose (ED_{50}) of 0.5 pmol. The ED_{50} for T32B11 was 3 pmol, for MRC OX-7 was 7 pmol and for MRC OX-7 F(ab')$_2$ was 15 pmol. MRC OX-7 IgG at the highest dose employed (15 pmol) had no effect on NE induced eating. The dose response curves of intact IgG preparations and the F(ab')$_2$ fragment had similar slopes suggesting that Fc dependent supplementary processes, including C-mediated cytotoxicity, do not contribute significantly to the biological effect. Subclass differences among the MC antiThy-1.1 IgG antibodies may contribute to the observed differences in relative activity through restrictions related to affinity, avidity or microspecificity. Monoclonal antibody against cell membrane antigens with nonrepeating determinants do not crosslink sufficiently to cause aggregation (capping) which could result in nonspecific disruption of membrane function. We tentatively conclude, therefore, that antibody binding to the Thy-1 glycoprotein at the 1.1 allotypic determinant directly impairs some aspect of postsynaptic cholinergic transmission.

77.4 EXPERIMENTAL MODIFICATION OF THE MICRO-ENVIRONMENT OF THE RECEPTOR FOR ACETYLCHOLINE. Y. Lass, G.Goldberg*, E.M. Landau, Dept. of Physiol. & Pharmacol. Sackler School of Medicine, Tel Aviv University, Ramat Aviv, Israel.

The ACh receptor is an integral membrane protein, deeply embedded in the lipid matrix of the membrane. As such it will be affected by changes in both its lipid and its aqueous micro-environment. The binding of ACh is assumed to produce a conformational change in the receptor which in turn will cause an ionic channel to open. The study of the small current fluctuations observed during the application of ACh ("ACh noise"), allows one to determine both the open-time (τ) and the average conductance (γ) of the single receptor channel. Changes in the receptor micro-environment may thus affect both γ and τ. Indeed a study of the effects of temperature on the single channel conductance in chick muscle cells in culture ("myoballs"), revealed a discontinuous relationship between γ and temperature. Thus, γ was unaffected as the bathing temperature was decreased in the range of 37°C to 20°C. Below 20°C, γ decreased sharply as the temperature was lowered. It was suggested that at this transition temperature the membrane lipid underwent a phase transition, i.e. the lipids "froze" at low temperature. The increased stiffness of the membrane around the receptor would restrict the conformational change and thus decrease the single channel conductance. It is also known that the composition of the aqueous micro-environment also profoundly affects the receptor. Of particular importance are the divalent cations and the H^+ions. Increasing the concentration of the former causes a block in the ACh receptor channel. Similarly reducing the pH causes a marked decrease in the single channel conductance. We have recently discovered that in the chick myoball, an increase in pH causes a large increase in the single channel permeability. The channel permeability is thus amenable to improvement by experimental means. If this effect is mediated by hydroxylation of a specific site, it may be possible to devise pharmacological tools to achieve the same effect. To describe the properties of such a site may thus be the first step in finding a new pharmacological approach to the improvement of the function of the neuromuscular receptor for Acetylcholine.

77.5 PURIFICATION OF A PUTATIVE CNS ACETYLCHOLINE RECEPTOR FROM RAT BRAIN. G.E. Kemp*, R.L. Furner*, and B.J. Morley. Neurosciences Program, University of Alabama Medical School, Birmingham, ALA. 35294 and Neurochemistry Laboratory, The Boys Town Institute for Communication Disorders in Children, Omaha, NE 68131

α-bungarotoxin (Butx) is a well-established marker for nicotinic acetylcholine receptors (nAChRs) found at the skeletal muscle neuromuscular junction. Butx is also known to bind to a protein from the mammalian CNS with biochemical and pharmacological properties closely resemble peripheral nAChRs, and it has been proposed that this protein is an nAChR. Using a modification of a protocol used for purification of mammalian muscle nAChR), it has been possible to purify this putative CNS nAChR from rat brain. Purification steps include subcellular fractionation, Trition-X-100 solubilization, α-cobratoxin biospecific adsorption, DEAE-Sephadex ion exchange chromatography, Con A-Sepharose 4B adsorption, and Sepharose 6B gel filtration. The product binds approximately 3 pM of ^{125}I-Butx per μg protein. Sodium dodecylsulfate polyacrylamide gel electrophoresis revealed 4 polypeptide chains of 44,000, 50,000, 56,000 and 62,000 daltons. The purified product does not detectably cross-react with antibodies directed against purified Torpedo or Electrophorus nAChR or with IgG obtained from patients with Myasthenia Gravis that cross-react strongly with rat muscle nAChR.

The affinity ligand 4-(N-maleimide) α-benzltrimethylammonium (MBTA) is known to block 1 or 2 Butx sites on Torpedo and Electrophorus nAChR, a finding we have extended to nAChR purified from Narcine brasiliensis and denervated rat skeletal muscle. In contrast, MBTA blocks 100% of Butx binding sites to the CNS protein. If Butx labels only 1 of 2 nAChR ligand sites (the MBTA sensitive site) a second site might be left available for agonist-mediated conductance responses. This explanation is consistent with reports that Butx labels nicotinic sites in several CNS and CNS-derived tissues, but does not block nicotinic conductance responses in these tissues.

77.6 DIFFERENCES BETWEEN JUNCTIONAL RECEPTOR AND EXTRAJUNCTIONAL RECEPTOR MAY BE DUE TO CARBOHYDRATE RESIDUES. D. S. Dwyer, R. J. Bradley and G. E. Kemp*. Neurosciences Program, University of Alabama in Birmingham, Birmingham, AL 35294.

It is now well established that junctional receptor (JR) and extrajunctional receptor (EJR) differ in immunological properties as judged by their interaction with antibodies from patients with myasthenia gravis. EJR appears to contain an antigenic determinant not found on JR. One possible source of these differences may be the carbohydrate moieties which are attached to the receptor protein. Purified acetylcholine receptor from denervated muscle (EJR) was exposed to a mixture of exo- and endoglycosidases to remove carbohydrates. α-Bungarotoxin binding was not affected by this procedure. The enzyme treated EJR had a decreased affinity for the lectin, Con A, indicating that some of the carbohydrates had been removed. The treated receptor was then assayed by immunoprecipitation and inhibition of toxin binding assays using serum from myasthenic patients. The conventional immunoprecipitation assay detected no differences in antibody binding to treated or untreated EJR precluding gross structural changes. However, values for the inhibition assay were decreased by as much as 20%. This finding was confirmed using a modified immunoprecipitation assay which measures immunoglobulin binding to the toxin binding site. Thus, removal of carbohydrates from EJR decreased the binding of myasthenic IgG. Enzyme treatment of JR (from normal muscle) did not alter inhibition values by those patients capable of blocking toxin binding. After enzyme treatment, EJR more closely resembles JR as defined by its immunological properties. It is concluded that carbohydrate residues on the 40,000 m.w. subunit determine some of the differences between JR and EJR. These carbohydrates may be involved in the arrangement and stabilization of AChR at the neuromuscular junction.

81.1 LOW CONCENTRATIONS OF LSD MAY BLOCK REUPTAKE OF LATERAL INHIBITORY TRANSMITTER IN LIMULUS RETINA. Leonard Kass, Peter H. Hartline, and Alan R. Adolph. Eye Research Institute, Boston, MA 02114.

Accumulated evidence implicates 5-HT as the transmitter for lateral inhibition in Limulus lateral eye. Each facet in this simple compound eye contains a dozen receptor cells electrically coupled to a single spike-generating eccentric cell. Eccentric cells in neighboring facets form (lateral) inhibitory synapses with each other. Thus, lateral inhibition can be evoked in a test eccentric cell by stimulating its neighbors with light. We have examined the effects of LSD at this putative 5-HT synapse by extra- and intracellular recordings from eccentric cells. LSD is commonly believed to agonize or antagonize 5-HT action at postsynaptic receptor sites in many vertebrates and invertebrates. Our results indicate that LSD acts presynaptically. We propose the following hypothesis for LSD action in Limulus lateral eye: In 1-5μM LSD, partial blockade of 5-HT presynaptic receptors for reuptake prolongs 5-HT lifetime in the synaptic cleft and thereby enhances inhibition; in 5-20μM LSD, more sites are blocked leading to accumulation of synaptic transmitter and consequently to postsynaptic desensitization. Evidence against postsynaptic LSD action: (1) Structural specificity of postsynaptic receptor for 5-HT appears to preclude direct LSD interaction (Adolph and Kass, J. gen. Physiol. 74:549, '79). (2) We now report that LSD, but not 5-HT, action is markedly reduced when added to a High Mg^{++}/Low Ca^{++} bathing medium which prevents transmitter release. This indicates that the predominant action of LSD is not postsynaptic. We are currently investigating whether the higher [LSD] exerts any direct action on postsynaptic receptors. Evidence favoring presynaptic uptake blockade hypothesis: (1) Presynaptic reuptake receptors appear nonspecific enough to accommodate the LSD molecule (Adolph and Kass, '79). (2) We have shown that light-evoked lateral inhibition from adjacent eccentric cells onto a single eccentric cell is enhanced in low [LSD] and suppressed in higher [LSD]. (3) A different way of activating the inhibitory synapse at a test cell is by stimulating the optic nerve axons of neighboring eccentric cells. This antidromically evoked inhibition uses a more direct neural pathway and thus serves as an important control for LSD's effect on light-evoked inhibition: antidromically evoked inhibition also exhibits enhancement at low [LSD] and suppression at higher [LSD]. In contrast, 5-HT causes desensitization and reduction of lateral inhibition at all concentrations. (4) The strength of lateral inhibition that has been enhanced by low [LSD] decays (perhaps desensitizes) more rapidly than in the normal eye. The specific hypothesis presented above can account for diverse LSD effects reported in the mammalian brain literature such as: (i) "blocking", "facilitating", "potentiating", "mimicking", and other agonistic/antagonistic effects sometimes within the same tissue; (ii) concentration dependence of LSD action; (iii) effect of LSD on 5-HT turnover rate; and (iv) LSD binding to 5-HT synaptic membrane sites.

81.2 LOCALIZATION OF DOPAMINE-STIMULATED ADENYLATE CYCLASE ACTIVITY IN RETINA. G.W. De Vries*, K.M. Campau* and J.A. Ferrendelli (SPON: A.I. Cohen). Div. of Clin. Neuropharm. and Depts. of Neurol, Pharm. and Ophthal., Washington Univ. Med. Sch., St. Louis, MO. 63110.

Dopamine has been shown to stimulate retinal adenylate cyclase activity in a number of vertebrate species. Previous studies have suggested that this dopamine-stimulated activity is found primarily in the inner retina, but its relationship to regions known to contain dopaminergic nerve terminals has not been clearly defined. Therefore, we have attempted to determine the location of this enzyme more accurately using quantitative histochemical techniques.

In preliminary studies of adenylate cyclase in homogenates of whole rabbit and mouse retina we observed that its basal activity was 45-55 pmoles/mg prot/min. This was increased 50-80% by the addition of dopamine (50 μM) alone. As in other regions of the CNS, EGTA (0.5 mM) depressed basal activity of the enzyme but not the stimulatory effects of dopamine. We also found that GPP(NH)P (30 μM), an analogue of GTP, increased enzyme rate and maximal adenylate cyclase activity (113-123 pmoles/mg prot/min) was seen when EGTA, dopamine and GPP(NH)P were all included in the assay mixture.

In both rod-dominant rabbit and cone-dominant ground squirrel retinas, basal adenylate cyclase activity (no additions) in microdissected retinas had a similar pattern of distribution. The greatest activity (150-180 pmoles/mg dry wt/min) was found in the inner plexiform layer. Lesser activities were observed throughout the remainder of the retina, with relatively high levels in the outer plexiform (30-40 pmoles/mg dry wt/min) and inner segment (60-70 pmoles/mg dry wt/min) layers. GPP(NH)P, in the presence of EGTA, stimulated enzyme activity in all retinal layers. The addition of dopamine further increased adenylate cyclase activity, but only in the inner plexiform, inner nuclear and outer plexiform layers of the rabbit retina and only in the inner plexiform layer of the ground squirrel retina.

It has been suggested (Watling et al., Nature 281: 578, 1979) that all dopamine receptors in the retina are linked to adenylate cyclase. If, in fact, this is the case, the above results indicate that dopamine receptors are found in both plexiform layers and in the inner nuclear layer of rabbit retina, but are confined to only the inner plexiform layer in ground squirrel retina. This suggests that dopamine may have different physiologic actions in various animal species.

81.3 SPECTRAL SENSITIVITY OF LIGHT EVOKED ACH RELEASE FROM THE RABBIT RETINA. Stephen C. Massey* & Dianna A. Redburn. Dept. Neurobiol & Anat., Univ. Texas Med. Sch., Houston, Texas, 77025.

There is substantial evidence that ACh is a retinal neurotransmitter. All the cholinergic markers are localised in the inner portion of the rabbit retina, specifically with amacrine cells, and ACh may be released by light stimulation. Using an in vivo rabbit eye-cup preparation, loaded with (3H)- Ch, we have attempted to identify the peak spectral sensitivity for the light evoked release of (3H)- ACh which is calcium dependent while the efflux of (3H)-Ch is unchanged; therefore, in this series of experiments, a rapid perfusion system was set up and increments in the efflux of total radio-activity were taken to be indicative of ACh release. Light stimulation was provided by a tungsten source via an electronic shutter driven at 2 Hz (50ms for 2 min) with narrow band filters equalized with regard to intensity and attenuated with neutral density filters. Experiments were carried out under mesopic or low photopic conditions.

The intensity response curve showed the threshold for light evoked release of ACh at 520 nm to be approximately 9 log quanta/cm^2/flash; this is below the intensity required to record the ERG under these conditions. The response range from threshold to maximum covered 3-4 log units. An intensity giving a half maximal response at 520 nm was chosen to examine the spectral sensitivity curve which showed a peak at 500-520 nm. These preliminary results represent a sensitive method to monitor the activity of retinal cholinergic neurones and may be used to characterize the afferent pathways associated with this specific cell type.

81.4 NEUROTRANSMITTER AND DRUG RECEPTOR LOCALIZATION IN THE RETINA. J.K. Wamsley, J.M. Palacios, D.L. Niehoff and M.J. Kuhar (SPON: S. Bird). Johns Hopkins School of Medicine, Departments of Pharmacology and Psychiatry, Baltimore, MD 21205.

Having developed as a neuronal outgrowth of the embryonic diencephalon, the retina has served as an easily accessible model for the study of the central nervous system. Cytochemical studies have provided evidence of many putative neurotransmitter candidates in the retina, and binding studies have indicated the presence of the appropriate neurotransmitter receptors. We have localized the distribution of neurotransmitter receptors in the retina of rat, monkey and human eyes using a new in vitro technique of autoradiography which is suitable for diffusible compounds (Young and Kuhar, Brain Res., 179:255-270). A subset of amacrine cells in the inner nuclear layer have been proposed to be GABAergic. We have, accordingly, localized high affinity GABA receptors in the inner plexiform layer of the retina. Benzodiazepines, which are thought to act in conjunction with GABAergic mechanisms in some systems, were found to have receptors in the inner plexiform layer as well. This benzodiazepine binding was enhanced in the presence of unlabeled GABA. Using ^{3}H-QNB we were also able to localize muscarinic cholinergic receptors in the inner plexiform layer. Another subset of amacrine cells are thought to be dopaminergic. In the rat retina, we have utilized ^{3}H-spiperone to label both dopamine receptors and serotonin receptors. By displacing ^{3}H-spiperone binding with unlabeled ADTN we localized substantial concentrations of dopamine receptors in the inner and outer plexiform layers as well as over the layer of photo-receptor cells. Very few of these sites appear to be displaceable with cinanserin indicating few, if any, serotonin$_2$ receptors are present in the retina. Interestingly, we were able to localize beta-adrenergic receptors in the inner plexiform layer, outer plexiform layer and over the layers of receptor cells of the retina. Very few of these sites were displaceable with 10^{-7}M zinterol, indicating there are beta$_1$ receptors in the retina. Our preliminary observations indicate the dopamine receptor and beta-adrenergic receptor distributions are the same in the monkey and human retina as well.

These receptor localizations support some of the notions of neurotransmitter-receptor interactions between amacrine cell and ganglion cell processes in the inner plexiform layer and raise some new interesting questions about possible interactions in outer retina layers.

81.5 NEURAL LOCALIZATION OF SUBSTANCE P-LIKE IMMUNOREACTIVITY IN RABBIT RETINA. E. V. Famiglietti, Jr., N. C. Brecha and H. J. Karten. Dept. of Anatomy, Wayne State Univ. Sch. of Med., Detroit, MI 48201 and Dept. Neurobiology, SUNY, Stony Brook, NY 11794.

Substance P-like immunoreactivity was localized in rabbit retina using immunohistochemical techniques. Retinas were fixed in 4% paraformaldehyde, with or without 0.1M D,L lysine-HCl and 0.01M sodium periodate. Frozen sections were incubated in a monoclonal antiserum to substance P, and were otherwise processed by standard FITC immunofluorescence techniques. Specific immunoreactivity was established by absorption of the antiserum with 10uM synthetic substance P.

Specific substance P-like immunoreactivity was observed within cell bodies near or at the inner border of the inner nuclear layer (INL) and in the ganglion cell layer (GCL). Beaded and smooth dendritic processes of these cells formed 3 fluorescent bands in the inner plexiform layer (IPL), roughly corresponding to strata (S) 1, 3, and 5 of a 5-tiered stratification. S5 was most prominent and S3 least prominent. Processes were occasionally seen in the INL and outer plexiform layer (OPL), and rarely in the axon layer. This laminar organization of immunoreactive cell bodies and processes was found both in central and in peripheral retina.

One population of immunoreactive cell bodies in the INL gives rise to a single, stout process that descends to and ramifies in S5 of the IPL. A second population gives rise to thinner, multistratified processes which ramify in S1, S3 and S5. Immunoreactive cell bodies in the GCL bear 1 to 3 dendrites which ramify solely in S5. Correlation with Golgi preparations suggests that the first type of immunoreactive cell may give rise to the processes seen in the INL and OPL. The second type of cell appears identical to a wide-field, multistratified amacrine cell with beaded dendrites.

These studies have demonstrated at least 2 populations of amacrine cells with substance P-like immunoreactivity in rabbit retina. In addition, many reactive cells are present in the GCL. Apparently, the great majority of these are displaced amacrine cells, while a small minority may be ganglion cells. It is noteworthy that substance P-like immunoreactive dendrites are distributed in the same 3 strata as are the dendrites of catecholamine-containing and indoleamine-accumulating amacrine cells.

81.6 GLYCINE MEDIATES TRANSIENT IPSPs AND GABA MEDIATES SUSTAINED IPSPs IN MUDPUPPY RETINAL GANGLION CELLS. D.R. Dvorak *, J.H. Belgum * and J.S. McReynolds. Department of Physiology, University of Michigan, Ann Arbor, MI 48109.

We have shown that center illumination produces both transient and sustained IPSPs in mudpuppy retinal ganglion cells. This report examines the role of amino acids as possible neurotransmitters mediating these inhibitory responses. Intracellular recordings were obtained from neurons in the superfused eyecup preparation. When added to the superfusate in 5 mM concentrations, L-aspartate and L-glutamate depolarized ganglion cells via conductance increases, while glycine, taurine and GABA hyperpolarized the same cells, also via conductance increases. Similar results were obtained when synaptic transmission was blocked by the presence of 4 mM cobalt chloride.

Dose-response functions were obtained for glycine and GABA. Over the range 0.1 mM to 10 mM the effects (increase in membrane conductance) were dose-dependent and adequately described by a Michaelis-Menten relationship. Effects of applied glycine were selectively antagonized by strychnine (<0.1 mM) and effects of applied GABA were selectively antagonized by picrotoxin (<0.1mM). (Taurine effects were in all respects indistinguishable from those of glycine and were consistent with it acting as a glycine analogue.)

Transient IPSPs were reversibly eliminated by strychnine (0.01 mM). Sustained IPSPs were reversibly eliminated by picrotoxin (0.01 mM). Recordings from bipolar and amacrine cells show that these effects can not be attributed to action of the blockers on presynaptic cells.

These results strongly imply that glycine mediates transient IPSPs and that GABA mediates sustained IPSPs in ganglion cells. If, as we suspect, amacrine cells are the source of these inhibitory inputs, then transient amacrines ought to release glycine and sustained amacrines ought to release GABA.

Supported by NIH Research Grant EY 01653.

81.7 CENTER STIMULI ELICIT TRANSIENT AND SUSTAINED IPSPs IN MUDPUPPY RETINAL GANGLION CELLS. J.H. Belgum *, D.R. Dvorak * and J.S. McReynolds. (SPON: T.J. Morrow) Department of Physiology, University of Michigan, Ann Arbor, MI 48109.

Illumination of the receptive field center of retinal ganglion cells elicits two distinct types of inhibition. Transient IPSPs occur at on and off in all classes of ganglion cells. Current-voltage relationships show that the transient IPSPs are due to a large conductance increase. This transient input is evident even with the smallest spots tested (40 µm diameter) and at intensities within two log units of threshold.

The second form of inhibition is a sustained IPSP which occurs in all off-center and certain on-off ganglion cells. This sustained IPSP is also produced by small, centered spots, but is maintained for the duration of the stimulus. Like the transient IPSP,this response is also due to a large increase in membrane conductance. Sustained inhibition is a clear exception to the widely held idea that sustained responses of ganglion cells are due entirely to modulation of excitatory input from bipolar cells.

These results show that inhibition in ganglion cells is not restricted to surround pathways. We also suggest that at least two different types of presynaptic neurons provide these inhibitory inputs: 1) cells which depolarize transiently at on and off, probably transient amacrines, and 2) cells which have a maintained depolarizing light response, probably sustained amacrines.

Supported by NIH Research Grant EY 01653.

81.8 SECONDARY LABELING OF RETINAL NEURONS BY A RETROGRADELY TRANSPORTED DYE. R. H. Masland and U. C. Dräger. Department of Neurobiology, Harvard Medical School, Boston, MA 02115.

The fluorescent dye 4,6,diamidino-2-phenylindole (DAPI) is avidly transported by retinal ganglion cells. In the course of some other experiments we noticed that it also labels retinal neurons other than the ganglion cells. When we applied the dye to the cut optic tract of the rabbit, we found that two to three days later the majority of cells in the ganglion cell layer was brightly labeled, but a distinct second population was very faintly labeled. Taken together, the labeled cells accounted for all of the neurons present in the ganglion-cell layer. Since at least 20% of the cells of the rabbit's ganglion-cell layer are displaced amacrines (Hayden et al., '80) this indicated transneuronal movement of the dye. When we waited 5-7 days after application of the dye, fluorescence was seen in the inner nuclear layer, and by 10 days the majority of the cells there was labeled.

These phenomena were seen even more clearly in the mouse, where the distance over which the dye must be transported is shorter than in the rabbit. One day after application of DAPI often observed brightly labeled ganglion cells surrounded by halos of faintly labeled cells. When we applied a mixture of horseradish peroxidase and DAPI to the optic tract we found HRP to be present in the brightly labeled cells but not in the surrounding, faintly labeled cells.

The mechanism of the retrograde transneuronal spread of DAPI is unclear. It could be due simply to leakage from the ganglion cell bodies, but we do not observe such leakage in the brain proper: When various thalamic nuclei were labeled by cortical application of the dye, the nuclei were sharply delineated, with labeled cells immediately adjacent to unlabeled ones. Focal injection of DAPI into the mouse tectum produced secondary labeling of retinal neurons, but in the same animals cortical neurons projecting to the tectum were surrounded by unlabeled neighbors. Alternatively, the ganglion cells and other neurons of the inner retina might make contact in some manner that allows the cell-to-cell passage of the DAPI molecule. Gap junctions among amacrine cells and between amacrine and bipolar cells have been reported (Famiglietti and Kolb, '75; Kolb, '79), but such contacts by ganglion cells have apparently not been observed.

81.9 LARGE RETINAL GANGLION CELLS: THEIR ISOLATION AND ANTIGENIC PROPERTIES. S.E. Kornguth and E. Langer*. Depts. of Neurology and Physiol. Chem., University of Wisconsin, Madison, WI 53706

Antisera were prepared against large ganglion cells isolated from ox retina. In retina, only the large ganglion cells specifically bound the fluorescein labelled γ-globulins. Cone cells reacted equally with immune and control (preimmune) γ-globulin. In other brain regions the immune γ-globulin bound granule, stellate and Purkinje cells in the cerebellum; neurons of the lateral geniculate nucleus, superior colliculus, superior olive and substantia nigra; ependymal cells surrounding the fourth ventricle. The reaction with other organs including kidney, adrenal, lung, heart and liver was examined; only renal tubule cells reacted specifically. The retinal antigens isolated by affinity chromatography consisted of two proteins or subunits as determined by electrophoresis on polyacrylamide gels containing SDS. The predominant protein had a molecular weight of 49,000 and a minor component had a weight of 52,000 daltons. The retinal protein is similar to benzodiazepine receptor in molecular weight, solubility characteristics, tissue distribution and cellular localization. The cells from ox retina were dispersed in a solution containing 4% polyvinyl pyrrolidone, 5 mM $CaCl_2$, 1% rabbit serum albumin, mM HEPES buffer (pH 7.1) and 0.4% formaldehyde. Dispersion was accomplished by repeated passage of tissue through a stainless steel cytosieve and nylon cloth. The dispersed cells were separated by centrifugation through a discontinuous sucrose gradient. Greater than 95% of the cell bodies recovered at the 1.75-1.9 M sucrose interface had a diameter exceeding 28 μm. Recovered cell bodies retained their plasmalemmas. To develop antibodies against the isolated cells, rabbits were injected subcutaneously with the cells suspended in Freund adjuvant and then intravenously with the cells suspended in a sucrose solution. Precipitin lines were obtained between immune sera and triton X-100 solubilized ganglion cells placed in Ouchterlony plates. IgG fractions of normal and control sera were prepared by $(NH_4)_2SO_4$ fractionation and subsequently by chromatography on DEAE cellulose. The γ-globulins were labelled with fluorescein and incubated with 6 μm thick sections of ethanol fixed tissue. The immune γ-globulins reacted specifically with the large ganglion cells in ox, rabbit, cat, macaque, rat and goldfish retinas. Affinity columns were prepared by coupling immune and control γ-globulins to Sepharose 4B. Two proteins were eluted with 3 M sodium thiocyanate from the column containing immune γ-globulins. Immunoelectrophoresis revealed that the eluate contained two antigens: one was neutral at pH 8.6 and the other was cationic. Supported in part by a gift from Mr. and Mrs. L. Weiss and a grant from the U.W. Med. School.

81.10 MORPHOLOGICAL CLASSIFICATION OF RABBIT RETINAL GANGLION CELLS. Franklin R. Amthor*, Clyde W. Oyster and Ellen S. Takahashi. School of Optometry, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

In addition to conventional Golgi methods, intraretinal injections of horseradish peroxidase (HRP) have been used to stain ganglion cells (and other neurons) in rabbit retina. Although the HRP method is selective in that not all cells are stained, we have stained cells in visual streak and numerous peripheral locations. Moreover, the stained cells represent the full range of soma sizes observed in conventional Nissl stained preparations and the dendritic field sizes are comparable to those observed in Golgi material.

It is clear that a number of different morphological classes are represented in the ganglion cell population. The classification is based on consideration of stratification in the inner plexiform layer (evaluated by three-dimensional reconstruction and/or serial sections), soma and dendritic field size, retinal location, complexity of branching pattern, and special features such as dendritic spines and dendritic flare. Both qualitative (subjective) and quantitative evaluation methods are being used.

Some of the results lead to indirect correlations of morphology with the known functional classes of rabbit ganglion cells and these will be considered. This work was supported, in part, by USPHS Grants EY02207, EY00033, and EY7033.

81.11 CHANGES IN THE SPATIAL AND TEMPORAL DISTRIBUTION OF CENTER AND SURROUND RESPONSES IN X- AND Y- CELLS WITH VARYING STIMULUS ON TIMES. Alan Stein* and John K. Stevens (SPON: T. DAVIS). Dept. of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104 and Playfair Neuroscience Unit, University of Toronto, Toronto, Ontario M5T2S8.

Using the response plane method (Stevens and Gerstein, 1976), we have investigated the spatiotemporal organization of the center and surround of X- and Y- retinal ganglion cells in the cat. The response plane graphically represents the firing probability of a cell as a function of space and time. By varying the stimulus on-time from 10-500 msec, the spatial distribution of the receptive field components could be directly demonstrated.

For Y- cells it was found that with short stimulus on-times (10-80 msec) the sustained component of the center response (excitation and inhibition) disappears. The surround response (excitation and inhibition) can then be seen to extend into the center of the field, and importantly it is temporally delayed with respect to the center response. There is very little variation in the spatial extent of the field with different stimulus on-times.

For X- cells studied with short stimulus on-times (10-30 msec) it was found that the surround response (excitation and inhibition) also extends into the center of the field but in contrast to Y-cells, it has the same latency as the center response (excitation and inhibition). The spatial extent of X- receptive fields was found to decrease progressively with shorter stimulus on-times. That is, the organization of the field components and their relationship in space and time remains constant, but they are all proportionately smaller.

We have shown that the surround response in both X- and Y-cells is present in the center of the field. For Y- cells the surround response is temporally delayed with respect to the center response while for X- cells the center and surround responses have essentially the same latency. We interpret the decrease in the spatial extent of X- receptive fields with short stimulus on-times as evidence for a systematic decrease in the sensitivity of the receptive field components from the center to the periphery of the field. In contrast, the fact that the spatial extent of Y-fields is nearly constant with decreasing stimulus on-times appears to reflect a relatively flat sensitivity distribution of the receptive field components across space.

(Supported by NIH EY01832).

81.12 THE SYNAPTIC BASIS OF CENTER-SURROUND ANTAGONISM IN THE MUDPUPPY RETINA. T. E. Frumkes and P. A. Coleman*. Dept. Psych., Queens College of CUNY, Flushing, New York 11367.

The synaptic mechanisms underlying the receptive field (RF) organization of mudpuppy retinal neurons was assessed by means of intracellular recording and current injection. Under our cone-dominated conditions, photic stimulation of the RF center of hyperpolarizing bipolar cells (HPBCs) produces a hyperpolarization accompanied by a resistance increase: if the RF center is continuously adapted, surround stimulation produces a depolarization accompanied by a resistance decrease (commonly, diffuse stimulation produces little measured change in input impedance). Previous evidence suggests 1) photoreceptors (Rs) release neurotransmitters maximally in the dark, 2) horizontal cells (HCs) mediate bipolar cell receptive fields, and 3) that there is no feedback onto mudpuppy Rs. Collectively, the foregoing indicates that the R and HC released neurotransmitters cause, respectively, a conductance increase and decrease in HPBCs. In contrast, photic stimulation of the RF center of depolarizing bipolar cells (DPBCs) produces a depolarization accompanied by a resistance decrease: if the RF center is continuously adapted, surround RF stimulation produces a hyperpolarization accompanied by a resistance increase. These results suggest that the R and HC released neurotransmitters cause, respectively, a conductance decrease and increase in DPBCs.

Most ganglion cells (GCs) demonstrate transient IPSPs at light onset and offset which can be attributed to neurons with no obvious center-surround antagonism (i.e., amacrine cells). Receptive fields obtained with sustained photic stimuli, however, suggest that the spatial organization of "on" and "off" responses within GCs can be attributed respectively to the DPBC and HPBC, both of which release excitatory neurotransmitters when depolarized. Thus, the depolarization and decrease in resistance produced by stimulating the RF center of "on" GCs becomes smaller if the surround is additionally stimulated. In "off" GCs, the disfacilitation (hyperpolarizing response component involving a resistance increase and a positive reversal potential) produced by stimulating the RF center becomes smaller with additional stimulation of the surround. Similarly, the RF organization of excitatory responses of some on-off GCs can be attributed to an excitatory input from both bipolar types.

82.1 LEYDIG CELLS: AN ELECTRICAL NETWORK WITHIN THE SEGMENTAL C.N.S. OF LEECH. K.T. Keyser* and C.M. Lent. Neurobiol. SUNY, Stony Brook 11794 and Neurosci. Brown Univ., Providence, RI 02912.

Each of the 21 segmental ganglia in the leech Macrobdella decora contains two Leydig cells which can be identified by their position and electrophysiological characteristics. They exhibit "spontaneous" action potentials (1 to 10 per sec) and the two cells within each ganglion are electrically-coupled ($V_2/V_1 = 0.3$). Leydig cells in adjacent ganglia are mutually-excitatory, such that an impulse in one causes an impulse in both ipsilateral Leydig cells in adjacent ganglia. Interganglionic latency is constant for any cell pair and is unchanged by 20 mM Mg^{++} saline. This interganglionic latency is constant regardless of the direction of impulse conduction, and when assessed with results of "collision" experiments, we conclude that a common axonal pathway mediates these ipsilateral interactions. If a Leydig cell is driven, with intracellular currents, to fire impulses at frequencies of six to ten per sec, ipsilateral cells in adjacent ganglia are unable to follow in a one to one fashion and instead exhibit impulse failures.

These intra- and inter-ganglionic properties are consistent with the observed branching patterns of Leydig cells injected with HRP. Each cell projects to adjacent ganglia via its ipsilateral connectives and there sends processes to the periphery via lateral roots. Furthermore, the injection of Lucifer Yellow reveals dye coupling between paired ganglionic Leydig cells as well as between ipsilateral interganglionic cells. The combination of spontaneous activity, intraganglionic coupling and interganglionic interactions appears to generate a constant, low frequency of impulse activity within the Leydig cell network, and therefore within their processes in the periphery. The efferent impulse activity of these neurons is always conducted by the roots of adjacent ganglia and it has some unexpected properties. We have not been able to discern a sensory or motor function for these identifiable neurons. (Supported by NIH grant NS-14482 to C.M.L.)

82.2 HYDROSTATIC PRESSURE REDUCES SYNAPTIC EFFICIENCY BY BLOCKING PRESYNAPTIC CALCIUM INFLUX. J.L. Parmentier, L.A. Orr* and P.B. Bennett. F.G. Hall Environmental Laboratory, Duke Univ. Medical Center, Durham, North Carolina, 27710.

Hydrostatic pressure has been studied on the naturally evoked responses of an identified synapse in the abdominal ganglion of Aplysia californica while iontophoresing acetylcholine onto the soma of the postsynaptic cell. 100 ATM of pressure reduced by 66.5% (S.D. 4.5%, n=10) the amplitude of the EPSP recorded in neuron R15 after en passant stimulation of the right visceropleural connective. There was no change in the synaptic latency, the time-to-peak or the time constant of decay of the postsynaptic response. The same pressure did not alter either the amplitude or the kinetics of the excitatory ACh iontophoretic response on R15 and did not affect either Cl- or K+ dependent inhibitory responses to applied ACh on other ganglion cells. These results strongly suggest that the effect of pressure is on some presynaptic mechanism.

In order to determine if pressure is altering aspects of transmitter storage or mobilization the RCl-R15 synapse was stimulated for 60 sec at 0.5, 1 and 2 Hz. Compression to 100 ATM reduced the size of all stimulated EPSPs but did not affect the relative heights of synaptic depression, frequency facilitation and posttetanic potentiation which occur at this synapse. However, when the amplitude of the EPSP was increased by raising the level of calcium in the bathing sea water from 10mM to 15 mM the application of pressure reduced the height of the EPSP back to control values. In six experiments 100 ATM of pressure was sufficient to return the amplitude from 208% due to high calcium to 110% of control. Previous studies have shown that pressure reduces the amplitude of the slow inward current in R15 which underlies burst behavior in this cell and is known to be carried predominantly by calcium ions (Parmentier et.al. Undersea Biomed. Res. 6:75-91, 1979). Similar studies on other Aplysia neurons and the squid giant axon have shown only slight effects of pressure on resting membrane potential. We conclude that pressure exerts its effects on synaptic efficiency by interfering with the presynaptic calcium influx in RCl-R15 required for synaptic transmission. Pressure also reduces the amplitude of the response at the inhibitory synapse RCl-L11. Inhibition by pressure of inhibitory synapses in the central nervous system could explain the pressure induced hyperexcitability syndrome experienced by whole animals, including man, during deep diving.

82.3 EFFECT OF LITHIUM ON CONDUCTANCE INCREASES TO SEVERAL TRANSMITTERS IN APLYSIA. A. M. Williamson*, D. O. Carpenter and T. C. Pellmar. Physiology Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20014.

Lithium is an element important in treatment of manic-depressive illness, and its mode of action is of considerable interest. It is also an important tool for understanding the physiology of ion conducting channels and their receptors, since lithium shares the same chemistry as sodium (Na) and potassium (K) while being physically smaller. It is against that background that we have investigated the effect of lithium on conductance increase mechanisms in Aplysia californica.

In these studies lithium was used as a total replacement for Na in artificial seawater (Li-seawater). In most of the experiments the cells were never exposed to Li-seawater for more than 30 min because irreversible changes in the current-voltage relationship occurred with prolonged exposure. Li-seawater reduced the rapid increase in Na conductance elicited by the iontophoretic application of ACh in RB cells of the abdominal ganglion and of DA and serotonin in neurons of the buccal ganglion. Chloride conductance increases in medial pleural cells resulting from iontophoretic application of ACh, glutamate, and GABA were also reduced in Li-seawater. The change in amplitude of K conductance increase to ACh in medial cells generally paralleled changes in the input resistance as measured by injection of hyperpolarizing current pulses.

$MgCl_2$·mannitol was also used as a substitute for Na, and its effects on iontophoretic responses were compared with those of Li-seawater. $MgCl_2$·mannitol seawater completely abolished Na responses and effected a transient decrease in chloride responses.

These results reveal a difference between the effects of Na replacement by lithium and replacement by $MgCl_2$·mannitol. Those differences may reflect the pharmacological action of lithium.

82.4 SUBTHRESHOLD OSCILLATIONS UNDERLIE THE cAMP-INDUCED DISCHARGE OF APLYSIA PEPTIDERGIC NEURONS. L. K. Kaczmarek and F. Strumwasser. Division of Biology, California Institute of Technology, Pasadena, CA 91125.

The peptidergic bag cell neurons in the abdominal ganglion of Aplysia californica respond to brief synaptic stimulation or to certain cAMP analogs by generating a long lasting afterdischarge (30 min) of synchronous action potentials. We have used bag cells that have been dissociated from one another and maintained in primary culture to investigate the mechanism of this repetitive discharge (Strumwasser et al. Soc. Neurosci. Abstr. 4, 207, 1978; Kaczmarek et al. Soc. Neurosci. Abstr. 5, 249, 1979). We have found by intracellular recording from such isolated cells that sustained subthreshold oscillations, enduring for several hours, can be generated in response to the cAMP analog 8-benzylthio cAMP (8BT-cAMP). The two methods that have been used for the application of 8BT-cAMP to bag cells are extracellular addition to the culture medium (0.5 mM) and intracellular application by pressure injection from microelectrodes (tips 0.5-1.5 µm) containing 20 mM 8BT-cAMP in .3 M KCl. The mean latency to the onset of oscillations following extracellular application of 8BT-cAMP was 27 min (N=14) and their occurrence was associated with the onset of a repetitive discharge and enhanced spike broadening. The oscillations, however, persisted following the end of the discharge and reached peak-to-peak amplitudes about 10 mV. They remained unaffected by 5 x 10^{-5} M tetrodotoxin but could be abolished by extracellular addition of $CoCl_2$ (12 mM). In two experiments in which bag cells were penetrated with 8BT-cAMP-containing-micropipettes the oscillations reached a steady amplitude (4.5 mV) and frequency (~1/sec) shortly following penetration which endured for over an hour, presumably due to 8BT-cAMP leakage from the micropipette. These cells were used to examine the voltage sensitivity of the oscillations. Small hyperpolarizing currents diminished the amplitude and lowered the frequency while larger hyperpolarizing currents abolished the oscillations. Depolarizing currents increased both the amplitude and frequency. When repetitive firing was induced by depolarizing currents the frequency of firing was the same as that of the underlying oscillations which persisted even after adaptation of the firing rate. It is likely, therefore, that these oscillations underlie the mechanism of discharge induced by 8BT-cAMP in bag cells. In experiments in collaboration with U. Walter, F. D. Wilson and P. Greengard we are injecting the catalytic subunit of cAMP dependent protein kinase into cultured bag cells to determine if subthreshold oscillations, spike broadening and other membrane effects of 8BT-cAMP are mediated by protein phosphorylation. [This work was supported by NIH grant NS 13896.]

82.5 INVOLVEMENT OF CALCIUM CHANNELS IN SHORT-TERM DESENSITIZATION OF RECEPTOR-MEDIATED CYCLIC GMP FORMATION IN MOUSE NEUROBLASTOMA CELLS. E. El-Fakahany* and E. Richelson. Dept. of Psychiatry and of Pharmacology, Mayo Foundation, Rochester, MN 55901.

Mouse neuroblastoma clone N1E-115 cells have muscarinic and histamine H_1 receptors that mediate cyclic GMP formation, an effect which is dependent upon extracellular Ca^{2+}. This cyclic GMP response undergoes rapid and largely specific desensitization upon exposure of cells to high concentrations of agonist (Richelson, E., Nature, 272:366, 1978; Taylor, J. E. and Richelson, E., Molec. Pharmacol., 15:462, 1979), without any significant loss in receptor sites (Taylor, J. E., El-Fakahany, E., and Richelson, E., Life Sci., 25:2181, 1979), or guanylate cyclase specific activity (El-Fakahany, E. and Richelson, E., unpublished data). Incubation of cells with manganous chloride resulted in a rapid and transient increase in cyclic GMP formation. This effect was dependent upon the concentration of Mn(II) with an EC_{50} of about 100 μM. The manganese response progressively increased with increasing external Ca^{2+} concentration and reached its maximum at 6-8 mM Ca^{2+}. In the absence of Ca^{2+}, the effect of manganese was abolished. The Mn(II) effect was antagonized by verapamil but not by atropine or pyrilamine, suggesting that Mn(II) increases Ca^{2+} influx without interacting with the muscarinic or histamine receptors. When cells were desensitized to carbachol, histamine or both agonists there was a marked decrease in the ability of Mn(II) to stimulate cyclic GMP formation (see table). We conclude that short-term desensitization of the receptor-mediated cyclic GMP responses in these cells is associated with a state in which the calcium entry mechanisms are inactivated.

TABLE

Condition	% Control Cyclic GMP Formation Stimulated By: Carbachol (1 mM)	Histamine (1 mM)	Mn(II) (1 mM)
Cells desensitized with 1 mM carbachol (30 min)	0	82	48
Cells desensitized with 1 mM histamine (30 min)	87	0	56
Cells desensitized with both agonists (1 mM each, 30 min)	0	0	17

82.6 METHYLATION OF MEMBRANE PHOSPHOLIPIDS IN STRIATAL SYNAPTOSOMES R. E. Boehme* and R. D. Ciaranello (SPON: S. M. Stahl). Lab. of Developmental Neurochemistry, Dept. of Psychiatry, Stanford Univ. Sch. Med., Stanford, CA 94305.

The relative concentrations of several membrane phospholipids are important determinants of erythrocyte membrane fluidity and beta-adrenergic receptor levels. Alterations of phospholipid concentrations can be induced by beta-adrenergic agonists, and are mediated by S-adenosylmethionine-dependent methyltransferase reactions. The present studies were undertaken to determine if similar processes exist in dopaminergic systems of rat brain.

Purified synaptosomes were rapidly prepared from rat striata and preincubated 30 minutes at 4° with 0.2 mM [3H]S-adenosylmethionine (SAM). During this period, SAM was rapidly and actively taken up to produce a stable level of free intrasynaptosomal SAM. Subsequent incubation of the synaptosomes at 37° induced the incorporation of tritium into phospholipids. This reaction proceeded linearly for 30 to 40 minutes.

Inclusion of dopamine in the incubation medium resulted in a dose-dependent stimulation of phospholipid methylation. A maximal stimulation of 4-fold was achieved with 0.3 mM dopamine. Neither norepinephrine, epinephrine, nor acetylcholine stimulated methylation at any concentration. Following dopamine stimulation under the above conditions, the major methylated phospholipid was phosphatidylcholine. Levels of tritiated phosphatidylmonomethylethanolamine and phosphatidyldimethylethanolamine were not significantly altered by dopamine. Stimulation by dopamine was only partially blocked by either haloperidol or cis-flupenthixol. This suggests that non-receptor-mediated processes are at least partially responsible for the observed dopamine-stimulated phospholipid methylation.

82.7 THE ROLE OF RNA POLYMERASE IN THE β-ADRENERGIC RECEPTOR-MEDIATED INDUCTION OF CYCLIC AMP PHOSPHODIESTERASE IN C6 GLIOMA CELLS. J. P. Schwartz, P. Onali* and E. Costa. Lab. Preclin. Pharmacol., NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032

In C6 glioma cells, the activation of the β-adrenergic receptors causes a sequelae of events, including the rise in cyclic AMP content, the activation of cytosolic cAMP-dependent protein kinase and the translocation of the catalytic subunit of protein kinase into the nucleus. This cascade of events causes several long-term changes including the increase in activity of a molecular form of cyclic nucleotide phosphodiesterase. Chromatography of C6 glioma cell extracts on a DEAE-Sephacel column separates two forms of phosphodiesterase, which differ in their substrate specificity and Ca^{2+} activation characteristics. The activity of the form which hydrolyzes only cyclic AMP is specifically increased following the activation of β-adrenergic receptors.

This increase of phosphodiesterase is blocked by cycloheximide, and by actinomycin D, suggesting that new synthesis of protein and mRNA is required. RNA polymerase II, the enzyme responsible for mRNA synthesis, can be measured in nuclei prepared from C6 glioma cells. This enzyme requires Mn++ (150-200 mM). Its activity is proportional to the amount of nuclear protein (from 25-200 μg protein) added, and is linear with time for 20 to 30 min. The polymerase activity is inhibited in vitro by either actinomycin D (53% inhibition at 24 μM) or α-amanitin (78% inhibition at 1.1 μM). Incubation of intact cells with either actinomycin D (3.2 μM) or α-amanitin (2.7 μM) blocks the isoproterenol-stimulated induction of the phosphodiesterase without affecting basal activity. Neither of these drugs blocks protein kinase translocation into the nucleus, further supporting the idea that both actinomycin D and α-amanitin block phosphodiesterase induction by inhibiting RNA polymerase II in the cell nucleus. An isoproterenol treatment of the cells which induces phosphodiesterase fails to increase the RNA polymerase II activity of nuclei, presumably because isoproterenol treatment induces a small number of proteins and the limited increase in the RNA polymerase II activity required is below the limits of detection.

82.8 A QUANTITATIVE STUDY OF DOPAMINE IN SUPERIOR CERVICAL GANGLIA OF THE RABBIT. A.G. Karczmar, A. Ingerson* and N.J. Dun. Dept. of Pharmacol. Loyola Univ. Stritch Sch. Med. Maywood, IL 60153.

The content of dopamine (DA) in superior cervical ganglia (SCG) of the rabbit was measured quantitatively under various experimental conditions by means of a sensitive HPLC method. The mean DA content of ganglia freshly removed from the animals and frozen immediately in dry ice was 2.08 ± 0.53 μg/g tissue (n=7, mean ± S.D.). When ganglia were placed in oxygenated Krebs solution for 1-2 hr, the level of DA decreased to about 20% as compared with the immediately frozen ganglia. Unilateral preganglionic denervation after 7-14 days reduced the DA content to about 25% compared to that of the contralateral intact ganglia. Exposure of the ganglia for 5-10 min to high KCl (50-100 mM) Krebs solution did not cause any apparent change in the DA content as compared with ganglia exposed to Krebs solution for the same duration. The DA content of the ganglia removed from animals injected with reserpine, 2 mg/kg for 1 day, was not statistically different from ganglia removed from animals injected with saline. Pretreatment of the rabbits with an irreversible inhibitor of aromatic amino acid decarboxylase, α-monofluoromethyldopa, 250 mg/kg for 1 day or 50 mg/kg for 3 days, did not significantly lower the DA content in the SCG (MFMD, courtesy of Centre de Recherche Merrell International). As measured by the sucrose gap method, the amplitude of positive (P) potential recorded from the surface of ganglia removed from rabbits treated with reserpine or MFMD was not statistically different from that of the ganglia removed from animals injected with saline. The DA level of the ganglia superfused with bethanechol (0.6 mM) for 20-25 min, which abolished the P as well as the late negative potential as demonstrated in the sucrose gap recording, showed no statistical difference from that of the ganglia superfused with Krebs solution. Our results show that the ganglionic content of DA is not altered significantly by amine depletors, reserpine or MFMD, and is resistant to a muscarinic agonist, but is markedly reduced by preganglionic denervation or superfusing the ganglia with Krebs solution for 1-2 hr, and that there is no close correlation between ganglionic content of DA and the amplitude of P potential. (Supported in part by NINCDS Grants NS15848 and NS06455).

82.9 A NEUROCHEMICAL AND NEUROPHYSIOLOGICAL STUDY OF SEROTONIN IN THE SUPERIOR CERVICAL GANGLIA OF THE RABBIT. N.J. Dun, A. Ingerson* and A.G. Karczmar. Dept. of Pharmacol., Loyola Univ. Stritch School Med. Maywood, IL 60153.

Serotonin (5-HT) was determined quantitatively in rabbit superior cervical ganglia (SCG) by means of a sensitive HPLC method. The mean content of 5-HT in immediately frozen ganglia was 0.216 ± 0.08 μg/g tissue (n=6, mean ± S.D.). Superfusing the ganglia with Krebs solution for 1-2 hr, or sectioning of the preganglionic sympathetic trunk for 7-14 days did not significantly alter the content of 5-HT. Exposure of the ganglia to high KCl (50-100 mM) Krebs solution for 5-10 min caused a 34% decrease of the 5-HT content as compared with ganglia exposed to Krebs solution for the same duration. Reserpine (1 mg/kg for 1 day) reduced ganglionic content of 5-HT to about 50% of that of the ganglia removed from animals injected with saline. Perfusing the ganglia with a muscarinic agonist, bethanechol (0.6 mM) for 30 min did not appreciably affect the 5-HT content. The electrophysiological effects of 5-HT on single neurons were studied using intracellular recording techniques. Superfusing the ganglia with 5-HT (1-100 μM) caused, in the majority of neurons, a membrane depolarization of low amplitude and short duration; the depolarization was accompanied in most cases by a reduction in input resistance. The ganglion cells showed rapid desensitization to the depolarizing effect of 5-HT. In the concentrations of 10-100 μM, 5-HT effectively suppressed and blocked the fast-epsp or the synaptic action potential even in neurons where depolarization and/or change in membrane resistance was small and/or absent. In several neurons, 5-HT (10 μM) reduced the amplitude of fast-epsp without altering appreciably the resting membrane potential or the response of ACh potential elicited by iontophoretic application of ACh to the surface of the ganglion cells. The present study shows that a substantial quantity of 5-HT is present in the SCG of the rabbit, and that it is most likely to be postsynaptic in origin. The action of 5-HT on sympathetic neurons appears to be complex, in addition to the postsynaptic depolarizing effect, 5-HT may inhibit synaptic transmission by reducing the amount of ACh release from preganglionic nerve fibers. (Supported in part by NINCDS Grants NS15848 and NS06455).

82.10 EFFECTS OF TRH, NE, AND ACh ON RAT HYPOTHALAMIC THERMOSENSITIVE NEURONS. Steven K. Salzman* and Alexander L. Beckman (SPON: T.L. Stanton). Alfred I. duPont Institute, Wilmington, DE 19899.

Thyrotropin releasing hormone (TRH) has been shown to reverse the hypothermia induced by a variety of centrally-acting agents, to exert direct hyperthermic effects on body temperature (T_b) following intracranial application, and to alter the firing rate of neurons in several regions of the CNS. In view of this, we have examined the effects of TRH on thermosensitive neurons in order to determine if TRH-induced changes in T_b can be attributed to its action on these functionally-identified cells. The responses of these neurons to TRH were compared to those obtained with norepinephrine (NE) and acetylcholine (ACh).

Sprague-Dawley rats were anesthetized with urethane (1gm/kg, i.p.) and placed in a stereotaxic instrument. Two bilateral, water-perfused, stainless steel thermodes, implanted rostral to the preoptic/anterior hypothalamus (POA), were employed to vary hypothalamic temperature (T_h) from 32-42°C. T_h was monitored by a bead thermistor inserted into a stainless steel re-entrant tube implanted in the POA to the left of midline, symmetrical with the contralateral POA recording site. Recordings of extracellular single unit discharges and iontophoretic application of test compounds were made with 5-barrel glass micropipettes.

Of 107 neurons that were tested for their response to changes in local temperature, 31 of 66 temperature-insensitive (TIS), 12 of 29 warm-sensitive (WS), and 9 of 12 cold-sensitive (CS) neurons were tested with at least one of the three compounds and are described here.

WS neurons were inhibited by TRH (6 of 11), inhibited by NE (8 of 10), and excited by ACh (6 of 12). CS neurons were mildly inhibited by TRH (5 of 7), excited (1 of 6) or inhibited (4 of 6) by NE, and inhibited by ACh (2 of 5). TIS neurons were inhibited by TRH (16 of 31), excited (3 of 22) or inhibited (15 of 22) by NE, and excited (5 of 20) or inhibited (1 of 20) by ACh. Only inhibitory effects of TRH were observed on each class of neurons. In addition, 4 of 6 WS, 3 of 3 CS, and 11 of 11 TIS neurons that were inhibited by TRH were also inhibited by NE. By contrast, no such parallel was noted between the effects of TRH and ACh.

Considering the higher proportion of WS versus CS cells commonly reported in the POA and the relatively more pronounced inhibitory effect of TRH on WS versus CS cells reported here, these data suggest that increases in T_b following intraventricular or intrahypothalamic administration of TRH are mediated by its inhibitory action on warm-sensitive neurons. 83.1 STRETCH REFLEXES IN NORMAL HUMAN TRICEPS SURAE. C. Kaufman*, A. Berardelli*, M. Hallett*, E.J. Fine*, B.J. Linder*, D. Loo*, P. Kamitsuka*, J. Lazarre*, S.R. Simon* and W. Berenberg*. (SPON: H.R. Tyler). Gait Lab., Children's Hosp. Med. Ctr., Boston, MA 02115.

Stretch of an actively performing muscle usually produces several reflex responses. Previous studies of the triceps surae have revealed only a single significant response, presumably the monosynaptic reflex, prior to the onset of voluntary activity (Gottlieb, G.L. and Agarwal, G.C., J. Neurophysiol. 42:91, 1979). We have studied this muscle group further with slower rates of stretch and have identified additional longer-latency reflex components. Subjects sat in a chair and pressed their foot against a pedal attached to a torque motor. The ankle was dorsiflexed at various velocities and EMG from the triceps surae was recorded. The motor produced perturbations with maximal velocities of 100 to 200 °/sec at 50-100 msec into the movement.

When the ankle was at rest only a single response was seen. This response increases in amplitude with increasing velocity of stretch, is not altered by voluntary attempts to reduce or augment it, but is significantly reduced by vibration of the Achilles tendon.

When the ankle is stretched while the foot is pressing down on the pedal, an early response is followed by one and sometimes two later responses. The early response is similar in latency and behavior to the single response seen without background force. The first of the two long-latency responses has a stable latency, is often larger in magnitude than the early response and increases in amplitude with increasing velocity of stretch, often showing less pronounced increase at the faster velocities. The second of the long latency responses was present in 30% of subjects, had a greater amplitude and probability of occurrence at slower velocities and a shorter latency with faster velocities. The three responses were not modifiable by intent, but were suppressed by vibration of the Achilles tendon.

The behavior of these long-latency responses is different from that of long-latency responses in upper extremity muscles and indicates that there are a variety of mechanisms for long-latency stretch reflexes.

83.2 FURTHER EVIDENCE THAT THE GOLGI TENDON ORGAN MONITORS THE ACTIVITY OF A DISCRETE SET OF MOTOR UNITS WITHIN A MUSCLE. Marc D. Binder. Dept. of Physiol. & Biophys., Univ. of Wash, Seattle, Washington 98195.

Direct confirmation of the Houk and Henneman (J. Neurophysiol. 30: 466-481, 1967) model of tendon organ activation requires studies in which both a tendon organ and the muscle fibers of a motor unit which excites or unloads it are "marked" and their anatomical relationship reconstructed histologically. However, in the absence of these data the model can still be tested by considering its implicit predictions. If it is true that the motor units which excite a tendon organ do so because one or more of their fibers insert directly into the receptor capsule and that only such "in-series" fibers can provide an adequate stimulus, then the combined contraction of all the remaining motor units should be incapable of exciting the receptor regardless of the amount of force generated in the muscle. Moreover, since there are some motor units which can unload a given tendon organ, the receptor's response to whole muscle contraction should be less vigorous than its response to contraction of just the in-series units alone. The present study was designed to test these predictions by comparing the responses of tendon organs in cat soleus to stimulation of different groups of subdivided ventral root filaments. In general, the results support the Houk and Henneman model. It was found that when all the ventral root filaments containing motor units which excited a given tendon organ were separated out, concommitant stimulation of all those remaining failed to excite the receptor, even when these filaments accounted for over 90% of the muscle's peak tetanic tension (10/11 experiments). Moreover, a tendon organ's response to stimulation of just those filaments which contained excitatory motor units often exceeded that to whole muscle stimulation. Exceptions to the latter result indicate that the discharge of some tendon organs may be influenced by "off-line" forces. 83.3 MODULATION OF LATE STRETCH REFLEXES DURING A CYCLIC ELBOW MOVEMENT. W. A. MacKay, H. C. Kwan, J. T. Murphy and Y. C. Wong*. Dept. of Physiology, Univ. of Toronto, Toronto Ont. M5S 1A8 Canada

Human subjects, with right forearm fixed in a manipulandum, performed a continuously repeated horizontal elbow movement between two target zones. The movement cycle consisted of EXTENSION-HOLD-FLEXION-HOLD over a period of 2 seconds. During the cycle, stretch reflex efficacy was tested by delivering controlled ramp displacements to the forearm with a torque motor, and monitoring EMG responses. Each 50 msec phase of the movement was tested with small pulses in both directions. Biceps and triceps EMG were recorded with skin electrodes, then rectified and integrated. No observable monosynaptic reflexes were elicited by the stimulus. Prominent late reflexes appeared in certain phases of the cycle, at latencies of 35-65 msec (M2) or 65-120 msec (M3). Neither was usually present at rest. The M3 reflex appeared in the agonist muscles about 150-350 msec prior to active contraction. An M2 response appeared just before onset of the active contraction, leading it by only 50-150 msec. Under static conditions, reflex amplitudes were simply related to background EMG levels in the tested muscle up to a saturation level. But during the movement cycle, reflex amplitudes were uncorrelated to the simultaneous level of EMG activity. They were greatest in the preparatory period and dropped once the muscle started actively contracting. During the deceleratory phase they were briefly restored, then disappeared. A measure of relative change in central gain of the stretch reflexes exclusive of motoneuronal excitability was calculated by dividing reflex responses by concurrent EMG background (obtained in trials with no torque pulses) and comparing the quotients to those obtained at similar EMG levels but under static conditions. The results, as a function of cycle phase, suggested that channels utilizing proprioceptive information are important for the initiation of dynamic phases of movement.

83.4 MYOTATIC REFLEX CONTRIBUTIONS TO LOAD COMPENSATION AND STABILITY. Gerald L. Gottlieb, Gyan C. Agarwal, and Robert J. Jaeger, Department of Physiology, Rush College of Health Sciences, 1753 W. Congress Parkway, Chicago, Illinois. 60612.

A blood pressure cuff at the thigh was used to occlude blood flow to the leg while torque pulses dorsiflexed the foot of normal human subjects. The subjects were instructed to resist the pulses and restore the foot to its original position as rapidly as possible. (For details see Gottlieb and Agarwal, J. Neurophysiol., 1979 & 1980).

About 20 minutes after inflation of the cuff to 150 mm hg, the soleus myotatic reflex (latency of about 40 ms) vanishes. (Independent measurements of the Hoffmann reflex show it to disappear after the same delay). Associated with this disappearance, we observe a reduction in amplitude of the earliest portions of the post-myotatic EMG (latency of about 120 ms) and a slowing of the corrective movement which brings the foot back to its original position. Analysis of the distribution of post-myotatic latencies shows an increase in both its variance and mean; not a simple shift to longer latencies. The fastest post-myotatic responses occur at the same latency, even in the absence of the myotatic reflex.

Linear systems analysis of the mechanical behavior of the foot suggests that the myotatic reflex may not act to stabilize the joint. Computation of the transfer function between torque and angular rotation leads to the conclusion that the joint has less damping when the reflex is intact than when it is not. This, and the finding that ultimate correction of foot position is slowed, leads to a hypothesis that local feedback loops provide fast, fine control to the final common pathway to quicken a response, even at the cost of stability under some circumstances. (Supported by NIH Grants NS-12877 NS-12877 and NSF Grant ENG-7608754)

83.5 LONG-LATENCY STRETCH REFLEX OF THE HUMAN THUMB PRIOR TO THE INITIATION OF VOLUNTARY MOVEMENT. M.Hallett* and C.D.Marsden*. (SPON: E.T.Hedley-Whyte). Department of Neurology, Institute of Psychiatry, London, England.

Electroencephalographic events such as the contingent negative variation and bereitschaftspotential have suggested that there are changes in cortical neuronal firing during the second prior to the initiation of voluntary movement. Recordings of single cell activity in monkey cortex have apparently confirmed this suggestion. Long-latency stretch reflexes in the long thumb flexor can be produced when the muscle is engaged in voluntary movement, but not usually when the muscle is relaxed. Experiments were undertaken to see if the long-latency stretch reflex would be enhanced in this one-second period just prior to voluntary movement.

Subjects placed the distal phalanx of one thumb on a lever attached to the spindle of a torque motor. They were told to relax the thumb until they heard a high tone, after which they were to make a rapid flexion movement. One second (or in some experiments 0.5 sec.) prior to the high tone they heard a low tone which was a reliable warning about the coming of the high tone. In the first experiment responses to stretches were compared at various times during the interval between the low and high tones. In 3 of 5 subjects the stretch reflex appeared to increase in amplitude as the stretch got closer to the voluntary movement. Because results were not consistent a second experiment was done carefully comparing stretch between a low and high tone and stretch with thumb relaxed without tones (along with controls for each of these two conditions without stretches). In only 5 of 17 subjects was the reflex before voluntary movement larger than the reflex without preparation for voluntary movement. These subjects could not relax completely and baseline EMG activity was often greater with the tones than without them. Subjects who relaxed well had no reflex in either circumstance, while subjects who relaxed poorly had a large reflex which did not vary significantly. A gradual increase in baseline EMG activity between the tones would appear to be responsible in those trials in the first experiment which exhibited growth of the stretch reflex.

In this period prior to the initiation of voluntary movement there appears to be no stretch reflex unless there is background EMG activity and no change of the stretch reflex other than that which can be related to subtle changes in background EMG activity. Either the long-latency stretch reflex does not mirror the cortical changes prior to movement or the cortical changes themselves are a direct correlate of the background EMG changes.

83.6 SPINDLE PRIMARY RESPONSES TO SUDDEN DISPLACEMENTS OF THE HUMAN WRIST. K-E. Hagbarth*,R.R. Young,J.V. Hägglund* and E.U. Wallin* Department of Clinical Neurophysiology, University Hospital, Uppsala, Sweden, and Clinical Neurophysiology Laboratory, Massachusetts General Hospital, Boston, MA 02114

An abrupt angular displacement at a joint, stretching voluntarily contracting muscles, produces segmentation of the EMG. Three discrete EMG bursts are usually seen, the 1st of which represents the spinal stretch reflex. The 2nd and 3rd have been considered "longloop reflexes" passing through cerebral structures including motor cortex. A single afferent input at the start of stretch was assumed to produce all 3 EMG bursts. In order to record the muscle afferent response to such displacements, intraneural tungsten microelectrode recordings (microneurography, Vallbo et al., Physiol. Rev., 59: 919-957, 1979) of single or multi unit activity were made from median or radial nerve fascicles in 17 experiments in 3 normal human subjects. Flexion or extension movements at the wrist were produced by several devices including a torque motor.

With angular displacements exceeding 200 deg/sec and amplitudes 10-20 deg, segmentation of muscle afferent activity was always recorded. In addition to bursts of primary spindle activity following the sudden start and stop of abrupt angular displacements, one or two more bursts of spindle impulses occurred during the stretch movement itself. This segmented afferent response,from primary endings which are remarkably sensitive to mechanical perturbations during muscle stretch, may be due to fluctuations in the velocity of stretch resulting from previously described non-linear viscous properties of muscle. Such irregularities appear inevitable even when smooth torque pulses produce the stretch.

This segmented afferent input following abrupt limb displacements is followed, at latencies compatible with operation of segmental stretch reflex mechanisms, by segmented EMG activity. Even with much smaller displacements than noted above, it is difficult to produce only one burst of afferent activity. When that is accomplished, only one burst of EMG activity is seen. Though they do not disprove the presence of "longloop reflexes", our observations document difficulties inherent in assumptions about reflex pathways which are based only on timing of EMG responses to a presumably simple stretch stimulus. These results provide evidence in man for Ghez and Shinoda's hypothesis, derived from studies of spinal cats, (Exp. Brain Res., 32: 55-68, 1978) that "receptor properties and/or spinal mechanisms involved in the stretch reflex are sufficient to produce a segmented (EMG) response".

83.7 EFFECT OF DANTROLENE SODIUM ON THE DISCHARGE OF PRIMARY SPINDLE AFFERENTS DURING FUSIMOTOR STIMULATION. Petit, J.E.*, Cameron, W.E., and Murthy, K.S.K., Division of Neurosurgery, University of Texas Medical School, Houston,Texas 77030.

The excitation-contraction coupling process in a muscle may be affected by the drug dantrolene sodium (Dantrium^{R}, Norwich-Eaton) which has been suggested to interfere with the release of calcium from the sarcoplasmic reticulum (Desmedt and Hainaut, J. Physiol. 265: 565-585, 1977). In a recent study (Murthy, Jami, Petit and Zytnicki, Fed. Proc. 39: 579, 1980), it was shown that the action of dantrolene is predominantly on the faster contracting muscle fibres of the FF and FR motor units. The muscle fibres of the slow twitch type S motor units were comparatively resistant to the action of this drug. The present experiments extend the observations to effects on intrafusal muscle fibres as inferred from a study of muscle spindle Ia afferent responses to stimulation of gamma fusimotor axons.

Experiments were performed in 9 cats (2.0 - 4.0 kg) anesthetized with sodium pentobarbital. The left hindlimb was completely denervated except for the nerve to the peroneous tertius muscle. The dorsal and ventral roots of L6, L7 and S1 were sectioned. Single spindle Ia afferents were functionally isolated from split dorsal root filaments and single fusimotor efferents were likewise isolated from split ventral root filaments. The discharge of Ia afferents was recorded in response to the tetanic stimulation (75 pps for 3 seconds) of single gamma efferents before and after the administration of the drug. A 3mg/kg dose of dantrolene sodium (dissolved in propylene glycol 3mg/ml) was injected I.V. at a rate of 2ml/min.

A total of 113 fusimotor effects due to 61 gamma axons acting on 59 Ia afferents were studied. Effects of the drug consisted of (1) a small reduction in the mean level of discharge during maintained tetani, (2) a reduction in the variability of the mean discharge, and (3) a slowing of the rise of the spindle response at the onset of fusimotor stimulation.

(Supported by NINCDS grant #NS-14702. The authors acknowledge the gift of Dantrium by Norwich-Eaton Pharmaceuticals, Inc.)

83.8 THE NECK MUSCLE AFFERENT PROJECTION TO THE SUPERIOR COLLICULUS IS FROM THE GROUP III AFFERENTS. V. C. Abrahams and C. J. Turner*. Dept. of Physiology, Queen's University, Kingston, Ontario. K7L 3N6

Two systems of muscle afferents are known to be the origin of substantial projections to the superior colliculus. One system takes origin in extraocular muscle and the other in the large dorsal muscles of the cat neck. In experiments on chloralose anaesthetised cats, it has been possible to show that a signal is conveyed from extraocular muscle receptors indicating the onset of a saccade and also the position of the eye in the orbit during a saccade. Experiments in chloralose anaesthetised cats were undertaken to see what information could be recorded in the superior colliculus during controlled stretch of neck muscles at parameters known to excite the large population of muscle spindles present in these muscles. Although evidence from electrical stimulation was used to identify units in the superior colliculus receiving neck muscle afferent input, only a very small number of units (8 of 69) were found to respond during passive stretch of neck muscle. Careful examination was therefore made of the threshold of trains of electrical impulses applied to neck muscle nerves which led to unit activity in the superior colliculus. Units were rarely excited by stimuli adequate only to stimulate Group I and II fibres. Almost invariably units in the superior colliculus could only be activated by stimuli in excess of 2 x threshold. At this stimulus strength many Group III muscle afferents are excited. The assumption from these experiments is that it is the Group III afferents (which constitute an unusually high proportion of the myelinated fibres of neck muscle) which give rise to the projection to the superior colliculus. This would explain why controlled neck muscle stretch is an ineffective stimulus to unit discharge. Early analysis of receptor properties of Group III afferents from large dorsal neck muscles suggest that only a minority are sensitive to algesic chemicals. The most effective stimulus so far found is pinch of the muscles.

83.9 DETERMINATION OF CHANGES IN REFLEX BEHAVIOR DURING TRANSITIONS FROM ONE TASK TO ANOTHER. J.F. Soechting and F. Lacquaniti*. Lab. of Neurophysiology, Univ. of Minnesota, Minneapolis, MN 55455.

A method has been developed which permits the identification of linear systems whose parameters are varying with time. Pseudo- random binary m- sequences of length n are used as the input. The manner in which the system's parameters vary is assumed to be unknown except that the time course of the variations is fixed relative to the onset of the sequence. Impulse responses for the output at each interval of the sequence are obtained by cross- correlations using n trials, in each of which the sequence has been shifted by one interval.

This method has been used to study changes in reflex behavior of biceps and triceps in response to torque perturbations applied to the forearm of human subjects when the motor task changed. In particular, we asked the subjects to switch from "resist the applied perturbation" to "do not resist", or vice versa, as quickly as possible upon command. Perturbations were applied for one second prior to and two seconds following the command. It was found that changes in reflex amplitude followed an approximately exponential time course, with a time constant of 140 ms for the transition from "resist" to "do not resist" and one substantially longer (220 ms) for a transition in the other direction. The method is also being used to study changes in reflex behavior during the initiation, control and arrest of simple movements.

83.10 NONLINEAR INTERACTIONS OF STRETCH REFLEXES IN THE DECEREBRATE CAT. J.W. Aldridge and R.B. Stein. Dept. of Physiology, Univ. of Alta., Edmonton, Alberta, Canada. T6G 2H7

Previous studies from this laboratory have described nonlinear properties for contractions of soleus and plantaris muscles[1]. The following experiment extends the analysis to stretch reflexes. Reflexes were elicited in decerebrate cats with two brief muscle stretches separated by a variable interval (30-600 ms). Tension output, EMG activity and neural activity were recorded. In a linear system the response to the second stretch would be equal to the response to the first. The contribution of this second stretch to the total output was extracted by subtracting the response to the first stretch from the total response. A greater output to the second stretch compared to the first indicates a nonlinear potentiation. A smaller output signifies a depression.

Three phases of nonlinearity during the reflex were observed in the tension output. For short intervals (< 100 ms) following a stretch, the contribution of the second reflex to the total tension was depressed. This was followed by a period of potentiation (100-200 ms) and then a longer period of depression (200-600 ms). At intervals of 80 msec or less in soleus, the second stretch actually diminished the tension from the first stretch. This occlusion probably resulted from disrupting bonds already formed.

The pattern of nonlinearity for EMG output was qualitatively similar to that of tension. This suggests that the nonlinearity of reflexes cannot be attributed to muscle properties alone. Unlike tension and EMG, the neural activity from the second stretch was relatively unchanged. The neural responses mainly represent afferent activity[2] implying that the nonlinear reflex properties are not due to altered sensory input. Confirmation of these nonlinear reflex properties was obtained using electrical stimulation to elicit H-waves. All nonlinearities other than the early occlusion were seen with the nerve shocks.

In conclusion, an occlusion of stretch reflexes due to muscle properties has been described. Other nonlinearities are not due to afferent changes and the qualitatively similar behaviour of EMG activity and tension output points to the motoneuron as a possible site for these effects.

84.1 RESPONSE PROPERTIES OF IDENTIFIED SENSORY INTERNEURONS IN THE SIXTH ABDOMINAL GANGLION OF THE CRAYFISH. K. A. Sigvardt, G. Hagiwara* and J. J. Wine. Dept. of Psychology, Stanford Univ., Stanford, Ca. 94305.

We are characterizing a group of approximately 50 sensory interneurons in the sixth abdominal ganglion of the crayfish whose axons are the exclusive pathway for the transmission of processed sensory information from the tailfan to the rest of the animal's nervous system.

To date we have described 107 interneurons by intracellular injection of Lucifer yellow and have determined many of their response properties. Using the combined physiological and anatomical profile of each cell we have tentatively determined that these 107 represent 53 individual neurons. Most of these neurons fall into five relatively homogeneous classes.

Type A interneurons (n=20) fire to whole field water movement. They are directionally selective; half fire only to headward water movement and half fire only to tailward movement. All neurons are non-adapting, spontaneously active, and all have non-electrogenic cell bodies.

Type B interneurons (n=6) fire only when the tailfan or the water surface near the tailfan is touched. They are not directionally selective. They are not spontaneously active and the cell bodies are non-electrogenic. All Type B neurons are inhibited by roots outside the receptive field or by the giant axons.

Type C interneurons (n=4) include both nearfield and tactile cells, with response properties much like Type B cells. They are distinctive in having bilateral, multisegmental receptive fields, and electrogenic cell bodies. Unlike Type A and B cells, these neurons produce a long barrage of spikes in response to strong root shocks. All adapt to repetitive stimulation.

Type D interneurons (n=7) are proprioceptive interneurons. They are spontaneously active and the somata are non-electrogenic. Two of the three have multisegmental, ipsilateral receptive fields.

Type E interneurons (n=9) are proprioceptive interneurons with no spontaneous activity, electrogenic cell bodies, and bilateral, multisegmental receptive fields. The cells respond to strong root shocks with a long barrage of spikes.

Our analysis may eventually provide the first case in which all members of a sensory interneuron pool have been indentified. The interneurons are of special interest because they are afferent to several well-described motor systems.

84.2 CERCAL SENSORY PROJECTIONS IN DERMAPTERA AND NOTOPTERA. John S. Edwards and Eldon Ball. Zoology Dept., Univ. of Wash., Seattle, WA 98195 and Dept. of Neurobiol. Australian Nat. Univ., Canberra, Australia.

Of the several orthopteroid insect orders, the cercal sensory system and associated giant interneurons are known in detail from only two, represented by the blattid Periplaneta americana and the gryllid Acheta domesticus. This study describes cercal projections and giant interneurons in two further orders, the Dermaptera represented by Forficula auricularia and the Notoptera by Grylloblatta sp.

In Dermaptera the cerci are modified to form forceps and thus assume a motor rather than sensory function. In Notoptera the annulate cerci are sensory and are intermediate in form between gryllids and blattids. Cercal sensory projections to the terminal ganglion are closely similar in Dermaptera and Notoptera, and distinctly different from those of blattids and gryllids. The major postero-lateral glomerulus characteristic of the latter two groups is absent. Four submedian projections in ipsilateral anterior, mid, posterior and far posterior positions. A loosely organised glomerulus occupies the sub-dorsal mid region from which some fibres extend into the connectives. A minor ventral projection also extends forward to the connectives.

The distinctive giant interneurons of Periplaneta and Acheta have no comparable counterparts in Forficula or Grylloblatta, but a group of relatively large axons, about 10 μm in diameter may be their homologs, for the largest spikes recorded from the ventral nerve cord of Grylloblatta are evoked by stimulation of cercal mechanoreceptors.

This work was supported in part by NIH grant NB 07778.

84.3 CONNECTIVITY BETWEEN IDENTIFIED SENSORY CELLS AND IDENTIFIED GIANT INTERNEURONS OF THE COCKROACH PERIPLANETA AMERICANA. Darryl L. Daley and Jeffrey M. Camhi. Sect. Neurobiology and Behavior Cornell Univ., Ithaca, NY 14853

The giant interneurons (GI's) of the ventral nerve cord of the cockroach are thought to be involved in initiating and orienting the directional escape response to wind puffs. The wind-sensitive receptors are filiform hairs located on the ventral surface of each of the two cerci (peg-like abdominal appendages). Each hair is innervated by a single sensory cell. Each sensory cell responds maximally to one direction of wind, but gives some excitatory response to wind over a range of about 180°. The hairs are arranged on the cerci in longitudinal columns. For 9 of these columns, it is known that all the hairs of a given column have the same best excitatory direction. The best excitatory direction is different for different columns. We have investigated the relative contribution that single columns of sensory hairs make to the response of individual GI's.

Synaptic input from single columns of hairs was recorded from the somata of both directionally selective and omnidirectional GI's. Single columns of filiform hairs were isolated from neighboring columns of hairs by first plucking out the unwanted hairs and then covering their bases with glue. (Generally all but six hairs in one column were inactivated in this way.) In response to controlled puffs of wind, synaptic potentials and sometimes action potentials could be recorded over approximately 180° of wind angle. In general, the maximal response in the GI occurred at the best angle for the column of hairs being stimulated.

GI 1, a somewhat directionally selective interneuron, receives excitatory synaptic input from columns of hairs on both the ipsilateral and contralateral cerci. Some of the columns that excite GI 1 have their best excitatory direction within the range of wind angles to which GI 1 is most responsive. However, synaptic input from at least one column of hairs whose best excitatory direction falls within the range of wind angles to which GI 1 is least responsive also excite GI 1. GI 2, an omnidirectional cell, receives excitatory synaptic input from columns of hairs with their best excitatory directions in all four quadrants surrounding the animal. We are currently examining interactions among other hair columns and the GI's to reveal further excitatory and possible inhibitory connections, and how these inputs shape the directionality of the GI's.

This work was supported by NIH grant NS 09083-10.

84.4 ELECTRON MICROSCOPY OF PUTATIVE CHEMOSENSORY STRUCTURES IN PLEUROBRANCHAEA CALIFORNICA. Gene Matera*and W.J. Davis, Thimann Labs, Univ. of Calif. at Santa Cruz, Santa Cruz, CA 95064

We have examined histologically a number of areas of the body of Pleurobranchaea californica with special emphasis on the known chemosensory areas -- the rhinophores, tentacles, oral veil, mouth and lips. Our studies indicate that one type of structure occurs in the sensory epithelium of all chemosensory areas, and nowhere else. These putative chemoreceptive sites are found at a very high density in the sensory epithelium of the lumen of both the rhinophore and tentacle, and at a lesser density in the oral veil, mouth and lips. Scanning electron microscopy has shown ciliated structures protruding through the epithelium, bearing many (200 or more) long cilia. Each receptor is a discreet entity about 10 micrometers in diameter. They appear, in the rhinophore and tentacles, evenly spaced in a dense array, at a density of approximately 5-10 X 10^3 per square millimeter. These receptors are complex in structure, bearing at least two distinct types of cilia. These include long, straight cilia resembling the presumably motile cilia of the foot, gill and elsewhere. Most of the cilia, however, have characteristic round spatula-like tips. These spatulate cilia are morphologically very similar to the long immotile (or very slow) olfactory cilia found in the frog (Reese 1965). Extracellular nerve recordings have shown that the rhinophore and oral veil tentacle are sensitive not only to food substances, but also to pH, salinity, osmolarity, and touch. These receptors may be multimodal, a possibility that is consistent with their morphological complexity. Transmission electron microscopy and light microscopy sections have shown that these putative chemoreceptors send projections into the peripheral ganglia associated with the sensory epithelium of both the rhinophore and tentacle.

The oral veil sensory apparatus, unlike that of the rhinophore and tentacle, is more spatially segregated, occurring only at the tips of specialized papillae which are everted or retracted in response to chemical stimulation. The sensory epithelium is organized into large (hundreds of micrometers), highly innervated floral-like regions which include centrally located putative chemoreceptors morphologically similar to those found in the rhinophore and tentacle. Similar structures have also been found in the mouth and lip regions. Other regions of the body also bear innervated sensory epithelium, but no other area examined to date has shown these putative chemoreceptors bearing spatulate cilia other than the areas known to have chemosensory capacity. We therefore hypothesize that these receptors underlie chemosensation in Pleurobranchaea.

84.5 ODOR AND PUFF SENSITIVE NEURONS IN THE SNAIL TENTACLE. Ronald Chase. Dept. Biology, McGill Univ., Montreal, Que., H3A 1B1.

Behavioral evidence indicates that the snail tentacle houses a sensitive and functionally complex olfactory system. In order to study this system physiologically, electrical recordings have been obtained from the tentacular ganglion and its digitate extensions into the sensory epithelium. The experiments utilized excised posterior tentacles of the terrestrial snail Achatina fulica. The tip of the tentacle was pinned out and exposed to clean air puffs or odors. A stimulus delivery system was arranged to provide precision control of air flow rate and duration. The use of solenoid valves permitted the insertion of odor-laden "air plugs" into a continuous airstream, with negligible distrubance of flow.

Extracellular recordings were obtained with suction electrodes. The signal:noise ratio was typically 3:1. These experiments demonstrated a sensitivity to air puffs with velocities as low as 25 mm/sec. Responses were of the ON-OFF type at low velocities, but sustained at velocities of several hundred mm/sec. Odor sensitivity was tested at 27 recording sites in 13 different preparations; each site yielded a response to air puffs. Four of the sites produced an unambiguous olfactory response to a mixture of fresh vegetable odors. Afferent responses to air puffs and vegetable odors were also recorded from the tentacular nerve using the sucrose gap method.

Intracellular recordings have been obtained only in the digitate extensions of the tentacular ganglion. The current sample consists of 44 cells, each with a minimal holding time of two min. Sixteen of the cells were held for more than 10 min. The resting potentials ranged from 45 mV to 80 mV with a mean of 57 mV. Two cell types have been encountered. Type I cells generally show no spontaneous activity, although some units produce undershooting spikes, especially during electrode penetration. EPSPs are reliably evoked by electrical stimulation of the tentacular nerve (centrifugal effect). Olfactory stimulation produced a slow depolarizing potential in a minority of type I cells (1 mV to 3 mV). The sensitive units responded reliably to three natural food odors, and one showed a preference for food odors over either amyl acetate or benzaldehyde. Type II cells constitute about 15% of the sample. They are characterized by frequent spontaneous EPSPs (up to 7 mV) and overshooting action potentials. No olfactory responses have yet been recorded from Type II cells.

The physiological data are consistent with previously published anatomical descriptions of the tentacle, which also indicate the presence of two cell types in the digitate extensions. Thus, following the anatomical classification, Type I cells are tentatively identified as receptors, and Type II cells are tentatively identified as interneurons.

84.6 LOCALIZATION OF DENDRITIC FIELDS AND TERMINAL ARBORIZATIONS IN SUSTAINING FIBERS OF THE CRAYFISH VISUAL SYSTEM. B. Waldrop and R.M. Glantz. Dept. of Biology, Rice Univ., Houston, Tx 77001

Sustaining fibers (SF's), tonic light-on cells, are functionally identified interneurons in the crayfish that transmit information from the optic ganglia to the brain via axons in the optic tracts. Fourteen SF's have been identified in each optic tract on the basis of their functional receptive fields.

We have impaled SF's and filled them with the fluorescent dye Lucifer Yellow (supplied by Dr. Walter Stewart of NIH), to visualize their morphological features. The major dendritic structures consist of a large transverse process, located along the proximal edge of the medulla externa, which gives rise to small fibers parallel to the long axis of the eyestalk. The small fibers project into the neuropile of the medulla externa. The terminal arborizations in the brain consist of tightly clustered varicosities located bilaterally at the bases of the optic tracts and in the optic neuropiles. Some fibers appear to project a fine axonal process to the contralateral optic tract. Electrophysiological studies of the same cells show that intracellularly injected current interacts with light-mediated synaptic input to determine the spike output frequency.

A major goal of this work is to correlate the dendritic distributions of identified interneurons with their visual receptive fields.

84.7 PATTERNS OF SYNAPTIC INTERCONNECTION IN THE DRAGONFLY LAMINA. Christine Armett-Kibel* and I.A. Meinertzhagen, Dept. of Biology, Univ. of Massachusetts-Boston, Boston, MA and Life Sciences Centre, Dalhousie University, Halifax, N.S. Canada.

Description of the connectivity between identified neurons is a major motivation for the analysis of simple nervous systems. A favourable system for that analysis is provided in the visual system of arthropods by the many parallel pathways between the compound eye and optic neuropiles. The modular synaptic composition of these neuropiles is analysed in the dragonfly (Sympetrum rubicundulum) in the unit module, or cartridge, of the outermost neuropile, or lamina. An ultimate goal is to arrive at a matrix of synaptic interconnections between the small, fixed number of uniquely identifiable elements constituting the lamina cartridge. A previous study (Meinertzhagen, Armett-Kibel and Frizzell: Cell Tiss. Res. 206: 395, 1980) reports the number of these elements as 16: 8 receptor axons, 2 of which (the long visual fibres) pass through the lamina; 5 monopolar cells and three additional unidentified cells all with axons. The cartridge thus receives an input from 8 receptor axons and has an output of up to ten axons which connect to a corresponding cartridge in the next most central neuropile, the medulla.

Synaptic connectivities of the five monopolar cells (the larger, MI & MII, and the smaller, hitherto undocumented MIII-MV) and two long visual fibres (R6, R7) have been analysed from extended series of electron micrographs. The analysis also uncovered the existence of another element (or elements) with widespread processes, and connectivities suggesting a role in intracartridge local circuit interactions.

Of the two long visual fibres, R6 is presynaptic only to the monopolar cell MII while R7 is presynaptic to both MII and MV. Thus, of the five monopolar cells, two (MI, MII) receive a general receptor input while a third (MV) has a receptor input exclusively from R7. MIV receives a small input from both MI and MIII. In addition, MIII and MIV are both postsynaptic to the unknown element of possible local circuit function. This element not only insinuates itself at a location postsynaptic to the chief receptor synapses upon MI and MII but also forms dyadic synapses upon receptors and other processes of its own kind (thus constructing possible reciprocal synaptic interconnections and serial synapses, respectively). MIII and MIV may substitute postsynaptically at either of these dyadic locations. There are similarities between the connectivities of the processes of this unidentified element and those of the α-β system in the fly's lamina.

84.8 IONIC MECHANISMS UNDERLYING LIGHT-EVOKED DEPOLARIZATIONS IN THE RETINA OF STROMBUS, A MARINE GASTROPOD. K.S. Chinn* and H.L. Gillary. (SPON: D. Russell). Bekesy Laboratory for Neurobiology, University of Hawaii, Honolulu, HI 96822.

The retinal type 2 cells of Strombus luhuanus described by Quandt and Gillary (J. Exp. Biol. 1979, 80, 287) show characteristic light-evoked depolarizations (LED). The responses to brief flashes of white light exhibited two peaks or phases (amplitudes ca. 15mV). The latency to the first peak was generally ca. 0.2 sec while that to the second was 0.5-1.0 sec. The ionic mechanisms underlying the LED were studied by examining the effects on intracellularly recorded potentials of perfusion media (modified ASW) having different ionic compositions or pharmacological agents. The experiments indicate: 1) The resting potential of these cells is governed primarily by $[K^+]$; the resting potential changed approximately 50 mV/10X $[K^+]_o$. 2) The LED was tetrodotoxin-insensitive, remaining unchanged at concentrations of up to $6x10^{-6}$M TTX. 3) Lowering $[Na^+]_o$ by replacement with choline or tetramethylammonium ions decreased both phases of the response. This decrease, approximately a linear function of log $[Na^+]_o$, was greater for the second phase than the first. 4) Total replacement of Na^+ with Li^+ markedly reduced phase 1 (in some cases to zero); this also reduced phase 2, but less than phase 1. 5) Lowering pH from 7.7 (normal) to 5.5 reversibly abolished phase 2 while phase 1 was only reduced after an initial increase. 6) The results of application of 4-amino pyridine and tetraethylammonium chloride suggest the occurrence during the LED of a K^+ current. The onset of this current occurs sometime during phase 1 and lasts throughout phase 2. 7) Input resistance decreased in two phases, corresponding to the respective phases of the LED. 8) Changing $[Ca^{++}]_o$, substituting Sr^{++} for $[Ca^{++}]_o$, or adding Mn^{++} markedly affected the waveform of the LED. Lowering $[Ca^{++}]_o$ increased the response amplitude. The results indicate that the LED arises from two separate Na^+ conductance increases as well as an increase in K^+ conductance. These conductance changes may be modified by divalent cations. (Supported by NIH Grant EY 01531).

84.9 GRADED NEURAL INTERACTION BETWEEN AXONS FROM THREE SIMPLE EYES OF AN INSECT. Charles P. Taylor* (SPON: C.H.F. Rowell). Grad. Group in Neurobiology, Univ. of California, Berkeley, CA 94720.

Axons in the nerve leading from the retina of one of the three dorsal ocelli (simple eyes) of a locust (Orthoptera, Acrididae) were studied by intracellular recording and dye injection with Lucifer Yellow. The three ocelli were stimulated independently by ON steps of light to investigate interactions between the three eyes.

Seven (10-20 μm diam.) anatomically identifiable large interneurons (LIs) lead from the retinal neuropile of the median ocellus to the brain (Goodman, 1976, Cell Tiss. Res. 175:183). In response to a flash of light(which depolarizes receptor cells) LIs hyperpolarize with a characteristic waveform which is similar to that observed in other invertebrate visual systems.

Three physiological categories of response to light ON were recorded from axons of the median ocellar nerve: 1) Hyperpolarization from median stimulus only; small amplitude depolarization from stimulation of either lateral ocellus. 2) Hyperpolarization from stimulation of either the median or one lateral ocellus (lateral stimulus produced smaller response); small amplitude depolarization from stimulation of the remaining lateral ocellus. 3) Hyperpolarization from stimulation of the median ocellus; smaller amplitude hyperpolarization from stimulation of either lateral ocellus. These categories could not be distinguished by stimulation of the median ocellus alone. Simultaneous stimulation of two or more ocelli caused summation of the responses.

Subsequent examination of dye fills made through the recording electrode revealed that category 1 corresponds anatomically to the two Ml-cells of Goodman which have a single axon leading from the median ocellar retina to the brain. Category 2 corresponds to the four ML-cells of Goodman which each have a large axon communicating between the retinas of the median and one lateral ocellus. Category 3 has tentatively been identified with the single M2-cell of Goodman.

The depolarizing responses were shown to accompany a decrease in membrane time constant, and were reversibly eliminated by bath application of picrotoxin (1 mg/ml) (which left the hyperpolarizing responses relatively unchanged).

One hypothesis which accounts for these results is that the ML-cells inhibit the response of the Ml-cells via a picrotoxin-sensitive mechanism. This would serve the behavioral function of the ocelli in registering changes of the animal's orientation with respect to the horizon (Taylor, in preparation). Responses caused by changes in illumination of the entire visual world would be inhibited, while stimuli to the median ocellus only would not.

85.1 FUNCTIONS OF OTOCONIAL AND AUDITORY ORGANS OF THE BULLFROG INNER EAR IDENTIFIED WITH INTRACELLULAR DYE. R. A. Baird, H. Koyama*, E. L. Leverenz*, and E. R. Lewis. Electronics Research Laboratory, University of California, Berkeley, CA 94720.

After functional identification, individual afferent fibers in the VIIIth nerve were iontophoretically filled with the intracellular fluorescent dye Lucifer Yellow and subsequently traced to their peripheral origins. To date, this study has provided direct corroboration of organ to organ functional divisions proposed as early as 1925 for the otoconial organs and papillae of the frog inner ear (McNally, W. & Tait, J., Am. J. Physiol. *75*: 155-174, 1925; Ashcroft, D.W. & Hallpike, C.S., J. Laryng. *49*: 450-458, 1934; Ross, D., J. Physiol. *86*: 117-146, 1936; MacNaughton, I. & McNally, W., J. Laryng. *61*: 204-214, 1946; Frischkopf, L., Capranica, R.R. & Goldstein, M.H., Proc. IEEE *56*: 969-980, 1968). In addition, it has demonstrated heretofore unsubstantiated functional divisions within three of those organs (Lewis, E.R. & Li, C.W., Brain Research *83*: 35-50, 1975; Lewis, E.R., Scanning Electr. Microsc. *9(2)*: 4-9-304, 1977). Approximately 100 fibers have been identified functionally and traced, and the results are summarized in the following table:

FUNCTIONAL DIVISIONS OF THE INNER EAR

FUNCTION	PERIPHERAL ORIGIN
Auditory (c.f. 1 kHz - 2 kHz)	Basilar papilla
Auditory (c.f. 400 Hz - 1 kHz)	Amphibian papilla (posterior)
Auditory (c.f. below 400 Hz)	Amphibian papilla (anterior)
Vibratory	Sacculus
	Lagena (striolar region)
Vestibular: responses to head position/linear acceleration	
Tonic only	Lagena (extrastriolar region)
	Utricle (extrastriolar region)
Phasic and Phasic/Tonic	Lagena (striolar region)
	Utricle (striolar region)

Some lagenar vibratory units also exhibited tonic response to head position. A few units in each of the two major branches of the VIIIth nerve exhibited both auditory and vibratory sensitivity, but were insufficiently filled with dye to be traced. The functional distributions listed in the table show marked correspondence to distributions of hair-cell morphological types observed by Lewis & Li (1975).

85.2 RECEPTOR ORGANIZATION IN THE UTRICLE OF THE GUITARFISH INNER EAR. Christopher Platt. Dept. Biological Sciences, Univ. Southern California, Los Angeles, California 90007.

The utricle of the inner ear is an otolith organ that often is considered to be gravistatic. But among elasmobranchs, some rays have a part of the utricular macula, the lacinia, which is covered only by otolithic membrane and responds to vibration (Lowenstein & Roberts, J. Physiol. 114:471, 1951). Recently, the guitarfish Rhinobatos productus, a more primitive elasmobranch, also has shown both gravistatic and vibrational sensitivity in the utricle (Budelli & Macadar, J. Neurophysiol. 42:1749, 1979).

It seemed pertinent to see whether the epithelial surface of the guitarfish utricular macula has regional structural differentiation that might relate to these functional distinctions. Fresh tissues were fixed in situ with buffered glutaraldehyde, removed and post-fixed with osmium tetroxide, and dried by the critical-point method for scanning electron microscopic study.

The utricle of small adults (ca. 1 Kg) contains roughly 100,000 hair cells in a rostro-caudally elongated macula of roughly 4 mm^2. Medially, the macular margin is quite sharply defined, but the lateral margin has an unusual fringed appearance, where narrow groups of hair cells interdigitate with narrow wedges of peripheral supporting cell groups. Cellular orientation is based on the asymmetric location of the single kinocilium in the apical ciliary bundle of each hair cell. Usually in vertebrates the utricular pattern contains only two groups of oppositely oriented cells, separable by a single dividing line. The guitarfish pattern instead confirms earlier TEM reports of "patchy" distributions in the ray; a local clump of cells sharing the same orientation may be surrounded by a population of the opposite orientation. The utricular floor contains large areas of similarly oriented cells, with a few boundary lines that can be drawn; but the lacinia, extending caudally up the utricular wall and roof and covered only by otolithic membrane as in the ray, has a much finer grain of patchiness. The predominant orientation over the whole macula is transverse to the long axis. Hair cell bundles show a variety of forms similar to those in teleosts. Short kino- and stereocilia occur at the macular edge, long kinocilia with short stereocilia occur near the margins, but over most of the macula the cells have kinocilia 5-8 μm long and tallest stereocilia of 3-7 μm. There is not as clearly distinct a striolar band of prominent hair cells as in many teleosts.

The difference in otolithic covering and the difference in patchiness between utricle and lacinia are not accompanied by other surface features distinctly different enough to suggest regional differentiation of gravistatic and vibrational reception in the guitarfish.

85.3 VESTIBULOTOXICITY IN THE CHICK CAUSED BY STREPTOMYCIN. J. C. Park and G. M. Cohen. Department of Biological Sciences, Florida Institute of Technology, Melbourne, Florida 32901.

We are using the chick as a model system for auditory and vestibular studies. In the present experiments, 7 day-old male white leghorn chicks were injected daily for as many as 30 days in different subcutaneous sites on the breast with streptomycin sulfate at one of three dosages: 400, 800, or 1200 mg/kg. The birds were weighed daily to determine rates of growth and tested for impaired equilibrium. Birds were sacrificed daily to follow cytopathic changes in the cristae ampullares using light and electron microscopy.

Bodily growth and maturation continued normally but growth lagged slightly at 800 mg/kg before catching up by the second week. The birds began to tremble by the third day at the two higher dosages and by the fifth at the lowest. By the 14th injection, one-third of the birds trembled at least mildly and two-thirds trembled moderately or severely. However, the tremor began to subside shortly thereafter, possibly because of visual and proprioceptive compensation. The birds perched on wooden dowels for tests of vestibular function. When hooded, birds displayed moderate to severe dysequilibular symptoms. In some instances, the birds could not maintain their balance on the dowel even when unhooded. Controls showed no disabilities under either condition.

In the ampulla, dark cells were damaged earlier than other cell types. The first intoxicatory symptoms appeared regularly by the third injection. Cytopathic changes involved retraction of basal processes, vacuolization of cytoplasm, mitochondrial damage, and rearrangement of organelles. Resistant dark cells showed little, if any, intoxicatory damage but they accumulated glycogen, in both the somata and basal processes. Severely damaged dark cells often abutted intact ones. The small, cuboidal dark cells, located on the ampullary periphery, were most sensitive, whereas the larger, columnar cells, flanking the crest, were most resistant. (Supported in part by NIH grant RR09032)

85.4 DIFFERENCES BETWEEN PROPERTIES OF AFFERENTS INNERVATING HORIZONTAL AND VERTICAL CANALS OF THE BULLFROG. Robert J. Peterka* (SPON: David L. Tomko). Electrical-Biomedical Eng. Dept., Carnegie-Mellon Univ. and Dept. Otolaryngology, Univ. of Pittsburgh, School of Medicine, Pittsburgh, PA 15213.

The amplitude of displacement of a point within the bullfrog's horizontal canal (HC) cupula was shown to depend on the location of that point (McLaren and Hillman, Neuroscience 4: 2001-2008, 1979). McLaren also found differences in response properties of afferents innervating different portions of the HC crista (doctoral thesis, 1977). It was postulated that these differences may result from local variations in the displacement of the cupula. Since the shapes of vertical canal (VC) critae and cupulae resemble one another but differ somewhat from the configuration of the HC crista and cupula (Hillman, Brain Behav. Evol. 10: 52-68, 1974), one might expect that properties of VC afferents would also resemble one another and differ from those of the HC afferents.

To test this, resting discharge and dynamic response properties of eighth nerve afferents innervating all three canals of adult bullfrogs were characterized using data from intracranial, extracellular single unit recordings. Response parameters were obtained using transfer function curve fits to gain and phase data determined from responses to pseudorandom stimulation. Properties of VC afferents were similar to one another but differed from those of the HC afferents in certain aspects. Compared to the VC afferents, a larger proportion of HC cells had 1) high resting discharge rates (greater than 10 spikes/sec), 2) low coefficients of variation (less than 0.4), 3) large gain constants (greater than 20 spikes-sec^{-1}/deg-sec^{-2}), and 4) longer time constants (greater than 5 sec). Afferents which did not show any evidence of response adaption were also more prevalent in the HC afferent population than in the VC cells. Finally, there was no correlation between gain constant and time constant parameters from VC cells, whereas the relationship between these parameters for HC afferents indicated that the population could be clearly divided into two groups. One group consisted of high gain, short time constant cells; the other contained a wide range of time constants but had lower gains.

Most of the average differences between HC and VC afferent response parameters and resting discharge properties were not large since the differences usually occurred in the tails of the distributions of these values. However, taking the data as a whole, the conclusion that the population of HC afferents had certain properties which differed from those of the VC's appeared to be reasonable. Whether or not these differences are directly correlated with cupula structure remains to be determined.

85.5 CORRELATION OF SEMICIRCULAR CANAL AFFERENT RESPONSE DYNAMICS WITH SWIMMING MOVEMENTS IN THE GUITARFISH. D.P. O'Leary and R.F. Dunn, Div. Vestibular Disorders, Dept. Otolaryngology, Univ. of Pittsburgh School of Medicine, Eye and Ear Hospital, Pittsburgh, PA 15213.

Dynamic response characteristics of vertical semicircular canals are thought to be similar to those from horizontal canals of the same mammalian species. But analyses of different canal diameters in fish showed significant differences, that were considered, on the basis of biophysical modeling, to be correlated with the different dynamic ranges of swimming movements that stimulate vertical as opposed to horizontal canal planes (Howland and Mascii, J. Embryol. exp. Morph., 29, 721, 1973). Our data from first-order canal afferents of the guitarfish show directly that the response dynamics of vertical and horizontal canals differ in ways that match the swimming dynamics of this animal.

Isolated labyrinths of the guitarfish (Rhinobatos productus) were aligned at the center a computer-controlled turn table for maximal stimulation of either the horizontal or anterior canal planes. Bandlimited white noise rotational acceleration stimuli were used to characterize the response dynamics of each afferent unit, through cross-correlation and cross-spectral analyses. Two major classes of response dynamics were observed from horizontal canal afferents, those maximally sensitive to fast head movements versus those sensitive to slow movements (O'Leary, Dunn & Honrubia, J. Neurophysiol., 39, 631, 1976). In contrast, only responses from the slow movement class were observed from anterior canal afferents, although systematic recordings were made from afferents shown to innervate specific regions of both cristae (Dunn, J. Comp. Neurol. 183, 779, 1979; Dunn and O'Leary, these abstracts 1980). Plots of gain versus frequency of afferent responses showed average gains from anterior canal cells that were 1/10 those of the fast class of horizontal canal cells, at frequencies above 1 Hz.

Profile drag measurements on the cartilaginous head were made to determine differences in drag coefficients during slow underwater rotations about the guitarfish's three principle axes. The arrowhead shape of the head, with broad dorsal and ventral surfaces, results in side-to-side swimming movements with drag coefficients that are at most 1/12 those of movements about roll or pitch axes. These theoretical predictions were confirmed by observations of 16 mm films and a computer simulation of swimming guitarfish. Swimming head movements that occur in planes that stimulate horizontal canals are faster, because of profile drag, than those that occur in planes that stimulate vertical canals. This behavioral difference is correlated with our finding that a fast class of afferent responses was present in horizontal canal fibers that was not observed in anterior canal fibers.

(Supported by NIH Grant NS-12494).

85.6 SPATIAL DISTRIBUTION OF NERVE FIBERS THROUGH THE ANTERIOR AMPULLARY NERVE IN GUITARFISH. R.F. Dunn and D.P. O'Leary, Div. Vestibular Disorders, Dept. Otolaryngology, Univ. of Pittsburgh School of Medicine, Eye & Ear Hospital, Pittsburgh, PA 15213.

The anterior ampullary nerve (AAN) approaches the anterior ampulla as a single nerve trunk which branches close to the ampulla. All nerve fibers approach the ampulla at right angles to the longitudinal axis of the anterior crista. The nerve bundles form a fan in a medial-lateral plane relative to the head. The medial and lateral bundles are quite large; each containing 35-40% of the nerve fibers contained in the AAN. The remaining 20-30% of the AAN fibers are divided into 9-11 small central bundles. Projection patterns made by the nerve bundles onto the anterior crista are: medial bundle to the medial crista bulbus; the small central bundles to the crista angustarum; and the lateral bundle to the lateral crista bulbus.

Taking advantage of this projection pattern to the anterior crista, it is possible to record from specific regions of the crista (i.e. each crista bulbus and the crista angustarum), and to compare the impulse responses between these areas. Further, the AAN responses can be correlated to those previously observed in the horizontal ampullary nerve (O'Leary, D.P., et al, J. Neurophysiol., 39: 631, 1976). It is therefore relevant to determine the course of nerve fibers comprising each nerve bundle group within the AAN since the recordings are generally obtained from nerve fibers in the AAN trunk.

Consecutive serial one micron cross sections were prepared from Araldite 502 embedded AAN. The series began at the anterior crista, proceeded centralward through the bundles to include 1.5 mm of the AAN trunk. Every sixth section was photographed, and the nerve fibers were color-coded on each photograph. When the small central bundles were considered collectively, they retained their central position within the AAN with some displacement caudally by the medial bundle nerve fibers, and rostrally by the lateral bundle fibers. Based upon these preliminary findings, it appears that the AAN trunk is organized such that nerve fibers in the medial portion of the AAN trunk project to the slopes and crest of the medial crista bulbus; the central fibers innervate the slopes and crest of the crista angustarum; and the lateral fibers project to the slopes and crest of the lateral crista bulbus.

85.7 EFFERENT VESTIBULAR NEURONS PROJECT TO VARIOUS SEMICIRCULAR CANAL CRISTAE IN BOTH LABYRINTHS WITH AXON COLLATERALS. D.W.F. Schwarz, Sat Bir Khalsa*, I.E. Schwarz*, and J.P. Landolt. Lab. of Otoneurology, Univ. of Toronto, Toronto, Ont. Canada.

We attempted to assess the specificity of efferent vestibular control by determining how discrete efferent projection to individual semicircular canals is organized, using morphological and electrophysiological techniques in pigeons. A large proportion of efferent neurons recorded extracellularly in the caudal pontine reticular nucleus responded with antidromic spikes to discrete electrical stimuli of more than one semicircular canal nerve in the same labyrinth. A number of cells could be so excited by such stimuli in either labyrinth. Many efferent neurons can be retrogradely labelled by HRP injected in one crista as well as by [^{3}H]- Adenosine in another crista. A smaller number of cells can be retrogradely labelled by injection of Evan's Blue into all cristae of one side and also by Bisbenzimide into all cristae of the other side. The extensive collateralization of individual efferent axons within the labyrinths demonstrated by these experiments explains the lack of a topographical separation of efferent neurons projecting to different cristae. It is also explained why there is no systematic increase in the number of retrogradely labelled cells when an increasing number of cristae is injected. It must be concluded, that efferent control can hardly be specific for directions of head rotation.

85.8 MECHANISMS DETERMINING STEADY-STATE DISCHARGE PATTERNS AND RESPONSE DYNAMICS OF VESTIBULAR AFFERENTS. J.M. Goldberg, C.E. Smith* and C. Fernández*. Univ. Chicago, Chicago, IL 60637

Vestibular afferents characterized as regularly or irregularly discharging differ in several other respects, including fiber caliber, afferent response dynamics and response to efferent stimulation. We were interested in examining the mechanisms responsible for differences in discharge regularity. At least two possibilities need to be considered. Afferents could differ in (1) the "noisiness" of their synaptic input or (2) their post-spike recovery times. The two mechanisms lead to different predictions concerning the response to galvanic currents. If post-spike recovery were involved in determining variations in discharge regularity, then irregular afferents should be more sensitive to galvanic currents than are regular afferents. In contrast, variations in synaptic noise should not influence galvanic sensitivity.

Vestibular-nerve recordings were made in barbiturate-anesthetized squirrel monkeys. Electric currents of 5-sec duration were delivered via an electrode implanted in the perilymphatic vestibule. Excitatory (cathodal) and inhibitory (anodal) responses were similar in magnitude and both were linearly related to current strength. Galvanic sensitivities were 5-10x greater in irregular, as compared to regular, units. A parallel difference in sensitivities was observed when 50-μsec shocks were used. Shock-response times were brief (ca. 0.3 msec) so as to preclude the involvement of synaptic mechanisms. Galvanic responses can be silenced by inhibitory head rotations, suggesting that the currents act on the afferent terminal, rather than on the parent axon. Post-spike recovery was measured by determining short-shock thresholds at several fixed times after naturally occuring action potentials. Irregular units had faster recovery times than did regular units, showing that differences in galvanic responses cannot be solely explained by variations in the afferents' passive electrical properties. The faster recovery of irregular afferents should make them more sensitive to synaptic, as well as to artificial, currents. Irregular discharge, it may be suggested, offers no functional advantage in its own right. Rather it is a necessary consequence of the mechanisms leading to an enhanced sensitivity.

Comparisons were made of the afferents' responses to sinusoidal galvanic currents and sinusoidal head rotations. Velocity-sensitive response dynamics, including a high-frequency gain enhancement and phase lead, were seen during natural, but not during galvanic, stimulation. The velocity-sensitive response dynamics would thus appear to arise at a relatively early stage of the transduction process.

85.9 AFFERENTS TO THE VESTIBULAR COMPLEX IN RAT. A HORSERADISH PEROXIDASE STUDY. J. A. Rubertone* and W. R. Mehler (Spon. J. Norvell.) NASA-Ames Research Center, Biomedical Research Division, Moffett Field, Ca. 94035.

Rats are used extensively in biomedical studies related to the rigors of space flight. Most of this experimentation is concerned with various physiological responses to labyrinthine mediated stimuli. An accurate interpretation ofsuch data relies on a complete understanding of the vestibular system in rat. A review of the literature, however, reveals a relative paucity of data on vestibular connectivity in rat.

The present study is the first in a series of experiments designed to illucidate the afferent and efferent connections of the rat vestibular complex. Vestibular nuclei and subgroups were injected stereotactically with horseradish peroxidase (Sigma VI) in 18 cases to date. Iontophoretic injections were performed at a current of 1.0-3.0 μa using micropipettes ranging from 20-60 μm in tip diameter. Following survival times of 23-48 hours animals were perfused with 0.9% heparinized saline followed by a buffered 1.5% glutaraldehyde, 1.0% paraformaldehyde solution. Following immersion in a buffered 30% sucrose solution for 15-24 hours brains were frozen and sectioned at 50 μm in either transverse, parasagittal or horizontal planes. Sections were collected and processed according to the diaminobenzidine (Graham, R. C. and M. J. Karnovsky, J. Histochem. Cytochem., 14:291, 1966), benzidine dihydrochloride (Mesulam, M-M., J. Histochem. Cytochem., 24:1273, 1976), and tetramethyl benzidine techniques (Mesulam, M-M., J. Histochem. Cytochem., 26:106, 1978). All sections were examined under both light and dark field microscopy. Injections of the spinal vestibular nucleus (SpVN) resulted in HRP-labeled neurons in the central cervical nucleus and superior vestibular nucleus (SVN) bilaterally. Contralateral labeling also occurred in the SpVN, medial vestibular nucleus (MVN) and fastigial nucleus. HRP-positive cells were present in similar locations following injections of MVN. Injections of SVN resulted in labeled somata in the contralateral SpVN, MVN, SVN, and subgroup y. The connectivity of the lateral vestibular nucleus as well as the question of vestibular afferents originating in the reticular formation and regions other than the cerebellum will be discussed.

85.10 VISUAL AND GRAVICEPTIVE INFLUENCES ON LOWER LEG EMG ACTIVITY DURING BRIEF FALLS Roger W. Wicke* and Charles M. Oman
Man Vehicle Laboratory, Massachusetts Institute of Technology, Cambridge, MA 02139

Human subjects were suspended in a safety harness 17 inches above the floor by a steel cable connected to a computer controlled force generator (magnetic particle brake). After the subjects were unexpectedly released, various controlled patterns of downward acceleration (less than 1 G) could be produced. During the falls, EMG activity was recorded simultaneously from the gastrocnemius, soleus, tibialis anterior, rectus femoris, and biceps femoris, along with knee and ankle joint angle in one leg. Subjects were tested eyes closed and also eyes open, both in darkness and in light using a wide field visual display. The display scene could be moved downwards at exactly the same velocity as the moving subject, left fixed with respect to the laboratory ("normal visual field"), or moved upwards at a speed equal to the subject's falling velocity ("upward moving visual field"). Ten vestibularly normal subjects each underwent a total of 45 drops, experiencing 3 replications of each vision/motion combination used. Under normal visual field conditions, both short and long latency EMG responses were seen, which were dependent on the magnitude of the acceleration stimulus. Certain of the visual conditions significantly altered both the short and the long latency responses in most of the muscles tested. Effects were particularly prominent in the gastrocnemius and soleus, and were also more pronounced during slow (0.5 G) falls. The upward moving visual field condition increased the short latency EMG reaction in gastrocnemius and soleus. A preliminary model for visual-vestibular interaction in short latency EMG responses is presented.

85.11 RESPONSE CHARACTERISTICS OF VESTIBULOSPINAL NEURONS OF DIFFERENT SIZES TO SINUSOIDAL STIMULATION OF MACULAR LABYRINTH RECEPTORS. R.Boyle* and O.Pompeiano. Ist.Fisiologia Umana, Catt.I, Univ. di Pisa, 56100 Pisa, Italy.

The functional significance of cell size within the lateral vestibular nucleus of Deiters (LVN) has been investigated in decerebrate, cerebellectomized cats by recording the responses of vestibulospinal neurons to natural stimulation of macular labyrinth receptors and correlating these responses with the conduction velocity (CV) of the corresponding axons. Only antidromically identified neurons projecting to the lumbosacral segments of the spinal cord (lLVN) were tested during slow sinusoidal tilt around the longitudinal axis at 0.026 Hz (10° peak amplitude).

CV of the recorded units varied from 45.0 - 118.7 m/sec (mean: 84.3 ± 17.1, S.D., m/sec). An inverse correlation was found between CV and resting discharge rate, which ranged in different units from 1.7 - 134.4 imp./sec (mean: 44.5 ± 22.7, S.D., imp./sec). 80/136 (i.e. 58.8%) units responded with a periodic modulation of their firing rate to the sinusoidal input. The higher the CV, the greater was the sensitivity of the first harmonic of the response, expressed in percentage change of the mean discharge rate per degree of displacement; this was a general finding, which indicates that the pool of lLVN neurons represents a rather homogeneous population of cells, differing only in size and in certain size-dependent properties. However, within individual experiments units were encountered which had comparable CV but large variations in resting discharge rate and response sensitivity, or the converse. These observations suggest that size-independent differences in both firing rate and sensitivity depend either or intrinsic neuronal properties or on differences in connectivity of the macular labyrinth input on cells of similar size.

Most of the responses of lLVN neurons to tilt were related to the direction of stimulus orientation, 48/80 (i.e., 60.0%) units excited during side-up tilt and 21/80 (i.e., 26.2%) units excited during side-down tilt. The units of the former group had a significant slower CV, higher resting discharge rate and lower response sensitivity than those of the latter group. However, exceptions to this rule were observed in individual experiments.

85.12 CORTICO-CORTICAL CONNECTIONS TO THE VESTIBULAR CORTICAL AREAS IN THE CAT. R. Ramírez-Camacho*, C. Avendaño and F. Reinoso-Suárez. Dep. Morfología, Fac. Medicina, Univ. Autónoma, Madrid 34, Spain.

Two areas have been defined in the cat's cerebral cortex from which short-latency potentials are recorded after vestibular stimulation: one situated in the anterior suprasylvian sulcus (ASSS) and another in the region of the postcruciate dimple (PCD), in the posterior sigmoid gyrus. Both areas are topographically included within Woolsey's area SI. Although there is a good deal of information regarding the cortico-cortical connectivity of SI, both by morphological and electrophysiological methods, only brief comments are found on the cortical input to these particular areas.

We have made unilateral single or multiple injections of a 50% solution of HRP either in ASSS or PCD of adult cats. Total volumes injected ranged between .06 and 1.0 μl. Controls received similar injections in other portions of SI and in SII. After 48 h survival animals were perfused and brains processed according basically to Graham and Karnovsky (1966) and Mesulam (1978) procedures.

Area PCD receives a fairly large number of projections from the rest of the posterior sigmoid gyrus (all layers, mainly III and VI), the anterior portion of the lateral gyrus (layer V), the posterior portion of the coronal gyrus (predominantly layers II and III) and the infero-posterior portion of the anterior ectosylvian gyrus (layers II-VI). The connections to the vestibular area in ASSS have a similar origin, although showing a distinctive topography: the anterior portion of ASSS receives connections from the posterior sigmoid gyrus; the middle portion from the anterior portion of the lateral gyrus and the posterior portion of the coronal gyrus, and the caudal portion from most of the anterior ectosylvian gyrus, except from that region projecting on PCD. Further, a consistent projection was found from the bottom and lateral bank of the posterior rhinal sulcus (layer V) to the upper bank of ASSS.

Contralaterally, fewer projections were observed, although their topographical arrangement was essentially the same.

86.1 POSSIBLE INVOLVEMENT OF BRAIN EPINEPHRINE IN CONTROL OF LUTEINIZING HORMONE SECRETION IN RATS. W.R. Crowley and L.C. Terry, Depts. of Pharmacol. and Neurol., Univ. of Tenn. Cntr Hlth Sci., Memphis, TN 38163.

Norepinephrine has been proposed as a stimulatory neurotransmitter for the secretion of Luteinizing Hormone (LH) because noradrenergic receptor blockers and synthesis inhibitors interrupt episodic LH release, block ovulation and prevent the stimulatory effects of ovarian hormones. However, these drugs should also interfere with central epinephrine neurotransmission. The purpose of the present study was to test whether brain epinephrine (EPI) systems may also be involved in control of LH secretion. Sixty day old female rats were ovariectomized and allowed 4 week's recovery. One group of females received 50 ug estradiol benzoate subcutaneously and were sacrificed 2 hr later (acute inhibitory feedback). A second group received 50 ug estradiol, followed 72 hr later by 2 mg progesterone and were killed 6 hr later (stimulatory feedback). A third control group were given oil vehicle only. Thirty minutes prior to these injections, one half of the animals in these 3 groups were treated with 50 mg/kg of 7,8 dichloro-1,2,3,4-tetrahydroisoquinoline (SKF64139), an agent that blocks epinephrine synthesis by inhibiting the activity of phenethanolamine-N-methyltransferase. Animals treated with estrogen plus progesterone also received a second injection of this drug 2.5 hr after progesterone. The remaining rats received saline vehicle. After decapitation, trunk blood was collected and LH concentrations were determined by a double antibody radioimmunoassay, using NIAMDD procedures. Levels of catecholamines in the hypothalamus were measured with a radioenzymatic assay.

In the ovariectomized, hormonally untreated rats, SKF64139 significantly decreased plasma LH levels (200 $\pm$ 22 ng/ml vs 288 $\pm$ 18 ng/ml), and completely suppressed the surge of LH induced by estrogen plus progesterone (151 $\pm$ 26 ng/ml vs 671 $\pm$ 118 ng/ml). The drug also tended to potentiate the acute inhibitory effects of estradiol alone (115 $\pm$ 13 ng/ml vs 162 $\pm$ 14 ng/ml). The concentrations of EPI in the hypothalamus were significantly reduced by SKF64139 in oil vehicle-(-33%)and in estrogen plus progesterone-treated rats (-35%), but there were no significant changes in hypothalamic concentrations of norepinephrine or dopamine. These results suggest (1) that EPI may participate in the physiological regulation of LH secretion and (2) that the inhibitory effects on on LH release observed with adrenergic antagonists may be due to an action on brain epinephrine systems.

86.2 OPIATES AND AGGRESSION IN FEMALE DEERMICE. H. Monder, N. Yasukawa* and J. J. Christian*. Dept. of Biological Sciences, State Univ. of New York at Binghamton, NY 13901.

Female deermice (Peromyscus leucopus) show increased levels of aggression against other females during proestrus, late in pregnancy, and during the first week of lactation. These periods are associated with increased serum levels of prolactin (PRL). Injections of PRL produce increased aggressive behavior in female deermice against other female mice (Gleason et al., submitted).

Morphine produces increased levels of serum PRL, while naloxone reduces PRL levels in rodents. To determine if pharmacological manipulation of PRL levels affects aggression, female P. leucopus were injected with either 1.0 or 2.0 mg/kg morphine sulfate, 1.0 mg naloxone HCl, or the drug vehicle. Injected animals were observed, under red light, during the dark part of the illumination cycle. Injections were given ½ an hour before testing. Immediately after injection animals were placed in a 'neutral arena'; a plastic cage with an opaque central divider. A noninjected naive female was placed on the other side of the divider. The central divider was removed and the animals were observed for 10 minutes.

Control animals in diestrus did not show aggressive behavior against the noninjected opponent. Those animals treated with the lower dose of morphine did not differ from controls. All the animals treated with 2 mg/kg morphine sulfate attacked their opponents. However, attacks were initiated only if the opponents approached the treated animal. Morphine treated animals were not aggressive, but also did not show any submissive behavior. They approached and attempted to sniff and groom their opponent.

These studies indicate that morphine and naloxone affect aggressive behavior in mice. Further studies are underway to determine if these behavioral changes are due to the effects of the drugs on hormonal levels.

86.3 MORPHINE EXERTS TESTOSTERONE-LIKE EFFECTS IN THE HYPOTHALAMUS OF THE CASTRATED MALE RAT. T. J. Cicero, E. R. Meyer*, S. M. Gabriel*, R. D. Bell*, and C. E. Wilcox*. Dept. of Psychiatry, Washington University School of Medicine, St. Louis, MO 63110

Previous research has indicated that endogenous opioids participate in the regulation of activity in the hypothalamic-pituitary-luteinizing hormone (LH) axis and mediate the negative feedback control exerted by testosterone. If this assumption is correct, then two predictions can be made. First, the effects of testosterone should be competitively inhibited by narcotic antagonists; and, second, opiates should mimic the acute and chronic effects of testosterone in the castrated male rat. The results of the present investigations support both of these predictions. We found that naloxone competitively antagonized the depressive effects of testosterone on serum LH in the castrated rat and, conversely, that testosterone competitively antagonized the LH-releasing properties of naloxone. In addition, morphine and testosterone both depressed serum LH levels in a dose-dependent fashion in the acutely castrated animal. Moreover, morphine was just as effective as testosterone in reversing the castration-induced fall in hypothalamic-LH-releasing hormone (LH-RH), which occurs in the chronically castrated male rat. On the other hand, morphine failed to reverse the long-term changes in pituitary LH content and increase in serum LH, which is consistent with prior observations that morphine affects only the hypothalamic aspect of the hypothalamic-pituitary-LH axis in the male rat. These results thus support the concept that an as yet unidentified opioid-containing neuronal system regulates activity in the hypothalamic-pituitary-LH axis and mediates the effects of testosterone on this axis.

86.4 FURTHER EVIDENCE THAT REPEATED ADMINISTRATION OF 5-METHOXY-N,N-DIMETHYLTRYPTAMINE TO MALE RATS INCREASES THE SENSITIVITY OF POSTSYNAPTIC SEROTONIN RECEPTORS INVOLVED IN PROLACTIN SECRETION. M.Simonovic and M.Y.Meltzer, Depts. of Psychiatry and Pharmacological and Physiological Sciences, University of Chicago Pritzker School of Medicine, Chicago,Illinois 60637.

Rat prolactin (PRL) secretion can be stimulated through a serotonin(5HT)-dependent process. A potent 5HT agonist, 5-methoxy-N,N-dimethyltryptamine (5DMT) elevates serum PRL levels in male rats. We have recently reported (Eur.J.Pharmacol.58:399,1979) that repeated administration of 5DMT (5mg/kg,ip, every 3 hours for a total of 4 injections) has no effect on resting serum PRL levels 3 hrs after the last pretreatment dose, but it greatly potentiates PRL-releasing effect of a number of 5HT agonists including 5DMT. Stimulation of presynaptic 5HT receptors by 5DMT inhibits the activity of central 5HT neurons. We have hypothesized that repeated 5DMT administration, according to the schedule outlined above, may, by virtue of its greater and longer-lasting presynaptic effects, produce prolonged disruption of central 5HT transmission and lead to increased sensitivity of postsynaptic 5HT receptors.To further test this hypothesis we have studied the effect of this drug treatment on the hypothalamic 5HT levels and turnover. Repeated administration of 5DMT had no effect on the steady-state 5HT levels, but it significantly decreased the rate of hypothalamic 5HT accumulation after the inhibition of brain monoamine oxidase with pargyline (75 mg/kg,ip). These results are consistent with the hypothesis that repeated 5DMT administration decreases the activity of central 5HT neurons. Inhibition of 5HT synthesis with p-chlorophenylalanine (PCPA, 300 mg/kg,ip, 24 hrs earlier) markedly lowered (-70%) hypothalamic 5HT levels. PCPA treatment, like the repeated 5DMT administration, potentiates PRL response to serotonergic stimulation. Repeated administration of 5DMT to PCPA-treated rats did not further potentiate PRL stimulation by 5DMT. Enhanced PRL response to 5HT stimulation was evident after one or four days of repeated 5DMT administration. Similar results were obtained 24 hrs after acute or chronic (200 mg/kg,ip, daily, 4 days) administration of PCPA. These results show that enhanced PRL response to 5HT agonists persists as long as the interference with the serotonergic transmission.

These results are consistent with the hypothesis that repeated 5DMT administration increases sensitivity of postsynaptic 5HT receptors involved in the regulation of rat PRL secretion. The importance of 5DMT dose and inter-dose interval will also be discussed.

86.5 ACUTE ADMINISTRATION OF CLONIDINE ELEVATES PLASMA CONCENTRATIONS OF IMMUNOREACTIVE BETA-ENDORPHIN IN RATS. D.J. Pettibone and G. P. Mueller. Department of Physiology, Uniformed Services University of the Health Sciences, Bethesda, MD. 20014.

Several studies have demonstrated recently that the systemic administration of the alpha-adrenergic agonist, clonidine ($CATAPRES_R$), produces analgesia in rats and mice. Since the release of pituitary opiate peptides has been implicated in the mechanisms of certain forms of analgesia (i.e. stress-induced, acupuncture), we have studied the effects of clonidine administration on plasma levels of beta-endorphin (B-END) as measured by radioimmunoassay. This RIA detects less than 10 pg B-END immunoreactivity and exhibits negligeable cross-reactivity with related peptides including beta-lipotropin (<3%)(Mueller, Endo., A518, 1979).

The subcutaneous (s.c.) administration of clonidine·HCL (0.5 mg/kg) to male, Sprague-Dawley rats (150-200g) maximally raised ($p<0.05$) plasma B-END concentrations from a control value of 0.22 ± 0.04 ng/ml ($\bar{x}$ ± SEM) to 0.59 ± 0.05 ng/ml by 15 minutes post-injection. This rise in plasma B-END, which returned to control levels within 60 minutes after injection, was dose-dependent up to 0.5 mg/kg; larger doses (1 or 2.5 mg/kg, s.c.) had no further effect. The administration of alpha-adrenergic blocking agents, phentolamine (1, 3, or 10 mg/kg,i.p.)or yohimbine (1 mg/kg,i.p.), 30 or 60 minutes, respectively, before clonidine (0.5 mg/kg,s.c.) produced a 50% inhibition of the clonidine-induced elevation in plasma B-END concentrations. In contrast, the rise in plasma B-END produced by clonidine was not altered by a beta-receptor antagonist, propranolol (1 or 5 mg/kg, i.p.), when given 45 minutes before clonidine. None of the adrenergic blocking agents alone significantly influenced basal levels of plasma B-END.

These data suggest that the acute administration of clonidine to rats enhances the release of pituitary B-END partly through the activation of alpha-adrenergic receptors. It is presently unknown whether clonidine is acting directly at the level of the pituitary or at sites within the central nervous system. The extent to which the effects of clonidine on pituitary B-END release may be related to the drug's analgesic properties remains to be determined.

86.6 A POSSIBLE INHIBITION BY ENDOGENOUS OPIATES ON THE PROGESTERONE-INDUCED LH SURGE IN LONG-TERM OVARIECTOMIZED FEMALE RATS. E. Terasawa, L.V. Rubens*, W.E. Bridson* and D.W. Lincoln Wisc. Reg. Primate Res. Ctr., Univ. of Wisc., Madison, WI 53706

It has been suggested that endogenous opiates are involved in controlling the release of oxytocin by a presynaptic inhibitory mechanism (Clarke et al., Nature, 282:746-748, 1979). In order to determine the possible involvement of an opioid mechanism in LHRH release, the effect of naloxone on the progesterone-induced LH surge was examined in ovariectomized estrogen primed rats. Normal cyclic female rats of Sprague-Dawley strain were ovariectomized at one of two times prior to the experiments either 4-6 weeks (long-term OVX) or 2-3 days (short-term OVX). They were housed under controlled illumination, 14 h light (500-1900) and 10 h darkness. All animals were injected s.c. with 5 µg estradiol benzoate at 1200 (day 0) and received an indwelling catheter implantation in the external jugular vein under ether anesthesia between 1000-1200 on day 1. On day 2, 1.0 mg progesterone was injected s.c. at 1200, and naloxone was administered at 1400, 1600 and 1800. Serial blood samples (0.5 ml) were obtained through the catheters at 1130, 1300, 1430, 1630, 1830, and 2030, and plasma LH was measured by means of RIA. Baseline LH values before progesterone injection in long-term OVX animals were higher than those in short-term OVX animals. A progesterone-induced LH surge attained its peak at 1630 in both long-term OVX and short-term OVX controls. The magnitude of the LH surge in both control groups did not differ. Naloxone injections, however, greatly enhanced the magnitude of the progesterone-induced LH surge in long-term OVX animals ($df = 1,15$, $F = 6.25$, $p < 0.025$, ANOVA2), whereas, it did not induce significant effects in short term OVX animals ($df = 1,13$, $F = 1.87$, $p > 0.10$).

Therefore, it is suggested that endogenous opiates inhibit the progesterone-induced LH surge in long-term ovariectomized estrogen-primed rats. However, the reason for the lack of response to naloxone in short-term ovariectomized animals, remains unknown.

86.7 EFFECTS OF DIAZEPAM WITH XYLAZINE ON GONADOTROPIN RELEASE IN THE FEMALE RAT. J.A. Keller-Halbe, B.K. Jenkin *, D.W. Lincoln and E. Terasawa. Wisc. Reg. Primate Res. Ctr., Univ. of Wisc., Madison, WI 53706

Because most anesthetic drugs, such as barbiturates and urethane, interact with neurosecretory cells in the medial preoptic area and the hypothalamus, suitable anesthetics for neuroendocrine research have yet to be established. Since the combination of diazepam, a sedative, and xylazine (α_2 - adrenergic agonist), a nonnarcotic analgesic, does not block suckling-induced oxytocin release (Lincoln, unpublished), an attempt was made in the present study to determine whether this anesthetic combination would be suitable for research in reproductive neuroendocrinology. In the 1st experiment, effects on spontaneous ovulation of the combination of xylazine and diazepam were compared to the effects of diazepam in combination with fentanyl, a narcotic analgesic. Regular 4 and 5 day cyclic rats, confirmed by daily vaginal smears, were housed in a room lighted 14 h (500-1900 h) and determined for critical period of ovulation on the afternoon of proestrus by pentobarbital injections. Administrations of 6 mg/kg diazepam and 6 mg/kg xylazine before the critical period induced anesthesia for 179 ± 3 min (N=11 ataxia and no withdrawal reflex), but did not block spontaneous ovulation (9 of 11 animals ovulated, 12.6 ± 0.6 ova/ovulating animal were counted). In contrast, injections of 12 mg/kg diazepam and 60 µg/kg fentanyl induced a similar period of anesthesia, 189 ± 12 min (N=8), and blocked spontaneous ovulation (1 of 8 animals ovulated). In the 2nd experiment, effects of diazepam and xylazine on the release of LH were investigated in intact proestrous animals. Intact rats were injected with both drugs before the critical period, decapitated at 1730, 1930 and 2130, and trunk blood was collected. For controls, animals were decapitated at 1300, 1730, 1930 and 2130. Serum LH was measured by RIA. The LH surge occurred in controls at 1730 and 1930, while it did not occur until 1930 or later (2130) in drug injected animals. Diazepam and xylazine thus induce a delayed LH surge in intact rats.

Therefore, neither the combination of diazepam and fentanyl nor diazepam and xylazine are useful for the study of hypothalamic control of gonadotropin release. However, the present experiment indicates that diazepam and xylazine anesthesia suppresses hypothalamic neurosecretory cells selectively, e.g. the LHRH neuronal system.
(Supported by NIH Grants RR-00167 and HD-11355.)

86.8 MELATONIN MODULATES RAT PROLACTIN SECRETION BY STIMULATING CENTRAL SEROTONIN RECEPTORS. M.Y.Meltzer, M. Simonovic and V.S. Fang*, Depts. of Psychiatry and Medicine, University of Chicago Pritzker School of Medicine, Chicago, Illinois 60637.

A number of serotonin (5HT) analogs known to stimulate central 5HT receptors elevate rat serum prolactin (PRL) levels. Melatonin (M), an O-methoxylated 5HT derivative synthesized by the pineal gland, stimulates rat PRL secretion. In order to assess possible 5HT agonist properties of M we have compared its effects on PRL secretion in male rats with those of 5-methoxy-N,N-dimethyltryptamine (5DMT), a known 5HT agonist. M(50 mg/kg,ip) or 5DMT (10 mg/kg,ip) produced marked but short-lasting rise in serum PRL levels. PRL levels were maximally elevated 15 min and returned to baseline 30 min after the treatment. M (10,25 or 50 mg/kg,ip) or 5DMT(1, 5 or 10 mg/kg,ip) stimulate PRL secretion in a dose-related manner. The D-R curves for the two compounds were parallel; 5DMT is about five times more potent than M. Pretreatment with a 5HT antagonist,mianserin (5 mg/kg,ip, 30 min earlier), blocked the PRL-releasing effect of both drugs. Inhibition of 5HT synthesis with p-chlorophenylalanine (300 mg/kg,ip, 24 hrs earlier) markedly lowered (-70%) hypothalamic 5HT levels and greatly enhanced PRL response to M or 5DMT. This effect is probably due to increased sensitivity of 5HT receptors secondary to 5HT depletion. These results suggest that M, like 5DMT, increases PRL secretion by direct stimulation of postsynaptic 5HT receptors.
