SOCIETY FOR NEUROSCIENCE

ABSTRACTS

VOLUME 9, PART 2

13th ANNUAL MEETING
BOSTON, MASSACHUSETTS
NOVEMBER 6–11, 1983

Made in the United States of America
International Standard Book Numbers
Part 1 0-916110-13-3
Part 2 0-916110-14-1
Both Parts 0-916110-15-X
Library of Congress Catalog Card Number 75-7761

Proper citation form for this volume:
Soc. Neurosci. Abstr., Vol. 9, Part 2, p. xxx, 1983.

Program Committee	**iv**
Chronological List of Sessions	**v**
Thematic List of Sessions	**vii**
Abstracts in Session Order*	
Wednesday, November 9–Friday, November 11	**759-1248**
Author Index	**1249**
Key Word Index	**1273**

***4764 volunteer abstracts, 20 symposium and workshop abstracts.**

1983 PROGRAM COMMITTEE

John G. Hildebrand, *Chair*
Columbia University

Neal H. Barmack
Neurological Sciences Institute

Allan I. Basbaum
University of California

Michael V. L. Bennett
Albert Einstein College of Medicine

Ira B. Black
Cornell University

Marc Colonnier
Hospital of L'Enfant-Jesus

Martha Constantine-Paton
Princeton University

Joseph T. Coyle
Johns Hopkins University School of Medicine

Irving Kupfermann
Columbia University

Dennis M. D. Landis
Massachusetts General Hospital

Eduardo R. Macagno
Columbia University

Peter R. MacLeish
Harvard Medical School

Mortimer Mishkin
Laboratory of Neuropsychology, NIMH

Paul H. O'Lague
University of California

Edward M. Schmidt
Laboratory of Neural Control, NIH-NINCDS

Lawrence P. Schramm
Johns Hopkins University School of Medicine

James H. Schwartz
Columbia University College of Physicians and Surgeons

Michael J. Brownstein, *Consultant*
Laboratory of Clinical Science, NIH

David H. Cohen, *ex officio*
State University of New York

Jennifer H. LaVail, *ex officio*
University of California School of Medicine

Dominick P. Purpura, *ex officio*
Stanford University School of Medicine

CHRONOLOGICAL LIST OF SESSIONS

CONTINUED FROM SOCIETY FOR NEUROSCIENCE ABSTRACTS, VOLUME 9, PART 1

(see page vii for Thematic List of Sessions.)

Session Number and Title	Page

WEDNESDAY

Slide Sessions—1:00 PM

223. Development and plasticity: retinotectal system II .. 759
224. Epilepsy: kindling II 762
225. Subcortical auditory pathways III 765
226. Regeneration: central III 768
227. Cardiovascular regulation: central transmitters II ... 772

Poster Sessions—1:00 PM

228. Skin, muscle, joint, and visceral receptors 775
229. Pain: afferent nociceptors 779
230. Pain: central pathways 782
231. Pain modulation: anatomy and pharmacology 785
232. Pain modulation: pharmacology 790
233. Opiates, endorphins, and enkephalins: physiological effects III 796
234. Retina II 800
235. Retina and retinal projections 809
236. Subcortical visual pathways I 813
237. Subcortical visual pathways II 817
238. Visual cortex: intrinsic organization III 820
239. Learning and memory: pharmacology II 824
240. Learning and memory: pharmacology of conditioning 828
241. Neurogenetics 832
242. Development of invertebrates II 834
243. Development and plasticity: trophic agents II 836
244. Development and plasticity: trophic interactions II 842
245. Morphogenesis and pattern formation 847
246. Cell lineage and differentiation I 852
247. Synapse elimination, competition, and neuron death II 855
248. Neural plasticity in adult animals III 859
249. Muscle afferents 862
250. Vestibular, visual, and oculomotor plasticity 865
251. Cerebellum: anatomical studies 869
252. Basal ganglia: behavior and pharmacology II 873
253. Regional neuropharmacology 877
254. Presynaptic mechanisms I 879
255. Blood-brain barrier II 885

Special Lectures—5:15 PM

256. The regulation of neuroendocrine gene expression. J. P. ROSENFELD ..... No abstract
257. The memory trace found? Neural substrates of basic associative learning in the mammalian brain. R. F. THOMPSON ..... No abstract
258. The ontogeny of the peripheral nervous system studied with an avian model. N. LEDOUARIN ..... No abstract

Session Number and Title	Page

THURSDAY

Symposia—8:30 AM

259. Post-translational processing of neuropeptide precursors and neuronal proteins. *Chaired:* H. GAINER 890
260. Efferent control of the organs of hearing and equilibrium. *Chaired:* S. M. HIGHSTEIN 890

Slide Sessions—8:30 AM

261. Opiates III 890
262. Retina III 894
263. Cell lineage and differentiation II 897
264. Feeding and drinking: cues for need state III 900
265. Peripheral autonomic nervous system II 903
266. Epilepsy: physiology II 906
267. Visual cortical development 910
268. Invertebrate learning and behavior II 913
269. Human neuropsychology II 916
270. Somatosensory system 920

Poster Sessions—8:30 AM

271. Aging I 923
272. Aging II 928
273. Development and plasticity: denervation 932
274. Development and plasticity: autonomic nervous system 935
275. Developmental disorders 938
276. Development and plasticity: biochemical and pharmacological correlates I 942
277. Development and plasticity: limbic system 946
278. Basal ganglia: physiology 949
279. Auditory cortex 953
280. Visual cortex: extrastriate visual areas II 957
281. Acetylcholine: biosynthesis and regulation 959
282. Acetylcholine: cellular structures and projection pathways 963
283. Acetylcholine: biosynthesis and electrophysiology .. 967
284. Brain metabolism I 971
285. Motivation and emotion: self-stimulation 976
286. Motivation and emotion 978
287. Sprouting I 982
288. Sprouting II 985
289. Catecholamines: biochemical characterization I 989
290. Catecholamines: biochemical characterization II 994
291. Catecholamines: adrenergic physiology 999
292. Catecholamines: dopaminergic physiology 1005
293. Opiates, endorphins, and enkephalins: receptors II 1010
294. Peptides: anatomical localization III 1014
295. Chemical senses: olfaction and taste II 1019
296. Synaptic structure and function I 1025

Session Number and Title	Page
297. Control of posture and movement II	1031
298. Disorders of the motor system: neural prostheses	1035
Symposia—1:00 PM	
299. Clocks in the test tube: toward a mechanistic analysis of circadian oscillators. *Chaired:* M. MENAKER	1039
300. Biochemistry of synaptic regulation. *Chaired:* M. B. KENNEDY and R. B. KELLY	1039
Slide Sessions—1:00 PM	
301. GABA and benzodiazepines: binding sites II	1039
302. Process outgrowth, growth cones, and guidance mechanisms II	1043
303. Subcortical visual pathways III	1046
304. Presynaptic mechanisms II	1049
305. Transmitters and receptors in disease II	1052
306. Colocalization of transmitters	1055
307. Stress, hormones, and the autonomic nervous system II	1057
308. Developmental specificity	1058
309. Aging III	1060
310. Pain modulation: behavioral analysis	1061
Poster Sessions—1:00 PM	
311. Comparative neuroanatomy I	1063
312. Biological rhythms: suprachiasmatic nucleus	1067
313. Biological rhythms II	1072
314. Hormonal control of behavior I	1076
315. Hormonal control of behavior II	1079
316. Sensorimotor integration	1082
317. Oculomotor brainstem mechanisms	1086
318. Cerebellum: transmitters and histochemistry	1090
319. Development and plasticity: endocrine control	1093
320. Development and plasticity: biochemical and pharmacological correlates II	1097
321. Diseases of synapses and axons	1102
322. Epilepsy: miscellany	1104
323. Catecholamines: dopamine receptors II	1108
324. Catecholamines: dopamine receptors III	1112
325. Catecholamines: adrenergic receptors	1117
326. Stress, hormones, and the autonomic nervous system III	1122
327. Modulators and modulations	1125
328. Opiates, endorphins, and enkephalins: physiological effects IV	1128
329. Peptides: biosynthesis and metabolism II	1132
330. Effects of drugs on receptors	1137
331. Drugs of abuse: nonopiates II	1145
332. Catecholamines: anatomical localization	1149
333. Biogenic amines II	1152
334. Cardiovascular regulation: morphological aspects	1157
335. Respiratory regulation	1160

Session Number and Title	Page
FRIDAY	
Symposia—8:30 AM	
336. The oculomotor role of the accessory optic system and pretectum: Is there a single vertebrate scheme? *Chaired:* J. WALLMAN	1165
337. Corticotropin releasing factor. *Chaired:* W. W. VALE	No abstract
Slide Sessions—8:30 AM	
338. Comparative neuroanatomy II	1165
339. Brain metabolism II	1168
340. Monoamines and behavior III	1172
341. Synaptic structure and function II	1175
342. Synaptogenesis II	1178
343. Immunohistochemistry of specific cellular components	1181
344. Excitatory amino acids II	1184
345. Membrane biophysics II	1187
346. Axoplasmic transport III	1190
Poster Sessions—8:30 AM	
347. Evoked potentials and EEG	1193
348. Sleep	1201
349. Peptides: receptors III	1205
350. Neuromodulators	1208
351. Subcortical organization	1213
352. Development of the visual system: cortex	1216
353. Visual cortex: cortico-cortical relationships	1219
354. Neural plasticity in adult animals IV	1221
355. Muscle II	1225
356. Basal ganglia: thalamic relationships	1229
357. Alcohol: environmental influences and electrophysiology	1231
358. Alcohol and barbiturates: biochemistry	1233
359. Alcohol: behavior	1239
360. Neurotoxicity III	1244

Sessions end at 12:45 PM, Friday, November 11.

THEMATIC LIST OF SESSIONS

(Includes slide and poster sessions, symposia, and workshops only.)

Theme A: Development and Plasticity

Session Number	Session Title	Type	Day	Time
271.	Aging I	Poster	Thu	8.30 AM
272.	Aging II	Poster	Thu	8:30 AM
309.	Aging III	Slide	Thu	1:00 PM
246.	Cell lineage and differentiation I	Poster	Wed	1:00 PM
263.	Cell lineage and differentiation II	Slide	Thu	8:30 AM
44.	Cell recognition in development of the nervous system	**Symp.**	Mon	1:00 PM
274.	Development and plasticity: autonomic nervous system	Poster	Thu	8:30 AM
276.	Development and plasticity: biochemical and pharmacological correlates I	Poster	Thu	8:30 AM
320.	Development and plasticity: biochemical and pharmacological correlates II	Poster	Thu	1:00 PM
273.	Development and plasticity: denervation	Poster	Thu	8:30 AM
319.	Development and plasticity: endocrine control	Poster	Thu	1:00 PM
277.	Development and plasticity: limbic system	Poster	Thu	8:30 AM
17.	Development and plasticity: peripheral regeneration	Poster	Mon	8:30 AM
19.	Development and plasticity: retinotectal system I	Poster	Mon	8:30 AM
223.	Development and plasticity: retinotectal system II	Slide	Wed	1:00 PM
112.	Development and plasticity: sensory systems	Poster	Tue	8:30 AM
182.	Development and plasticity: trophic agents I	Slide	Wed	8:30 AM
243.	Development and plasticity: trophic agents II	Poster	Wed	1:00 PM
6.	Development and plasticity: trophic interactions I	Slide	Mon	8:30 AM
244.	Development and plasticity: trophic interactions II	Poster	Wed	1:00 PM
179.	Development of invertebrates I	Slide	Wed	8:30 AM
242.	Development of invertebrates II	Poster	Wed	1:00 PM
20.	Development of motor systems	Poster	Mon	8:30 AM
352.	Development of the visual system: cortex	Poster	Fri	8:30 AM
206.	Development of the visual system: retina and geniculate	Poster	Wed	8:30 AM
11.	Development of the visual system: retinothalamic projections	Slide	Mon	8:30 AM
92.	Development: endocrine control and transmitter plasticity	Slide	Tue	8:30 AM
275.	Developmental disorders	Poster	Thu	8:30 AM
308.	Developmental specificity	Slide	Thu	1:00 PM
132.	Developmental strategies for selective synapse formation	**Symp.**	Tue	1:00 PM
18.	Effects of activity and inactivity on development	Poster	Mon	8:30 AM
245.	Morphogenesis and pattern formation	Poster	Wed	1:00 PM
30.	Neural plasticity in adult animals I	Poster	Mon	8:30 AM
113.	Neural plasticity in adult animals II	Poster	Tue	8:30 AM
248.	Neural plasticity in adult animals III	Poster	Wed	1:00 PM
354.	Neural plasticity in adult animals IV	Poster	Fri	8:30 AM
241.	Neurogenetics	Poster	Wed	1:00 PM
78.	Neurotoxicity I	Poster	Mon	1:00 PM
198.	Neurotoxicity II	Poster	Wed	8:30 AM
360.	Neurotoxicity III	Poster	Fri	8:30 AM
151.	Nutritional and prenatal factors in development I	Poster	Tue	1:00 PM
197.	Nutritional and prenatal factors in development II	Poster	Wed	8:30 AM
64.	Process outgrowth, growth cones, and guidance mechanisms I	Poster	Mon	1:00 PM

302.	Process outgrowth, growth cones, and guidance mechanisms II	Slide	Thu	1:00 PM
204.	Regeneration: central I	Poster	Wed	8:30 AM
205.	Regeneration: central II	Poster	Wed	8:30 AM
226.	Regeneration: central III	Slide	Wed	1:00 PM
111.	Specificity of synaptic connections	Poster	Tue	8:30 AM
287.	Sprouting I	Poster	Thu	8:30 AM
288.	Sprouting II	Poster	Thu	8:30 AM
97.	Synapse elimination, competition, and neuron death I	Slide	Tue	8:30 AM
247.	Synapse elimination, competition, and neuron death II	Poster	Wed	1:00 PM
203.	Synaptogenesis I	Poster	Wed	8:30 AM
342.	Synaptogenesis II	Slide	Fri	8:30 AM
218.	The neurogenetics of identified cells	**Symp.**	Wed	1:00 PM
267.	Visual cortical development	Slide	Thu	8:30 AM

Theme B: Cell Biology

Session Number	Session Title	Type	Day	Time
42.	Axoplasmic transport I	Poster	Mon	8:30 AM
43.	Axoplasmic transport II	Poster	Mon	8:30 AM
346.	Axoplasmic transport III	Slide	Fri	8:30 AM
49.	Blood-brain barrier I	Slide	Mon	1:00 PM
255.	Blood-brain barrier II	Poster	Wed	1:00 PM
222.	Cell surface and related components	Slide	Wed	1:00 PM
103.	Cell surface, cytoskeleton, and related macromolecules	Poster	Tue	8:30 AM
72.	Cell and tissue culture: behavior of neural, glia, muscle, and model cells	Poster	Mon	1:00 PM
5.	Cell and tissue culture: neurons, glia, and neuronal models	Slide	Mon	8:30 AM
172.	Cellular aspects of disease	Poster	Tue	1:00 PM
104.	Cellular localization of receptors	Poster	Tue	8:30 AM
131.	Functions of glia	Poster	Tue	8:30 AM
88.	Identified cells	Poster	Mon	1:00 PM
343.	Immunohistochemistry of specific cellular components	Slide	Fri	8:30 AM
71.	Lipids, myelin, and glial proteins	Poster	Mon	1:00 PM
105.	Membrane structure and function	Poster	Tue	8:30 AM
173.	Metabolic studies	Poster	Tue	1:00 PM
184.	Molecular biology of gene expression	Slide	Wed	8:30 AM
102.	Morphology of neurons and glia	Poster	Tue	8:30 AM
91.	New approaches to the study of the mechanism of fast axonal transport	**Wksh.**	Tue	8:30 AM
87.	Staining and tracing techniques	Poster	Mon	1:00 PM
27.	Structure and function of the neuroendocrine cell	Poster	Mon	8:30 AM
176.	The acidic interior of secretory vesicles: mechanisms and implications for neurobiology	**Symp.**	Wed	8:30 AM

Theme C: Excitable Membranes and Synaptic Transmission

Session Number	Session Title	Type	Day	Time
10.	Action potential and ion channels I	Slide	Mon	8:30 AM
147.	Action potential and ion channels II	Poster	Tue	1:00 PM
148.	Action potential and ion channels III	Poster	Tue	1:00 PM
199.	Action potential and ion channels IV	Poster	Wed	8:30 AM

300.	Biochemistry of synaptic regulation	**Symp.**	Thu	1:00 PM
321.	Diseases of synapses and axons	Poster	Thu	1:00 PM
330.	Effects of drugs on receptors	Poster	Thu	1:00 PM
178.	Electrophysiology of CNS neuron	Slide	Wed	8:30 AM
200.	Electrophysiology of CNS neurons II	Poster	Wed	8:30 AM
322.	Epilepsy: miscellany	Poster	Thu	1:00 PM
118.	Epilepsy: physiology I	Poster	Tue	8:30 AM
266.	Epilepsy: physiology II	Slide	Thu	8:30 AM
23.	Excitable membranes and synaptic transmission: invertebrate studies	Poster	Mon	8:30 AM
149.	Membrane biophysics I	Poster	Tue	1:00 PM
345.	Membrane biophysics II	Slide	Fri	8:30 AM
70.	Membrane biophysics: voltage clamp and model analysis	Poster	Mon	1:00 PM
69.	Pharmacology of synaptic transmission	Poster	Mon	1:00 PM
135.	Postsynaptic mechanisms I	Slide	Tue	1:00 PM
213.	Postsynaptic mechanisms II	Poster	Wed	8:30 AM
254.	Presynaptic mechanisms I	Poster	Wed	1:00 PM
304.	Presynaptic mechanisms II	Slide	Thu	1:00 PM
50.	Sensory transduction I	Slide	Mon	1:00 PM
296.	Synaptic structure and function I	Poster	Thu	8:30 AM
341.	Synaptic structure and function II	Slide	Fri	8:30 AM

Theme D: Neurotransmitters, Modulators, and Receptors

Session Number	Session Title	Type	Day	Time
283.	Acetylcholine: biosynthesis and electrophysiology	Poster	Thu	8:30 AM
281.	Acetylcholine: biosynthesis and regulation	Poster	Thu	8:30 AM
282.	Acetylcholine: cellular structures and projection pathways	Poster	Thu	8:30 AM
38.	Behavioral pharmacology I	Poster	Mon	8:30 AM
39.	Behavioral pharmacology II	Poster	Mon	8:30 AM
36.	Behavioral pharmacology: dopamine	Poster	Mon	8:30 AM
37.	Behavioral pharmacology: serotonin	Poster	Mon	8:30 AM
101.	Biogenic amines I	Slide	Tue	8:30 AM
333.	Biogenic amines II	Poster	Thu	1:00 PM
291.	Catecholamines: adrenergic physiology	Poster	Thu	8:30 AM
325.	Catecholamines: adrenergic receptors	Poster	Thu	1:00 PM
332.	Catecholamines: anatomical localization	Poster	Thu	1:00 PM
289.	Catecholamines: biochemical characterization I	Poster	Thu	8:30 AM
290.	Catecholamines: biochemical characterization II	Poster	Thu	8:30 AM
13.	Catecholamines: dopamine receptors I	Slide	Mon	8:30 AM
323.	Catecholamines: dopamine receptors II	Poster	Thu	1:00 PM
324.	Catecholamines: dopamine receptors III	Poster	Thu	1:00 PM
292.	Catecholamines: dopaminergic physiology	Poster	Thu	8:30 AM
48.	Characterization of cholinergic receptors	Slide	Mon	1:00 PM
169.	Characterization of muscarinic receptors	Poster	Tue	1:00 PM
168.	Characterization of nicotinic receptors	Poster	Tue	1:00 PM
166.	Characterization of noncholinergic receptors	Poster	Tue	1:00 PM
167.	Coexistence of transmitters and neuromodulators	Poster	Tue	1:00 PM
306.	Colocalization of transmitters	Slide	Thu	1:00 PM
26.	Cyclic nucleotides	Poster	Mon	8:30 AM
216.	Excitatory amino acid neurotransmitters	**Symp.**	Wed	1:00 PM
77.	Excitatory amino acids I	Poster	Mon	1:00 PM
344.	Excitatory amino acids II	Slide	Fri	8:30 AM
120.	GABA and benzodiazepines: binding sites I	Poster	Tue	8:30 AM

301.	GABA and benzodiazepines: binding sites II	Slide	Thu	1:00 PM
121.	GABA and benzodiazepines: CNS distribution of binding sites	Poster	Tue	8:30 AM
122.	GABA and benzodiazepines: electrophysiology and behavior	Poster	Tue	8:30 AM
133.	Heterogeneity of neurotransmitter receptors	**Wksh.**	Tue	1:00 PM
209.	Interaction between neurotransmitters	Poster	Wed	8:30 AM
86.	Metabolism of transmitters and modulators	Poster	Mon	1:00 PM
327.	Modulators and modulations	Poster	Thu	1:00 PM
45.	Monoaminergic innervation of cortex: new evidence of anatomical and physiological specificity	**Symp.**	Mon	1:00 PM
350.	Neuromodulators	Poster	Fri	8:30 AM
129.	Opiates, endorphins, and enkephalins: anatomical localization	Poster	Tue	8:30 AM
170.	Opiates, endorphins, and enkephalins: biochemical characterization	Poster	Tue	1:00 PM
84.	Opiates, endorphins, and enkephalins: physiological effects I	Poster	Mon	1:00 PM
215.	Opiates, endorphins, and enkephalins: physiological effects II	Poster	Wed	8:30 AM
233.	Opiates, endorphins, and enkephalins: physiological effects III	Poster	Wed	1:00 PM
328.	Opiates, endorphins, and enkephalins: physiological effects IV	Poster	Thu	1:00 PM
99.	Opiates, endorphins, and enkephalins: receptors I	Slide	Tue	8:30 AM
293.	Opiates, endorphins, and enkephalins: receptors II	Poster	Thu	8:30 AM
94.	Peptide transmitters in invertebrates	Slide	Tue	8:30 AM
85.	Peptides: anatomical localization I	Poster	Mon	1:00 PM
134.	Peptides: anatomical localization II	Slide	Tue	1:00 PM
294.	Peptides: anatomical localization III	Poster	Thu	8:30 AM
40.	Peptides: biochemical characterization	Poster	Mon	8:30 AM
219.	Peptides: biosynthesis and metabolism I	Slide	Wed	1:00 PM
329.	Peptides: biosynthesis and metabolism II	Poster	Thu	1:00 PM
9.	Peptides: physiological effects I	Slide	Mon	8:30 AM
41.	Peptides: physiological effects II	Poster	Mon	8:30 AM
130.	Peptides: physiological effects III	Poster	Tue	8:30 AM
52.	Peptides: receptors I	Slide	Mon	1:00 PM
171.	Peptides: receptors II	Poster	Tue	1:00 PM
349.	Peptides: receptors III	Poster	Fri	8:30 AM
259.	Post-translational processing of neuropeptide precursors and neuronal proteins	**Symp.**	Thu	8:30 AM
53.	Regional localization of receptors and transmitters I	Slide	Mon	1:00 PM
211.	Regional localization of receptors and transmitters II	Poster	Wed	8:30 AM
175.	The dynorphin peptides	**Symp.**	Wed	8:30 AM
25.	Transmitter immunocytochemistry	Poster	Mon	8:30 AM
164.	Transmitter uptake, storage, and secretion I	Poster	Tue	1:00 PM
165.	Transmitter uptake, storage, and secretion II	Poster	Tue	1:00 PM
210.	Transmitters and receptors in disease I	Poster	Wed	8:30 AM
305.	Transmitters and receptors in disease II	Slide	Thu	1:00 PM
24.	Transmitters in invertebrates	Poster	Mon	8:30 AM

Theme E: Endocrine and Autonomic Regulation

Session Number	Session Title	Type	Day	Time
116.	Adrenal medulla	Poster	Tue	8:30 AM
160.	Cardiovascular regulation: central transmitters I	Poster	Tue	1:00 PM

227.	Cardiovascular regulation: central transmitters II	Slide	Wed	1:00 PM
31.	Cardiovascular regulation: functional aspects I	Poster	Mon	8:30 AM
55.	Cardiovascular regulation: functional aspects II	Slide	Mon	1:00 PM
159.	Cardiovascular regulation: hypertension and stress	Poster	Tue	1:00 PM
334.	Cardiovascular regulation: morphological aspects	Poster	Thu	1:00 PM
337.	Corticotropin releasing factor	**Symp.**	Fri	8:30 AM
96.	Endocrine control: central pathways I	Slide	Tue	8:30 AM
123.	Endocrine control: central pathways II	Poster	Tue	8:30 AM
35.	Endocrine and autonomic regulation: brain ventricular system	Poster	Mon	8:30 AM
34.	Endocrine and autonomic regulation: neural control of immune system	Poster	Mon	8:30 AM
314.	Hormonal control of behavior I	Poster	Thu	1:00 PM
315.	Hormonal control of behavior II	Poster	Thu	1:00 PM
32.	Peripheral autonomic nervous system I	Poster	Mon	8:30 AM
265.	Peripheral autonomic nervous system II	Slide	Thu	8:30 AM
212.	Pineal gland	Poster	Wed	8:30 AM
33.	Regulation of autonomic function I	Poster	Mon	8:30 AM

223.1 DOES TIMING PLAY A ROLE IN GENERATING ORDER IN THE INITIAL RETINOTECTAL PROJECTION? C. E. Holt* (SPON: W.A. Harris). Dept. of Biology, B-022, Univ. of California San Diego, La Jolla, California 92093.

At the outset of tectal innervation, retinal nerve fibres grow directly to their appropriate target areas to form an ordered visual map in Xenopus laevis (Holt and Harris, Nature 301:150-152, 1983). The question of whether a timing mechanism plays a role in establishing this early map has been examined. First, the normal schedule of axonal outgrowth from the early retina was characterised. Dorsal and ventral thirds of embryonic eyes were labelled by in vitro incubation in ^{3}H-proline (see ref. above). Experimental animals were fixed at each stage of development from the start of retinal axonal outgrowth (stage 28) to early stages of tectal innervation (stage 42). The timecourse and target specificity of axons from these two retinal extremes (dorsal and ventral) were compared autoradiographically. Fibres from dorsal retina were found to grow out of the eye first, along the optic pathway and into the tectum 10-12 hours ahead of ventral fibres. Thus, the tectal rudiment becomes innervated in a specific and sequential manner with the ventral part being innervated first by dorsal retinal fibres (stage 37/38) and the dorsal part second by the later arriving ventral fibres (stage 40).

To reverse this sequence of target innervation and thereby test the importance of temporal factors, heterochronic transplants were done from young to old embryos. Dorsal halves of eyes from stage 21 embryos were ^{3}H-proline labelled and transplanted to stage 27 hosts. Autoradiographs of brains were examined from stage 32 to 42. To control for possible retardation effects, ventral halves of eyes receiving stage 21 transplants were labelled and the timecourse of their fibre outgrowth compared with normal ventral fibre growth.

The heterochronic exchanges retarded dorsal fibre outgrowth by at least 12 hours so that they arrived in the tectum at stages 40 to 41. They had no effect on the timecourse of ventral fibre outgrowth. In most cases, ventral fibres grew out and innervated the tectum before the normally pioneering population of dorsal fibres. Despite this temporal disruption, the results showed that initial tectal innervation was specific: delayed dorsal fibres terminated in ventrolateral tectum while ventral fibres (induced pioneers) went to dorsomedial tectum.

It is concluded that temporal factors do not play a major role in vertebrate neural mapping.

223.2 THE SIMULTANEOUS ELIMINATION OF IMPULSE ACTIVITY AND NORMAL PATHWAYS DOES NOT PREVENT DEVELOPING RETINAL AXONS FROM REACHING THEIR NORMAL TARGETS. W. A. Harris. (Sponsor: F. Denaro) Department of Biology, B-022, University of California, San Diego, La Jolla, California 92093.

Retinal axons can grow to their appropriate targets along unusual pathways, as demonstrated by tracing the retino-tectal projections of eyes embryonically transplanted to genetically eyeless axolotls, (Harris, J.C.N. 194:303-317, 1980). They can also find their correct targets in the absence of impulse activity, as shown by studying the optic pathways from axolotl eyes embryonically transplanted to the TTX-harboring California newt (Harris, J. Neurosci. 2:339-353, 1982). In the present experiments these two factors were simultaneously eliminated. Retinal axons were challenged to grow along abnormal pathways in the absence of impulse activity.

Eye primorida were first transplanted from normal to eyeless axolotl embryos, making sure to graft the optic stalk onto an ectopic site in the host brain. These axolotl embryos were then parabiotically joined to California newt embryos. Both operations were completed by stage 28, i.e. before axons had left the eye. The result of the parabiosis was a paralysis of the "eyeless" axolotl twin due to the newt's TTX. The newt twin remained normally active. The pair was allowed to develop for about one week. When the axolotl twin reached approximately stage 44, a needle coated with HRP was jabbed into either the dorsal or the ventral part of the silent transplanted retina. After 2 days the animals were killed, fixed, cryostat sectioned, and reacted. The results from 21 such cases show normal projections: the dorsal retina to the ventrolateral tectum, and the ventral retina to the dorsomedial tectum. Unusual pathways were often taken to achieve these destinations. Control animals, both normal axolotls developing alone and normal axoltls parabiosed to newts, showed the same patterns. These results indicate that the retinal projections in the experimental group were basically normal.

Thus, fibers need neither impulse activity nor a particular pathway to navigate to their correct targets during development. Both factors can be eliminated simultaneously, yet retinal axons still find their way to the tectum and make an ordered map. Other experiments from our laboratory have ruled out timing mechanisms (Holt, above), and fiber-fiber interactions, the latter also in combination with the elimination of impulse activity (Ferguson, below) as crucial factors in the formation of the early retinotectal projection. Clearly, other sorts of cues must be more critical for axonal navigation in this system.

223.3 SIMULTANEOUS ELIMINATION OF NORMAL FIBER-FIBER INTERACTIONS AND IMPULSE ACTIVITY DOES NOT PREVENT APPROPRIATE TECTAL INNERVATION. Betty Alice Ferguson, Department of Biology, B-022, University of California, San Diego, La Jolla, Calif. 92093.

Retinal axons form a visual map upon first innervating the tectum during normal development in Xenopus (Holt and Harris, Nature 301:150-152, 1983). Mechanisms proposed to explain appropriate innervation patterns include (among others) timed outgrowth, activity dependent interactions, pathway selection, and fiber-fiber interactions. Temporal factors alone do not determine the pattern of innervation (Holt, above). In addition, axolotl retinal axons grow to appropriate targets along abnormal pathways in combination with TTX-blocked activity (Harris, above). This experiment tests the affect of simultaneously eliminating normal fiber-fiber interactions and Na^{+}-dependent impulse activity of the specificity of retinal-tectal innervation.

Embryonic eyes were removed from stage 25-27 Xenopus (prior to axon outgrowth), the dorsal (D) or ventral (V) third incubated in ^{3}H-proline (Holt and Harris, ref. above) and only the labelled third replaced in the embryo. The embryos were allowed to heal a few hours, then parabiosed to TTX-producing newt embryos, Tari cha torosa, and allowed to develop to stage 40-46. The parabiosis results in paralysis of the Xenopus embryo; the newt embryo is active as normal.

Control experiments (in collaboration with C. Holt) show that labelled D or V thirds stage 40-46 in nonparabiosed embryos grow to the appropriate tectal region (D; 21/23 appropriate; V 19/20 appropriate). In the 38 stage 44-46 parabiosed embryos which have tectal projections, 10/19 D eye projections were appropriate, 15/19 V eye projections were appropriate. The eye pieces in the remaining embryos expanded somewhat into inappropriate tectal areas; this occurred more at later stages.

Thus, despite disruption of normal fiber-fiber interactions and block of Na^{+}-impulse activity, retinal ganglion cells can grow to the tectum and project initially to appropriate areas; D eye to ventrolateral tectum, V eye to dorsomedial tectum. There may be an expansion later in development to uninnervated regions of the tectum.

223.4 DEVELOPMENT OF VISUAL PATHWAYS IN XENOPUS LAEVIS: AN AUTORADIOGRAPHIC ANALYSIS. P. Grant and P.M. Ma*. Dept. of Biology, University of Oregon, Eugene, Oregon 97403.

Continuing our studies of the rules governing optic fiber connectivity, we have completed an autoradiographic analysis of development of the optic fiber pathway in Xenopus. ^{3}H Proline (3×10^{-5}-1.0 µL) was injected into the eyes of embryos and larvae at different stages through metamorphosis. After 4 hrs. to 5 days (depending on stage), whole embryos, tadpole heads or isolated brains were fixed in Bouins, dehydrated, embedded in paraffin and serially sectioned at 10µ in three planes. Slides were dipped in Kodak NTB2 emulsion, dried and exposed for two weeks, developed in Kodak D19, counterstained with cresyl violet and mounted. Autoradiographs were photographed or drawn with camera lucida and serial section reconstructions prepared.

Optic fibers first arrive at the di-mesencephalic junction at stage 36/38. Some turn caudally, entering ventral, rostral and lateral mesencephalon (tectum), reaching dorsal tectum by stage 39/40. During development, fibers continue to extend progressively over the growing tectum with rostrocaudal, ventrodorsal and lateromedial trajectories, patterns correlating directly with the known order of tectal maturation. Meanwhile, other labeled fibers turn rostrally from the di-mesencephalic border to form pretectal and putative uncinate neuropils. Later, during stages 42-50, labeled fibers accumulate caudorostrally, first in the Bellonci neuropil (NB), then in the corpus geniculatum thalamicum and finally in the rostral visual nucleus, a temporal ordering corresponding to the caudorostral sequence of diencephalic maturation. The most ventral fibers at the di-mesencephalic border turn caudally at stage 38 beneath the mesencephalon and form the basal optic tract and neuropil (BON). As the BON enlarges during development, neuropil layers appear at stage 48-50, forming a dorsal-ventral pattern resembling the juvenile BON.

The first fibers of the ipsilateral diencephalic projection appear at stage 56/57, running up the lateral edge of the diencephalon. Fibers terminate in all diencephalic neuropils at about the same time. The ipsilateral NB, in contrast to the contralateral NB, is layered from the outset, with fibers terminating in several small peripheral regions separated by non-innervated gaps. Later, layering becomes more complex as contra- and ipsilateral projections segregate within the NB.

During development, most optic fibers enter the tectal neuropil along a rostrocaudal trajectory while others follow the opposite trajectory, entering diencephalic neuropils along a caudorostral trajectory. These patterns correlate with the temporal order of post synaptic target cell maturation and are consistent with a spatio-temporal model for the ordering of optic fiber connectivity.

223.5 HOW RETINA AND TECTUM GROW IN POSTEMBRYONIC GOLDFISH. Pamela A. Raymond. Department of Anatomy & Cell Biology, Univ. of Michigan Medical School, Ann Arbor, MI 48109.

In teleost fish throughout postembryonic life optic fibers from the retina grow into the optic tectum, where they form a retinotopic array of synaptic connections. Using ^{3}H-thymidine radioautography to label dividing cells and computer-aided graphics to reconstruct 3D shapes, I have charted the growth of retina and tectum in goldfish from hatching through adult life, to test the hypothesis that retinotectal connections change as a consequence of a mismatch in the patterns of growth.

In adult goldfish, both retina and tectum approximate a hemisphere, although the tectum is markedly lopsided, bulging forward rostrally and becoming almost planar caudally. In larval and young juvenile fish, up to about 80 days of age, the tectum is symmetric and somewhat flattened. Both retina and tectum enlarge by two mechanisms: 1) stretching of existing tissue and 2) addition of new neurons to the rim of the hemisphere. From hatching onward, the retinal germinal zone is circumferential; thus annuli of new optic fibers are added with growth. Addition of new tissue is at first equivalent at dorsal and ventral margins, but during the transition between larval and juvenile stages, ventral begins to lag behind dorsal (increments added ventrally are about 25% shorter). Growth by stretching is most prominent in peripheral retina: in one fish the central 25% of the retina increased 15% in area, whereas the most peripheral annulus, encompassing 10% of the retina, increased 40% in area over a 230 day period.

The tectal germinal zone is U-shaped at all post-embryonic ages. Germinal cells are absent from about 1/3 of the rim at the rostral pole, so that only partial annuli of new tectal cells are added. The gap in the tectal germinal zone is topographically equivalent to temporal retina. The consequences of this pattern of tectal cell addition are: 1) the asymmetric curvature of the adult tectal surface is generated and 2) the earliest formed part of the tectum is at the rostral pole. Thus in fish injected with ^{3}H-thymidine at larval stages and sacrificed as adults, a partial annulus of labeled cells abuts the rostral tectal pole and encloses a region, less than 10% of the total tectal surface area, which represents the larval tectum. An annulus of label in the retina encloses a region of similar relative area, but of different topographic location, in central retina, surrounding the optic disk. Because central retina always projects to central tectum, optic fibers derived from the larval retina must project to a region of the adult tectum which was not generated until postlarval life, and which is up to 1 mm away from the original site of termination of the larval fibers. (Supported by EY04318).

223.6 PLASTICITY IN THE RETINOTECTAL PROJECTION DURING NORMAL DEVELOPMENT: SLIDING CONNECTIONS IN RANA. S. E. Fraser. Department of Physiology & Biophysics, University of California, Irvine, CA 92717.

The retinotectal system of lower vertebrates shows a great degree of plasticity following experimental perturbations of either the retina or the tectum. Gaze and his coworkers realized that a similar plasticity may play a role in normal development because: (i) the retinotectal projection is ordered normally during development, (ii) the retina and tectum grow throughout development, and (iii) the patterns of growth do not match. They proposed that to compensate for this mismatch of growth patterns, the retinotectal projection must continually shift during development. Experimental evidence for this shift has been obtained in Xenopus (anatomical: Gaze, et al JEEM 53:103; physiological: Fraser J.Physiol. 305:113p; Dev. Biol. 95:105). However, these studies were limited by the small size and poor optics of the Xenopus visual system and the asymmetric growth of the Xenopus retina that may in part compensate for the growth mismatch.

Here I report on an extension of these results to a preparation that avoids these limitations: the Rana pipiens retinotectal projection. Light-pipe mapping of the retinotectal projection (Fraser J.Physiol 305:113p) was used to directly assay the region of the tectum at which the retina surrounding the optic nerve head terminated. Following this determination, a small electrolytic marker-lesion was placed at that location in the tectum. The animal was revived and allowed to develop for several days at which time the procedure was repeated. The interlesion distance should therefore yield a direct measure of the shift in the retinotectal projection during the inter-lesion time period.

Following fixation, the animals were imbedded in paraffin, sectioned at 10um and stained by the picro/panceau technique. The marker lesions appear as small darkened regions of cellular debris that persist for up to two weeks. Measurements of the lesion positions were made by counting the sections between lesion (anterior-posterior distance) and measuring the distance from the midline of the tectum to the lesion (medial-lateral distance).

Thirty Stage XIX animals were subjected to the double lesion protocol, of which nine lived and six were interpretable. The average shift in the position of the central retina was 275um ±80um (S.D.) from Stage XIX to Stage XXI (movement in the posterior-medial direction). This rate of shift obtained for Rana is at least double that observed in previous experiments on Xenopus and is consistent with the anatomical results recently obtained by Reh & Constantine-Paton (personal communication).

223.7 EYE-SPECIFIC STRIPES IN THE TECTAL LOBES OF THREE-EYED FROGS ARE DEPENDENT ON NEURAL ACTIVITY. M. Constantine-Paton and T. Reh, Biology Department Princeton University, Princeton NJ 08544.

Three-eyed Rana pipiens, produced by adding a third eye primordium to the early embryo invariably develop highly periodic eye-specific segregation in tectal lobes dually innervated by a host and the supernumerary optic tract. We have suggested that these stripes arise as a compromise between two mechanisms normally involved in producing the single retinotectal map: one which is dependent on cell surface affinities and aligns the afferent projection(s) within the tectum and a second that produces segregation and increases point to point order by maintaining as neighbors in the tectal lobe only terminals that arise from neighboring ganglion cells in the retina. We have now tested the idea that this second segregating mechanism is dependent on neural activity by blocking Na^+-dependent spikes in all optic nerves of 3-eyed tadpoles. Segregation was assessed by HRP histochemistry followed by autoradiography after labeling supernumerary projections with HRP and both normal eyes with ^{3}H-proline.

TTX was applied either in the vitreous or behind the eyes of tadpoles in a slow release plastic which assured continuous presence of low concentrations of the drug(10^{-6}-$^{-8}$M)for up to four weeks. Effective blocking doses were determined by recording in the tectal lobe and continued blockade of retinal input to the brain was assessed by using the optokinetic turning response of tadpoles. We established that 2 weeks after crushing the normal optic nerves of 3-eyed tadpoles the supernumerary retinal projection became continuous. By four weeks, the normal eye's projection regenerates to the tectum and covered most of it. By 6-7 weeks post-optic nerve crush (ONC) the periodic pattern of eye-specific segregation was once again pronounced. TTX blockade during the last three weeks of this process eliminated resegregation.

We have also subjected three-eyed tadpoles without ONC to TTX blockade for 2, 3 and 4 weeks. Animals sacrificed at two weeks show overlap in the rostral tectum but distinct interdigitating stripes in other regions of these lobes. After three weeks of blockade however, HRP labeled terminals in more central regions of the doubly innervated lobe began to invade stripes previously dominated by the host retina. After 4 weeks of blockade these terminals had spread to form a continuous projection throughout the doubly innervated tectal lobe.

We conclude therefore that action potential activity is crucial both to the development and to the maintenance of eye-specific segregation in the tecta of 3-eyed tadpoles. Supported by NIH Grants EY01872 and EY05579.

223.8 PEPTIDE-LIKE IMMUNOREACTIVITY IN REGENERATING ANURAN OPTIC NERVE FIBERS. Rodrigo O. Kuljis and Harvey J. Karten. Depts. of Neurology, Psychiatry and Neurobiology, S.U.N.Y. at Stony Brook, N.Y. 11794.

Peptide-like immunoreactivity (PLI) Has been shown in various classes of amacrine cells in vertebrate retinae. Ganglion cell layer elements, however, have been consistently PLI-negative (Brecha, Karten & Laverack, '79, Karten, Reiner & Brecha, '82). Interestingly, an elaborate pattern of PLI exists in the retino-recipient portion of the anuran optic tectum (Kuljis & Karten, '81 & '82c). This pattern is dramatically modified by retinal deafferentation, thus suggesting transsynpatic effects and/or the loss of PLI-containing retinal terminals (Kuljis & Karten, '82 & '83a). Furthermore, optic nerve ligation is followed by the appearance of PLI in the retinal stump of nerve fibers that suggests a post-traumatic response and/or the presence of normally non-demonstrable peptides in retinal ganglion cells (Kuljis & Karten, '82b & '83b). The present report further investigates the possibility of the presence of peptides in retinal ganglion cells by means of regeneration techniques.

Twelve specimens of Rana pipiens were subjected to unilateral optic nerve crushing. One hour to 120 days after surgery, substance P-, leucine enkephalin-, cholecystokinin octapeptide - and bombesin-like immunoreactivities were analyzed in the retinae and optic nerves by means of peroxidase-anti-peroxidase and fluorescence methods.

Retinal ganglion cell bodies failed to display unequivocal PLI throughout the whole postoperative period. PLI was observed in fine longitudinally oriented beaded fibers, often ending in an expansion directed towards the brain. During the first 2-3 months following the operation most of the fibers accumulated in the retinal stump of the optic nerve. Two to 3 months after surgery, some of the fibers traversed the injury site towards the brain, mainly on the periphery of the nerve, and fascicles of the fibers invaded the cerebral stump of the optic nerve. Some fibers reached the optic chiasm. Experiments are in progress to analyze the reinnervation of the tectum.

These observations support the possibility that retinal ganglion cells contribute to PLI in the tectum. However, the possibility that PLI present in regenerating optic nerve fibers is a post-traumatic response, not reflecting a normal feature of retinal ganglion cells, cannot be dismissed. 223.9 THE SUBSTRATE FOR OPTIC NERVE FIBRE GROWTH IN FISH. J.H.Scholes*and A.Maggs (SPON: M.Djamgoz). MRC Cell Biophysics Unit, King's College London, 26-29 Drury Lane, London WC 2. England.

Optic nerves in fish tend to be sheet-like, forming elaborate pleated patterns during post-embryonic growth (Scholes, J.H., Nature 278: 620, 1979). This arises because new retinal axons extend toward the brain throughout life in a narrow (20-30μm) growth tract at one edge of the nerve.

Seen by electron microscopy, the substrate encountered by growing fibres in the optic nerve has various unusual features which may underlie their tightly focussed tracking behaviour and the resultant pattern developed in the entire optic nerve. These are (1) that satellite cells of all kinds, and their processes, are excluded by the growing fibre bundle, and (2) that optic nerve fibre growth cones form a continuous queue, several wide, occupying a narrow track on the basal lamina surrounding the nerve. In growing animals, this matrix track has a complex reactive form, differentiated from the rest of the basal lamina at the surface of the optic nerve and CNS, which is populated to confluence by astrocytic end-feet.

Maintenance of this specialised substrate apposing growing fibres can be probed with labelled amino acids (particularly PRO) injected into the eye in less than endogenous concentrations. They enter the rapid transport mechanism of growing fibres specifically, arriving in the growth track in free, detergent accessible form. As seen by ARG of sections and of SDS-PAGE, they become available there for local synthesis of matrix proteins, particularly collagen.

223.10 PERSISTENCE OF A NORMALLY-TRANSIENT PATTERN OF SUPERFICIAL OPTIC AXON FASCICLES IN THE SUPERIOR COLLICULUS OF REELER MUTANT MICE M.A. Edwards and V.S. Caviness, Jr. E.K. Shriver Center, Waltham, Ma. 02154

We previously reported (Neurosci. Abst. 7:733,'81) that fascicles of optic fibers in normal mice initially course through the presumptive superficial grey stratum (SGS) of the superior colliculus (SC) but dissappear by an unknown mechanism by the end of the first postnatal week. In the adult reeler mutant mouse many optic axons have anomalous trajectories through the SGS rather than the underlying stratum opticum (SO), as in the normal (Frost et al, Neurosci. Abst. 8:821,'82). The developmental origin of the abnormal stratification in reeler is the subject of the present investigation.

Only subtle abnormalities of cell pattern are detected in the reeler tectum. These include a somewhat disorderly arrangement of superficial postmigratory cells, evident by embryonic day 16 (E16), and an apparent reduction in the width of the stratum marginale, apparent after postnatal day 1 (P1). The pattern of histogenesis of the visual layers of SC, as reflected in the positions of successively generated neuronal cohorts labeled with tritiated thymidine, is indistinguishable in the two genotypes. By E17, many cells heavily labeled by injections on E11 and E13 attain an overlapping distribution in the superficial layers of SC in normal and mutant animals alike. In both genotypes the initial retinal projection, as defined by anterogradely transported HRP and normal fiber impregnations on E15-16, consists of only superficial fiber bundles. By the day of birth (P0), the distribution of longitudinally coursing fiber bundles within presumptive SO and SGS is the same in both reeler and normal mice. In the normal mouse superficial fiber fascicles diminish progressively after P2 and are absent after P6; in the reeler by contrast, up to 50% of the bundles persist. The retinal origin of the fiber fascicles present in the normal SGS and upper SO is verified by their rapid disappearance following bilateral eye removal. After P10 the total number of fiber fascicles in both SO and SGS in the mutant is similar to that of SO in the normal, suggesting that there is no hyper-innervation in reeler SC. Thus it appears that a pattern of projection which is transient in the normal persists in the reeler mouse. It is uncertain whether the abnormal axons present at maturity in the mutant SGS correspond to those that are lost in the normal animal. Alternatively, many may be late-arriving fibers guided incorrectly to SGS instead of SO along a smaller number of abnormally persisting bundles. (Reseach supported in part by NIH grants NS 12005 and EYO 4549).

223.11 HEALING AND GROWTH PATTERNS AFFECT THE VISUOTECTAL PROJECTIONS IN EYE FRAGMENTS AND CHIMERIC EYES. C. F. Ide*, P. Reynolds*, C. Falk*, D. Kahn*, B. Szaro*, D. Reinschmidt* and R. Tompkins. Dept. of Biology, Tulane University, New Orleans, LA 70118.

The normal growth pattern of embryonic Xenopus eyes - basin cells withdraw from mitosis early and all new cells are added in annular rings from the ciliary margin - has heretofore been assumed to follow surgical ablation and chimeric eye construction. Hence, mirror image duplications resulting from one-third size nasal or temporal fragments as well as normal visuotectal projections resulting from heterotopic graft chimeric eyes suggested that regulative changes in positional information had occurred. Our data show that healing and growth patterns following such surgery are not normal and that specific healing patterns correlate with the visuotectal projections formed. Nasal and temporal one-third eye fragments, formed by ablation at stage 32-33 heal and, in about 50% of the cases, survive to make eyes in the postmetamorphic animals which have mapable visuotectal projections. Most nasal one-third eyes and a minority of temporal fragments heal by the extrusion of cells from the center of the cut edge into the region of the ablation, forming a tongue of cells between the distal cut edges. These tiny anatomical duplicates develop into eyes with duplicated visuotectal projections. Most temporal one-third fragments and a minority of nasal fragments heal by rounding up; that is, the distal cut edges collapse to meet in the region of the ablation. This healing pattern is correlated with the formation of unduplicated visuotectal projections. During tongue formation, neurons and undifferentiated cells are transferred from the original fragment into the tongue in a disorderly array, but quickly sort out to reform normal retinal architecture. We postulate that the tongue cells retain their original determination to connect to the same tectal positions as the fragment from which they originate, despite their new positions, and that this mosaicism, coupled with cell movement into the tongue, establishes duplicate visuotectal projections. Heterotopic dorsal into antero-ventral grafts, performed at stage 32-33 using tetraploid cells to mark the graft, sometimes form mosaic visuotectal projections. In many cases, marked graft cells are found in the dorsal portion of the eye, contrary to expectation. The demonstration that retinal neurons can move, sort out, and, in the case of heterotopic graft chimeric eyes, come to reside in their region of origin during healing and early growth of surgically perturbed eyes must force a re-evaluation of studies of surgically perturbed eyes where the assumption of normal growth leads to the conclusion that regulative alterations of positional information have occurred. 224.1 INTERACTIONS BETWEEN CHEMICAL AND ELECTRICAL KINDLING: C.G. Wasterlain* and D. Fairchild* (SPON: I. Gerson). Epilepsy Research Lab, VAMC, Sepulveda, CA. 91343, Dept. of Neurology and Brain Research Institute, UCLA School of Medicine.
Previous work in our laboratory has suggested that the genesis of the kindled focus involves a great deal of both neurochemical and neuroanatomical specificity. The current study reinvestigates the interaction between chemical and electrical kindling in two anatomical locations: the amygdaloid region and the septal-hippocampal complex. The amygdala was implanted with chemitrodes in which the tips of the bipolar stainless steel electrode and of the injection cannula were closely approximated. For septal-hippocampal kindling, the stimulating electrode was implanted high in the medial septum , the cannula in the dorsal hippocampus. Medial septal stimulation resulted in prominent hippocampal afterdischarges, which were abolished by transsecting the fimbria, suggesting mediation through the septal-hippocampal excitatory pathway which provides over 90% of the muscarinic innervation of the hippocampus. Half the animals were kindled electrically, and one day after kindling (three stage 5 seizures) was obtained, chemical kindling was begun. The other half was kindled chemically first, then electrically. The results differed with the anatomical location. With amygdaloid implants, the rate of electrical kindling of naive animals did not differ significantly from that of rats which had first been fully kindled chemically. Similarly, the rate of chemical kindling did not show a significant dependence upon a previous electrical kindling experience. However, in both cases a non-significant trend toward positive transfer was observed. In the septal-hippocampal group, by contrast, significantinteractions were observed in both directions. Rats previously kindled by electrical medial septal stimulation displayed accelerated carbachol hippocampal kindling compared to their naive counterparts. Similarly, kindling by electrical septal stimulation was faster in rats previously kindled by repeated carbachol injections into dorsal hippocampus than in a naive group. These results suggest that chemical and electrical kindling involve similar mechanisms, and that the extent to which transfer occurs reflects the degree to which they share a common chemical anatomy. We hypothesize that carbachol kindling of the hippocampus and electrical kindling of the medial septum share a common excitatory muscarinic stimulation of hippocampal neurons, and that the site(s) of interaction may be in part located in these neurons or in their projections. 224.2 **GLUTAMERGIC AFFERENTS FROM PYRIFORM CORTEX TO AMYGDALA ARE INVOLVED IN ELECTRICAL KINDLING OF THE RAT.** **Isaac L. Crawford, Jonathan E. Walker, Richard W. Homan, and Maria Barletta*. Departments of Neurology and Pharmacology, UTHSC, Southwestern Medical School and VA Regional Epilepsy Center, Dallas, TX 75216**

We designed studies to determine whether glutamate may be involved in kindling of the amygdala in rats. Stainless steel bipolar electrodes were stereotaxically implanted in the left basolateral amygdala of experimental and control rats; the left pyriform cortex was ablated, while control rats were sham operated. Daily stimulation (400 uA, 1 sec, 60 Hz) began one week later. Rats were sacrificed 24 hours after their third consecutive stage 5 seizure. Pyriform ablation markedly prolonged the time to kindling compared to controls (39 ± 6 vs 11 ± 1 day, $p<0.001$). In the amygdala of kindled sham operated rats high affinity glutamate uptake was not significantly different from that in the contralateral amygdala of the same animals (27.5 ± 3.4 vs 21.7 ± 2.1 umol/hr/g wet weight). In contrast, removal of the pyriform cortex reduced high affinity glutamate uptake to less than half that in the amygdala of the unoperated side.

In a second series of experiments, rats were kindled and then the pyriform cortex was ablated. Sham operated controls rekindled within 2 days, while experimental rats required 7 ± 2 days to regain stage 5 seizures. These findings indicate the potential importance of a glutamergic input in the development of the kindling process and its less critical role in the persistence of kindling. The results also suggest that the influence of glutamergic afferents may be largely postsynaptic.

224.3 GLUTAMIC ACID: THE ROLE OF A NEUROTRANSMITTER IN THE FACILITATION OF KINDLING AND THE DEGENERATIVE DISORDERS OF THE CNS, M. Girgis and K. Harris*. Dept. of Anatomy, Univ. of Sydney, N.S.W., Aust.

The prolonged depolarizing effect, with subsequent lowering of threshold of stimulation that would be associated with an abnormal accumulation of excessive quantities of glutamate, could indicate a causal role of glutamate as a trigger factor in epileptic discharge. By direct application of exogenous glutamate, we have been able to successfully chemically kindle the amygdala obtaining stage 4 seizures. Intracerebral implantation of 'chemitrodes' was done in limbic structures of cat brains. In some experiments, repeated injections were made by a microsyringe. In others, steady-state flow of glutamate was produced by means of an osmotic minipump lasting one to two weeks. In some experiments, we used kainic acid in minimal doses prior to the glutamate minipump, and this catalyzing the reaction, acted as a primer in the production of the original (pathological) locus as found in the human disorder. Stage 6 seizure was observed in these preparations.

On perfusion, degenerative changes were observed in the brains of the glutamate preparations (these were greatly pronounced in the kainate experiments). Histologically, sclerotic plaques were seen diffusely in different brain areas in both preparations. EEG recordings showed very high amplitude spike activity at the site of injection, which later spread to other brain areas.

Similar EEG results were found in earlier experiments where cholinergic agents were used for producing animal models of limbic epilepsy (Girgis, M., Neurosci., 6:1965, 1981). As stimulation of acetylcholine receptors results in sustained seizure activity which damages the brain by unknown mechanisms, and as endogenous glutamate has possible excitotoxic action, it seems likely that glutamate may have a role in the brain damage associated with sustained limbic seizures.

Recent studies support the theory of glutamate as an endogenous neurotoxin. (Brookes, N., et al, Soc. for Neurosci. Abst., 23:15, 1982). By extrapolation, glutamate is therefore capable, via its necrotizing effect, of producing the epileptic focus associated with limbic epilepsy. The feasability of glutamate or glutamate-using systems being implicated in neurodegenerative disorders, as yet of unknown etiology, is also under investigation.

224.4 BENZODIAZEPINE-RELATED MECHANISMS IN THE AMYGDALOID KINDLING MODEL OF EPILEPSY IN THE RAT. W. S. Schwark, M. Haluska* and P. Blackshear*, Department of Pharmacology, New York State College of Veterinary Medicine, Cornell University, Ithaca, NY 14853.

Neuropharmacological and neurochemical investigations of the involvement of the benzodiazepine-GABA receptor-chloride ionophore complex in the seizure state induced by amygdaloid kindling were undertaken in adult male rats. Intraperitoneal diazepam markedly inhibited seizure intensity and afterdischarge duration in this seizure model, with an ED50 of approximately 2 mg/kg. The inhibitory potency of a series of benzodiazepines (including medazepam, diazepam, clonazepam and nitrazepam) on amygdaloid kindled seizures approximately paralleled their depressant effect on maximal electroshock-induced seizures and their Ki for [^{3}H]-diazepam binding in rat brain membranes. Intraventricular administration of inosine (150 µg), a putative endogenous benzodiazepine receptor ligand, significantly increased seizure latency and significantly decreased afterdischarge duration. Intraperitoneal muscimol (1 mg/kg), a GABA receptor agonist, also produced a significant prolongation of seizure latency.

In vitro binding studies with [^{3}H]-diazepam in brain membranes obtained from normal rats indicated that two populations of benzodiazepine receptors exist in brain regions such as the frontal cortex, i.e., a high affinity population (KD = 6.3 ± 1.2 nM; Bmax = 0.79 ± 0.19 pmol/mg protein) and a low affinity population (KD = 28.2 ± 4.9 nM; Bmax = 1.71 ± 0.27 pmol/mg protein). In contrast, a single benzodiazepine receptor type was found in the cerebellum (KD = 6.8 ± 0.8 nM; Bmax = 0.85 ± 0.08 pmol/mg protein). [^{3}H]-Diazepam binding properties were not altered in the cerebellum or frontal cortex of kindled rats which had not experienced a seizure within 1 week prior to the time of sacrifice. However, significant increases in cerebellar KD and Bmax values were observed in kindled rats which experienced a seizure just prior to death. In addition, inosine-induced increases in KD of [^{3}H]-diazepam binding were markedly impaired in cerebellar tissues obtained from kindled rats. Our data support the idea that alterations in endogenous mechanisms mediated by the benzodiazepine receptor complex may be instrumental in the epileptogenesis produced by amydgaloid kindling.

224.5 INTERACTIONS OF CARBAMAZEPINE WITH BENZODIAZEPINE SYSTEMS IN AMYGDALA KINDLING. Susan R.B. Weiss* and Robert M. Post. Biological Psychiatry Branch, NIMH, Bethesda, MD 20205.

The mechanism of action of carbamazepine, an anticonvulsant with efficacy in manic-depressive illness (Post, Psychol. Med. 12:701-704, 1982), is not known. Marangos et al. (Eur. J. Pharmacol., 1983, in press) observed that carbamazepine weakly displaced ligands binding at the central benzodiazepine site and more potently displaced [^{3}H] Ro 5-4864 which binds to the "peripheral" site. We examined whether carbamazepine's effects on benzodiazepine receptor systems are related to its anticonvulsant efficacy.

Rats, implanted with electrodes in the amygdala, were stimulated once-daily until major motor seizures were reliably produced. The anticonvulsant effects of carbamazepine (10 and 15 mg/kg) were studied following pretreatment with vehicle or the relatively pure antagonists of the central benzodiazepine binding site (Ro-15-1788 and CGS-8216). A ligand acting at the "peripheral" benzodiazepine binding site (Ro 5-4864) was also used. Pretreatment with the antagonist Ro-15-1788 (5 and 10 mg/kg), which significantly reverses the anticonvulsant effects of diazepam, had no effect on carbamazepine's ability to inhibit kindled seizures or afterdischarge duration. The antagonist CGS-8216 (5 and 10 mg/kg) was also ineffective in blocking carbamazepine's anticonvulsant effects. In contrast, the "peripheral" benzodiazepine ligand Ro 5-4864 (5 mg/kg) inhibited the anticonvulsant effects of carbamazepine on amygdala-kindled seizures. Ro 5-4864 alone at this dose had little effect on the amygdala-kindled seizure or afterdischarge duration. These results, consistent with the binding data, suggest that carbamazepine's anticonvulsant effects on amygdala-kindled seizures are probably not mediated by a direct effect at the central benzodiazepine receptor site. Possible effects of carbamazepine at the so-called "peripheral" benzodiazepine site are suggested by these data and require further exploration.

224.6 KINDLED SEIZURES ARE PREVENTED BY A BENZODIAZEPINE ANTAGONIST, Ro15-1788:EVIDENCE FOR MULTIPLE BENZODIAZEPINE RECEPTORS. M.L. Riives* and H. A. Robertson, Dept. of Pharmacology, Dalhousie University, Halifax, N. S. Canada B3H 4H7.

In many tests, an imidazodiazepine (Ro15-1788) blocks sedative, anxiolytic and anticonvulsant actions of benzodiazepines such as diazepam. At the same time Ro15-1788 is apparently devoid of intrinsic activity. We used Ro15-1788 to test the hypothesis that an endogenous benzodiazepine-like compound might be working to inhibit the development of amygdaloid kindled seizures. Rats were injected with vehicle, Ro15-1788 (1 or 10 mg/kg, i.p.), diazepam (3 mg/kg) or Ro15-1788 plus diazepam 10 min. before the daily kindling stimulus.

Surprisingly, both Ro15-1788 and diazepam retarded the development of kindled seizures. Most significantly, however, Ro15-1788 completely abolished the sedative-ataxic effects of diazepam (as measured by a vertical screen test) but did not affect the anticonvulsant effects of diazepam.

Because the anticonvulsant effects of Ro15-1788 were antagonized by another benzodiazepine antagonist (CGS 8216), we can presume that the anticonvulsant effects of Ro15-1788 are mediated by a benzodiazepine receptor.

These results suggest that Ro15-1788 is a partial agonist at an anticonvulsant benzodiazepine receptor but is a pure antagonist at the sedative receptor. This supports the idea of distinct and separate benzodiazepine receptors for sedative and anticonvulsant actions.

224.7 Hippocampal Kindling: Peptide and Adrenal Hormone Modulation of After-Discharge and Behavioral Depression, G.A. Cottrell, C. Nyakas*, R. de Kloet*, B. Bohus* and D. de Wied*. Rudolf Magnus Institute for Pharmacology, University of Utrecht, Vondellaan 6, 3521 GD Utrecht, The Netherlands.

Hormones can play a role in seizure behavior, at least a permissive role, since ß-endorphin, Leu- or Met-enkephalin produce after-discharge (AD) activity and convulsions and corticosteroids affect the convulsive threshold. We were interested in the effect of hormone manipulation on established seizure behavior. Hippocampal-induced seizures were of special interest since this structure has been implicated in epilepsy and is also part of the neuroendocrine system.

Using hippocampal kindling, a reproducible method for generating characteristic seizures, we have examined the effects of ACTH-like peptides and adrenal steroids on AD and the subsequent behavioral depression (BD). Male wistar rats were kindled daily (1 sec, 60 Hz biphasic square wave, 1 msec pulse duration at threshold AD-eliciting intensity) through 1 bipolar dorsal hippocampal electrode. EEG was recorded from the contralateral hippocampus.

In Experimental Series 1, kindled rats were injected subcutaneously with either peptide or saline 1 hr before the kindling session. Saline was injected between peptide tests until AD and BD values returned to normal. The duration of the AD and BD was reduced jointly or individually by several ACTH-like fragments (ACTH (1-16), ACTH (7-16), [D-Phe7]ACTH (7-16), ACTH (4-16), αMSH vs ACTH (1-16), [D-Phe7]ACTH (7-16), ACTH (4-7), [D-Phe7]ACTH (4-10), ACTH (4-16), resp.) and by γ2-MSH. This indicates that the structural requirements are different for the effects on these two variables.

In Experimental Series 2, the rats were adrenalectomized (ADX) or sham-operated under ether. There was a complex series of changes in AD and BD during the first 24 hrs after ADX, culminating at Day 1 in markedly decreased AD and BD, which returned to normal over the next several days. These changes were normalized after replacement of the ADX group with low doses of corticosterone (0.5 mg/kg s.c.).

Thus, we observed that opiocortin fragments and pituitary-adrenal hormones are important in the expression and maintenance of hippocampal kindled seizures. These findings reinforce the notion that the hippocampus is a neuroendocrine integrator which functions both as a controller of pituitary function and as a target organ for peptide and steroid hormones.

224.8 POTENTIATION OF ARGININE VASOPRESSIN'S CONVULSIVE EFFECTS BY SOMATOSTATIN. D.M. Burnard, Q.J. Pittman and W.L. Veale, Departments of Medical Physiology and Pharmacology, University of Calgary, Calgary, Alberta T2N 4N1.

Both arginine vasopressin (AVP) and somatostatin (SS) have convulsive effects when administered into a lateral cerebral ventricle of the rat (Cohn & Cohn, Brain Res. 96: 138, 1975; Kasting et al., Can. J. Physiol. Pharmacol. 58: 316, 1980). The first exposure to AVP increases the likelihood of a convulsion upon subsequent administration, but no such sensitization process has been reported for SS. The present work sought to determine whether SS and AVP would cross-sensitize, whereby exposure to one convulsive agent lowers the convulsive threshold and potentiates the response to the other agent.

Male Long Evans rats implanted with intracerebroventricular (icv) guide cannulae were subjected to one of the following treatments: (1) 2.5 µg SS icv on day 1 and 1.0 µg AVP icv on day 3; (2) 1.0 µg AVP icv on day 1 and 2.5 µg SS icv on day 3; and (3) 1.0 µg AVP icv on days 1 and 3. Behaviors were then recorded and scored according to a pre-determined behavioral code over a 10 minute period.

Rats receiving 1.0 µg AVP icv on days 1 and 3 exhibited an increase in convulsive behavior following the second administration of AVP. Rats receiving 2.5 µg SS icv on day 1 showed minimal changes in behavior, but when 1.0 µg AVP icv was administered 2 days later, all rats exhibited barrel rotations and myoclonic-myotonic convulsions. This type of behavior is normally seen following a second injection of AVP icv, therefore, SS had increased the sensitivity of the brain to the convulsive action of AVP. When the reverse protocol was performed, however, no such cross-sensitization was observed. Animals given 1.0 µg AVP icv on day 1 displayed periods of immobility and staring, as expected, but there was no convulsive behavior in response to 2.5 µg SS icv on day 3.

The present work demonstrates that SS sensitizes the brain to the seizure-inducing effects of AVP, but, under the present experimental conditions, AVP does not potentiate the response to SS. This may indicate that AVP's convulsive properties do not generalize in a similar manner or to the same degree as SS's.

This work was supported by the MRC of Canada. DMB is an MRC student; QJP is an MRC scholar.

224.9 NALOXONE EFFECTS ON SEIZURE SUPPRESSION AND KINDLING DEVELOPMENT. S. Caldecott-Hazard, L. Katznelson*, R.F. Ackermann, J. Engel, Jr. Dept. of Neurology, UCLA, Los Angeles, CA 90024.

Previous studies have found that endogenous opioid peptides are released by kindled seizures. These opioids have been hypothesized to play roles in postictal behavioral depression, seizure development, or in postictal seizure suppression (a stimulus, following a seizure by a short interval, elicits an afterdischarge (AD) with reduced or absent behavioral signs). In the present study, naloxone was used to simultaneously investigate the role of opioids in seizure development and postictal seizure suppression. Rats were implanted with bipolar stimulating electrodes in the amygdala and with recording electrodes on the cortex. Kindling was developed by stimulating at 60 Hz for 1 sec with a threshold sufficient to evoke an AD on the first stimulation. All rats were stimulated every 10 min for 1 hr per day, for 4 days. Naloxone (10 mg/kg,ip) was administered every 20 min to one-half of the rats and the control group received saline. The behavioral severity of the seizure ("kindling stage," Racine) and the AD duration were noted following each kindling stimulation. It was found that naloxone had no effect on the kindling rate as seen by the progressively increasing behavioral stages of the 1st stimulation on each day in both saline and naloxone rats. Also, the mean number of stimulation trials until each rat showed a fully generalized (stage 5) seizure was not significantly different between saline and naloxone rats. However, following the 1st stimulation of each day, the kindling stage for the saline rats decreased with each subsequent stimulation. In contrast, the naloxone rats maintained statistically significant higher kindling stages throughout the daily stimulations. Similarly, naloxone partially blocked the shortening of the AD durations seen following repeated seizures under saline conditions.

In order to study the effects of naloxone under conditions of increased postictal seizure suppression, rats were administered naloxone or saline and were stimulated every 10 min for 5 hrs on 1 day. The saline rats demonstrated moderate seizures (stages 1-2) for the 1st 2 hrs of stimulation, then the seizure stage decreased until ADs were often elicited without behavioral signs (stage 0). The naloxone rats maintained significantly more intense seizures (stages 2-4) for 3 hrs, followed by stage 1-2 seizures. Only one naloxone animal achieved a stage 5 seizure. AD durations were similar for all rats for the 1st 2 hrs. While the durations shortened in the naloxone rats, they first increased and then decreased in saline rats.

These data provide additional evidence that opioids may not be significantly involved in the development of kindling, but that they may play a role in a separate yet concurrent phenomenon, postictal seizure suppression.

224.10 EFFECT OF AMYGDALA KINDLING ON PYRIFORM CORTEX RESPONSE: INTRACELLULAR STUDIES WITH IN VITRO SLICE. D.C. McIntyre*, R.K.S. Wong and R. Miles (SPON: T. Tombaugh). Dept. Psychology, Carleton Univ. Ottawa, Ont. and Dept. of Physiol. and Biophysics, UTMB. Galveston, TX 77550.

The depletion of norepinephrine (NE) with neurotoxin 6-hydroxydopamine markedly facilitates the rate of amygdala kindling (e.g., McIntyre et al. Exp. Neurol.:1981). We now studied the cellular action of NE on neurons in the amygdala-pyriform area in order to assess the regulatory role of NE in the kindling-induced seizure activities. Experiments were carried out in vitro using coronal slices prepared from amygdala-kindled and implanted control Wistar rats. Antecedent amygdala kindling involved stimulating the right amygdala through a bipolar electrode with a 60 Hz sine wave of 50 or 100 μA twice daily until 6 generalized stage-5 convulsions were recorded. During intracellular studies, pyriform neurons were activated by stimulation of the basolateral, lateral or cortical amygdala nuclei via a bipolar tungsten electrode. In the control experiments two types of e.p.s.p.'s were evoked by such stimulation--first, an initial short latency event directly elicited by the shock and, second, a following barrage of recurrent e.p.s.p.'s generated via local neuronal interaction. In the kindled tissue, the recurrent e.p.s.p.'s were marked potentiated and were often sufficient to initiate synchronized population bursts as well as afterdischarges. NE (10^{-6}M) in the perfusate reversibly suppressed the recurrent e.p.s.p.'s in the control slices. Accordingly NE (10^{-6}M) also suppressed synchronized bursts and afterdischarges in the kindled tissue. Additional experiments showed that the α_2 agonist clonidine (10^{-6}M) produced the same effect as NE while the α_1 agonist phenylephrine (10^{-5}M) was ineffective. Interestingly the β agonist isoproteronol (10^{-6}M) appeared to potentiate the recurrent synaptic events.

The results indicate, as in vivo, that NE is an effective inhibitor of amygdala-pyriform neuronal activities and that this effect of NE is probably mediated via the presynaptic receptors.

224.11 AGE-RELATED CHANGES IN KINDLED SEIZURE DEVELOPMENT. K.A. Welsh and P.E. Gold. Department of Psychology, University of Virginia, Charlottesville, Virginia, 22901.

Considerable evidence in the Fischer F-344 rat indicates specific age-related declines on a variety of neurobiological and behavioral measures. The present study investigated possible age-related changes in the kindled seizure model of neuronal plasticity.

Bipolar stimulating electrodes were implanted bilaterally into the basolateral nucleus of the amygdala in both 3- and 12- month old Fischer F-344 rats. One week after surgery, afterdischarge (AD) thresholds were determined and kindling trials begun (unilateral, monophasic square waves, 60 Hz, 250 uA, 1 sec duration, one stimulation per day). Trials were continued for 30 days until each animal had demonstrated at least 3 consecutive stage 5 seizures. Stimulation was then discontinued and the permanence of kindling was tested two weeks later.

Prior to kindling, there were no significant differences in AD thresholds or durations in the 3- and 12- month old rats. In addition, the rate of kindling (as assessed by increases in AD duration) was comparable for the two age groups for at least the first 7 daily trials. Soon afterward, however, the AD durations digressed; 12-month old rats reached an asymptotic AD duration of 60 sec while the 3-month old rats continued to develop longer seizure durations over the next 3 weeks reaching an asymptote of 110 sec ($P < 0.01$). The development of behavioral convulsion stages (Racine 5 point scale) exhibited a pattern consistent with the electrographic results; aged rats required more trials (15.4 trials vs 10.7 trials) before demonstrating behavioral clonus. Despite these differing kindling rates, the kindled convulsions appeared to be permanent in each group; all animals exhibited convulsions on the first retest trial after a 2-week interval.

These findings indicate that the development of kindled seizures exhibits substantial age-related changes. Because AD thresholds and patterns are initially similar, the differences in kindling are probably not attributable to differences in sensitivity to the stimulation. Although the neurobiological basis of the age-related deficit in kindling remains to be clarified, these results are consistent with other physiological data suggesting impaired synaptic efficacy in the brains of aged animals (e.g. Landfield et al., Br. Res., 1978,150,85). Such functional changes may underlie the kindling deficit and prove important to the aging deficits observed in other forms of neuronal and behavioral plasticity.

224.12 INTRACEREBRAL INFUSIONS OF COLCHICINE ABOLISH KINDLED EPILEPTOGENIC FOCI IN CATS. N.R. Carlson*, K.D. Laxer*, and M.A. Mason* (SPON: R. Dow). Good Samaritan Hosp., Portland, OR 97210. Previous studies have shown that kindled epileptogenic foci produce morphological and functional changes in neurons in parts of the brain remote from the stimulating electrode. To test the hypothesis that these changes are maintained by neural activity of cells in the vicinity of the focus we infused the region of the focus with colchicine. This drug temporarily interferes with various neural functions, including axoplasmic flow and generation of action potentials. Cannulas were made from 22-ga spinal hypodermic needles, insulated except for the tip and the stylet, which protruded approximately 0.5 mm. They were chronically implanted in the amygdalas of cats. Kindled seizures were produced by repeated daily electrical stimulation through the cannulas. After stage V or VI seizures were reliably produced and seizure stimulation thresholds were measured, the stylet was removed and colchicine (or control substances) were slowly infused (20 min) through 27-ga hypodermic needles inserted into the cannula. Brain stimulation resumed after a recovery interval of 13-15 days. Infusion of 15 uL of colchicine (2mg./ml.) abolished seizures even after stimulation intensity was increased to 1800-2500 uA (median preinfusion threshold, 500 uA) in five cats. In one cat seizures could be produced, but the threshold was raised from 400 uA to 1500 uA. In contrast, seizure thresholds were not elevated by control infusions of equivalent amounts of saline (two cats) or lumicolchicine (four cats). Infusions of 5 uL of colchicine (four cats) had small effects; data are being collected from cats receiving 10 uL. Histological examination showed that the effects were not related to tissue damage caused by the drug.

225.1 PRIMARY PROJECTIONS TO COCHLEAR NUCLEI FROM CHRONICALLY DEAF COCHLEAS. D.B. Webster. Kresge Laboratory, Department of Otorhinolaryngology, L.S.U. Medical Center, New Orleans, LA 70119.

Pigmented guinea pigs were deafened at one month of age by a subcutaneous injection of kanamycin (400 mg/kg) followed two hours later by an intravenous injection of ethacrynic acid (40 mg/kg). This drug treatment results in a loss of all cochlear hair cells (except about 20 outer hair cells in the apical turn). By eight months following drug treatment, the spiral ganglion neuronal population is reduced to 13% of its normal number; this residual population remains stable. In the present experiment, the guinea pigs were allowed to survive for 18 to 29 months following drug treatment. Ten were then given discrete lesions of the spiral ganglion in the basal, second, or apical turn, allowed to survive for 4 additional days, and then anesthetized and perfused with 10% formalin. Their cochleae were studied to determine the extent of lesioning; their brainstems were examined by the Fink-Heimer method for axonal degeneration. Another 10 animals were treated with horseradish peroxidase (Sigma VI, 30%) placed on the cochlear nerve which had been surgically severed at the apex, second turn, or basal turn. These guinea pigs were sacrificed 24 to 48 hours later and their brainstems studied using the tetramethyl benzidine method. The results demonstrate that the residual spiral ganglion neurons of chronically drug-deafened guinea pigs project to the cochlear nuclei in a cochleotopic pattern which is indistinguishable from that seen in normal guinea pigs, save that it is much sparser.

Supported by NIH grants NS-12510 and NS-11647.

225.2 TUNING PROPERTIES OF SINGLE UNITS IN THE VENTRAL COCHLEAR NUCLEUS OF GUINEA PIGS IN RESPONSE TO ELECTRICAL STIMULATION OF THE COCHLEA. I. Glass* (SPON: M.J. Mustari). Dept. of Physiol. and Biophys., Univ. of Washington, Seattle, WA 98195

Tuning properites of auditory neruons to electrical stimulation of cochlear afferents are relevant to selection of stimulation frequencies and electrode locations for auditory neural prostheses. Single units in the ventral cochlear nucleus of acutely anesthetized guinea pigs were tested with pure continuous sinusoids presented through a tubular free fit implant in the scala tympani. Implants had two or four electrodes along the axis of the scala with 1 mm separations.

Best frequencies were consistently in the 100 Hz range (50-250 Hz) with thresholds of about 0.063 mA p-p. Tuning curves were usually symmetrical with slopes of 3-4 dB/octave, both below and above the best frequency. The relative sharpness of the tuning curves, as measured by Q_{10}, averaged 0.2. Dynamic ranges as determined by saturation of the rate-intensity functions for the various frequencies were 3-15 dB. No significant difference was found in these measures between responses evoked by the apical vs. the basal pairs of electrodes.

Units were found to have phase-locked responses to electrical stimulation of frequencies up to 12800 Hz. When tested with two pairs of electrodes, the frequency following patterns of a given unit to each pair were usually distinct.

These observations suggest that the electrical signal stimulates selective parts of a cochlear nerve fiber (e.g., dendrites vs. axons), and/or different populations of cochlear nerve fibers innervating the same cochlear nucleus neuron.

225.3 PERSISTENCE OF CALYCES OF HELD IN THE MEDIAL NUCLEUS OF THE TRAPEZOID BODY AFTER PERINATAL TRANSNEURONAL DEGENERATION OF THE CONTRALATERAL VENTRAL COCHLEAR NUCLEUS. W.B. Warr, K.W. Nordeen* and L.M. Kitzes*. Boys Town National Institute for Communication Disorders in Children, Omaha, NE 68131, and Department of Anatomy, College of Medicine, University of California, Irvine, CA 92717.

It is well established from studies in the cat and rat that the globular cells of the ventral cochlear nucleus (VCN) project via large diameter axons to the medial nucleus of the trapezoid body (MNTB) of the opposite side. Moreover, these globular cells are the source of the large cup-shaped terminals, the calyces of Held, found one per cell on the principal cells of MNTB. In the present study, the right and left MNTBs were examined in Bodian-stained material from adult gerbils subjected at 2 days of age to destruction of one cochlea. This ablation invariably resulted in the complete transneuronal degeneration of the VCN. However, despite the degeneration of the entire large-fiber component in the ipsilateral ventral acoustic stria, the MNTB contralateral to the ablation contained many large-diameter axons and many principal cells with a calyx terminal. The MNTB ipsilateral to the ablation appeared similar to that of unoperated controls. These findings indicate that the neonatal cochlear ablation and the resulting transneuronal degeneration of VCN produces a remarkable alteration of axonal connections within the adult auditory brain stem. The development or maintenance of this anomalous innervation of the MNTB may provide an indication of the normal process of development in this nucleus. (Supported by NSF Grant BNS-82-09987 to W.B. Warr, and NIH Grant NS-17596 to L.M. Kitzes.)

225.4 FINE STRUCTURE OF THE LATERAL SUPERIOR OLIVARY NUCLEUS IN THE ALBINO RAT. J.S. White. Dept. of Anatomy, Creighton Univ. Sch. of Med., Omaha, NE 68178.

The lateral superior olivary nucleus (LSO) is one of the three main auditory nuclei of the superior olivary complex involved in the processing of binaural input. The major cell type in this nucleus, the principal cell, is known to receive input directly from the ipsilateral anteroventral cochlear nucleus and from the contralateral anteroventral cochlear nucleus by way of an intervening synapse in the medial nucleus of the trapezoid body. A recent study of the origins of the olivocochlear bundle in the rat indicates that the LSO also contains a population of small olivocochlear neurons that project exclusively to the ipsilateral cochlea. The present study was undertaken to examine the morphology of, and the types and arrangement of synaptic terminals on each of these two types of cells.

In thin-sectioned material, principal cells typically display large central nuclei with a slightly infolded nuclear envelope, and abundant cytoplasm. In many instances, a large dendrite could be seen emanating from one or both poles of the cell body, and extending for some distance into the surrounding neuropil. Almost the entire surface of the cell soma and the proximal parts of the dendrites are contacted by numerous synaptic terminals containing either rounded or flattened vesicles. Terminals with flattened vesicles were found predominantly on the cell soma, while those with rounded vesicles usually were apposed to the dendrites. Olivocochlear neurons in the LSO are smaller, and display nuclei with highly infolded nuclear membranes. The somatic surface of these cells are contacted by only a few synaptic terminals that contain rounded vesicles.

It seems reasonable to suggest that the two types of terminals in synapse with the principal cells are related to the two known sources of input to this nucleus. It remains to be determined, however, if either the anteroventral cochlear nucleus or the medial nucleus of the trapezoid body also project to the small olivocochlear neurons in the LSO. (Supported by a grant from the Deafness Research Foundation).

225.5 THE FINE STRUCTURE OF THE LATERAL SUPERIOR OLIVARY NUCLEUS OF THE CAT. Nell Beatty Cant. Department of Anatomy, Duke University Medical Center, Durham, NC 27710.

The synaptic organization of the middle limb of the lateral superior olivary nucleus of the cat was analyzed in the electron microscope. The predominant cell type--the fusiform cell--has dendrites that extend from opposite poles of the cell body toward the margins of the nucleus, where they terminate in distal, spiny branches. Approximately 85% of the somatic and proximal dendritic surfaces are apposed by large synaptic terminals containing small, flat synaptic vesicles. Away from the cell body, the dendrites form numerous synaptic contacts with large synaptic terminals containing large, round vesicles in addition to contacts with the terminals with flat vesicles. The most distal dendritic branches and their spiny appendages appear to form synapses almost exclusively with the terminals with large, round vesicles. A very rare type of terminal that contains small, round vesicles may form synapses with either the somatic or dendritic surfaces. A few small cells are interspersed among the fusiform cells, but they are more commonly located around the margins of the nucleus. The small cells form few axosomatic contacts.

It is likely that the terminals with small, flat vesicles arise in the medial nucleus of the trapezoid body and are inhibitory in function, whereas the terminals with large, round vesicles arise in the anteroventral cochlear nucleus and are excitatory. The differential distribution of the two inputs on the somatic and dendritic surfaces must be an important determinant of the physiological response properties of these cells to binaural acoustic stimuli.

225.6 LAMINAR PROJECTIONS TO THE INFERIOR COLLICULUS AS SEEN FROM INJECTIONS OF WHEAT GERM AGGLUTININ-HORSERADISH PEROXIDASE IN THE SUPERIOR OLIVARY COMPLEX OF THE CAT. J.H. Casseday and E. Covey, Div. of Otolaryngology, Duke Univ. Med. Center, Durham, N.C. 27710.

Small injections of wheat germ agglutinin conjugated to horseradish peroxidase were placed in divisions of the superior olivary complex via microelectrodes that were also used to monitor the electrophysiological response to tone bursts. Injections in lateral superior olive (LSO) and medial superior olive (MSO) resulted in bands of anterograde label in the lateral and central parts of the central nucleus of the inferior colliculus. In frontal sections, these labeled areas appear as vertical bands tilted slightly from ventrolateral to dorsomedial. After very small injections only a single band is seen, approximately 100 μm wide, but it often extends throughout most of the central nucleus in the caudal to rostral and dorsal to ventral dimensions. After larger injections several bands are seen. Between each band is a label-free area approximately equal in width to the band itself. Injections in low-frequency areas of LSO produce bands in lateral parts of the inferior colliculus. The same area of the inferior colliculus is labeled after injections in the low frequency area of MSO but it is not clear if the bands from LSO are superimposed on the bands from MSO. Injections in high-frequency areas of LSO produce bands in medial locations. The projection bands are always located in the inferior colliculus ipsilateral to the injection and appear bilateral only after injections in LSO. That these bands of label are not merely projections to areas rich in cells or sparse in cells is shown by the observation that cells are seen in equal proportion both within and adjacent to the bands. An injection in the dorsomedial periolivary area yielded widespread, diffuse anterograde labeling throughout most of the inferior colliculus, including both central and pericentral areas, suggesting that not all ascending projections to the inferior colliculus have a laminar organization. Retrograde transport after small injections in LSO revealed bands of labeled cells in the anterior divisions of the anteroventral cochlear nucleus. These bands were oriented in a dorsolateral to ventromedial direction, probably in register with isofrequency contours. The results raise the possibility that the laminar projections from LSO and MSO interleave or overlap with projections from some other source or with one another. [Supported by NIH grant NS 12322.]

225.7 Comparison of responses to interaurally delayed low frequency tonal and wide-band noise stimuli in the cat's inferior colliculus. Joseph C.K. Chan, Dexter R.F. Irvine, Alan D. Musicant*, and Tom C.T. Yin. Dept. of Neurophysiology, Univ. of Wisconsin, Madison, WI. 53706.

Many low frequency neurons in the central nucleus of the inferior colliculus (ICC) of the cat are sensitive to variations in interaural time differences (ITD's). This sensitivity is manifested in cyclic interaural delay curves at different frequencies within the neuron's response area. Most studies of delay sensitivity have used pure tones, and there is little information on delay sensitivity to more natural, spectrally-complex sounds. We have examined the delay sensitivity of ICC neurons using band-pass filtered noise and have tested the hypothesis that the response to noise can be predicted from the responses to pure tones.

Experiments were carried out on adult cats anesthetized with sodium pentobarbital. Conventional dichotic stimulation and extracellular recording techniques were used. Low-pass Gaussian noise sequences with a flat spectrum up to a specified cut-off frequency (usually 4 kHz) were generated digitally. The tone and noise stimuli were delivered from a digital stimulus system. The binaural beat stimulus was used to obtain data on pure tone delay sensitivity over the entire response area of the cell.

The results indicate that cells with periodic ITD sensitivity functions for tonal stimuli also show delay sensitivity to noise. The noise curves are characterized by either a maximum or a minimum response within the physiological range of ITD for the cat (about 350 usec). For most cells, the shape of the noise delay curves is invariant with stimulus intensity. The extent to which a given cell's response to noise can be predicted from its response to tones has been assessed by comparing the noise curve with a composite tone curve, obtained by averaging the delay curves for individual frequencies. For most neurons, there is a close correspondence between the noise and composite tone delay curves: the general shapes of the two curves are similar and the maxima, minima and slopes occur at approximately the same ITD's. Thus, it appears that the delay sensitivity of ICC cells to low-pass noise can be predicted from their responses to tones.

When narrow-band noise signals are used, the periodicity of the delay curve depends upon the spectral composition of the signal. Studies are in progress to determine whether the delay curve for narrow-band noise restricted to a portion of the cell's response area matches the composite tone curve averaged over the corresponding frequency range.

225.8 EFFECTS OF TRANSECTING THE THREE ACOUSTIC STRIAE ON THE AUDITORY UNIT ACTIVITIES OF THE INFERIOR COLLICULUS IN THE CAT, Paul W. Y. Hui* (SPON: William D. Neff). Center for Neural Sciences, Indiana University, Bloomington, IN 47401

Auditory units were isolated in the inferior colliculus (IC) before and after transections of the trapezoid body (TB), the intermdeiate acoustic stria (IAS) and the dorsal acoustic stria (DAS). Units isolated on the same tracks before and after the transecions were compared. It was found that:

1. Partial lesion of the TB reduced the population of the binaural units and the contralateral excited units. The ipsilateral unit population was proportionally increased. The values and ranges of the latencies after the transections were also increased. The post-stimulus histogram (PSH) changed from the conherent type to the more diffuse type.

2. Complete transection of the TB did not eliminate all the binaural units nor the contralaterally excited monaural units.

3. Complete transections of the TB, IAS and DAS eliminated all the contralaterally excited monaural units. A small population of binaural units was still remained. This indicated that the IC also processed binaural inputs from neural centers other than the superior olivary complex (SOC).

4. The percentage increase of ipsilaterally excited monaural units in all the cases was the same as the percentage decrease of binaural units after the lesions.

225.9 A MAP OF AUDITORY AZIMUTH AND ELEVATION IN THE CAT'S SUPERIOR COLLICULUS. J.C. Middlebrooks and E.I. Knudsen. Dept. of Neurobiology, Stanford University, Stanford, CA 94305.

We have explored the representation of sound space in the cat's superior colliculus (SC) by measuring the selectivity of neurons for sound location and correlating this spatial tuning with the location of neurons in the SC. Single units were recorded extracellularly in anesthetized adult cats. Auditory stimuli consisted of noise bursts generated by a movable speaker. Visual stimuli were projected on a hemisphere which was placed in front of the cat during visual testing. Recording sites were marked with electrolytic lesions and later were identified histologically.

Unit responses to acoustic stimulation were encountered in the intermediate and deep layers. All auditory units were selective for sound location. Although some units had delimitable auditory receptive fields, others exhibited above background responses to stimuli presented at any location. However, regardless of the size of its receptive field, each unit exhibited spatial tuning in the form of a peak response to a limited range of stimulus locations. We compiled spatial response profiles of single units by counting the number of spikes elicited per stimulus presentation as the location of the noise source was varied systematically in azimuth and elevation. The best area of a neuron was defined as the area in which sound stimuli elicited responses greater than 75% of maximum. The centers of best areas ranged in azimuth from ipsilateral 30^{o} to contralateral 100^{o} and in elevation from $+45^{o}$ to -60^{o}. Many auditory units also responded to visual stimulation. For each bimodal unit, the centers of its visual field and auditory best area were approximately aligned.

The best areas of units varied systematically with their locations within the SC. Best areas shifted in azimuth from frontal to contralateral along a rostral to caudal axis and in elevation from superior to inferior along a medial to lateral axis. In the intermediate gray, azimuths from 0^{o} to 80^{o} contralateral were mapped continuously with a slight relative magnification of frontal space. Most of the mediolateral axis in that layer was devoted to representing a narrow range of 35^{o} in elevation located around the visual plane. The representation of higher and lower elevations was markedly compressed. Although some units were tuned sharply for locations outside of the visual range, the range and internal topography of the auditory map conformed closely with that of the visual map. In addition to revealing the topography of the map of auditory space in the SC, these data suggest the form in which space might be represented elsewhere in the central auditory system.

225.10 EARLY AUDITORY EXPERIENCE ALIGNS THE AUDITORY MAP OF SPACE IN THE OPTIC TECTUM OF THE BARN OWL. E. I. Knudsen. Dept. of Neurobiology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

The optic tectum contains maps of auditory and visual space that are mutually aligned. At the single unit level, this alignment is manifested as a coincidence of the optimal locations of auditory and visual stimuli. How does the alignment of spatial maps from different sensory modalities come about? Is the underlying circuitry shaped by experience? To investigate this question I altered in young barn owls the binaural localization cues associated with each point in space, then examined the tectum for changes in the auditory map. Binaural cues were disrupted in four young barn owls (ages 31 to 45 days) by suturing a foam rubber plug into one external meatus. The experimental birds and 3 control birds were raised to maturity (7 months) in an aviary. As adults, these birds were fitted with chambers for repeated neurophysiological recording from the tecta. Each owl was anesthetized with ketamine hydrochloride and positioned in a sound room containing a speaker-movement system. Noise bursts were used to determine auditory receptive fields and best areas (location for maximal response); moving bars and spots projected onto a hemisphere were used to map visual receptive fields. The hemisphere was removed during auditory testing.

In control birds, auditory best areas and visual receptive fields of units in the rostral portion of the tectum exhibited a mean misalignment of 0.0° in azimuth and -2.1° in elevation (n = 46). In three experimental birds with ear plugs still in place, the average misalignments were respectively 0.0° azimuth, -2.3° elevation; right 1.8°, +4.8°; and right 4.5°, +3.6°. The fourth owl was not recorded from before its ear plug was removed. The approximate alignment of fields in birds experiencing altered binaural inputs indicates that these bimodal units had developed new specificities for binaural cues spatially consistent with their visual fields.

When the ear plugs were removed, the auditory fields and best areas moved abruptly away from the side of the unplugged ear causing the auditory and visual fields to become grossly misaligned. The misalignment of the auditory and visual receptive fields persisted for up to 5 months.

The results demonstrate that the alignment of the auditory map of space in the optic tectum is regulated by early auditory experience. The persistence of the altered auditory map in adult birds suggests that the mechanism for adjusting neuronal specificities for binaural cues is lost or greatly slowed in the adult nervous system.

225.11 AURAL REPRESENTATION WITHIN AN ISOFREQUENCY LAMINA OF THE MUSTACHE BAT'S INFERIOR COLLICULUS. L.S. Ross*, J.J. Wenstrup*, and G.D. Pollak. (SPON: R. Bodenhamer). Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

The greater mustache bat, Pteronotus parnellii, uses a constant frequency echolocation call in which most of the energy is concentrated in the 60 kHz second harmonic. Within the central nucleus of the inferior colliculus, there is a large architectonically defined subdivision, the dorsal posterior division (DPD), occupying almost 35% of its volume. The DPD is an isofrequency lamina in which all neurons have the same best frequency that corresponds to the 60 kHz component of the echolocation calls. In this study, we analyzed the aural representation of neurons in the DPD and how these features are mapped upon this subdivision.

Three types of units were observed; 1) E-O units were excited by contralateral stimulation but were unaffected by ipsilateral stimulation; 2) E-E units were excited by both contralateral and ipsilateral stimulation; and 3) E-I units whose excitatory responses to contralateral stimulation could be inhibited by ipsilateral stimulation.

Each type was segregated within the DPD and occupied regional territories: E-O units were found dorsally and laterally: E-E units were found in bands located ventro-laterally; while E-I units occupied a thick band in the medial portion of the DPD, sandwiched between the E-O band dorsally and the E-E band ventrally. Thus within this isofrequency lamina, units having similar binaural properties are topographically arranged. It seems likely that this arrangement is a consequence of the distribution of converging inputs from lower acoustic centers. Supported by grants from the NIH and NSF.

225.12 TOPOGRAPHICAL REPRESENTATION OF INTERAURAL INTENSITY DIFFERENCES WITHIN AN ISOFREQUENCY LAMINA OF THE MUSTACHE BAT INFERIOR COLLICULUS. J.J. Wenstrup*, L.S. Ross*, and G.D. Pollak. Dept. of Zoology, Univ. of Texas, Austin, TX 78712.

Recent experiments have demonstrated that different classes of binaural response properties are segregated in isofrequency contours of mammalian auditory centers, yet the neural organization of responses within each of these classes has remained poorly understood. We now report the results of experiments in which we find systematic shifts in E-I response properties with depth in a single isofrequency lamina of the inferior colliculus of the mustache bat, Pteronotus parnellii.

Responses of single units and unit clusters to monaural and dichotic sound stimuli were obtained within the dorsal posterior division (DPD) of the mustache bat inferior colliculus. Neurons within the physiologically and anatomically distinct DPD are tuned to the 60 kHz constant frequency component of the bat's sonar pulse.

E-I responses were found in the medial region of the DPD, ventral to a band of E-O units. Within this region, dorsoventral electrode penetrations first encountered E-I responses in which the ipsilateral stimulus inhibited the excitatory response to contralateral sound at intensities typically 30 dB greater than the contralateral stimulus. With increasing electrode depth, inhibition by the ipsilateral sound occurred at successively lower intensities relative to the contralateral stimulus. The deepest E-I units encountered in a penetration were inhibited by ipsilateral sound intensites 0 to 10 dB below the contralateral sound. This pattern of E-I responses was clearly observed in most of the medial penetrations through the E-I band. Cases in which successive E-I units did not display a systematic shift in ipsilateral inhibitory thresholds were generally located more laterally.

Such organization is likely to provide a neural substrate of sound localization dependent upon intensity cues, and may thus constitute an internal representation of external auditory space.

Supported by grants from the NIH and NSF.

225.13 COMBINATION-SENSITIVE NEURONS IN THE AUDITORY THALAMUS OF THE MUSTACHED BAT. J.F. Olsen* and N. Suga. Biology Dept., Washington U., St. Louis, MO 63130

We have been recording extracellularly from single units in the auditory thalamus of the mustached bat (Pteronotus parnellii). The biosonar signal (pulse) of this bat consists of a long constant-frequency component (CF) which terminates with a brief frequency-modulated component (FM). The auditory cortex contains two types of neurons (FM-FM and CF/CF) which are sensitive to combinations of signal elements in the pulse-echo pair (Suga et al., Science 203:270, 1979; Suga and O'Neill, Science 206:351, 1979). The responses of CF/CF and FM-FM neurons are respectively facilitated by the CF or FM component of the fundamental of the pulse plus the CF or FM compononent of a higher harmonic of the echo. CF/CF neurons are tuned to Doppler-shifted echoes, whereas the response of FM-FM neurons encodes echo delay. We have found similar CF/CF and FM-FM neurons within the auditory thalamus. Most thalamic FM-FM neurons are tuned to particular echo delays between 0.4 and 18 msec. Figure 1 illustrates the response of an FM_1-FM_2 neuron as echo delay and amplitude are varied. This unit responds weakly to the echo FM_2 presented alone, a response which is facilitated by the addition of the FM_1 of the pulse. The lines are isoimpulse-count contours which give the net increase in response evoked by the stimulus pair. The trailing edge of this neuron's delay tuning curve is sharpened by the presence of an adjacent inhibitory area (shaded in figure). Figure 2 shows a facilitative tuning curve for a thalamic CF_1/CF_2 neuron. Typically these tuning curves are not sharply tuned to the fundamental, but very sharply tuned to the second harmonic. Figures 1 and 2 also illustrate that FM-FM and CF/CF neurons are tuned to particular echo amplitudes. We have also found neurons which are tuned to single CF or FM stimuli. Since combination-sensitivity has not yet been discovered in the ascending auditory pathway below the thalamus, it seems likely that this response property may originate within the thalamus itself.

REGENERATION: CENTRAL III

226.1 MATURE OLIGODENDROCYTES HAVE THE CAPACITY TO DIVIDE FOLLOWING EXPERIMENTAL DEMYELINATION IN THE ADULT CENTRAL NERVOUS SYSTEM. Lynn S. Arenella* and Robert M. Herndon. Center for Brain Research, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

While neurons are generally considered to be non-dividing cells, the mitotic capacity of glial cells is an issue which has been debated since the turn of the century. Today it is accepted that astrocytes and microglia have the capacity to divide in response to injury, disease, and in the normal course of aging, but a similar capacity for mature oligodendrocytes remains a controversial issue. There is, however, substantial evidence that replacement of oligodendrocytes occurs following demyelination and preceding remyelination both in vivo and in vitro. The origin of these oligodendrocytes remains unclear. They could arise from the division of pre-existing oligodendrocytes or from the division and subsequent differentiation of unspecialized precursor cells. In order to study this problem, we combined autoradiographic techniques, utilizing a pulse label of ^{3}H-thymidine to determine the identity of cells about to undergo mitosis, with the lysolecithin-induced model of primary demyelination.

Swiss mice, 9 to 10 months of age, were each injected with 2 µl of 1% lysolecithin in saline in the thoracic region. Mice were injected i.p. with 5.0 or 14.0 µCi/gm (methyl-^{3}H)thymidine and perfused 1 hr later on days 2, 5, 8 and 28 post-lysolecithin. Serial thick (1.5 µm) and thin sections were prepared for light and electron microscopic autoradiography.

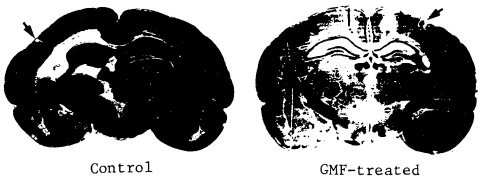
Two days after lysolecithin injection, labeled macrophages were present both within the immediate vicinity of the injection site and in the surrounding area where by day 5 they had removed enough myelin debris to produce a discrete edematous zone of bare axons. Just outside this area of myelin destruction, labeled astrocytes, first evident at day 2, were numerous at days 5 and 8. Labeled oligodendrocytes, although rare at day 2, appeared first outside the zone of myelin destruction. At days 5 and 8, numerous labeled oligodendrocytes could be found in the zone surrounding the injection site where remyelination, barely apparent at day 5, was well underway at day 8. By day 28, all surviving axons had been remyelinated, many, in fact, by invading Schwann cells.

The presence of dividing oligodendrocytes before myelin debris has been cleared from most axons suggests that oligodendrocytes, like astrocytes, have the capacity to divide in response to injury. While the presence of bare axons may further influence the proliferation and migration of these cells, it does not seem to be an essential requirement for the regeneration of oligodendrocytes in these lesions. The finding of oligodendrocytes capable of dividing in older animals, lends support to observations of an active multiple sclerosis lesion suggesting "an apparent proliferation" of these cells in the plaque margin (Raine et al., 1981). Our results show that oligodendrocyte proliferation precedes and accompanies successful regeneration of CNS myelin.

226.2 IN VIVO EFFECT OF GLIA MATURATION FACTOR ON CEREBRAL REGENERATION. Ramon Lim and Joyce F. Miller*. Div. of Neurochemistry and Neurobiology, Dept. of Neurology, Univ. of Iowa, Iowa City, IA

Glia Maturation Factor (GMF), first detected in our laboratory in 1972, is a 15,000 dalton acidic protein capable of stimulating astrocytic proliferation and differentiation in vitro. We now report the in vivo effect of GMF in enhancing cerebral regeneration. Newborn rats were injured in the parietal region on one side of the brain by piercing an 18 gauge needle through the skull, creating a puncture wound 4 mm deep. Five litters of rats were used for the study and rats from each litter were randomly assigned into experimental and control groups. Experimental animals (N=26) were treated with intraperitoneal injections of beef GMF (50 nanograms GMF in 10 ul of 0.2 M phosphate buffer, pH 7.4) on 3 consecutive days starting from the time of injury, whereas control animals (N=24) were treated with similar injections where GMF was replaced by 50 nanograms of bovine serum alumin. Twenty-five days after birth, the brains were removed, fixed, paraffin-embedded, and serial coronal sections 10 microns thick were made and stained with H & E. One representative section from each brain, cutting through the region of maximal injury, was photographed and the areas defined by the left and the right cerebral hemispheres were measured with a digitized planimeter.

The measurements demonstrated that in control animals the cerebral hemisphere of the injured side was 19% smaller than the normal side ($p < .0001$), but in the GMF-treated animals no difference in size was detected. Analysis of variance showed that the effect of GMF was highly significant ($p < .0001$) and could not be attributed to sex or litter differences. No evidence of glial scar formation was seen at the site of injury upon immunostaining for Glial Fibrillary Acidic Protein, whether or not the rats were treated with GMF. The results indicate that GMF promotes cerebral regeneration and suggest a potential therapeutic value for GMF in brain damage. (Supported by NIH grant CA-31796 and NSF grant BNS-8308341 and by a Veterans Administration Career Investigatorship to R.L.)



226.3 NORMAL DEVELOPMENT AND REGENERATIVE GROWTH OF NORADRENERGIC FIBERS TO THE LATERAL GENICULATE NUCLEUS OF THE RAT. L.L. Rose* and P.W. Land. Department of Anatomy, M.U.S.C., Charleston, SC 29425 and University of Pittsburgh, Pittsburgh, PA 15261.

Locus coeruleus axons have the capacity to reinnervate certain regions of the brainstem, but not cortex, following postnatal lesions with the neurotoxin 6OHDA. This ability may be correlated both with the proximity of the innervated region to the locus coeruleus and the maturational stage of the normal noradrenergic (NA) innervation of the region at the time of neurotoxic lesion. We studied the normal development of the NA innervation of the dorsal lateral geniculate nucleus (dLGN) of the pigmented rat and the effect of early postnatal 6OHDA treatment. Litters of Long-Evans rats were divided into two groups: control (uninjected) and 6OHDA-treated. We administered 6OHDA (Regis; 100 mg/kg free base in 0.5% ascorbate) on postnatal days 0, 1, 2 and 3. Control and 6OHDA-treated animals were sacrificed on days 0 through 10, day 21, and as adults. The younger animals (P0-P10) were perfused with a glyoxylic acid solution (Lidov, et.al., 1978) and reacted with the SPG method of De La Torre (1980). For the older ages, fresh tissue was reacted according to this procedure.

The adult dLGN receives an extremely dense, intensely fluorescent NA innervation which sets it apart from surrounding thalamic nuclei. The innervation develops postnatally, with only a few delicate fluorescent terminals present on P0. The number and intensity of fluorescent fibers increases daily, and by P10 the pattern resembles that of the adult, although it is less dense.

A single injection of 6OHDA was sufficient to cause the disappearance of almost all fluorescent terminals in the dLGN. Continued treatment until P3 maintained this depletion, and few NA fibers were visualized in the dLGN until the second postnatal week. By day 8, the innervation resembled that of the control P0 animal. The number of fibers continued to increase, and by day 21 the innervation was quite heavy but still not as dense as in controls. No cortical reinnervation by NA fibers was seen during this time.

These results show that, unlike the cortical NA projection, NA axons are able to reinnervate the dLGN after postnatal neurotoxic lesion. In addition, NA fibers normally innervate the dLGN after retinal afferents have reached the geniculate, but before they exhibit adult organization. This allows for a possible influence of noradrenergic fibers on the final pattern of afferent termination in the geniculate. (Supported by NIH grant EYO3447).

226.4 EFFECT OF GM_1 GANGLIOSIDE TREATMENT ON THE RECOVERY OF DOPAMINERGIC NIGRO-STRIATAL NEURONS AFTER DIFFERENT TYPES OF LESION. G. Toffano, G. Savoini*, C. Aldinio*, M. Valenti*, K. Fuxe* and L.F. Agnati*. Department of Biochemistry, Fidia Research Laboratories, 35031 Abano Terme, Italy, Department of Histology, Karolinska Institutet, 104-01 Stockholm, Sweden, Department of Human Physiology, University of Modena, 41100 Modena, Italy.

Many types of central neurons exhibit capacity for axon sprouting and generation of new connections in response to injury, not only in the developing but also in the mature CNS (Björklund A. and Stenevi U., Physiol. Rev., 59:62-100, 1977; Cotman C.W. et al., Physiol. Rev., 61:684-784, 1981). The intensity of CNS tissue to recover after injury seems to depend on the extent and localization of the damage, and on the presence of factors with repressive or stimulatory neuronotrophic activity. Among the factors affecting neurite growth response, a particular role has been recently attributed to GM_1 monosialoganglioside. Indeed GM_1 potentiates the NGF-induced differentiation of pheochromocytoma PC12 and DRG dissociated cells in culture, conversely antibodies against gangliosides prevent the neurite-promoting effect of NGF in DRG and the neuronal outgrowth from regenerating goldfish retinal explants. We have recently demonstrated that GM_1 administration facilitates the dopaminergic reinnervation of the striatum (Toffano G. et al., Brain Res., 261:163-166, 1983) and apparently maintains the number of dopaminergic cell bodies in the substantia nigra (Agnati L.F. et al., this meeting) after unilateral hemitransection in adult rats. However, GM_1 fails to stimulate the recovery of nigro-striatal dopaminergic markers when dopaminergic neurons are lesioned by injecting directly 6OH-DA (from 2 to 8 g) in the MFB (A 3.5, L 2.0, V 7.3; König Klippel Atlas). The different process involved in the degeneration of dopaminergic neurons after the mechanical or the chemical lesion may be relevant for understanding the mechanism of action of GM_1 on neuronal repair in vivo after injury. Moreover, when 6OH-DA (4 g) is injected in the ispilateral or contralateral MFB of animals with unilateral hemitransection and treated for 15 days with 30 mg/kg GM_1, the ganglioside effect is abolished.

These results indicate (i) that the recovery of biochemical and immunohistochemical parameters of the nigro-striatal dopaminergic pathways induced by GM_1 treatment occurs only in a certain type of lesion; (ii) that the terminal sprouting of DA fibers in the striatum after hemitransection is a response of the ipsilateral unlesioned axons and (iii) that the contralateral nigro-striatal pathway may play a role in the regulation of such a response.

226.5 CHRONIC GM-1 TREATMENT CAN PROTECT AGAINST RETROGRADE CELL BODY DEGENERATION IN THE ASCENDING DOPAMINE PATHWAYS AND INDUCE MORPHOFUNCTIONAL RECOVERY IN THE STRIATAL DOPAMINE NERVE TERMINAL SYSTEMS FOLLOWING PARTIAL LESIONS. L.F. Agnati, K. Fuxe*, L. Calza*, C. Farabegoli*, L. Cavacchioli*, F. Mascagni*, G. Toffano* and M. Kalia*. (SPON: J.L. Osterholm). Dept. of Human Physiology, University of Modena, Modena, Italy.

Male Sprague-Dawley rats have been hemitransected at the level of the mesodiencephalic junction producing a partial lesion of the mesostriatal dopamine (DA) pathway. Chronic treatment with the ganglioside GM-1 was initiated immediately following the operation and lasted for 56 days (10 mg/kg, i.p., daily). The tyrosine hydroxylase immunocytochemistry, using both the indirect immunofluorescence method and the PAP method, and amine fluorescence histochemistry were performed to demonstrate the various types of DA cell bodies, dendrites and nerve terminal systems. The amine turnover was analyzed by measuring the catecholamine fluorescence at various time intervals following treatment with the tyrosine hydroxylase inhibitor α-methyl tyrosine methyl ester. The DA receptors were analyzed by means of quantitative receptor autoradiography using the radioligands ^{3}H-spiperone and ^{3}H-N-propylnorapomorphine. Chronic GM-1 treatment induced on the lesioned side a blockade of the retrograde cell body degeneration, increased the density and length of DA dendrites and produced a regeneration of the DA innervation of the striatum by inducing regrowth from surviving DA nerve terminal systems (collateral sprouting). At the postsynaptic level GM-1 treatment prevented the appearance of DA receptor supersensitivity as well as the shrinkage of the striatal area seen on the lesioned side without ganglioside treatment. These changes in the characteristics of the DA receptors were associated with the prevention of the development of the behavioural signs of DA receptor supersensitivity as revealed in studies on rotational behaviour using apomorphine. In intact animals chronic treatment with GM-1 also produced effects on the ascending DA systems by reducing DA turnover within the large diffuse (CCK-negative) DA nerve terminal networks of the nuc. accumbens and the nuc. caudatus putamen. These results underlined that gangliosides not only can induce "trophic" actions, but also effects on the transmission processes in the intact DA neurons. Gangliosides may represent a new type of Parkinson's disease making possible not only symptomatic treatment as with l-dopa, but a true cure by counteracting the degenerative processes within the DA neurons of the substantia nigra.

226.6 EFFECT OF GM_1 GANGLIOSIDE ON MONOAMINE NEUROTOXIN INDUCED ALTERATION OF THE POSTNATAL DEVELOPMENT OF NORADRENALINE AND SEROTONIN NEURONS. G. Jonsson*, H. Kojima* and A. Gorio (SPON: H. Aldskogius). Dept. of Histology, Karolinska Institutet, Stockholm, Sweden and Fidia Research Lab., Abano Terme, Italy.

Exogenous administration of gangliosides has been shown to promote neuronal regrowth processes and functional recovery after a nerve damage. It was therefore considered of interest to investigate the effect of GM_1 ganglioside treatment on the alteration of the postnatal development of noradrenaline (NA) and serotonin (5-HT) neurons in rat brain produced by the selective monoamine neurotoxins 6-hydroxydopamine (6-OH-DA; a catecholamine neurotoxin) and 5,7-dihydroxytryptamine (5,7-HT; a 5-HT neurotoxin) respectively. The effects were analyzed using neurochemical (measuring endogenous monoamine levels and ^{3}H-monoamine uptake) and histochemical (Falck-Hillarp) techniques. Neonatal treatment with 6-OH-DA (100 mg/kg s.c.) or 5,7-HT (50 mg/kg s.c.) causes a marked and permanent degeneration of distal NA or 5-HT nerve terminal projections in the brain (e.g. in the cerebral cortex and spinal cord) as well as a NA or 5-HT hyperinnervation in regions close to the NA or 5-HT perikarya in the brainstem (a pruning effect). The 6-OH-DA treatment produces in addition a permanent sympathectomy. Administration of GM_1 alone (4x30 mg/kg s.c., 24 hr interval) to newborn rats had no significant effect on the postnatal development of the NA and 5-HT parameters analyzed. Neither were any effects on the central dopamine neurons observed. It was also found that GM_1 treatment did not appear to have any detectable effects on the 6-OH-DA and 5,7-HT induced alteration of the central NA and 5-HT neurons when analyzing the animals at the age of one week. These findings suggest that GM_1 treatment did not interfere with the primary neurodegenerative actions of 6-OH-DA and 5,7-HT. At the age of one month there were signs of a counteracting effect of GM_1 on the 6-OH-DA and 5,7-HT induced changes of NA and 5-HT neurons respectively. This effect of GM_1 was most clear-cut with respect to the 5,7-HT induced 5-HT nerve terminal degeneration in the cerebral cortex where it was found that the endogenous 5-HT levels were 72% (frontal cortex) and 41% (occipital cortex) of control after 5,7-HT + GM_1 treatment as compared to 26% and 20% respectively after 5,7-HT treatment alone. It was furthermore observed that GM_1 treatment had a moderate counteracting effect of the 6-OH-DA induced sympathectomy, noted both in the iris and the superior cervical ganglion. Taken together, the present results suggest that GM_1 ganglioside treatment may have a degeneration preventing and/or a regrowth stimulatory action on NA and 5-HT neurons damaged by a selective neurotoxin in the neonatal stage. 226.7 FETAL CORTEX GROWTH AND FUNCTION IN DEGENERATING ADULT PERIPHERAL NERVE. Yipeng Tang* and Jerald J. Bernstein. Lab. of CNS Injury and Regen. Res., VA Med. Ctr. and George Washington Univ. Sch. of Med., Dept. Physiology and Neurosurgery, Washington, D.C.

Fetal cortex (E11, 12, 15) implanted into crushed, perineurial minced sciatic nerve grows, differentiates, and matures for up to 120 days. Host peripheral nerves grow through the implant and reinnervate the foot. The following experiments in the rat (Wistar, 300 gms) determine if E11 fetal cortex implants can survive in degenerating peripheral nerve and perhaps innervate denervated muscle. Twenty (5 per group, 7, 14, 21, 30 DPI) rats had sciatic nerve transection at midthigh, the proximal stump tied, reflected and sutured into muscle. The distal stump was tied. The second nerve to the biceps femoris muscle was crushed, a slit made in the epineurium and the perineuria minced with scissors. E11 gestation females had the fetuses removed and placed in complete Tyrode-Ringer solution. A 1.0 mm cube of fetal cortex was placed into the adult host epineurium with a jewlers forceps. Prior to intracardic perfusion, all proximal and distal sciatic stumps and implanted biceps femoris nerves were stimulated electrically (5V., 0.2 msec. 1.0 Hz). Cortical neurons were observed ultrastructurally for the duration of the experiment. Implant growth was poor. The neurons observed had mature nuclei, immature cytoplasmic organelles and were predominantly unipolar. A neuropile was present which contained axodendritic synapses. Macroglia, Schwann, fiboblast and connective tissue sheath cells were observed. In two cases (30 DPI) stimulation of the implanted biceps femoris nerve resulted in weak biceps femoris muscle contraction, whereas stimulation of both sciatic stumps did not. Ultrastructurally, these implants had neurons, a neuropile, the distal biceps femoris nerve contained nerve fibers and the muscle had reinnervated and degenerated end plates. These data show that E11 cortex implants can survive 30 DPI in degenerating peripheral nerve and innervate muscle. (Sponsored by the Department of Navy, ONR, CB-030-82050 and the Veterans Administration).

226.8 BIORESORBABLE NERVE GUIDES BRIDGE TRANSECTED OPTIC NERVE. R. Madison[1] & R.L. Sidman[1], T.H. Chiu*[2], and E. Nyilas*[2], Departments of Neuroscience and Neuropathology, Childrens Hospital and Harvard Medical School[1], and Instrumentation Laboratories, Inc.[2], Boston, MA. 02115.

Nontoxic bioresorbable "nerve guides" (synthetic L-polylactates) were implanted to bridge the intracranally transected optic nerve in adult rats. A 1.5 mm length of the guide (0.75mm I.D., 1.10mm O.D.) was filled with a collagen matrix (bovine; 95% Type I, 5% Type III; Vitrogen, Flow Laboratories) containing 0.5 mg/ml fibrinogen (bovine, Cal Biochem) and 0.4 mg/ml fibronectin (bovine, Kor Biochemicals), and was then implanted, with both the distal and proximal nerve stumps inserted into the guide. Animals were killed 4 (N=1), 6(N=2), and 12 (N=2) weeks following surgery and processed for transmission electron microscopy (TEM).

Four weeks after implantation the "nerve guide" lumen contains a cable of tissue throughout its length. This tissue is well vascularized (see Greatorex, et. al. this volume). TEM shows fibroblasts, macrophages,astrocytes, oligodendrocytes, Schwann cells, numerous unmyelinated axons and a few isolated myelinated axons to be present in the guide. Cable diameter is approximately 0.05 mm.

Six weeks after implantation cable diameter has increased to 0.18 mm. The previous loose stromal network has changed to a more densely packed fibrous bundle containing numerous unmyelinated and isolated small myelinated fibers. Since peripheral sympathetic fibers will invade the central nervous system (CNS) following both nonspecific and specific CNS lesions (Madison and Davis, Exp. Neurol. 80 (1); 167-177, 1983), the possibility that the unmyelinated axons in the guide originated peripherally was tested by performing bilateral superior cervical ganglionectomies (SCGX) 3 weeks prior to the sacrifice of the 12-week animals.

Cable diameter at 12 weeks had enlarged to 0.24mm. The persistence of unmyelinated axons following SCGX is strong evidence that many of these axons have a central origin. At 12 weeks several small (<1μ) myelinated fibers are dispersed throughout the cable as are several axons that are in the process of becoming myelinated. Studies are in progress to unequivocally identify the source of the axons found in the guide.

The mamalian optic nerve and nontoxic bioresorbable "nerve guides" should prove useful for understanding principles of neuronal plasticity and regeneration in the adult CNS. Supported by NIH grants NS14768, N007017, and HD06276.

226.9 PNS GRAFTS ENHANCE AXONAL ELONGATION FROM NEURONS IN FETAL MESENCEPHALON TRANSPLANTED INTO THE ADULT RAT BRAIN. A. Aguayo, A. Björklund* U. Stenevi*and T. Carlstedt*.Neurosciences Unit, McGill University, Montreal,Canada; Department Histology, University of Lund, Lund, Sweden; Department of Anatomy, Karolinska Institute, Stockholm, Sweden.

Recent transplantation experiments have demonstrated the feasability of a) replacing neuronal populations with exogenous nerve cells (Björklund & Stenevi, Physiol. Rev. 59: 62, 1979) and b) enhancing the growth of axons by grafting nonneuronal components of the PNS into the injured brain (Benfey & Aguayo, Nature 296: 150, 1982). We now report the successful combination of both these techniques in the same animal.

METHODS: Host animals. In female Sprague-Dawley rats weighing approximately 250 g, the right nigrostriatal pathway was damaged by a stereotactic injection of 6-OH-DA (8 μg free base in 4 μl, 0.2 mg/ml ascorbate saline). Fetal neuronal grafts. From 6 to 8 weeks later a portion from the ventral mesencephalon of rat embryos was placed intracranially over the right superior colliculus of the host brain stem. PNS grafts: At the same time, a "bridge" linking the fetal neuronal implant and the host striatum was made by transplanting a segment of heterologous sciatic nerve. This "bridge", 2 to 3 cm in length, was placed extracranially beneath the scalp. Through burr holes in the skull, one end of the "bridge" was placed in contact with the fetal implant while the other end was inserted into the caudate nucleus. Fetal and PNS grafts were from rats of the same inbred strain as the hosts.

RESULTS: Histologic examination for dopaminergic fluorescence three months after grafting revealed that PNS grafts were innervated by monoaminergic neurons from the mesencephalic implant. Axons from grafted nerve cells extended along the entire PNS "bridge" and reached the previously denervated caudate nucleus of the host brain. Fluorescent axons showed minimal branching in their long course through the PNS "bridges" but formed dense, albeit short, terminal arborizations within the CNS regions they reached.

CONCLUSIONS: 1. Combinations of fetal neuronal and PNS grafts have been used in vivo to provide both a source and a substrate for axonal growth. 2. Implanted monoaminergic neurons replacing damaged nerve cells in the host brain were shown to have grown axons the entire length of the 2 to 3 cm PNS conduits to reach the striatum, a normal target of nigral projections. 3. Conditions extrinsic to the growing axons appear to influence both fiber elongation and terminal branching.

226.10 DAMAGED OLFACTORY BULB NEURONS REGENERATE AXONS INTO PNS GRAFTS. Beth Friedman and A.J. Aguayo, Neurosciences Unit, The Montreal General Hospital, Montreal, Quebec, Canada.

Peripheral nerve segments grafted into different regions of the rat brain and spinal cord are innervated by CNS neurons but it is not known if such innervation is due to collateral sprouting from nerve cells that retain their normal projections or if it arises by the regrowth of interrupted fibers. Because mitral cells, which normally project to the olfactory cortex via the lateral olfactory tract (LOT) have been shown to grow axons along PNS grafts (Friedman and Aguayo, '82) we have now attempted to determine whether such neurons still innervate the olfactory cortex by using the retrogradely transported fluorescent dyes True Blue (TB), a cytoplasmic label, and Nuclear Yellow (NY), a nuclear tag, to label these projections.

In 11 adult Sprague Dawley rats, an approximately 1 cm long autologous segment from the sciatic nerve was inserted into the olfactory bulb. From 8-20 weeks after grafting, a 3% solution of either TB or NY was placed in gelfoam onto the cut end of the extracranial portion of the graft for one hour; 48 hours later, gelfoam soaked in the second (different) dye was inserted and left in a transection made in the LOT. The rats were perfused transcardially with chilled saline followed by fixative. The brain was removed and tissue sections cut at 25 μm were examined by epi-illumination fluorescence.

In 5 of the grafted olfactory bulbs application of dye (TB or NY) to the graft produced labeled neurons in the olfactory bulb. These could be identified as mitral cells on the basis of cell shape (with TB) or position of the labeled profile in the mitral cell layer (with NY). The most striking finding is that 99% of these neurons which innervate the graft were not labeled by the dye placed in the LOT (202/204 neurons). On the other hand, many of these neurons were adjacent to mitral cells that had failed to innervate the graft but were singly labeled by the dye placed in the LOT, an indication that these cells still projected to the olfactory cortex.

Thus almost the entire population of mitral cells that innervated PNS grafts lacked projections to the olfactory cortex. This suggests that the innervation of peripheral nerves grafted to rat olfactory bulb arises from the growth of projection axons that were interrupted at the time of grafting and not from the extension of axon collaterals of cells that maintained their normal connections.

226.11 GAD IMMUNOREACTIVITY IN TRANSPLANTED MOUSE NEOCORTEX. L.M. Smith, M.F. Bear, D.E. Schmechel* & F.F. Ebner. Div. of Biology and Medicine, Brown Univ., Providence, RI 02912 & Div. of Neurology, Duke Univ., Durham, NC 27706.

Embryonic neocortex transplanted into that of an adult host will survive and develop many features of normal cortex. Our ultrastructural observations have revealed numerous flat-symmetrical type synapses in the transplants. Because synapses with this morphology have been shown to contain GAD in normal rodent cortex, these data suggested that the transplants were richly innervated by GABAergic neurons. We have investigated this possibility further with immunocytochemistry using the GAD antiserum developed by Oertel et al. (1981).

Transplants were made by dissecting rectangular solids (.5x.5x4 mm) of neocortex from embryonic day 14 (E-14), E-17, and PND-0 donors and inserting them with a square capillary tube into the left parietal cortex of adult BALB/cj mice. The host animals were allowed to survive from 14 to 340 days before they were perfused with 10% formalin in saline containing 0.5% zinc salicylate. 30 um vibratome sections were reacted for immunocytochemistry according to the PAP method of Sternberger.

Immunoreactive cells, processes, and puncta were seen in the host cortex and in the transplants of all donor ages. The GAD-positive cells in the host cortex were multipolar or fusiform in shape and appeared evenly distributed in all cortical layers including some cells in layer I. Numerous puncta were also seen in all layers, with the highest density in layer IV. Abnormally high densities of GAD-positive puncta were frequently found in the middle layers of the host cortex near the transplant. Interestingly, the density of puncta was also markedly increased at all survival times in the region of the contralateral hemisphere homotopic to the transplant. The E-14 transplants grew to a relatively large size and contained a high density of Nissl-stained cells. However, GAD-positive neurons were virtually absent from E-14 cases and the puncta were of smaller caliber and fewer in number than at any other donor age. E-17 transplants grew to a moderate size and contained Nissl-stained cells, GAD+ neurons and GAD+ puncta in densities almost equivalent to the surrounding host cortex. PND-0 transplants were always small in volume, but developed immunoreactive neurons and puncta equivalent to the E-17 donors.

These results demonstrate that (1) GABAergic neurons can survive and differentiate in neocortical transplants, (2) the development of GAD+ cells and puncta varies as a function of donor age, and (3) Some GABAergic cells in the host brain respond to the transplantation procedure by local sprouting.

(Supported by NIH grant NS-13031)

226.12 THE DEVELOPMENT OF PEPTIDERGIC NEURONS IN CORTICAL AND HYPOTHALAMIC TRANSPLANTS INTO ADULT MOUSE CORTEX. F. F. Ebner, J. A. Olschowka and D. M. Jacobowitz. Div. of Bio. and Med., Brown Univ. Prov., R.I. 02912 and Lab. of Clin. Sci., NIH-NIMH, Beth.,Md.20205

Neurons from embryonic neocortex and hypothalamus will survive transplantation into the neocortex of adult mice. It is unknown whether the transplants develop the types of neurons found in their source areas. We were also interested in whether peptide-containing processes would grow across the interface into and out of the transplants. We have studied the development and distribution of peptide-containing processes and cells using immunocytochemical localization of the four peptides demonstrated to date in neocortex (vasoactive intestinal polypeptide, VIP; cholecystokinin CCK; pancreatic polypeptide, PP; and somatostatin, SST), as well as five peptides demonstrated in the normal hypothalamus, but not in neocortex (alpha-melanocyte stimulating hormone, MSH; arginine-vasopressin, AVP; corticotropin-releasing factor, CRF; beta-endorphin, END; and substance P, SP).

Neocortical and hypothalamic tissue for transplantation was taken from embryos at 13-16 days of gestation and implanted by capillary tube into the neocortex of 22 adult BALB/cj mice. Neocortex was placed in the left hemisphere, and hypothalamus from the same embryo into the right hemisphere. All 22 recipient animals lived for 4-6 weeks. All 44 transplants survived and contained healthy-appearing neurons. For processing, the brains were cut in a cryostat at 16 um, preincubated for 1 hour in PBS with 4% normal goat serum, and for 48 hr at 4°C in one of the 9 different antisera.

In the cortex-to-cortex transplants, the four peptides seen in the host cortex also developed in the transplant; namely, VIP,CCK, PP and SST. No cells or processes were immunoreactive for MSH, AVP, CRF, END or SP. The processes that develop in the transplant appear to be distributed throughout the transplant, but do not course out of (or from the host into) the implant in detectable numbers. In the hypothalamus-to-cortex transplants, immunoreactive processes and/or cells were labelled with all 9 peptides,but the relative densities of label were markedly different. SP processes formed the densest plexus in all hypothalamic transplants.

These results indicate that peptide neurons which normally develop in the donor structure continue to do so when they develop in a host animal's cortex. Peptide-containing processes do not appear to sprout between donor and host tissue.

(Supported by internal and external (#NS-13031) grants from the NIH).

226.13 TRANSPLANTS OF VASOPRESSIN NEURONS INTO NEONATAL BRATTLEBORO RATS: DEFINING THE OPTIMAL DONOR AGE. D.M. Gash, L.B. Dick* and G.J. Boer*. Dept. of Anatomy, University of Rochester, Rochester, N.Y. 14642 and the Netherlands Institute for Brain Research, Amsterdam, the Netherlands.

Over the past five years, our laboratory has investigated the development and function of fetal hypothalamic tissue transplanted into adult Brattleboro rats homozygous for the diabetes insipidus trait. The present study was conducted to determine the survival and viability of fetal and neonatal hypothalamic transplants into five day neonatal Brattleboro rats.

Prenatal transplant material was obtained from timed-pregnant Long-Evans rats at 11-, 13-, 15-, 16-, 17-, 19-, and 20-days post-coitus (dpc) and neonatal tissue from 0- and 5-day old rat pups. Transplants from 11- and 13-dpc embryos were of the ventral diencephalon containing the presumptive Supraoptic Nucleus (SON). Grafts from the older donors contained the SON proper which had been dissected free from a 1 mm thick coronal section through the anterior hypothalamus.

Transplants were introduced into the third ventricle of ether-anesthetized 5-day neonatal Brattleboro pups via a hand-held spinal needle inserted through an incision in the skull at bregma. At about 40 days following surgery, recipients were perfused with Zamboni's fixative and their brains processed for vasopressin and neurophysin thick-section immunocytochemistry.

The results showed a clear demarcation in this model system between the capability for survival of 11-17 dpc grafts (29/30 viable) and grafts of 19 dpc and older tissue (6/24 survived). In addition, all transplants of 11-17 dpc tissue contained neurophysin-positive neurons while these neurons were only seen in two grafts of 19 dpc and older tissue. These data suggest a close correlation between the ability of a neuron to survive transplantation and its stage of development. In the normal rat fetus, the 17th embryonic day is a time of rapid growth and differentiation of the SON (C.D. Sladek, et al., Peptides 1: Suppl. 1, pp. 51-67, 1980). Events occurring at this period include ultrastructural development of the cytoplasmic apparatus for hormone synthesis, detection of vasopressin in the SON by radioimmunoassay, and axonal outgrowth of neurophysin-positive fibers. In addition, noradrenergic innervation of the SON is being established by the 17th fetal day. It appears, from our present results, that isolation of the SON after initiation of axonal outgrowth and/or noradrenergic innervation, which occurs in transplantation of 19 dpc and older SON, may greatly impair survival of magnocellular vasopressin neurons. Neurons not fully differentiated, as in 11-17 dpc tissue, maintain a greater degree of plasticity than older tissue, and are better able to survive the rigors of transplantation under the conditions inherent in this present experiment.

226.14 REDUCED TRAUMATIC RESPONSE FOLLOWING NERVE TRANSECTION THROUGH THE USE OF POLYVINYL ALCOHOL AND CHLORPROMAZINE. L. de Medinaceli and A. C. Church. Adult Psychiatry Branch, NIMH, Saint Elizabeths Hospital, Wash. D.C. 20032

Two agents, polyvinyl alcohol (PVA) and chlorpromazine (CPZ), were used at the time of transection of the sciatic nerve in the rat. These substances were tested for their efficacy in reducing some of the degenerative processes that occur in the nerve stumps following transection. We felt that by minimizing these post-traumatic events, we could more effectively promote functional recovery (L. de Medinaceli et al., Exp. Neurol., in press).

Given PVA's physico-chemical properties, we hypothesized that it would reduce the swelling that develops at the tips of the nerve stumps after transection. Through the use of photomicrographs and blind raters, it was determined that PVA significantly prevented such swelling. It is felt that this property of PVA leads to an increased precision in the realignment of the nerve tips and thus provides improved results.

The influx of extracellular calcium into an injured axon has been shown to trigger Wallerian degeneration. We hypothesized that calcium's effect was mediated through its activation of calmodulin, and that by antagonizing calmodulin we could interfere with the degenerative processes. Since CPZ has been shown to inhibit calcium-calmodulin binding, we tested the effects of this agent on degeneration. Sciatic nerves were transected and left in situ with the experimental group receiving locally applied CPZ and the controls receiving Ringer's solution for 24 hours. The nerves were then removed, fixed and stained with Bodian's silver protein method. Our preliminary results showed that under the light microscope CPZ retarded Wallerian degeneration during this period. The CPZ-treated nerve had an appearance that was similar to an undamaged nerve. The initial stage of Wallerian degeneration was visible throughout the control nerve. We interpret these results as supporting our hypothesis concerning the role of calmodulin in Wallerian degeneration. It must be emphasized that the use of these two agents is not the only requirement for a good nerve repair since, in our experience, many other conditions must be met in order to obtain consistently good functional recovery.

227.1 CENTRAL DOPAMINE INHIBITION IN THE SINOAORTIC DENERVATED RAT AS MEASURED BY TYROSINE HYDROXYLASE ACTIVITY AND DOPAMINE CONCENTRATION. N. Alexander, Y. Hirata* and T. Nagatsu. U.S.C. Sch. of Med., Dept. of Med. and Tokyo Inst. of Tech., Dept. of Life Chem., Los Angeles, CA 90033; Yokohama 227

Previous studies showed that resection of arterial baroreceptor nerves affects norepinephrine and epinephrine metabolism in discrete brain nuclei; in this study we show that the dopamine (DA) system is inhibited. Male, Wistar rats, 280-330 gms, were used for total sinoaortic denervation (SAD) or for sham operation (SO). Three days after operation rats were decapitated, brains frozen and cut into 300 µm thick sections. Six, 0.5 mm diam. "punch" samples were obtained from both caudate and substantia nigra areas. Tyrosine hydroxylase activity (TH) and DA concentration were measured by high-performance liquid chromatography-electrochemical detection. Results were, SAD vs. SO rats: TH (pmol/min/mg protein) in caudate, 158 ± 26 vs. 327 ± 46 ($p < 0.01$) and in substantia nigra, 386 ± 40 vs. 740 ± 130 ($p < 0.02$); caudate DA (pmol/mg protein), 296 ± 50 vs. 500 ± 70 ($p < 0.05$). In conclusion, this study shows, for the first time, that arterial baroreceptor reflex pathways affect the central DA system. Further studies are needed to determine if impaired arterial baroreflex function contributes to known reductions in DA metabolism of certain disease states.

227.2 QUALITATIVE AND QUANTITATIVE IMMUNOCYTOCHEMICAL STUDIES OF THE DISTRIBUTION OF MONOAMINE NERVE CELL BODIES IN THE FUNCTIONALLY DEFINED SUBNUCLEI OF THE NTS IN THE RAT. K. Fuxe*, M. Kalia, T. Hökfelt*, L. Agnati*, A. Härfstrand* and M. Goldstein. (Spon: C. P. Bianchi). Dept. Histol. Karolinska Inst., Stockholm 104 01 and Depts. Neurol. and Pharm. Thomas Jefferson Univ., Phila., PA 19107.

Previous studies have demonstrated the existence of monoamine containing cell bodies in the dorsal medulla including the nTS. However, there is no information available with regard to the distribution of these cell bodies in relation to the functionally distinct subnuclei of the nTS. In 25 adult, colchicine treated rats (180µgi.c.), the distribution of monoamine containing neuronal perikarya in the nTS was studied with immunoperoxidase and immunofluorescence techniques using antibodies raised against TH, DBH & PNMT. The sections were counterstained with cresyl violet after intial photography to determine the location of the cytoarchitectonically distinct subnuclei of the nTS. The results are summarized in Table 1. The A2 monoamine cell group (Dahlström & Fuxe'64) was localized in the mnTS,ncom and dmnX and contained TH and DBH positive nor-adrenergic neurons. In addition adrenergic neurons (PNMT positive) were identified in the periventricular region (PVR) and dorsal parasolitarius region (dPSR). Thus, there appears to be a differential distribition of monoamine neurons in the nTS. The mnTS which has been implicated in gastrointestinal function (Kalia and Mesulam'80a) contains noradrenergic neurons and the dPSR and PVR which are associated with cardiac and baroreceptor activity (Kalia and Kropilak '81; Katz and Karten '79, Kalia and Welles '80) contain adrenergic neurons. This suggests that monoamine neurons in the nTS have different roles in central autonomic regulation. Supported by HL 30991, Am.Hrt.GRT.81-978, Swedish Med. Res.Grt.14X-04246-10B .

227.3 DISTRIBUTION OF NEUROPEPTIDE NERVE TERMINALS WITHIN THE SUBNUCLEI OF THE NUCLEUS OF THE TRACTUS SOLITARIUS OF THE RAT. M. Kalia, K. Fuxe* and T. Hökfelt*. Dept. Neurol. Thomas Jefferson Univ. Phila. PA 19107 and Dept. Histol. Karolinska Institutet, Stockholm 104 01 Sweden.

The location of substance P, enkephalin, somatostatin (SRIF) and neurophysin II immunoreactive nerve terminals and preterminal processes in the nucleus of the tractus solitarius (nTS) and the adjacent regions of the dorsal medulla was examined using the indirect immunofluorescence method combined with cytoarchitectural identification of subnuclear groups in the same section. In 22 adult Sprague-Dawley rats 14 µm thick serial cryostat sections were incubated with antisera raised against substance P, enkephalin, SRIF and neurophysin II. All four peptides were examined in adjacent sections at five different rostro-caudal levels in the medulla, from 1mm caudal to the obex to 2 mm rostral to the obex. The sections were photographed and then counterstained with cresyl violet so that the location of the immunoreactive nerve terminals could be related to cytoarchitectonically distinct subnuclei. The vlnTS, vnTS, ni and nI (the subnuclei associated with respiratory function) showed moderate density of SRIF, scattered substance P and enkephalin and no neurophysin II immunoreactive nerve terminals. The dlnTS, dnTS and ncom (the subnuclei associated with cardiac and baroreceptor function) showed moderate density of neurophysin II, substance P and enkephalin immunoreactive nerve terminals. The mnTS (the subnucleus associated with gastrointestinal function) showed moderate amounts of substance P and weak immunoreactivity for the other three peptides. The densest collection of peptide immunoreactivity however, was found outside the nTS in the adjacent periventricular region (PVR), dorsal and ventral parasolitarius regions (dPSR and vPSR). These regions represent the sites where the dendrites in the adjoining nTS subnuclei project. The vPSR contains moderate density of substance P and enkephalin immunoreactivity; the dPSR contains enkephalin immunoreactivity in moderate amounts and the PVR contains substance P and enkephalin immunoreactivity implicating these peptides in respiratory, cardiovascular and gastrointestinal modulatory function respectively. Since diffferent peptides were found in the somatic and dendritic regions of a given cell group it can be concluded that a single neuropeptide might be serving different functions on a given class of nTS neurons. These different effects of neuropeptides might be responsible for the integrative functions involved in central autonomic regulation.

227.4 A SLICE PREPARATION OF THE RAT NUCLEUS TRACTUS SOLITARIUS (NTS): NEURONAL ACTIVITY AND RESPONSES TO NEUROPEPTIDES. G.B. Siggins[1], J. Champagnat*[2], L.Y. Koda[1], and M. Denavit-Saubie[2]. [1]A.V. Davis Ctr., The Salk Inst., P.O. Box 85800, San Diego, CA 92138 and [2]Lab. Physiologie Nerveuse, Dépt. Neurophysiologie appliquée, C.N.R.S., Gif-sur-Yvette, France 91190.

The NTS plays a key role in cardiovascular and respiratory function. Vagal and glossopharyngeal afferents in the tractus solitarius (TS) terminate in the NTS, where they evoke excitatory effects. The NTS contains many putative transmitters, including several neuropeptides. We have developed an in vitro slice preparation of the NTS to help clarify the synaptic interactions in the NTS and the role these peptides may play. Albino rats (100-170g) were decapitated at the upper cervical spinal cord. The brainstem was removed and placed in cold (4°C) physiological salt solution (PSS) gassed with 95% O_2, 5% CO_2. Coronal slices (350-500 um thick) were cut on a tissue chopper, placed in PSS in the recording chamber and then completely immersed and continuously superfused with PSS (31-35°C) at 1-2 ml/m. We recorded single units and stimulated the TS with a concentric electrode. Most extracellularly recorded neurons (70%; n = 110) discharged spontaneous spikes at 0.5-10/s. Sixteen neurons were recorded intracellularly; most of these were silent. Membrane potentials of -50 to -70 mV and evoked action potentials of 50 to 100 mV were recorded; input resistances of 20 MΩ were estimated. Forty of 70 neurons tested were activated by TS stimulation with 3-10 ms latencies to a single spike. This driven activity is probably orthodromic because: 1) spike latencies varied by several ms with low frequency stimulation; 2) collision tests were negative; 3) intracellularly, evoked spikes always arose from an excitatory postsynaptic potential. Inhibitory phenomena also appear in the slice. Spikes evoked by TS stimulation were followed by a 30-100 ms silent period, during which a second stimulus failed to evoke a spike. In some intracellular recordings, flurries of small, spontaneous depolarizations indicative of inverted inhibitory postsynaptic potentials appeared after injection of chloride. Superfusion of Substance P (0.01-1 nM) increased the firing rate of 8 of 10 neurons tested. Met-enkephalin (1 uM) decreased the firing rate in 3 neurons, and had no effect in another 4 cells. Somatostatin 28 (0.1-1 µM) decreased firing in 5 of 5 cells. We believe this preparation will be useful for study of synaptic transmission in the NTS, where many amines and neuropeptides may play critical roles in cardiovascular and respiratory function. 227.5 MICRO-INJECTION OF SOMATOSTATIN RELATED PEPTIDES INTO THE RAT NUCLEUS TRACTUS SOLITARIUS: BLOOD PRESSURE. L. Y. Koda, N. Ling*, C. Bakhit, S. G. Madamba* and F. E. Bloom. The A. V. Davis Center and Neuroendocrinology Laboracory, The Salk Institute, La Jolla, CA 92037.

The nucleus tractus solitarius (NTS) provides a model to examine the functional role of central peptidergic and monoaminergic neuron systems in the regulation of blood pressure. To examine the possible role of somatostatin in cardiovascular regulation, we have micro-injected various peptide fragments of somatostatin 28 (SS28) into the area of the NTS. Male Sprague Dawley rats (150-250g) were anesthetized (pentobarbitol), and placed in a sterotaxic apparatus. Blood pressure was measured from the abdominal aorta. Various concentrations of SS28, peptide fragments of SS28 or yohimbine were injected into the caudal NTS. Injection of vehicle (500nl/10s; 50-80um diameter pipette) alone was followed by a small (2mmHg) decrease in blood pressure. SS28, SS28(1-12) and SS28(15-28) (somatostatin 14) all caused an immediate and statistically significant decrease in blood pressure as compared to vehicle. SS28(1-10) had no significant effect. SS28 was tested at three doses (2.5, 25 and 250pmols); the other peptides were tested only at the 250pmol dose. The low dose of SS28 caused an 8mmHg drop in blood pressure, the medium dose, a 10mmHg drop and the high dose a 16mmHg drop. SS28(1-12) caused a significantly ($p<.01$) less drop in blood pressure (6mmHg) when compared to either SS28 or SS28(15-28) (23mmHg). Since the injection of catecholamine analogs into the NTS or locus coeruleus has been reported to decrease blood pressure, we examined the effect of SS28 on the in vitro release of tritiated norepinephrine (*H-NE). Preliminary results indicate that SS28 (500 nM) enhances the potassium (30-50 mM) induced release of *H-NE from both NTS and locus coeruleus slices. Based on these in vitro release results we attempted to block the hypotensive effect of SS28 with a unilateral NTS injection of yohimbine (alpha adrenergic blocking agent) 10 min prior to an ipsilateral NTS injection of 250pmols SS28. Three doses of yohimbine were tested (6.25, 62.5 and 625 pmols). The 6.25 pmol dose caused a brief 20-25mmHg drop in blood pressure but did not block SS28. The 62.5 pmol dose caused a brief 20-40mmHg drop in blood pressure and partially blocked the SS28 hypotensive response. The 625pmol dose of yohimbine had little effect on blood pressure by itself but blocked the subsequent hypotensive dose of SS28. These data indicate that the C-terminal portion of somatostatin is important for the hypotensive potency of intramedullary injected somatostatin related peptides and that catecholamine-peptide interactions may be important to our understanding of CNS cardiovascular control mechanisms. 227.6 CARDIOVASCULAR EFFECTS OF A1 LESIONS ARE ATTENUATED BY PRE-TREATMENT WITH INTRACISTERNAL 6-HYDROXYDOPAMINE. M.J. West, J.M. Elliott,* B.H. Stead,* and J.P. Chalmers*. (SPON: C. Straznicky). Centre for Neuroscience, Flinders University, South Australia, 5042.

Electrolytic lesions in the ventrolateral medulla coinciding with the A1 group of norepinephrine cells (A1 lesions) produce acute hypertension and bradycardia (Blessing, W.W., West, M.J., & Chalmers, J.P., Circ. Res., 49: 949, 1981). In the present study we have investigated the role norepinephrine (NE) cells and their projections may play in mediating these cardiovascular effects, by pretreating rabbits with intracisternal (ici.) 6-hydroxydopamine (6OHDA).

In preliminary experiments, 6OHDA (600 µg/kg free base) dissolved in normal saline (NS), depleted spinal cord NE to less than 1% of control levels whereas the same dose of 6OHDA dissolved in 0.2% ascorbate saline (AS) only depleted spinal cord NE to 24% of control levels. There were no significant differences in depletion of NE in all other brain regions.

Animals which were to be lesioned received ici. injections of 6OHDA (400 µg/kg in AS or 600 µg/kg in NS), or of vehicle alone. One or two weeks later, A1 lesions were made under halothane anaesthesia and arterial blood pressure (BP) and heart rate (HR) were monitored for one hour. A segment of lower thoracic spinal cord was then taken for NE and 5-hydroxytryptamine (5HT) assay before the brain was perfused for histological assessment of the lesions.

The cardiovascular effects of A1 lesions in animals pretreated with 6OHDA in AS (n=7) were not significantly different from those in AS vehicle pretreated animals (n=9). BP increased by 37±8, and 35±7 mmHg and HR fell by 73±11 and 61±11 beats/min respectively. In the animals receiving 6OHDA in AS spinal cord NE was depleted to 23% and 5HT concentrations remained unchanged.

On the other hand, in animals given 600 µg 6OHDA in NS (ici.) spinal NE fell to 2% of control and 5HT levels were again not reduced. The increase in arterial pressure was almost halved (23±7 cf 39±6 mmHg) compared to rabbits treated with NS alone. The bradycardia was also reduced by 50% (-46±8 cf -83±10 beats/min).

These results suggest that depletion of spinal cord NE to 2% of control levels significantly attenuates the cardiovascular effects of A1 lesions. It seems likely therefore that the cardiovascular effects of A1 lesions are mediated, at least in part, by NE projections descending from the brainstem.

227.7 VASOACTIVE INTESTINAL POLYPEPTIDE, BUT NOT SUBSTANCE P OR ACETYLCHOLINE IS THE POTENTIAL CEREBRAL VASODILATOR TRANSMITTER. T.J-F. Lee, A. Saito* and I. Berezin*, Dept. of Pharmacol., So. Ill. Univ. Sch. of Med., Springfield, IL 62708 and Dept. of Neurosci., McMaster Univ., Hamilton, Ontario, Canada.

Cerebral blood vessels of several species have been shown to receive vasodilator nerves. The nature of the dilator transmitter however has not been positively identified. Acetylcholine (ACh), substance P (SP) and vasoactive intestinal polypeptide (VIP) have been shown to be present in cerebral blood vessels. When exogenously applied, these substances have been shown to relax cerebral blood vessels under certain conditions both in vivo and in vitro. The possible role of these substances as vasodilator transmitters in cat cerebral arteries is therefore examined by pharmacological and ultrastructural immunocytochemical techniques. The results indicate that ring preparations of the cat cerebral arteries with intact endothelial cells relax upon application of VIP, ACh and SP at low concentrations but constrict with application of higher concentrations of ACh and SP. In contrast, the cerebral arterial rings without endothelial cells (removed by mechanical rubbing) constrict exclusively upon application of ACh and SP at any concentration examined. These arteries without endothelial cells however still relax upon application of VIP and upon transmural nerve stimulation (TNS). These results suggest that the effect of direct action of ACh and SP on smooth muscle cells is constriction. Both ACh- and SP-induced relaxations depend on intact endothelial cells; presumably they release a dilator substance from the endothelial cells which then causes vasodilation. On the other hand, VIP-induced relaxation is independent of endothelial cells. VIP seems to relax smooth muscle directly. Since the nerve terminals of any type are confined to the adventitial layer of the vessel wall, the wide distance between nerve and endothelium makes it very unlikely that the nerve-released ACh and SP can induce vasodilation indirectly through the endothelial cells. Taken together, these results suggest that VIP acts more like a dilator and SP and ACh more like constrictor transmitters. Results from immunocytochemical studies using the protein A-gold technique indicate that VIP-like immunoreactivity is indeed found in the large granular vesicle in the nerve terminals and axons. The immunoreactivity persisted following chronic sympathetic denervation, indicating that VIP-like substance is present in the granular vesicles of the nonadrenergic nerves. It is therefore suggested that a VIP-like substance, but not ACh or SP, is the potential vasodilator-transmitter in the cat cerebral blood vessels. (Supported by NIH HL 27763, AHA/IHA and Southern Illinois University School of Medicine.)

227.8 ROLE OF THE CHOLINERGIC SYSTEM IN THE CEREBROVASCULAR VASODILATION ELICITED BY STIMULATION OF THE DORSAL MEDULLARY RETICULAR FORMATION IN RAT. C. Iadecola, M.D. Underwood*, T. Ishitsuka, D.J. Reis, Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

Electrical stimulation of the fastigial nucleus of the cerebellum (FN) or of the dorsal medullary reticular formation (n. parvocellularis) (DMRF) increases regional cerebral blood flow (rCBF) globally throughout brain. However, the vasodilation elicited by stimulation of these two systems differs in that, outside of primary projection fields, FN increases rCBF independently of local metabolic activity (Nakai et al., Brain Res., 260:35, 1983), while DMRF increases both parameters proportionally (Iadecola et al., Brain Res., in press). Furthermore, we have recently found that cholinergic mechanisms play an important role in the cerebrovasodilation elicited by FN stimulation (Iadecola et al., Neurosci. Abst., 8:424, 1982). In the present study we sought to determine whether the metabolically-linked cerebrovascular vasodilation elicited by DMRF stimulation is also cholinergically mediated.

Rats were anesthetized (chloralose), paralyzed (tubocurarine) and artificially ventilated. Arterial pressure (AP), heart rate, and body temperature were continuously monitored and controlled and blood gases were kept in physiological range. DMRF or FN were electrically stimulated (50-100 uA; 50 Hz; 1 sec on/1 sec off) and AP maintained in the rCBF autoregulated range. rCBF was measured in 13 brain areas by using the 14C-iodoantipyrine technique with regional dissection (Nakai et al., Am. J. Physiol., 243:H226, 1982).

In controls (n=5), rCBF ranged from 62 ± 1 (ml/100 g x min) in corpus callosum to 119 ± 8 in inferior colliculus. Administration of atropine sulphate (0.3 mg/kg i.v.) in unstimulated animals did not change rCBF in any of the regions studied ($p>0.05$ vs. untreated controls). As before, electrical stimulation of DMRF (n=5) or FN (n=5) in untreated rats, increased rCBF globally ($p<0.005$) and maximally in cerebral cortex (DMRF: up to 223% of control in parietal cortex; FN: up to 200% in frontal cortex). In contrast, stimulation of FN in rats pretreated with atropine failed to increase rCBF ($p>0.05$; n=5), while the cerebrovascular dilation elicited by DMRF stimulation was not affected by the drug ($p>0.05$ vs. DMRF stim. in untreated animals; n=5). We conclude that: (a) atropine alone does not affect resting rCBF; (b) unlike FN, the vasodilation elicited by DMRF stimulation in not mediated by muscarinic receptors in brain and/or blood vessels. Cholinergic mechanisms do not seem to be involved in the cerebrovascular vasodilation secondary to increased cerebral metabolic activity. (Supported by Grant HL18974).

227.9 RELAXATION OF ISOLATED BOVINE, PORCINE AND HUMAN BRAIN ARTERIES BY VASOACTIVE INTESTINAL PEPTIDE (VIP) AND PARATHYROID HORMONE (PTH). Y. Suzuki*, D. McMaster*, K. Lederis*, F.E. LeBlanc*, M. Huang* and O.P. Rorstad (SPON: J.P.H. Wyse). Depts. of Pharmacology, Clinical Neuroscience and Medicine, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

Recent observations suggest that vasoactive intestinal peptide (VIP) may participate in the regulation of brain blood flow. We have studied the relaxant effect of VIP on isolated strips of bovine, porcine and human brain arteries including the middle cerebral artery (MCA, branches distal to the bifurcation), anterior cerebral artery (ACA, pericallosal or callosomarginal branches), posterior cerebral artery (PCA) and basilar artery (BA). VIP (0.3 to 300 nM) elicited a dose-dependent relaxation, in all three species studied, of arteries which had been contracted with prostaglandin $F_{2\alpha}$ or KCl. The relative responsiveness of bovine arteries to VIP was MCA ≃ ACA > BA ≃ PCA. The ED_{50} (relative to maximal vasorelaxation by papaverine) of the VIP effect on all bovine brain arteries studied ranged from 3 to 14 nM. The ED_{50} of the VIP effect on porcine BA and human MCA were 4.5 nM and 1.9 nM respectively. PHI (a peptide having considerable structural homology with VIP) relaxed bovine arteries at a slightly lower potency compared to VIP, whereas the other homologous peptides, secretin and glucagon, were inactive. Interestingly, PHI has considerably more homology with the C-terminal half of VIP than do secretin and glucagon. The fragments VIP-(1-12) and VIP-(10-28) had neither agonist nor antagonist activity on brain arteries, but VIP oxidized at methionine to the sulfoxide (by dilute H_2O_2) or to the sulfone (by performic acid) retained the vasorelaxant effect of the intact peptide. Native bovine parathyroid hormone (bPTH)-(1-84) and synthetic bPTH-(1-34) potently relaxed the bovine MCA and BA, porcine BA and human MCA with the following ranges of ED_{50} for all the arteries studied: bPTH-(1-84), 11 to 23 nM; bPTH-(1-34), 9 to 14 nM. Pretreatment of arterial strips with a PTH inhibitor, [Nle^8,Nle^{18},Tyr^{34}] amide, attenuated the vasorelaxant effect of both PTH preparations. In conclusion: (i) VIP and PTH relax a variety of brain arteries from cattle, hogs and humans. The potencies of the vasorelaxant effect of VIP and PTH are consistent with the potencies for stimulation of adenylate cyclase by these two peptides (Huang and Rorstad, unpublished observation); (ii) The structure-activity relationships for VIP relaxation are complex; and (iii) The bovine arteries from the anterior part of the circle of Willis are more responsive to VIP than those from the posterior part.
(Supported by the MRC of Canada and the AHFMR).

227.10 CHARACTERIZATION OF THE PEPTIDE RESPONSIVENESS OF ADENYLATE CYCLASE IN BRAIN ARTERIES AND CEREBRAL CORTICAL MICROVESSELS. Minta Huang* and O.P. Rorstad, Dept. of Medicine, University of Calgary, Calgary, Alberta, Canada T2N 4N1.

An increasing body of evidence suggests that peptides may participate in the regulation of cerebral blood flow, possibly by vasodilation. On the basis that cAMP appears to be an intracellular messenger contributing to vasodilation by some vasoactive agents, we had previously studied the effect of several peptides, many of which are vasoactive, on vascular adenylate cyclase (AC). We have reported elsewhere that vasoactive intestinal peptide (VIP) and bovine parathyroid hormone (bPTH)-(1-34) potently stimulate AC in rat cerebral cortical microvessels with ED_{50} values of 100 nM and 6.3 nM respectively. We have subsequently extended our study to a broken cell preparation of bovine brain arteries consisting of branches from the circle of Willis and the basilar artery. AC in these arteries was stimulated by VIP, bPTH-(1-34) and PHI (a peptide having considerable structural homology with VIP) with respective ED_{50} values of 10 nM, 30 nM and 100 nM and respective efficacies of VIP ≳ PHI > bPTH-(1-34). These results are consistent with the observed potencies of VIP and bPTH-(1-34) for relaxation of isolated helical strips of bovine brain arteries (Suzuki, Lederis, Huang and Rorstad, unpublished observation). Combination of maximally active concentrations of VIP and PHI did not result in enhancement of the arterial AC response over that observed with either peptide alone. In contrast, combination of a maximally active concentration of bPTH-(1-34) with either VIP or PHI produced a quantitatively additive effect on arterial AC activity. These additivity studies agree well with our previous observations using cerebral cortical microvessels, consisting of capillaries, arterioles and venules. That is, maximally active concentrations of VIP and bPTH-(1-34) produced an additive effect on AC activity and use of a PTH inhibitor antagonized the AC response to bPTH-(1-34) but not to VIP. Interestingly, bovine cerebral cortical microvessels were relatively unresponsive to VIP, in that a 1 μM concentration effected only a 20-30% increase over basal AC activity. In contrast, bovine cerebral cortical microvessel AC actively responded to bPTH-(1-34) with a four-fold stimulation and an ED_{50} of 10 nM. In conclusion, our results suggest that: 1. Brain arterial, in addition to microvascular, AC is activated by VIP and PTH via pharmacologically distinct receptors for these two peptides, and 2. A very considerable difference exists between bovine brain arteries and cerebral cortical microvessels with respect to the responsiveness of their AC to activation by VIP but not to activation by PTH. (Supported by the MRC of Canada and the AHFMR).

227.11 SEROTONERGIC EXCITATION OF SYMPATHETIC PREGANGLIONIC NEURONS. Robert B. McCall. Cardiovascular Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

The intermediolateral cell column is the main site of origin of sympathetic preganglionic neurons (SPNs). This area of the spinal cord receives a dense input from serotonergic-containing neurons located in raphe pallidus, raphe obscurus and ventral areas of the medulla. However, the nature of the interaction between serotonergic neurons and SPNs remains controversial. In the present investigation, the effects of microiontophoretically applied serotonin (5-HT) on the extracellularly recorded discharges of SPNs were studied in anesthetized cats (n=119). Thoracic neurons were identified as SPNs if: 1) the onset latency of an antidromically evoked discharge remained constant over a range of stimulating intensities, 2) the response to stimulation was all or none and exhibited a sharp threshold, 3) the spike followed high frequencies of stimulation and 4) collisions between orthodromically conducted action potentials and antidromically elicited action potentials could be observed. Onset latencies of antidromically elicited action potentials ranged from 14 to 47 ms. Thirty percent of the SPNs were spontaneously active. These cells fired irregularly and had a mean discharge rate of 1.1 spikes/sec. Low ejecting currents of 5-HT (5-30 nA) invariably excited spontaneously active SPNs (n=22). 5-HT also excited the vast majority of quiescent SPNs (n=34), as well as neurons brought to discharge threshold by iontophoresis of the excitatory amino acid L-glutamate (n=7). A population of SPNs was identified which was insensitive to the excitatory effects of both 5-HT and L-glutamate (n=17). In contrast, current controls had no effect on the discharges of SPNs. Iontophoretic (5-10 nA, n=22) or intravenous (0.05-0.2 mg/kg, n=12) administration of the putative 5-HT antagonists methysergide and metergoline blocked the excitatory effects of 5-HT, but not L-glutamate, on SPNs. The blockade of the 5-HT-induced excitation was not associated with a local anesthetic action of methysergide or metergoline. Methysergide and metergoline reduced the firing rate of spontaneously active SPNs in intact animals. Iontophoretic 5-HT also excited SPNs in spinal animals (n=46) and this effect could be blocked by methysergide and metergoline. However the 5-HT antagonists failed to reduce the discharge rate of spontaneously active SPNs in spinal animals (n=8). These data provide strong evidence to support the contention that serotonergic neurons provide a tonic excitatory input to SPNs or to closely adjacent antecedent sympathoexcitatory interneurons.

227.12 EFFECTS OF SPINAL LESIONS ON SUBSTANCE P LEVELS IN RAT INTERMEDIOLATERAL CELL COLUMN: EVIDENCE FOR LOCAL SPINAL REGULATION. B.M. Davis, J.E. Krause, J.F. McKelvy and J.B. Cabot. Dept. of Neurobiology, SUNY at Stony Brook, Stony Brook, NY 11794.

Substance P (SP) has been localized to the neuropil of sympathetic preganglionic neurons (SPN's) in light and electron microscopic studies. Two recent reports have suggested that the majority of SP in the rat intermediolateral cell column (IML, site of SPN's) was contained in synaptic terminals of bulbospinal axons (Gilbert et al., Neurosci., 7:69, 1982; Helke et al., Fed. Proc., 41:1518, 1982). However, previous investigations in our laboratory indicated the presence of major SP spinal-SPN circuitry in pigeon. The present study examined SP levels in rat IML following various combinations of spinal lesions to discern the relative contributions of bulbospinal and intraspinal SP neurons to SP content in the IML.

70 male Sprague-Dawley rats, 60-90 days old, were used. Rat spinal cords were hemisected at spinal level C2 (n=12) or C7 (n=18) or hemisected at C7 and T7 ipsilaterally (n=12). All rats were killed 7 days after surgery except for 6 rats hemisected at C2, which were killed after 14 days. Right and left IML samples from T2-T3 were micropunched (500 um) and collected from lesioned and matched unoperated control (n=24) rats; SP content was measured by radioimmunoassay (RIA). Complete midthoracic (T5) transections were made in an additional 4 rats and the spinal cords processed for PAP immunohistochemistry following a 7 day survival time.

Following transection of thoracic spinal cord, SP-like immunoreactive staining was clearly evident in the IML caudal to the lesion. These SP positive fibers were studded with boutonal-like swellings and appeared normal. Following high cervical hemisection, depletion of SP (RIA measurements) was bilateral and equal in the IML: 25% depletion was observed after 7 days and 35% depletion after 14 days. However, rats which were hemisected at low cervical levels contained normal or elevated amounts of SP in the IML. The IML in double hemisected rats also contained normal amounts of SP.

Since SP remains in the IML following total transection, SP spinal-SPN circuitry must exist. However, depletion of SP following high cervical hemisection suggests the existence of a SP containing bulbospinal pathway to the IML. The observation that SP levels were normal or elevated following low cervical lesions is consistent with previous data which have shown that intraspinal SP neurons compensate for loss of SP in spinal cord (Tessler et al., Brain Res., 191:459, 1981). Sprouting or increased synthesis by intraspinal SP neurons could be responsible, suggesting an important homeostatic mechanism for maintaining SP content within the IML. (Supported by HL 24103 to JBC.)

228.1 DIGITIZED VIDEO ANALYSIS OF GLABROUS SKIN MOVEMENTS IN CROSS SECTION. R. H. Cohen* and C. J. Vierck, Jr. Dept. of Neuroscience and Center for Neurobiological Sciences, Univ. of Florida, Coll. of Med., Gainesville, FL 32610.

Glabrous skin of the fingertips of anesthetized macaques was cut and examined in cross section in order to determine the relationships between surface movements and underlying structures. A variety of simple tactile stimuli were applied to the surface as mechanical deformation was videotaped from a camera mounted on a dissecting microscope. Utilizing a video-to-computer analysis system, precise measurements of the skin surface profile and epidermal-dermal border from individual labelled frames were digitized for computer analysis by tracing the video image with a superimposed video-cursor. Details of underlying structures were enhanced with intra-vital dyes, yielding textbook-like images of glabrous skin. Distances between intermediate ridges, dermal papillae and limiting ridges, accurate to within 10 um, were measured during precisely controlled force and displacement conditions. A 1mm vertical indentation produced by a .5mm bar yielded a 65% decrease in the distance from the skin surface to the trough of a directly underlying intermediate ridge. Structures located more than 1.5mm from the original skin surface remained virtually motionless in the vertical dimension. This is an ideal condition for transmitting strain to superficial cutaneous mechanoreceptors. Preliminary comparision of the mechanical deformation of the superficial layers of the skin with that of the base of the intermediate ridge indicates that the skin is essentially homogeneous. This means that theoretical predictions of receptor activity can be modelled on basic principles of continuum mechanics. The homogeneous nature of the underlying structures of the skin does not support the notion proposed by Cauna (Anat. Rec., 119:449, 1954) that the intermediate ridges float freely in the loose connective tissue, acting as magnifying levers for the transmission of touch stimuli to the receptors beneath. On the contrary, the tips of the intermediate and limiting ridges are relatively fixed in position during vertical deformations.

228.2 VIBROTACTILE NEGATIVE MASKING. G. A. Gescheider, Dept. of Psychology, Hamilton College, Clinton, NY 13323, R. T. Verrillo and D. G. Pelli, Institute for Sensory Research, Syracuse University, Syracuse, NY 13210.

Negative masking occurs in audition, vision and vibrotaction when, in the presence of a masker, the test stimulus becomes detectable at intensities below the threshold level of the test stimulus. It is generally accepted that negative masking in auditory psychophysical experiments is an artifact of the definition of the test stimulus. In vibrotaction nonartifactual negative masking has been observed and interpreted to indicate the presence of a true energy threshold at the periphery. This hypothesis was tested psychophysically by requiring the subject to detect a sinusoidal test stimulus centered in a masker having the same frequency. The masked thresholds were measured against a background of continuous, narrow-band noise. The results confirm the finding of true negative masking in vibrotaction and support the hypothesis of a peripheral energy threshold in cutaneous mechanoreceptor systems.

228.3 CUTANEOUS SENSORY MEASURES FOR PATIENTS WITH HAND INJURIES: HAND REIMPLANTATION AND MEDIAN NERVE REPAIR. Sherry L. Berg* (SPON: Marcelle R. Morrison). DeVry Institute of Technology, Irving, Texas 75062.

Two young adult male patients, one with a hand reimplantation of 1 year and 5 months and another with a median nerve injury one month post-repair were examined for two-point threshold, pinprick sensitivity, evidence of sweating and report to hand emersion in beakers containing water at 40°, 35°, 25° and 20°C. Additionally, the Moberg measures of dexterity and tests for tactile identification were recorded as well as hand dynamometer readings to assess return of function. The uninvolved hand was used as an appropriate control.

The smallest two-point threshold for the reimplanted hand was 10mm, while the uninvolved hand showed differential sensitivities ranging from 3 to 10mm with the greatest sensitivity obtained from the tip of the index finger. For the median nerve injury, sensitivity was reduced by at least 2mm overall for the index finger. Pinprick discrimination for the median nerve injury was reduced and "blunt" was more frequently elicited when "prick" would have been the appropriate response. Both subjects demonstrated sweating in the involved extremity. Latency to establish thermoneutrality in the injured hand was increased and both individuals reported enhancement of intensity of thermal sensation for warm and cool emersions.

228.4 60-HZ ELECTRIC FIELDS IN AIR CAN STIMULATE CUTANEOUS MECHANORECEPTORS IN THE CAT. R. A. Jaffe, R. J. Weigel* and D. L. Lundstrom*, Neuroscience Group, Biology and Chemistry Dept., Battelle Memorial Institute, Pacific Northwest Laboratory, Richland, WA 99352.

Chronic exposure to 60-Hz electromagnetic radiation is known to affect the mammalian nervous system in a variety of subtle ways (Adey and Bawin, Neurosci Res Prog Bull 15:1, 1977; Jaffe et al., Bioelectromagnetics 1:131, 1980; Wilson et al., Bioelectromagnetics 2: 371, 1981). The mechanism whereby these effects are produced remains unknown. This mechanism may be of importance not only from an environmental health perspective but also in understanding any possible role for ephaptic transmission in the central nervous system. It is possible to hypothesize that the effects of electric fields are a result of direct interaction between neuronal membranes and either the surface or induced voltage and current. Alternatively, the biological effects could be produced indirectly, as a result of sensory stimulation and the resulting low-level stress. In order to test this alternative hypothesis, the existence of receptors, sensitive to electric fields, must first be demonstrated.

Using single fiber recording techniques in Ketamine anesthetized cats, we examined the responses of 233 receptor units comprising 10 cutaneous receptor categories. The hind foot and lower leg were exposed to a high-strength 60-Hz electric field while recording from dorsal root fibers supplying that region. Receptor units were categorized on the basis of optimal stimulus, stimulus-response characteristics and location. The number of units tested in each category was as follows: rapidly adapting high frequency (33); rapid adapting low frequency (6); type D hair follicle (40); type G hair follicle (71); type T hair follicle (22); rapidly adapting field receptor (15); slowly adapting type I (16); slowly adapting type II (13); slowly adapting type C (8); slowly adapting unidentified (7); and warm receptors (2). Receptor units in 4 categories generated action potentials in response to the presence of an electric field. The most sensitive receptors were the so-called rapidly adapting field receptors, with thresholds as low as 160 kV/m. This value is well below the local field strength used to produce many of the previously reported effects in animals.

In summary, we have demonstrated the existence of peripheral cutaneous sensory receptors capable of proportional transduction of 60-Hz electromagnetic radiation. We propose that chronic stimulation of these and perhaps other (e.g., vibrissa) receptors could account for many of the reported electric field effects in animals.

228.5 EFFECTS OF TEMPERATURE ON THE PSYCHOPHYSICAL CHARACTERISTICS OF NON-PACINIAN CUTANEOUS MECHANORECEPTOR SUBSYSTEMS. S.J. Bolanowski, Jr., Center for Brain Research, University of Rochester School of Medicine, Rochester, N.Y. 14642, and R.T. Verrillo, Institute for Sensory Research, Syracuse University, Syracuse, N.Y. 13210.

Psychophysical detection thresholds were obtained over a range of sinusoidal frequencies from 15 to 700 Hz using a small contactor (.008 cm^2), which preferentially excites the non-Pacinian subsystems. The responses of these subsystems were selectively enhanced or degraded by the use of carefully controlled (± 0.5°C) skin surface temperatures of 15, 20, 30, 40 and 43°C. The skin surface temperature was maintained by circulating water at the appropriate temperature through hollow chambers of the contactor's surround. The surround is approximately 33 cm^2 in area. All measurements were made on the thenar eminence. The results show several distinct frequency characteristics that are not of Pacinian-corpuscle origin. For example, the 43°C curve for low stimulus frequencies closely follows a U-shaped function thought to be mediated by Meissner corpuscles as based on electrophysiological evidence. Other portions of these same curves seem to suggest involvement of both Ruffini capsules (20°C, low stimulus frequencies) and Merkel cell-neurite (all temperatures, high stimulus frequencies) subsystems. Averaging of the threshold values across the controlled skin surface temperatures produces a flat function similar to the one commonly referred to as mediating the non-Pacinian (NP) system and described in the duplex theory of vibrotaction (Verrillo, R.T., The Skin Senses, edited by D.R. Kenshalo, Thomas, Springfield, Ill. 1968). The results suggest that the NP system is probably composed of more than one receptor type. As pointed out previously for the P system (Bolanowski, S.J., Jr. and Verrillo, R.T., J. Neurophysiol. 48:836, 1982) and again here, it appears that well controlled skin surface temperatures are necessary for the precise measurement of the various subsystems that mediate the sense of vibration.

228.6 EFFECT OF MECHANICAL STIMULUS SPREAD ACROSS GLABROUS SKIN OF RACCOON HAND ON TACTILE PRIMARY AFFERENT FIBER DISCHARGE. Benjamin H. Pubols Jr. Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, OR 97209.

Receptive field (RF) areas of cutaneous mechanoreceptors innervating the glabrous skin of the raccoon's hand are extremely small when measured at absolute threshold, ranging between 0.05 and 4.5 mm sq, with a median value < 1.00 mm sq (Pubols, L., and Pubols, B., J. Neurophysiol., 1973, 36, 1023-1037). Nevertheless, sufficiently intense suprathreshold stimuli may excite these receptors at a distance. In the present experiments, the role of spread of mechanical deformation of skin was investigated. One feedback-controlled mechanical stimulus probe (1 mm tip diameter) was used to indent the skin (constant depth = 1000 µm, constant velocity = 10 µm/msec) at varying distances from the center of a cutaneous RF, while a second probe was used to monitor vertical displacement of the skin at the site of the RF. Simultaneously, single unit action potentials were recorded from slowly adapting (SA) fibers of the median nerve.

As the stimulus probe moves away from the center of a palmar RF, vertical displacement of the RF declines approximately linearly over a distance of 4-5 mm. In contrast, spike discharge rate during the first 1/2 sec of static displacement is a negatively accelerated, decreasing function of distance between stimulus and RF center.

As the stimulus probe moves away from the center of a digital RF, effective stimulus spread is much less, and there may be no discharge when the stimulus is as little as 1 mm away from the RF center.

In a second type of test, palmar skin was indented 1000 µm at a distance of 2 mm from the RF center and displacement at the RF center was monitored. The monitored RF displacement depth and velocity were then duplicated with a stimulus probe centered over the RF. In most instances, displacement by the distant stimulus yielded fewer spikes than an equivalent displacement centered over the RF. In one exception, a presumed SA Type II unit yielded the opposite results.

These results indicate that (1) SA mechanoreceptors of the raccoon's glabrous skin can be excited by suprathreshold stimuli applied at some distance from the threshold RF, and (2) responses to these distant stimuli cannot be accounted for solely in terms of vertical displacements of the RF. Forces acting parallel, as well as perpendicular, to the skin surface must be considered in attempts to understand the contributions of viscoelastic properties of skin to transduction mechanisms in slowly adapting mechanoreceptors. (Supported in part by research grant NS-19487, USPHS).

228.7 SKIN WETTING INCREASES THE SENSITIVITY OF SA MECHANORECEPTORS IN THE GLABROUS FOREPAW OF THE RACCOON. B.G. Turnbull* & D.D. Rasmusson. Dept. of Physiology & Biophysics, Dalhousie University, Halifax, N.S. Canada B3H 4H7.

During preliminary experiments on mechanoreceptor afferents in the raccoon forearm, it was noted that response properties of afferents from the glabrous skin varied greatly depending on the dryness of the skin. Consequently, direct comparisons of afferent responsiveness were made before and after wetting the skin. Single unit recordings of fibres in the ulnar nerve were made using the dissection technique: a small number of fibers were placed across a platinum electrode in a bath of warm mineral oil and the action potentials of individual fibers were identified on an oscilloscope. Four types of mechanosensory fibres were routinely recorded (Pacinian, RA, SAI and SAII fibres) but only the SAI fibres were studied in the present experiments. Once classified, the receptive fields (RFs) were mapped using threshold and suprathreshold stimuli (applied via Semmes-Weinsteim aesthesiometers, Stoetling), first with the skin dry and the immediately following the application of 0.9% saline or tap water onto the RF.

The response threshold was found to be decreased after skin wetting (means: dry, 687 mg; wet, 202 mg). A t-test on the change in thresholds was statistically significant. In no case did skin wetting result in an increase in threshold. In addition to the decrease in threshold, there was an increase in receptive field size determined with any given suprathreshold stimulus.

These findings suggest that skin wetting enhances sensitivity of SAI mechanoreceptors in the raccoon forepaw, although at the possible expense of decreased spatial acuity at the receptor level. However, it appeared that the relative increase in firing was greater at the focus of the receptive field than it was at the RF periphery. More quantitative analysis of RF shape and responsiveness are in progress although the difficulties in quantifying skin wetness are noted. A similar increase in responsiveness was noted in SI cortex of the raccoon following skin wetting (Welker and Seidenstein, 1959). It is possible that this change in receptor sensitivity in the raccoon may be related to the often discussed (and controversial - c.f. Lyall-Watson, Proc. Zool. Soc., 1963, 191, 371) "food-washing" behavior of the raccoon.

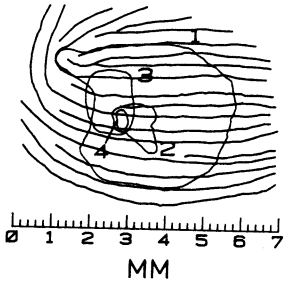
228.8 MAPPING RECEPTIVE FIELDS OF CUTANEOUS MECHANORECEPTIVE AFFERENTS BY MOVING SURFACE STRUCTURES LATERALLY OVER THE GLABROUS SKIN OF THE MONKEY HAND. R.H. LaMotte, L. Becerra-Cabal,* J. Whitehouse,* P. Marks* and J. Ngeow*, Dept. of Anesthesiology, Yale Univ. Sch. of Med., New Haven, CT 06510

By actively touching a smooth surface with the fingertip, humans can detect a single asperity of a very small height - on the order of 1 µm for a raised dot 600 µm wide or a straight edge (step) (R.S. Johansson and R.H. LaMotte, Somatosen. Res., Vol. 1, in press). We recorded evoked responses as these structures were moved across the receptive fields of single quickly-adapting (Meissner Corpuscle) glabrous mechanoreceptive afferents in anesthetized monkeys. The receptive field was mapped with von Frey monofilaments. Then a smooth transparent glass plate on which was etched a 605 µm wide dot or an edge (step) was moved across the receptive field. The area of contact with the skin was viewed through the plate with a microscope and videotaped so that off-line analyses could determine the position of the edge or dot on the skin at the occurrence of each action potential. The minimal asperity height capable of evoking a response was within 1-3 µm of human detection threshold. The receptive field, as shown below for one afferent (located on side of finger tip), differed depending on the type of stimulus used: a von Frey filament delivering 65 mN force (area 1), or 5 mN (area 2) or a glass plate, moving 20 mm/sec across the skin, containing either a single raised dot of 15 µm (area 3) or 3 µm (area 4) height. The greatest discharge was elicited by moving a dot or edge across the ridges, presumably due to greater lateral deformation of the ridges. The response to edges was greater moving against vs. moving off of the edge.



For asperities near threshold, the receptive fields were smaller (e.g. area 4) and obtained only by movement across the ridges. These results indicate the importance of (1) the interaction between geometries of surface microstructures and skin ridge patterns in determining the spatial organization of a mechanoreceptor's receptive field and (2) the role of Meissner afferents in tactile detection of a small asperity on a smooth surface.

Supported by USPHS grant NS15888

228.9 SENSORY RECEPTORS OF THE INCISIVE PAPILLA OF RAT HARD PALATE STUDIED BY PEROXIDASE CYTOCHEMICAL METHODS. Kwan Y. Chan and Margaret R. Byers. Ophthalmology, Anesthesiology and Biological Structure, University of Washington, Seattle, WA 98195.

The incisive papilla (IP) is a pyramid-shaped dome forming the most anterior part of the hard palate in the rat. On each lateral-facing slope of IP is the orifice of the incisive canal, which leads in a dorsal direction to the nasal cavities. Based on studies of serial sections of IP embedded in methacrylate, the medial wall of the canal is heavily populated with chemosensory corpuscles of 40-50 μm diameter, amounting to 30-40 corpuscles within a strip of epithelium 0.3 mm wide, 1 mm long. About a third of these corpuscles are located outside the canal on the lateral slope adjacent to the orifice. The trigeminal origin of the sensory innervation of IP was studied by injecting 2-6 μl of 5% WGA-HRP solution into each side of IP and allowing 24 hr survival for retrograde axonal transport to occur. The rats were perfused with fixative, the trigeminal ganglia (TG) dissected and frozen sections (40 μm) of TG were prepared and processed for peroxidase cytochemistry using the diaminobenzidine or tetramethylbenzidine method. Light microscopy showed that labeled neurons were localized in the lateral half of the maxillary portion of TG, numbering more in the ventral aspect than the dorsal aspect. Based on these data, the TG-derived sensory receptors of IP were further studied by injecting 18-20 μl of 5% WGA-HRP or 30% HRP solution into TG and allowing orthograde axonal transport to occur for 24 hr. The rats were perfused with fixative, the IP dissected, frozen sectioned and processed for peroxidase cytochemistry as above. Light microscopy showed distinct patterns of labeled nerve network at 3 locations: (a) the chemosensory corpuscles, (b) lamina propria of the lateral labium abutting the orifice of incisive canal, and (c) both intra- and subepithelial areas of the dome region of IP. Only the side ipsilateral to the injection site showed labeled nerve elements. Electron microscopy of epon-embedded sections showed that the labeled structures included myelinated and unmyelinated axons, preterminal axons, intracorpuscular (chemosensory) afferent termihals, intraepithelial "free" nerve endings, and various mechanoreceptor-like structures such as lamellated corpuscles in the lamina propria. Within the labeled structures, peroxidase reaction product was localized in vesicular and tubular profiles. Both the orthograde and retrograde labeling techniques were used to analyze and characterize on the ultrastructural level specific differences among the various sensory receptors and in their relationship to the closely associated non-neural elements. These data will be useful in further functional studies of the multiple sensory innervation of hard palate. [Supported by NIH grant # DE05159 and DE00099.]

228.10 LABELING AND NEUROTOXIN DENERVATION STUDIES OF THE MORPHOLOGICAL FEATURES OF THIN-FIBER CUTANEOUS INNERVATION. L. Kruger, B. E. Rodin, Y. Yeh,* S. L. Sampogna* and N. C. Brecha. Depts. of Anatomy, Anesthesiology and Medicine, UCLA Center for Health Sciences, Los Angeles, CA 90024.

The distribution of rat cutaneous nerves was examined in 1) normal animals, 2) following destruction of the thin sensory fiber population by neonatal capsaicin (CAP) treatment, 3) following destruction of the sympathetic postganglionic fibers by surgical extirpation and by neonatal 6-hydroxydopamine treatment, 4) following dorsal root ganglion injection of lectin-conjugated horse radish peroxidase (WGA-HRP) for axonal transport labeling of sensory fibers. Immunohistochemical labeling using antibodies to several peptides suspected of association with sensory nerve was examined with indirect fluorescence (FITC) and peroxidase-antiperoxidase (PAP) methods; some of the latter material was examined electron microscopically (EM).

The most striking finding was the widespread presence of labeled thin sensory fibers penetrating hairy and glabrous skin to below the epidermal stratum lucidum. A substantial proportion of the intraepidermal axons also display selective substance P-like (SP) immunoreactivity, although it is evident from EM observation that most C fibers in any bundle are not SP positive. Elimination of the majority of these intraepidermal axons in CAP-treated animals, but not following sympathectomy, strongly supports the view that these fibers serve a sensory role. Among the more numerous and richer variety of dermal afferent patterns, there is also evidence of thin fibers with SP immunoreactivity arborizing extensively around small blood vessels.

The variety of terminal branching patterns, vesicle and mitochondrial accumulations and peptide distribution remains unclassified, but thin fiber endings are generally distinguishable from most other varieties of cutaneous sense organs. Several morphological markers enable recognition of sensory and sympathetic unmyelinated fibers.

This research was supported by NIH grant NS-5685 and an NRS award to B.E.R.

228.11 CENTRAL PROJECTIONS OF PRIMARY AFFERENT NEURONS THAT INNERVATE THE TEMPOROMANDIBULAR JOINT CAPSULE IN CATS. N.F. Capra and K.V. Anderson. Dept. of Anatomy, Univ. of Miss. Med. Ctr., Jackson, MS 39216.

The receptor population of the temporomandibular joint capsule (TMJ) in cats includes Ruffini endings, paciniform corpuscles, Golgi endings, and free nerve endings. Branches of the auriculotemporal nerve, the deep temporal nerve, and the masseteric nerve contribute to the innervation of these receptors. The perikarya of the primary afferent neurons innervating the TMJ are located in the mandibular portion of the trigeminal ganglion (TG). The present study was performed to identify the distribution and site of termination of the central processes of TG neurons within the trigeminal brain stem nuclei.

The right TMJ was surgically exposed in six pentobarbital anesthetized adult cats. Under an operating microscope, a microliter syringe containing a solution of Horseradish peroxidase conjugated with wheat germ agglutinin (WGA-HRP, Sigma VI, 4% solution) was inserted into the posterior region of the TMJ. A total of 5-10 μl of WGA-HRP were injected into the joint. The animals were allowed to survive from 24-72 hours before euthanization. The animals were perfused with heparinized saline followed by a fixative containing 1.25% glutaraldehyde and 1% formaldehyde in a 0.1 M phosphate buffer (pH 7.40). The fixative was washed out with 0.1 M phosphate buffer solution containing 10% sucrose.

Serial sections of the right trigeminal ganglion and brain stem were sectioned at 50 μm and processed using tetramethylbenzidine (TMB) as a chromagen (Mesulam, 1978). Alternate sections were counterstained with neutral red and studied with bright field and dark field optics.

Labeled perikarya were identified in the mandibular region of TG. Both the peripheral and central processes of many of these cells were clearly labeled. The peripheral processes of the ganglion cells traveled in the mandibular division of the trigeminal nerve. Although most of these fibers were unbranched, on occasion bifurcation of the peripheral processes occurred before they entered the foramen ovale. The central processes of the TMJ afferents entered the brain stem and ended in the chief sensory nucleus or entered the spinal tract of the trigeminal nerve. Labeled fibers in the spinal tract were dorsally located and terminated primarily in the subnucleus oralis and the rostral part of the subnucleus interpolaris of the spinal nucleus of the trigeminal nerve. In the present series of experiments, fibers could not be traced into the subnucleus caudalis. These findings indicate that neural information from the TMJ concerning jaw position is processed in the rostral part of the trigeminal nuclear complex. (Supported by NIDR Research Grant DE06027)

228.12 THE DEVELOPMENT OF MECHANOSENSORY FUNCTION AND SYNAPTIC MORPHOLOGY WHEN REGENERATING AXONS ARRIVE AT NERVE-FREE MERKEL CELLS IN XENOPUS SKIN K. Mearow and J. Diamond. Dept. of Neurosciences, McMaster University, Hamilton, Ontario L8N 325.

Previous work in this laboratory has shown that the Merkel cell-neurite complex in salamander epidermis is a rapidly-adapting touch receptor. We now know (to be published) from TEM examination of serially sectioned salamander skin, using goniometric techniques, that each of the 2-4 boutons of the single functional axon supplying a Merkel cell has a reciprocal synaptic relationship with the cell. These investigations have now been extended to the skin of Xenopus, in which the Merkel cells occur around the visible openings of the cutaneous gland ducts. A voltage-controlled mechanical stimulator of 10 μm diameter was used to compare the mechanosensory thresholds when the stimulus was applied directly over the gland openings ("on" locations) to those when the stimulus was located between the openings, which are on the average about 50-100 μm apart. The most sensitive points were always the "on" ones, and the results indicated that these represented a single population of rapidly-adapting touch receptors; the locations of these coincided with those of the epidermal Merkel cell-neurite complexes, which therefore appear to have a mechanosensory function like the analogous structures in salamander skin. The preliminary EM findings indicate that in Xenopus too the boutons make reciprocal synapses with the Merkel cells. Our eventual objective is to determine whether reciprocal synapses are involved in the mechanosensory transduction process, and/or the trophic interactions that occur between nerves and Merkel cells.

One approach to understanding the possible significance of these reciprocal synapses is to follow the development of mechanosensitivity when sensory nerves grow into skin, and to see whether there is any correlation with any of the characteristic morphological features of the Merkel cell-neurite complex. These studies are being done in Xenopus, during the reinnervation of denervated skin, and the innervation of new skin that has regenerated in place of a portion excised earlier. Merkel cells were shown to be present in both situations; they survive denervation, and they appear in regenerated limb skin even in the absence of nerves. Ingrowing sensory axons eventually contact these Merkel cells, which thus act as targets for these nerves. Preliminary results suggest that the recovery of discrete touch spots requires that such contacts occur. The mechanosensitivity develops gradually however, and this is associated with the gradual maturation of the synapses at the Merkel cells. We hope to determine whether or not complete physiological recovery requires that there is a full restoration of the reciprocal synapse.

(Supported by N.I.H. Grant NS 15592-02).

228.13 FACTORS AFFECTING MECHANOSENSORY FUNCTION IN AN ISOLATED SALAMANDER SKIN-NERVE PREPARATION C.A. Nurse, M. Holmes* and J. Diamond. Dept. of Neurosciences, McMaster University, Hamilton, Ontario L8N 3Z5.

The mechanosensitivity of the salamander skin is based largely on the irregular distribution of rapidly-adapting touch receptors, whose morphological correlates are the epidermal Merkel cell-neurite complexes (Parducz et al., Neuroscience 2: 511-521). Though we now have evidence for the presence of reciprocal synapses between the sensory nerve endings and the Merkel cells, the relationship of this finding to mechanosensory transduction or its modulation remains obscure. In an attempt to investigate this further we have developed an isolated skin-nerve preparation, in which we monitor quantitatively the variation in mechanosensory thresholds in response to controlled manipulations of the fluid environment. The preparations show remarkable stability over a 20 hr period after repeated mappings in a glucose-supplemented, Hepes-buffered amphibian ringer (containing 1.8 mM Ca^{2+}, 1.6 mM Mg^{2+}); in addition they may be kept in enriched medium for at least 2 days at 4°C while retaining normal mechanosensitivity. The Ca^{2+}-antagonist Co^{2+} (2-10 mM) causes a progressive increase in mechanical thresholds within ½ hr of changing solutions; at the higher doses mechanosensory function is reversibly abolished (i.e. threshold stimulus exceeds 30X control). Within a similar time period the threshold is hardly affected by a 6-fold increase in (Mg^{2+}) or Ca^{2+}-removal, though addition of the chelating agent EDTA to Ca^{2+}-free ringer progressively reduces the mechanosensitivity. Of special interest was the effect of 1 mM La^{3+}, another Ca^{2+}-antagonist which blocks transmission at the neuromuscular junction (nmj). In the isolated skin-nerve preparation 1 mM La^{3+} caused a progressive decrease in mechanosensitivity and finally block, over a period of 3/4-1½ hr; however, in contrast to the nmj there was a progressive recovery towards normal sensitivity over the next 4 hr following La^{3+}-removal. Although many of the fine structural changes in the sensory nerve endings (even after recovery of mechanosensory function) resembled that seen at the nmj (e.g. marked reduction in vesicle population, presence of cisternae and coated vesicles), the Merkel cell appeared hardly affected by the La^{3+}-treatment. These results point to a role for Ca^{2+} near the transduction site but do not as yet distinguish whether the nerve ending or the Merkel cell is the transducer element. Other ionic and drug manipulations are presently being examined by correlative electrophysiological and EM techniques.

228.14 SYMPATHETIC MODULATION OF SLOWLY-ADAPTING TYPE I MECHANORECEPTORS IN THE CAT. W.J. Roberts, S. Elardo* and K. King*. Neurological Sciences Institute of Good Samaritan Hospital and Medical Center, Portland, OR 97210.

Activity was recorded from single, functionally-identified afferent units in the saphenous nerve of anesthetized cats. Repetitive mechanical stimulation of the receptive field with force steps was used to evoke activity in these units. Sympathetic activity was introduced by electrical stimulation of the ipsilateral lumbar sympathetic trunk (cut centrally) at 10 Hz. Touch domes were marked with india ink and the skin patch removed for histochemical analysis. Frozen sections were reacted with glyoxylic acid and examined for catecholamine fluoresence in or near the touch domes.

The mechanical threshold (step force required to produce firing in 50% of presentations) was tracked before and during 3 minutes of sympathetic stimulation (SS) for all units which failed to become "spontaneously" active during SS. The predominant sympathetic effect was a reduction in threshold. Of 18 units tested in 14 cats, 8 showed a marked reduction of >25% (mean change - 48.2% ± 17.7), 8 showed a slight or negligible decrease in threshold (-12.7% ± 7.2), and 2 showed an increased threshold (+68% ± 9.9). These effects persisted with little diminution throughout 3 minutes of SS. A small increase in the force exerted by the tissue against the probe was often observed to parallel the time course of the change in afferent excitability, however piloerection was rarely observed in the receptive field when examined at 30x magnification.

Seventeen other units in 9 cats became "spontaneously" active during SS. This activity began with a latency of 3 to 15 sec and showed an initial high rate which decreased with time but generally persisted throughout 3 minutes of SS. One of these 17 units was recorded from a male cat; the remainder were in females. Only 5 SAI units recorded in female cats failed to develop this "spontaneous" activity.

Intravenous administration of the α-adrenergic blocking agent phentolamine (2 mg/kg) reduced or blocked these sympathetic actions in all 8 units tested.

Histochemical analysis of 16 touch domes in 7 cats showed no catecholamine fluoresence in association with afferent fibers. This contrasts with earlier positive results for hair receptors (Roberts and Levitt, J. Comp. Neurol. 210, 204-209, 1982).

These sympathetic actions on SAI afferents are likely to be mechanically induced (vascular perhaps) because they are reduced by an adrenergic blocker yet no catecholamine efferents are seen in the touch domes.

228.15 EFFERENT FIBERS FROM BRAIN STEM NEURONS IN THE RAT CAROTID SINUS NERVE. A. Hess and I. Cassady*, Dept. of Anatomy, Rutgers Medical School, UMDNJ, Piscataway, NJ 08854 (SPON: S. Rosner).

The carotid body is innervated by the carotid sinus nerve (CSN) a branch of the glossopharyngeal. It is generally agreed that this nerve contains, by far, mostly sensory fibers. More recent studies using HRP retrograde uptake after severance of the CSN, however, have found brain stem motor neurons with HRP accumulation in the nucleus ambiguus (NA) and retrofacial nucleus (Rf); other studies using this same method have found no such neurons. Previous studies have used cats and report very variable numbers of neurons from cat to cat, even in the same study, or disagree on the distribution and organization of the HRP accumulating neurons. The rat is currently being used frequently for studies of the carotid body, and the contribution, if any, of brain stem efferent neurons to the CSN of the rat is unknown. The CSN of the rat was severed and HRP crystals applied to the proximal stump. In addition, various control studies were performed. The hypoglossal nerve was purposely cut in most of the animals at the same time as the CSN in order to ascertain that uptake of HRP had occurred. A small branch of the vagus nerve runs adjacent to the CSN. This nerve was purposely cut in several animals; the number of HRP cells in rats with tenth branch and CSN cut was compared to the number found after CSN cut only.

Nerve cut	Neuron location & no.	Distribution
CSN, 12	NA, 14; Rf, 4	scattered
CSN, 12	NA, 0; Rf, 10	grouped
CSN, 12	NA, 6	scattered
	Rf, 27	grouped
CSN, 12	NA, 9; Rf, 0	scattered
CSN, 10, 12	NA, 85, Rf, 2	grouped
CSN, 10, 12	NA, 133; Rf, 1	grouped

Accidental or intentional interference with the branch of the tenth nerve results in an increased number of HRP-positive neurons.

CSN cells tend to occur in rostral portions of the NA and its rostral continuation as the Rf. The distribution of cells is variable from rat to rat: grouped with 4-5 cells at one level in the same section or scattered with only one or, at the most, two cells in each section. In some rats, cells can be restricted to either NA or Rf. Neurons contributing axons to the CSN have not been found in any location other than NA or Rf. No contralateral neurons accumulating HRP have been found.

Because of what appears to be an inherent variability in location and number of brain stem neurons contributing axons to the CSN nerve, more rats are being studied.

228.16 CONTRACTIONS OF CHAIN FIBERS IN ISOLATED CAT MUSCLE SPINDLES. R.E. Poppele, P. Iaizzo* and D.C. Quick*. Lab. of Neurophysiology, Univ. of Minnesota, Minneapolis, MN 55455.

Contraction of intrafusal muscle in spindles modifies the behavior of spindle sensory endings. Activation of fusistatic fibers may cause contractions in chain and bag2 fibers, whereas fusidynamic activation effects only bag1 fibers. We have examined the local changes of length in intrafusal muscle that result from fusimotor stimulation in isolated spindles. Measurements of strain (change in length per unit length) were made from motion picture records of different regions of a spindle during nerve stimulation. In the example illustrated below, stimulation at 80/sec evoked a contraction (local shortening) of chain fibers in one pole of an isometric spindle. The contraction pulled the sensory endings toward that pole and shortened that half of the spindle. The focus of contraction was about 2 mm from the primary ending where chain fibers shortened by as much as 15%. Closer to the sensory region, the same fibers were stretched by as much as 11% with the maximum stretching occuring in the region of the secondary ending. A bag fiber, which we classified as a bag1, appeared to be unloaded by the chain contraction, showing a 3-5% shortening along its entire length in that pole. The findings indicate a loose lateral coupling between bag and chain fibers and suggest that the reduction in dynamic index of the primary sensory response often seen with fusistatic stimulation may be due to a reduced stretch on bag1 fibers.

228.17 LACK OF COMPARTMENTALIZATION OF THE HUMAN JAW STRETCH REFLEX. Anne Smith*, Carol A. Pratt, and Christopher A. Moore*. Department of Audiology and Speech Science and Physical Education; Purdue University, West Lafayette, Indiana 47907.

Downward "step" displacements of the human mandible produce large, transient, short latency (8 ms) EMG responses in jaw-closing muscles. These transient EMG responses, in turn, produce large increases in jaw-closing force. Based upon estimates of the reflex stiffness of the human jaw-closing system, Cooker et al. (J. Physiol., 308: 61-78, 1980) suggested that the monosynaptic jaw stretch reflex is a potent or "high gain" pathway that can make a significant contribution to the stability of the mandible.

In contrast, Appenteng et al. (J. Physiol., 179: 409-423, 1978) suggested the monosynaptic jaw muscle spindle afferent projection in the cat was "relatively weak." This suggestion was based on their finding that EPSP's could be recorded in only a small fraction of jaw-closing motoneurons using the technique of spike-triggered-averaging from single afferents in the mesencephalic nucleus of the fifth nerve. Appenteng et al. suggested that this relatively selective projection might be appropriate for the jaw-closing muscles which are complex in their anatomy and functions. In other words, spindles from one part of a muscle would project only to those motoneurons with mechanically similar actions. This interpretation is consistent with the views of Botterman et al. (Amer. Zool., 18: 135-152, 1978) that afferents of most muscle systems are organized in terms of muscle compartments.

When a stretch reflex is elicited by displacing the mandible, all of the jaw-closing muscles are stretched, presumably synchronously, producing a large, synchronous discharge of muscle spindle afferents into the motoneuron pool. In pilot experiments we found that mechanical indentation of the tissue overlying jaw-closing muscles reliably elicited jaw stretch reflexes. Use of this stimulus allows more restricted activation of spindles and can be used to study the distribution of the stretch reflex in humans. A systematic study of responses of ten normal subjects was undertaken to determine the distribution of the responses to this "localized" stretch stimulus across synergistic muscles and across regions within one muscle. Our results show that the reflex response to this stimulus is not confined to the muscle stimulated, rather it is distributed across all jaw-closing synergists. In addition, there was no evidence that the "on-site" reflex response (response at the site of stimulation) as measured from the EMG tended to be larger than the "off-site" response. Our data support the hypothesis that the jaw stretch reflex pathway in humans is potent but do not support the idea of rigid compartmentalization of this reflex pathway.

PAIN: AFFERENT NOCICEPTORS

229.1 A QUANTITATIVE, ITCH-PRODUCING STIMULUS. R.P. Tuckett, Department of Physiology, University of Utah, Med. Ctr., Salt Lake City, Utah 84108.

This report focuses on two issues that are fundamental to the study of experimental pruritus. First, investigation of the sensation of itch has had a disdvantage not shared with other cutaneous modalities in that there has been no reproducible technique for inducing pruritus. A needle (20 guage) was attached to a strain guage transducer to aid in reproducibly penetrating the skin of human subjects who had given prior informed consent. Papain was chosed as a pruritogenic agent because of its ability to cause itching without mast cell degranulation. (Progressive dilutions of papain were prepared, starting from near saturation (150, 75, 37, 15, 7 and 0 units/ml, Sigma, St Louis, MO) in Hepes buffer, ph=7.4, and Cleland's reagent (a reducing agent to maintain papain reactivity, Sigma). Sterility was maintained by using a .22 um disk filter and sterile containers and was checked periodically by incubating samples in culture media and looking for bacterial growth. Solutions were applied in pairs to the forearms of human subjects, double blind and in pseudorandom order, with one member remaining the same (37 units/ml) while the other was varied.

The second issue to be addressed is that unlike other cutaneous modalities, my knowledge no experiments have been done relating the intensity of pruritic sensation to stimulus strength. A cross-modality psychophysical experiment was performed in which subjects were ask to match the intensity of itch with the intensity of a light, for the stimulus pairs described above. The subject controlled the voltage supplied to the light by turning a knob. The voltage waveform was digitized and analyzed by obtaining measures of itch magnitude, latency, time to peak, peak amplitude and duration. A value for itch magnitude was obtained by integrating the amount of voltage applied to the light over a standard period of time (3 min from the start of pruritus). Although no correlation (Kendall correlation coef.) was found between the absolute values of these variables and stimulus strength, there was significant positive correlation between the ratio of paired values and stimulus strength for itch magnitude (N=39, $p<0.0001$), time to peak (N=22, $p<0.0001$), peak amplitude (N=23, $p<0.02$) and duration (N=9, $p<0.08$), suggesting that day-to-day variation in human perception has a significant impact on the sensation of itch. No correlation was found between the ratio of latencies and papain concentration.

229.3 CHEMICAL SYMPATHECTOMY MAGNIFIES CAPSAICIN-INDUCED DEFICITS IN SENSATION AND NEUROGENIC INFLAMMATION: PARALLELS TO DYSAUTONOMIA. T. J. Coderre*, F. V. Abbott and R. Melzack*. Dept. of Psychology, McGill Univ., Montreal, P.Q. H3A 1B1

Pain sensitivity is mildly depressed by both capsaicin and chemical sympathectomy. This study reports on the effects of combining these two treatments on pain, tactile sensitivity and inflammation. One month after application of 1.5% capsaicin (CAP) to the sciatic nerve, rats were treated with 30 mg/kg of guanethidine (GUA) for 4-6 days. The effects of the combined treatment or each drug alone were as follows. Heat pain: The latency to withdraw the hind paw from 50°C water was increased by 47% by GUA, 240% by CAP, and 410% by CAP + GUA. Cold pain: Foot-withdrawal latencies from -6°C brine were unaffected by any of the treatments. Inflammatory pain (Formalin test): Behavioural responses to a s.c. injection of 0.05 ml of 2.5% formalin into the plantar surface of the hind paw were reduced by 60% by GUA, not at all by CAP, and 74% by CAP + GUA. Inflammatory response: Leakage of Evans Blue dye (50 mg/kg i.v.) was used as an index of neurogenic inflammation. After s.c. injection of 0.05 ml of 1.0% formalin into the plantar surface of the hind paw, the leakage of dye into the injected paw was mildly inhibited by GUA. Both CAP and CAP + GUA produced a marked reduction of the dye leakage. CAP inhibited dye leakage for 30 min., while CAP + GUA's effects lasted 3-4 hrs. Tactile sensitivity: Neither GUA nor CAP affected the latency for rats to detect and remove 8 mm discs of sticky tape applied to the dorsal and plantar surfaces of the hind paw. CAP + GUA produced a marked deficit in this test.

Thus, combining capsaicin with an antisympathetic treatment has a powerful synergistic effect on heat pain, inflammatory pain, tactile sensitivity and inflammation. The effects imply that these treatments interact to produce a large decrease in both the sensitivity of cutaneous receptors and the vegetative functions involved in responses to injury. In light of these data, it is interesting that the neuropathology of familial dysautonomia involves both peripheral sympathetic denervation and a preferential loss of unmyelinated afferents. The present data suggest that the mechanisms underlying the reduction in cutaneous sensitivity and neurogenic inflammatory responses in dysautonomia may involve an interaction between the peripheral sympathetic system and peptidergic afferents.

229.4 EVIDENCE FOR EPHAPTIC CONDUCTION BETWEEN UNMYELINATED FIBERS IN THE PERIPHERAL NERVE OF PRIMATES R. A. Meyer, S. N. Raja, J. N. Campbell and R. Burke*. Applied Physics Lab. and Depts. Neurosurgery and Anesthesiol./CCM, Johns Hopkins U., Balto., MD 21205

Coupling of electrical activity between peripheral nerve fibers, presumably ephaptic conduction, has previously been observed following various forms of nerve injury. Recently, coupling between myelinated nerve fibers in normal nerves of cats has been reported. We found that coupling occurs between unmyelinated, but not myelinated,nerve fibers in the normal peripheral nerve of the primate. In several cases, the nerve fibers were connected to a cutaneous nociceptor. Primates (3 baboons and 6 monkeys) were anesthetized with either pentobarbital infusion (4-6 mg/kg/hr) or halothane/N_2O (1.0%/66%). The animals were paralyzed with pancuronium and mechanically ventilated to eliminate artifacts due to muscle twitching. Recordings from single fibers in the superficial radial nerve were obtained from fine teased nerve strands. The strands were cut proximally such that only centripetally directed action potentials were recorded. Stimulating electrodes were placed on the parent nerve 3 cm proximal (PSE) and 3 cm distal (DSE) to the recording site. Action potentials at the recording site evoked by PSE stimulation were considered as an indication of coupling between nerve fibers. With stimulus intensities at the PSE low enough such that only A-beta and A-delta fibers were activated, no action potentials were recorded. However, in 20 cases, PSE stimulation intensities sufficient to excite unmyelinated fibers resulted in action potentials at a fixed delay at the recording electrode. Simultaneous stimulation of the PSE and DSE resulted in collision of this action potential only at DSE intensities sufficient to excite C-fibers. Collision techniques were also used to demonstrate the bidirectionality of this coupling. The conduction delays and the requirement for high intensity stimulation were indications that the coupling was between unmyelinated fibers. In at least 4 cases, one of the fibers involved in the coupling was a cutaneous nociceptor. Based on conduction delays and procaine application to the receptive field, the site of the coupling was estimated to be near the receptor. The time interval between stimulation at the PSE and arrival of the action potential at the recording site was transiently increased by mechanical stimulation of the receptive field. In one case tested, stimulation at the PSE (10 Hz for 3 sec) resulted in a transient reduction in response to heat at the receptive field of the nociceptive afferent. A likely explanation for these observations is that ephaptic transmission occurs between unmyelinated fibers in the normal peripheral nerve of primates. (Support: DOD contract #N00024-83-C-5301 and NIH grants NS-14447 and NS-00519)

229.5 SENSITIZATION OF UNMYELINATED NOCICEPTIVE AFFERENTS BY HALOTHANE, S.N. Raja, R.A. Meyer, J.N. Campbell, and R. Burke* The Johns Hopkins University, Baltimore, MD 21205

We recently reported that the response of nociceptive primary afferents to heat stimuli was altered by different general anesthetics. This study was designed to determine the following: Is the response raised by halothane or lowered by barbiturates? Is the anesthetic effect due to direct action on the cutaneous receptor or an indirect effect? The response to heat stimuli of C-fibers sensitive to both mechanical and heat stimuli (CMHs) were studied in monkeys. All fibers studied innervated the glabrous skin of the hand. The animals were mechanically ventilated and end-tidal CO_2 maintained between 35-40 torr. Heat stimuli were produced by a laser thermal stimulator. To determine the effects of halothane, monkeys were anesthetized with pentobarbital (IV infusion of 4-6 mg/kg/hr) and the responses to repeated heat stimuli of 5 CMHs were recorded while the inspired concentration of halothane was manipulated. The response of the fibers increased monotonically as the halothane concentration increased and returned to baseline when halothane was stopped. The mean response at 2% halothane was 191 $\pm$ 8% (S.E.M.) of the response without halothane. Comparable experiments were done using IV infusions of 1-4 mg/kg of methohexital with the monkeys anesthetized under 1% halothane and 66% nitrous oxide. The CMHs showed only a small if any change in response. We conclude that the difference in response with different anesthetics is mainly due to an increase in response induced by halothane. To see if the change in blood pressure induced by halothane might be responsible for the change in CMH response, blood pressure was maintained above the baseline using phenylephrine or ephedrine. These vasopressors by themselves induced no change in CMH response, whereas the response was still increased by halothane. In two experiments the the skin temperature was monitored as an index of skin perfusion. Following 10 min. of 1.5% halothane, the response of the CMHs to heat stimuli increased significantly whereas the skin temperature changed minimally. In additional experiments, sympathetic activity was blocked by procaine applied to the nerve proximal to the recording site or by section of the brachial plexus at the root level. Again, the response of the C-fibers increased when halothane was administered. In summary the response to heat of C-fiber nociceptive afferents increased in a dose-dependent manner to halothane. Alterations of blood pressure, skin perfusion, sympathetic tone, core temperature, or end-tidal CO_2 do not account for the observed increased response. The most likely explanation is that halothane sensitizes reversibly the nociceptive receptor in the skin. (N.I.H. grants NS-14447 and NS-00519)

229.6 IDENTIFICATION OF CUTANEOUS FIBRE GROUPS RESPONSIBLE FOR SIGNALLING NOXIOUS HEAT AND NOXIOUS MECHANICAL STIMULI IN THE RAT R. Doucette, E. Theriault and J. Diamond. Dept. of Neurosciences, McMaster University, Hamilton, Ontario L8N 3Z5.

When the back skin of a rat is lightly pinched or heated it activates the cutaneous endings of nociceptive fibres that run in the dorsal cutaneous nerves (DCNs) and reflexly excites the underlying cutaneous trunci muscle (CTM). Direct electrical excitation of the DCNs has revealed that only the Aδ and C fibres elicit reflex responses in this muscle, and that these are of clearly different latencies (15-20 msec and 60-80 msec respectively). We wanted to find out which fibre groups are activated by which particular nociceptive modality. To answer this question we used capsaicin, which is toxic to C fibres, but affects Aδ fibres minimally. In order to compare our results with those of others we used several additional behavioral tests; these included the tail flick reflex and the withdrawal response of paws to noxious mechanical and thermal stimuli. Two to three day old female Wistar rats were given a single subcutaneous injection at the back of the neck of either capsaicin (50 mg/kg) or vehicle; the tests were conducted 2-5 months later. The performance of vehicle-treated rats did not differ from untreated controls. Both the C fibre and the heat evoked component of the CTM reflex were absent in all capsaicin treated rats, but there was no detectable alteration in either the pinch or the Aδ component of this reflex. In accord with these results, noxious heat applied to either the hind paw or the tail evoked no response, or one with a significantly longer latency, but the animals still exhibited a normal reflex withdrawal to a pinch of the front and hind paws. However, though the skin behind the pads of the hind paws of the capsaicin-treated animals was relatively insensitive to thermal stimuli, that on the pads was only slightly less sensitive than normal. Similarly the heat sensitivity of the pads of the front paws seemed unaffected by the capsaicin even when it had been injected directly into the pad. One explanation of these findings is that noxious heat on the paw pads is not signalled by C fibres. We examined this possibility by using intravenously administered Evans blue dye to study the extravasation of plasma proteins that occurs when the peripheral terminals of nociceptive C fibres are antidromically excited. In normal, untreated animals extravasation was seen in all skin regions except in the pads of both front and hind paws. We conclude that (a) thermal nociception in skin regions other than paw pads is signalled primarily by C fibres, but in the pads most likely by Aδ fibres, and (b) noxious mechanical stimuli in all skin regions, including the paw pads, activate Aδ fibres.

229.7 A COMPARISON OF TRIGEMINAL THERMORECEPTORS OBSERVED IN CATS AND IN MONKEYS. D.A. Poulos and H. Hirata, Dept. of Anatomy and Div. of Neurosurgery, Albany Medical College, Albany, NY 12208.

In examining details of the response characteristics of primary afferent trigeminal cold receptors (T units), certain differences were observed between cat and monkey neurons. Extracellular recordings were obtained from trigeminal ganglion neurons in anesthetized (Nembutal and/or urethane) cats and in two species of monkeys (Saimiri sciureus and Macaca mulatta), the latter showing no differences between their T unit responses. Thermoreceptive neurons were tested using a standard sequence of skin temperatures held constant and step-like cooling stimuli below a 35°C preadapting standard.

All T units maintained temperature-dependent discharge activity over a range of constant skin temperatures. The steady temperature response profiles approximated bell-shaped distributions, with peak discharge rates for both types of animal occurring at 29°C. Cat T units, however, had decreased average firing rates e.g. 8/sec at 29°C as opposed to 15/sec in monkeys. Conversely, cat T units were responsive over a wider range of constant temperatures (45-9°C in cats, as opposed to 41-17°C in monkeys). In addition, bursting patterns of steady-state discharge activity were commonly seen in monkey T units while they were rarely observed in the cat.

The dynamic response profiles of T units to a series of rapid cooling stimuli starting from a 35°C preadapting temperature were similar for the two types of animal with the following exceptions: firstly, cat T units appeared to be more sensitive to smaller cooling steps since maximal dynamic activity was obtained within 2-4° cooling, whereas the averaged dynamic responses of monkey T units required 8° cooling to reach maximum firing rates. Secondly, over the colder range of stimulus temperatures (19°C and below) monkey T unit dynamic responses were brief and invariably followed by a post-excitatory cessation of activity for the remainder of the stimulus period. Cat T units, by comparison, did not display post-excitatory cessation over the range of temperatures tested, although a brief pause or slowing of firing sometimes occurred followed by a recovery of discharge. The latter result is consistent with the finding that cat T units are active over a much colder range of constant skin temperatures than are monkey T units.

Since the experimental methods used in these studies were identical, the observed differences in the behavior of cat and monkey thermoreceptors can thus far only be assigned to a "species" difference.

229.8 PROPERTIES OF CELL BODIES INNERVATING THE PULP CHAMBER OF PRIMARY AND PERMANENT CANINE TEETH. Terrell E. Jones*, Kenneth V. Anderson, and Norman F. Capra. Department of Anatomy, University of Mississippi Medical Center, Jackson, MS.

Many studies concerned with the innervation of tooth pulps have focused on the properties of axons near the point of entry to the pulp chamber. In general, studies of this type have characterized axons with regard to their degree of myelination, diameter and whether the fibers were afferent or efferent in function. The present study was designed to systematically examine the morphological properties of the cell somata of neurons in the trigeminal ganglia (TG) that innervate the canine teeth in cats. Special attention was focused on comparisons between neurons that supply primary teeth in kittens and those that supply permanent teeth in adults.

To identify TG neurons supplying canine teeth, horseradish peroxidase (HRP) was injected into the left upper canine teeth of four five-week-old kittens and four adult cats. Multiple, unilateral injections of HRP (Sigma VI, 40% solution) were made into the pulp chamber of each cat. Animals were euthanized and transcardially perfused 48 hours after the final pulpal injection. Frozen, serial sections (25 micra) were made of each TG and the tissue processed using the TMB method to enable visualization of the HRP reaction product.

Labeled cells were identified in each animal using bright field optics. A total of 713 labeled cells were observed in the four kittens, for an average of 178 TG neurons supplying each canine tooth in kittens. By contrast, 704 labeled neurons were observed in the adult cats for an average of 176 neurons supplying each canine tooth. The average diameters and perimeters of cell bodies supplying kitten canine teeth were 45.13 microns and 135.12 microns, respectively, while the average areas measured 1180.72 microns^2. In the case of neurons supplying permanent canine teeth in adult cats, the average diameters, perimeters and areas were 54.16 microns, 159.38 microns and 1473.82 microns^2, respectively.

The results of our studies indicate that single canine teeth in kittens are supplied by about the same number of TG neurons as are the canine teeth in adults. This is a somewhat surprising result, since the TG neurons have to supply greater numbers of adult teeth than kitten teeth (28 vs 20). There are, however, significant differences in the sizes of TG neurons that supply the teeth in kittens and adults, with those in kittens being generally smaller than those in adults. Studies are presently underway to identify the factors that might account for the differences in cell sizes observed in the present investigation and to functionally characterize the TG cells that supply the canine teeth in kittens.

229.9 TRIGEMINAL AXON COLLATERALS FROM SINGLE CELL BODIES DO NOT EXPLAIN REFERRED HEAD PAIN. T. O'Connor* and D. van der Kooy (Spon: A. Jakubovic). Department of Anatomy, University of Toronto, Toronto, Canada M5S 1A8.

The trigeminal nerve provides the main sensory pathway involved with intracranial head pain. Recent studies with cats have shown that afferent fibers from both the forehead and the middle cerebral artery have cell bodies in the same region of the opthalmic branch of the trigeminal ganglion, thus suggesting the possibility of bifurcated axons as a mechanism for referred head pain.

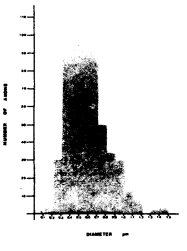
We have found that afferent trigeminal fibers to the forehead region of the rat, (frontal branch of the opthalmic division), do not share the same cell bodies as fibers to the middle cerebral artery. We have used a retrograde fluorescent double labelling technique in these experiments. True blue (5%, .2ul) was injected around the proximal region of the middle cerebral artery. The frontal branch of the opthalmic division of the trigeminal nerve was dissected out 1 day later and the proximal end was soaked in nuclear yellow (1%). Two days after the nuclear yellow injection the rats were anesthetized and sacrificed by intracardiac saline and then formalin perfusion. Ganglia were sectioned in a cryostat (32 um) and were examined with a heitz epifluorescent microscope.

Labelled cell bodies were distributed primarily in the opthalmic branch of the trigeminal ganglion. The labelled cells bodies were labelled with either true blue (blue fluorescing cytoplasm) or nuclear yellow (yellow fluorescing nucleus). There were no double labelled cells. In the opthalmic division most of the true blue labelled cells from the middle cerebral artery injections were nearby nuclear yellow labelled cells from the frontal branch injection. Thus it seems unlikely that trigeminal ganglion cells with bifurcating axons can provide a full explanation of referred headache pain. A more central mechanism would seem to be called for, however an interaction between the processes of cell bodies in the trigeminal sensory ganglia remains a possibility.

229.10 DIAMETERS OF AFFERENT UNMYELINATED AXONS IN THE CAT ARTICULAR NERVES. L.A. Langford. Physiologisches Institut der Universität Würzburg. D-8700 Würzburg. Federal Republic of Germany.

The medial and posterior articular nerves supplying the cat knee joint are considered to consist mainly of myelinated axons with only a small number of unmyelinated axons which are thought to be postganglionic efferent (sympathetic);however, Langford and Schmidt (Anat. Rec. in press, 1983) have demonstrated that 80% (800) of the total axons in the medial articular nerve are unmyelinated and only 20% (200) are myelinated. Similarly, the posterior articular nerve is 78% unmyelinated. Of the total axons in both nerves, all myelinated and 50% of the unmyelinated axons have their origins in the dorsal root ganglion cell and are therefore sensory. The remaining 50% of the unmyelinated axons arise from the sympathetic chain. In the present study the diameter distribution of this significant number of afferent unmyelinated axons is being determined in order to further characterize the most fundamental aspects of joint innervation.

After bilateral sympathectomy (L_3-S_3) and a degeneration time of 10-12 days, the animals were perfused with a 3% glutaraldehyde-3% paraformaldehyde solution. Sections of the medial and posterior articular nerves were removed and prepared for EM analysis according to the method of Langford and Coggeshall (Anat. Rec. 197: 297-303,1980). Montages of the nerves in cross section were made at a magnification of 10,000. The diameters of all unmyelinated axons were measured. The preliminary results from the medial articular nerve are shown in the following histogram.



Diameter measurements of the unmyelinated axons in the posterior articular nerve are in progress. Diameters of postganglionic efferent unmyelinated axons in deafferented articular nerves will also be compared to the afferent population.

229.11 AN ELECTRONMICROSCOPIC ANALYSIS OF THE INFRAORBITAL NERVE IN RAT. R.D. Mooney, A. Hess, M. F. Jacquin and R.W. Rhoades. (SPON: G. Krauthamer) UMDNJ-NJSOM & RMS, Piscataway, NJ 08854

The central representation of the mystacial vibrissae in rodents has become an important model for studying peripheral influences upon normal central nervous system development and also the effects of peripheral injury on central neural ontogeny. The infraorbital (IO) branch of the maxillary division of the trigeminal nerve innervates the vibrissae and, surprisingly in view of its importance as a model system, little is known regarding the normal composition of this nerve or the manner in which its organization might be altered by neonatal damage. As a first step toward answering these questions we have described the normal organization of the IO nerve using electronmicroscopic methods. Four nerves have been examined thus far. Just caudal to the infraorbital foramen at the level anterior superior alveolar foramen the nerve is composed of 18 to 25 bundles which range from 575 to 87,923 μm^2 in cross sectional area. Axon counts from thin sections taken at this level (all myelinated and unmyelinated axons were counted in each nerve) demonstrated that the IO nerve contains an average of 19,740 myelinated (s.d.=2,054) and 13,319 unmyelinated (s.d.=1,159) fibers. The maximum number of myelinated axons in a single bundle was 3,068 (s.d.=821) and the maximum number of unmyelinated axons was 2,464 (s.d.= 1,220). The largest number of myelinated and unmyelinated axons were generally found in the same fiber bundle.

All myelinated and unmyelinated axons along the major and minor axes of each bundle in each nerve were measured. Areas (including myelin sheaths for medullated fibers) were computed with a graphics tablet and converted to standard diameters. The average for the myelinated axons (N=5,207) was 4.42 μm (s.d. =1.76) and the fiber diameter distribution was essentially unimodal. That for the unmyelinated axons (N=1,052) was 0.60 μm (s.d.=0.16) and the distribution was again unimodal.

We have thus far examined one IO nerve from an adult rat subjected to section of this V branch at birth. The nerve (all data are from sections taken at the same level as those for the normal nerves) was comprised of 20 bundles with cross-sectional areas of 284-30,352 μm^2. It contained 5,260 myelinated and 2,747 unmyelinated fibers. The average diameter for the myelinated axons (N=472) was 3.01 μm (s.d.=1.1) and that for the unmyelinated fibers (N=175) was 0.61 μm (s.d.=0.20).

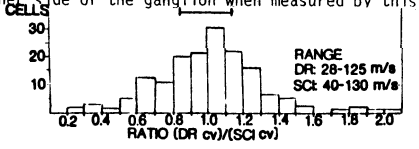
229.12 CONDUCTION VELOCITY CHANGES ALONG LUMBAR PRIMARY AFFERENT FIBERS IN CATS. A.J. Rindos and G.E. Loeb, Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20205.

Microelectrodes were inserted into L7 dorsal root ganglia (DRG) to record spikes from primary afferents. These were used to trigger simultaneous averaged records of activity from multiple tripolar electrode hooks around the L7 dorsal root (DR) and nerve cuffs around the sciatic (SCI) and posterior tibial (PT) nerves. Latencies were used to determine conduction velocities (cv) between various tripolar electrode pairs. A histogram of the ratios of overall DR to SCI cv is plotted below. The bar above the graph indicates an estimate of the range of uncertainties due to hardware limitations. Most units exhibited no significant change between SCI and DR cv, but PT cv averaged 85% of SCI cv. Changes in local SCI cv did not exceed experimental error. A current amplitude calibration pulse indicated no correlation between changes in local cv's and action current amplitudes.

CV's were also obtained by stimulating SCI or DR electrodes and measuring arrival time of the unit spike in the DRG. Distances were measured by laying a string from DRG center to stimulating cathode. SCI cv's obtained by stimulation and averaging were comparable for a given unit. However, DR cv's obtained by stimulation were consistently slower than those obtained by averaging. This underestimate was probably due to the relatively larger effect of the conduction delay between bifurcation and soma in the DRG. This variable delay also affected cv measured by latency between DRG spike and a single averaged potential.

Spike-triggered averaging between adjacent tripolar electrodes appears to be the most accurate way to measure cv, but it does have two significant sources of error: 1) For short latencies, digital sampling bin widtn introduces a significant uncertainty in peak time; for long latencies, sampling rates must be reduced to allow sufficient pretrigger storage in some averagers. Increased separation of electrodes reduces this problem. 2) Tripolar electrodes at the edge of an array may produce monopolar-like recordings with distorted waveforms which shift the observed peak. Nerve damage is also most likely at the edges due to kinking. CV in DRG axons was not significantly different on either side of the ganglion when measured by this technique.



229.PO THE ROLE OF ENDONEURIAL K^+ IN PROMOTING SPONTANEOUS ACTIVITY IN REGENERATING MAMMALIAN NERVE - SINGLE FIBER AND ENDONEURIAL K^+ RECORDINGS, P.A. Low. Neurophysiology Laboratory, Mayo Clinic, Rochester, MN 55905.

While extracellular K^+ is known to affect peripheral nerve membrane potential and excitability, its role in modulating spontaneous activity (SA) in damaged nerve fibers is largely unexplored.

The $[K^+]_e$ of normal rat peripheral nerve (sciatic and tibial) has recently been studied and found to be 3.7 mM (sd 0.7 mM)[1]. The present report is confined to the endoneurial K^+ and its relationship to spontaneous activity of regenerating nerve fibers. The left tibial nerve was crushed in 22 Sprague-Dawley rats and the endoneurial K^+ measured using K^+-ion sensitive microelectrodes 2 days to 3 months following crush. The $[K^+]_e$ was increased in the first 2 weeks with a progressive decline towards control values after that. Single fiber recordings were made from the tibial division of sciatic nerve in 13 animals. The mean number of single fibers studied per rat was 55.5 (sd 24.6). Spontaneous activity was present in all regenerating nerves (7-50% of single fibers had SA) and was maximal in the first 2 months (especially 2-4 weeks). Endoneurial K^+ was further increased by intra-arterial injection of potassium rich injectate into the supplying saphenous artery. Spontaneous activity was markedly enhanced when $[K^+]_e$ began to rise; there were further superimposed bursts of SA with the bolus. These findings suggest that $[K^+]_e$ increase is factor in enhancing SA in damaged nerve fibers.

PAIN: CENTRAL PATHWAYS

230.1 EFFECTS OF TRIGEMINAL TRACTOTOMY ON THE RAT'S PERCEPTION OF NOXIOUS AND NON-NOXIOUS FACIAL STIMULI. J. G. Broton and J. Peter Rosenfeld. Department of Psychology, Northwestern University, Evanston, IL 60201.

Trigeminal (V) tractotomy is a surgical procedure whereby the caudal V nuclear complex is selectively deafferented. When performed in cases of V neuralgia, patients are often relieved of the facial pain spasms, and become analgesic to noxious stimuli applied to the face. Perception of non-noxious stimuli remains. Primarily because of this evidence, the caudal V nuclear complex (nucleus caudalis) has often been considered to be the only part of the V complex which is important for the normal perception of facial pain. This belief has influenced animal researchers studying the mechanisms of facial nociception, such that almost all are directed to nucleus caudalis. Recent studies, however, have found that tractotomy does not result in dental analgesia in cats, monkeys or trigeminal neuralgia patients, nor in perioral facial analgesia in monkeys. We here report that rats receiving tractotomy-like knife cuts do not exhibit deficits in responsiveness to noxious heat delivered to several areas of the face.

Adult male Holzman albino rats were used. During testing, rats were tail-restrained and a heater device was attached to a previously implanted socket on the rat's head. Noxious heat stimuli were applied to each of five sites on the face, resulting in the production of nocifensive face-rubbing responses (FRs). Four days of baseline testing assured the reliability of responses. Tractotomy-like coronal cuts were made with a custom-made wire knife, which was lowered through a chronically implanted guide cannula. The effectiveness of the cuts was assessed by viewing the Fink-Heimer-stained degeneration in the descending V tract caudal to the cut. Rats were retested 24 hours after the cuts.

Post-tractotomy behavioral data on nine rats have thus far been collected. Results indicate that V tractotomies often did not produce significant elevations in FR latencies at any of the five facial sites tested. In three rats, increases were seen at perioral positions, while at non-perioral sites, FR latencies were at control levels. Reasons for the individual cut differences will be discussed. Work in progress will assess the effects of similar knife cuts on the perception of non-noxious air puff and heat stimuli, in addition to noxious heat. (Supported by NIH Grants GM23696 and DE05204 to JPR.)

230.2 RESPONSES IN TRIGEMINAL SENSORY NUCLEI TO TOOTH-PULP STIMULATION IN THE CAT:EFFECTS OF SURGICAL TRAUMA. R.W.Clarke* and B.Matthews. Dept. of Physiology, University Walk, Bristol BS8 1TD, U.K.

To excite trigeminal brain-stem neurones by electrical stimulation of tooth-pulp in an acutely-prepared cat in a stereotaxic frame, often requires stimulus intensities which are greatly in excess of those needed to excite the majority of the myelinated pulpal fibres, yet the latencies of the responses indicate that they are due to myelinated afferents. Furthermore, although approximately 40% of primary afferents from tooth-pulp respond to thermal stimulation of the intact tooth (Kollmann,W.,Matthews,B. & Suda,H., J.Physiol, 332 63P, 1982), attempts in our laboratory to record responses of neurones in the brain-stem to such stimuli have been unsuccessful. Other observations indicated that injury created in setting up the acute preparations caused a profound depression in the excitability of trigeminal neurones, lasting several hours. We have therefore investigated brain-stem responses to electrical and thermal stimulation of teeth in animals in which trauma immediately prior to recording was kept to a minimum.

In nine cats, a preliminary operation was carried out in which a small chamber was attached to the skull so that the head could be fixed and recordings made with minimal trauma on a subsequent occasion. A further three animals were prepared acutely with precautions to minimise trauma, including the use of atraumatic ear-bars. Ten other cats were prepared normally, without these precautions. Recordings were made using glass-coated tungsten microelectrodes and recording sites marked by small electrolytic lesions. All procedures were carried out under alphaxalone/alphadolone anaesthesia. Data were collected only when arterial blood pressure and end tidal CO_2 were within normal limits.

In both groups of animals prepared with minimal trauma, more than 95% of the units which responded to electrical stimulation required only a single stimulus of less than 100μA, 0.1 ms to excite them, comparable with the thresholds of the primary afferents. In cats prepared in the standard way,the thresholds of only 30% of units were in this range and 30% were above 1mA,0.1ms. There were no differencies in the latencies of the responses between groups. Of 197 units tested with thermal stimuli in minimally-traumatised cats, 101 responded preferentially to cooling (10^oC)of the intact tooth and 9 responded preferentially to heating (50^oC). Units were found at all levels of the trigeminal nuclei. These results show that greater summation of inputs is required to activate trigeminal neurones from tooth pulp in cats prepared in the standard way than if trauma is minimised. The mechanism of the depression has not been established. Supported by M.R.C.

230.3 CONVERGENT AFFERENT INPUTS AND RESPONSES EVOKED BY NOXIOUS AND NON-NOXIOUS OROFACIAL STIMULI OF NEURONES IN TRIGEMINAL (V) SUBNUCLEUS ORALIS. J.W. Hu*, G. Zhong*, N. Amano* and B.J. Sessle (SPON: F. Coceani). Fac. of Dentistry, University of Toronto, Toronto, Canada M5G 1G6.

Since subnucleus oralis as well as subnucleus caudalis (medullary dorsal horn) of the V spinal tract nucleus has been recently implicated in V brainstem mechanisms of pain, we have examined the response properties of oralis neurones to a variety of natural and electrical stimuli. Extracellular activity was recorded from 250 single oralis neurones in chloralose-anaesthetized cats; each neurone was functionally classified on the basis of its cutaneous receptive field properties as low-threshold mechanoreceptive (LTM), wide dynamic range (WDR), or nociceptive-specific (NS). In addition to noxious (e.g. pinch, heat) and non-noxious (tactile) stimuli, each neurone was tested for responsiveness to electrical stimulation of various cutaneous and oral mucosal sites, canine and premolar tooth pulp, visceral (superior laryngeal nerve) and C_3 neck afferents, and hypoglossal and temporalis muscle afferents; recording sites were confirmed histologically.

We verified previous findings of the "inverted head" somatotopy of oralis. The receptive field of 50% of the neurones was localized to the facial skin; for 25% it was restricted to the oral cavity, and for the remaining 25% it involved both cutaneous and intraoral sites. LTM neurones having localized orofacial receptive fields comprised 90% of the sample. The remaining neurones located within oralis were WDR and NS neurones; many nociceptive neurones were also located outside oralis in the adjacent reticular formation. The oralis nociceptive neurones responded to pinch, and some also responded to noxious radiant heat or algesic chemicals injected into lingual arterial branches supplying the tongue muscles. In terms of electrically induced responses, 50% of the oralis neurones could be excited by cutaneous or oral mucosal electrical stimuli applied outside the V division of their receptive field. Furthermore, 30% were excited by canine and 35% by premolar pulp stimulation. Visceral, neck, hypoglossal and temporalis afferent stimulation excited 35%, 10%, 20%, and 35%, respectively. The incidence of excitation from these convergent afferent inputs was higher for the WDR and NS neurones than the LTM neurones.

This study has confirmed that oralis is a somatotopically organized structure predominantly composed of LTM neurones. A small proportion of nociceptive neurones does however occur within oralis. Convergent afferent inputs evoked by electrical stimuli are prominent, and are particularly apparent in the nociceptive neurones.

230.4 TRIGEMINAL MEDULLARY DORSAL HORN NEURONS PROJECTING TO MEDIAL AND LATERAL THALAMUS. Carmella Angerbauer and Jonathan O. Dostrovsky (SPON: H.C. Kwan), Department of Physiology, University of Toronto, Toronto, Canada, M5S 1A8

The caudal segment of the trigeminal spinal nucleus, termed subnucleus caudalis or the medullary dorsal horn (MDH) is functionally and anatomically similar to the spinal cord dorsal horn and is believed to be the major relay site for nociceptive sensory input from the oral-facial region. The present study examined the characteristics of MDH neurons projecting to medial and/or lateral regions of thalamus.

Experiments were performed on 28 cats anesthetized with chloralose. Single unit extracellular recordings of MDH neurons were obtained using standard methods. An array of bipolar stimulating electrodes was placed in the contralateral thalamus. All stimulation sites were determined from cresyl violet stained histological sections. Neurons fulfilling the criteria for antidromic excitation from thalamus were characterized using various innocuous and noxious mechanical and thermal stimuli. A total of 29 projection neurons were examined in detail, of which 12 could be antidromically excited by stimulation in medial thalamic regions (parafascicular, subparafascicular, central medial, and principal ventromedial nuclei), 12 by stimulation in lateral thalamic regions (ventrobasal complex, zona incerta, and posterior complex) and 5 by stimulation in both regions. Neurons excited by stimulation in medial sites consisted of 6 nociceptive specific, 5 low threshold mechanoreceptive, and 1 innocuous thermal (cold). Neurons excited by stimulation in lateral thalamus consisted of 7 nociceptive specific, 2 wide dynamic range, and 3 low threshold mechanoreceptive. Those projecting to both regions were all low threshold mechanoreceptive. 4 neurons had receptive fields spanning the whole ipsilateral face, 3 had fields extending bilaterally across the whole body, and the remainder had relatively small fields within the trigeminal region. There was no clear relationship between receptive field size and thalamic stimulation site. These results indicate that in addition to the previously reported trigeminal projection to ventroposteromedial thalamus, there is a significant projection to more medial sites in thalamus.

Supported by NIH grant DE-05404.

230.5 PROPERTIES OF SPINOTHALAMIC TRACT CELLS LYING IN THE VENTROMEDIAL ZONE OF THE LUMBAR SPINAL CORD IN THE RAT. D. Menétrey, J. de Pommery (SPON:E.R. PERL). INSERM, Unité de Neurophysiologie Pharmacologique, U 161, 2 rue d'Alésia, 75014 Paris, France.

In an earlier study using the retrograde transport of horseradish peroxidase (Giesler et al., J. Comp. Neurol.,184 : 107, 1979) we have shown that a prominent spinothalamic projection issues from the ventromedial zone (VMZ) of the lumbar dorsal horn of the rat's spinal cord. A similar finding has been reported in the cat but not in the monkey (Trevino and Carstens, Brain Res., 98 : 177, 1975). Following confirmation of this projection in the rat (Chaouch et al., J. Comp. Neurol., 214 : 309, 1983) we undertook to characterise electrophysiologically it by studying antidromically identified spinothalamic tract (STT) neurons in immobilized rats under halothane anesthesia. Extracellular recording sites were located by injection of a dye, VMZ sites were selected from camera lucida observations.

Lumbar VMZ cells activated from the posterior levels of the thalamus had conduction velocities ranging from 11 to 27 m/s (m=18 m/s). As was predictable from their densely packed formation, the cell population of VMZ was very homogeneous in terms of its electrophysiological properties. They were activated from peripheral areas including both proprioceptive and cutaneous tissues. Effective stimuli were combinations of the joints and skin. Their background activities were directly related to the resting position of joints. A) The most frequent subpopulation had restricted ipsilateral receptive fields including ankle, joint of the digits and skin. Their background activity consisted of small groups of spikes (mostly doublets and triplets) which depended on the resting position of the ankle (flexion reduced it while extension increased it). The resting position of the ankle also potently affected the excitatory responses from skin (touch, pressure) or distal joints (extension of the digits). All excitatory inputs were from both large and fine myelinated fibers. A nociceptive radiant heat stimulus applied to the plantar sole was always effective in inhibiting the resting neuronal discharge. B) The second subpopulation had larger receptive fields and their background activity consisted of isolated spikes which depended on the resting position of the knee (flexion increased it while extension reduced it). Cutaneous pressure or pinch was very effective in inhibiting this activity. The inhibitory receptive fields varied in size with the largest involving both hindlimbs and ipsilateral forelimb.

The activities of VMZ cells are thus directly related to inputs from regions involved in locomotion and posture. As such a projection has not been shown in monkey (i.e. a mostly biped standing animal), it probably represents part of the system involved in the coordination of quadruped walking.

230.6 DIFFERENTIAL DIENCEPHALIC PROJECTIONS FROM THE SPINAL CORD AND THE GIGANTOCELLULAR RETICULAR AREA IN THE RAT : AN ANATOMICAL STUDY USING WGA-HRP WITH REFERENCE TO PAIN TRANSMISSION Marc PESCHANSKI*, Patrick W. MANTYH* and Jean-Marie BESSON*, INSERM U 161, 2 rue d'Alésia, Paris 75014, France and Dept of Anatomy, UCSF Medical School, San Francisco, CA 94143 USA (spon. Hugh A. Patterson)

In an attempt to define the actual sites of projection of two pathways involved in pain transmission, i.e. the spino-thalamic tract and the spino-reticulo-thalamic tract, an aqueous solution of wheat-germ agglutinin conjugated to horseradish peroxidase (WGA-HRP, 10 % Sigma) was iontophoretically injected through a glass micropipette using dc positive current either in the grey matter of the cervical or lumbar enlargement of the spinal cord, or in the nucleus reticularis gigantocellularis of the medulla (NGC) in male Sprague Dawley albino rats. 24 to 48 hours later, animals were killed with an overdose of sodium pentobarbitone, perfused transcardially with paraformaldehyde (1%) and glutaraldehyde (3%) in phosphate buffer (pH 7.4, .1M) and the brain cut frozen in 60 µm sections. Alternate sections were reacted for HRP using tetramethyl benzidine as a chromogen.

Spinal projections to the diencephalon were observed contralaterally in the lateral portion of the ventrobasal complex, the ascending branch of the intralaminar nucleus centralis lateralis and in the dorsal part of the nucleus submedius. In contrast, other than a light labelling in few ventral and medial thalamic structures, major projections of the NGC neurons were to be to the intralaminar nuclei, all of them receiving moderate density of labelling. In particular, in all cases, the area lateral to the parafascicular nucleus and defined in the present study as the nucleus center median contained numerous thin dividing fibers and dots of reaction product suggesting the presence of terminal boutons.

These anatomical data and the different electrophysiological characteristics of the thalamic neurons recorded in the same species in the ventrobasal complex (Guilbaud et al.,Pain 8,1980, 303-318) and in the posterior intralaminar region (Peschanski et al.,Exp.Neurol.,72,1981,226-238) i.e. in the sites of projection of the spino-thalamic and of the spino-reticulo-thalamic tracts respectively, are suggestive of a distinct role of the two pathways in pain transmission. The thalamic ventrobasal complex and the spino-thalamic system is possibly involved in the sensory-discriminative aspects of pain transmission and the nucleus center median and the spino-reticulo-thalamic system is possibly involved more in motor and/or behavioral responses related to pain.

230.7 NOCICEPTIVE NEURONS IN THE VENTRAL POSTERIOR THALAMUS OF THE AWAKE SQUIRREL MONKEY. T. J. Morrow and K. L. Casey. Neurology Research Laboratories, V.A. Medical Center, Ann Arbor, MI 48105.

Previous investigations of the ventral posterior (VP) thalamus in unanesthetized primates have failed to find neurons that respond differentially to noxious somatic stimuli. This study examines the responses of VP neurons to a variety of innocuous and noxious cutaneous somatic stimuli in the awake, partially restrained squirrel monkey.

Receptive fields and response properties were determined for 85 of 102 single neurons recorded from the ventral posterior lateral (VPL) and ventral posterior medial (VPM) nuclei of the thalamus in the awake squirrel monkey. These somatically responsive neurons typically discharged at rates of 1 to 20 pulses/second in the absence of intentional stimulation, and responded to innocuous or noxious, mechanical, somatic stimuli. All but 12 neurons with midline or bilateral receptive fields on the tail, responded to stimuli applied to a small fraction of a limb, the tail, trunk or face, contralateral to the recording site. Most neurons responded maximally to innocuous somatic stimuli such as hair movement (N=41) or light touch of the skin (N=38). Noxious cutaneous stimulation elicited no greater response from these neurons than innocuous stimuli.

Nine neurons, recorded from the lateral posterior part of VPL or the ventral posterior VPM, responded maximally to noxious mechanical somatic stimuli. These cells also discharged spontaneously at rates of 2 to 10 pulses/second and responded to light tactile stimulation of the skin, but not to hair movement. The most effective stimulus in each case was skin pinch sufficiently strong so to elicit withdrawal and occasionally vocalization. Noxious heat was no more effective than innocuous touch. Neurons responding exclusively to noxious stimuli were not found.

The neural activity evoked by noxious stimuli was not due to activation of central motor pathways. Active movements that were independent of the stimulus were not associated with unit discharge. Furthermore, passive limb movements, joint manipulations and muscle palpation did not evoke unit activity.

These studies have shown for the first time that, in the awake, behaving primate, there is a population of VPL/VPM neurons that is differentially responsive to noxious stimuli delivered to small, well-defined contralateral receptive fields. This finding complements and expands on the work of others in the anesthetized monkey and cat. Supported by the Veterans Administration and NIH Grant NS 12581.

230.8 CONVERGENCE OF PROJECTIONS FROM TOOTH PULP AND PERIODONTAL LIGAMENT ON SINGLE NEURONS IN FELINE NUCLEUS CENTRUM MEDIANUM. K.V. Anderson, N.F. Capra, H. Hirata and T. Jones*. Dept. of Anatomy, Univ. Mississippi Med. Ctr., Jackson, MS 39216.

Previous studies in our laboratory have shown that neurons in thalamic nucleus centrum medianum (CM) can be driven from the maxillary and mandibular teeth and from sites within the caudal zone of nucleus gigantocellularis in the brain stem reticular formation. The present studies demonstrate that CM neurons that respond to tooth pulp (TP) activation may also respond to activation of periodontal ligament (PDL) receptors.

Single cells were isolated in CM (A 6.5 to 8.0, L 2.0 to 4.0, H 2.5 to -2.5) of 10 pentobarbital anesthetized cats using tungsten microelectrodes. Cardiac rate, expired gases and body temperature were monitored throughout each experiment. CM neurons were identified by providing electrical stimulation to maxillary or mandibular canine tooth pulps and by mechanically tapping the surface of the canine teeth with a relay driven force applicator.

In the present studies, 100 neurons in CM were isolated which responded vigorously to PDL stimulation associated with the canine teeth. These cells responded with a latency that ranged from 5 to 30 msec. with an average latency of 21 msec. Ten of the cells that responded to PDL stimulation also responded to TP stimulation with latencies that ranged from 6 to 40 msec., with an average latency of 32 msec. All neuronal responses in CM to TP or PDL stimulation were excitatory and in each case the response latency following PDL stimulation was less than that following pulpal stimulation. In addition, neurons receiving converging sensory information showed more vigorous responses to pulpal stimulation than to PDL stimulation. Most CM neurons were more sensitive to ipsilateral than to contralateral stimulation, although many neurons could be activated bilaterally. In general, CM neurons sensitive to the maxillary teeth were located dorsally in the nucleus and those sensitive to mandibular teeth were located ventrally.

The present study identifies a population of midline thalamic neurons that receive convergent sensory information from both intrapulpal and extrapulpal receptors. These receptors are known to also provide inputs to various portions of the spinal trigeminal complex and to portions of the spinal cord. Taken together, these observations demonstrate that TP and PDL dental stimuli elicit convergent responses at several levels of the central nervous system and may have complex interactions within these nuclear regions. While the functional significance of this convergence in CM is, as yet, unknown, we would like to suggest a role for this midline system in sensory-motor integration and reflex functions.

230.9 REACTIONS OF CLAUSTRAL SINGLE CELLS TO THE TOOTH PULP STIMULATION IN CATS. P.J. Jastreboff*, M. Sikora*, A. Frydrychowski*, and P. Sloniewski* (SPON: R. Small). Dept. of Neurophysiology, Nencki Institute of Experimental Biology, 3 Pasteur Street, 02093 Warsaw, Poland.

Publications describing single unit recording from claustrum are scarce. Responses of claustral single cells to somatic, visual and acoustic stimulation have been recently reported. Taking into account the hypothesis of claustrum as a sensory regulator, which may prevent some types of inputs from reaching certain targets in the cortex, studies of the occurence of input of pain related information into the claustrum may provide valuable data towards this hypothesis. The tooth pulp stimulation was used as it can be easily controlled and can be taken as being nearly pure painful. A further point which needs to be clarified is whether the claustrum obtains afferents only from the cerebral cortex or from subcortical structures as well. In order to compare our results with previously published data the electrical stimulation of limbs was used as a parallel stimulation.

Experiments were carried out on 8 cats anesthetized with chloralose. The single unit activity was recorded from the central part of the claustrum. The majority of cells responded in a similar manner to tooth pulp and paws stimulation but there were cells with clear preference to a given type of stimulation.

Latencies of reactions evoked by tooth pulp stimulation were statistically significantly shorter than evoked by limb stimulation and in the former case latencies as short as 8 ms were observed. It is postulated that the central region of claustrum receives the projection from tooth pulp, and that part of it is coming not through the cerebral cortex but directly from the subcortical structures.

230.10 THE EFFECT OF SENSITIZATION AND NEMBUTAL ON THE RESPONSES OF PRIMATE SI CORTICAL NOCICEPTIVE NEURONS. D.R. Kenshalo, Jr. and W.C. Perkins*. Divisions of Neurbiology and Neurosurgery, Barrow Neurological Institute, St. Joseph's Hospital and Medical Center, Phoenix, AZ 85013.

Past research has shown that some neurons in areas 3b and 1 are responsive to noxious mechanical and thermal stimuli. Manipulations that alter the perception of painful stimuli should change the response characteristics of these neurons. We recorded from single neurons in SI cortex in young adult macaque monkeys (Macaca fascicularis). The animals were anesthetized with alpha-chloralose and maintained with supplements of sodium pentobarbital. Single units were isolated using tungsten microelectrodes. The cutaneous receptive fields were tested with innocuous and noxious stimuli. Innocuous stimuli included hair movement, light touch and pressure. Noxious stimuli applied to the skin included pinching and ascending noxious heat pulses (from an adapting temperature of 35°C to 43°, 45°, 47° and 50°C).

Repetition of the ascending sequence of noxious heat stimuli revealed a sensitization of the responses of 12 cortical nociceptive neurons. The threshold for a response to noxious heat was lowered and the responses to suprathreshold noxious heat stimuli were enhanced. The relative amount of sensitization of the response to noxious thermal stimulation exhibited by cortical nociceptive neurons was greater than either spinothalamic or thalamic nociceptive neurons.

The influence of Nembutal on the response of cortical nociceptive neurons was studied in 5 experiments. In two instances a bolus injection of 5 mg/kg of Nembutal completely eliminated responses to noxious thermal stimuli up to 55°C. In three other instances injections of Nembutal increased the threshold for a response from 50° to 55°.

Based on these findings, cortical nociceptive neurons respond in a consistent manner to some of the manipulations that are capable of altering the perception of painful stimulation.

Supported by NSF grant BNS-8217728.

231.1 THE ROLE OF THE A7 CATECHOLAMINE GROUP IN THE MODULATION OF PAIN PERCEPTION . J. Sagen and H.K. Proudfit. Dept. of Pharmacology, Univ. of Illinois at Chicago, Chicago, IL 60680.

Microinjection of alpha-adrenergic antagonists such as phentolamine (PTL) into the nucleus raphe magnus (NRM) produces potent analgesia. This suggests that neurons in the NRM are tonically inhibited by noradrenergic (NA) neurons and that blockade of this NA input disinhibits (activates) NRM neurons resulting in analgesia. Such analgesia appears to be mediated by bulbospinal NA neurons since it can be blocked by intrathecal injection of NA antagonists or by selective depletion of spinal cord NE produced by intrathecal 6-OHDA. These findings suggest that NRM neurons activate descending NA neurons which inhibit the transmission of nociceptive information at the level of the spinal cord. Although the location of these spinally-projecting NA neurons is not known, the A7 catecholamine group has been shown to project to the spinal cord. The purpose of the present studies was to determine whether the A7 nucleus is the origin of the bulbospinal NA pathway involved in mediating the analgesia produced by activating neurons in the NRM. To test this proposal, the effect of electrolytic lesions of the A7 nucleus on nociceptive threshold and the capacity of PTL injected into the NRM to produce analgesia was determined.

Female rats (225-250 g) were tested using the tail flick test to determine baseline nociceptive threshold. Animals then received either bilateral, unilateral, or sham electrolytic lesions of the A7 nucleus and a microinjection guide cannula aimed at the NRM was implanted under pentobarbital anesthesia. Tail flick latencies (TFL) were determined 1, 7, and 14 days following the lesion. At 14 days, PTL (10 ug in 0.5 ul of saline) was injected into the NRM and TFLs were determined 10, 20, and 30 min following the injection. Lesion and injection sites were verified histologically. Animals with either sham or unilateral A7 lesions exhibited no alterations in TFLs at 1, 7, or 14 days following the lesion. In contrast, animals with bilateral A7 lesions showed marked hyperalgesia 1 day following the lesion and partial recovery by 14 days. PTL injected into the NRM produced potent analgesia in animals with sham A7 lesions, but this analgesia was blocked in animals with either bilateral or unilateral A7 lesions. Spinal cord NE content in animals with unilateral or bilateral A7 lesions decreased to 73% and 60%, respectively, of that determined in sham-lesioned animals.

These studies support the suggestion that the spinally-projecting catecholamine neurons located in the A7 nucleus are involved in mediating the analgesia produced by activating neurons in the NRM. (This work was supported by USPHS Grant 18636 and the PMA Foundation).

231.2 HYPOALGESIA PRODUCED BY MICROINJECTION OF CARBACHOL INTO THE NUCLEUS RAPHE MAGNUS IS NOT DUE TO BLOOD PRESSURE CHANGES. M. S. Brodie and H. K. Proudfit. Dept. Pharmacology, Univ. of Illinois at Chicago, Chicago, IL 60680.

Previous reports from this laboratory have presented evidence for a functional cholinergic influence on neurons of the nucleus raphe magnus (NRM) involved in pain modulation. Microinjection of carbachol, a cholinergic agonist, into the NRM produces a profound hypoalgesia. It has been suggested that this suppression of pain perception is produced by the inhibition of incoming pain information at the spinal level. However, brainstem nuclei at the level of the NRM are thought to be involved in control of blood pressure, and elevation of blood pressure has been shown to cause a decrease in pain sensitivity. The purpose of this study was to determine whether the analgesia produced by microinjection of carbachol in the NRM is due to changes in blood pressure.

Sprague-Dawley derived rats(250-350 gm) were implanted with guide cannulae directed toward the NRM one week prior to blood pressure measurement or behavioral testing. In the first set of experiments, rats were anesthetized with urethane(1200 mg/kg, I.P.) and the carotid artery was cannulated. Body temperature was maintained at 37^{o}C, and a stable baseline blood pressure was obtained at least 15 min prior to microinjection of carbachol. Blood pressure was measured continuously for 60 min after microinjection into the NRM. Microinjection of carbachol (2.5 ug in 0.5 ul saline) was made at a rate of 0.5 ul/min using a Harvard pump. Microinjection of carbachol lateral or dorsal to the NRM produced an increase in mean arterial blood pressure (MAP) of 30.0 +/- 10.4 mmHg within 15 min. Blood pressure returned to normal within one hour. In contrast, microinjection of carbachol directly into the NRM produced no increase in blood pressure.

To further dissociate the interaction of blood pressure and pain sensitivity, the effect of hexamethonium, a ganglionic blocker, on carbachol-induced elevation in tail flick latency was tested. Pharmacological blockade of sympathetic ganglia should eliminate centrally mediated increases in blood pressure. Tail flick latency was assessed before any drug administration, 25 min after hexamethonium (2.8 mg/kg, I.P.), and at intervals after carbachol was microinjected into the NRM. Hexamethonium alone had no effect on tail flick latency, and the ganglionic blockade produced by hexamethonium did not attenuate the tail flick latency increase produced by carbachol microinjected into the NRM.

These data indicate that while brainstem cholinergic systems are involved in blood pressure modulation, the hypoalgesia produced by microinjection of carbachol into the NRM is not due to blood pressure elevation. Supported by USPHS Grant NS 18636.

231.3 EFFECTS OF NALOXONE AND ATROPINE ON SOMAN INDUCED ANTINOCICEPTION AND CENTRAL NEUROCHEMICAL CHANGES. J.A. Romano and T.-M. Shih, US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010.

Irreversible cholinesterase inhibitors have been shown to produce antinociception on the rat hot plate test (HP) and to produce elevations of acetylcholine (ACh) and choline (Ch) in brain. The present experiment examined: (1) the effect of soman on HP, (2) the possible antagonism of soman effects by atropine sulfate (ATR) or naloxone hydrochloride (NAL) pretreatment, and (3) the possible neurochemical link between production of HP antinociception and changes in rat brain ACh and Ch. HP latency (in sec) to hind paw lick or foot thump was recorded with HP temperature at 56.4^{o}C and a 30 sec cutoff. Animals were tested on HP prior to injection of saline (SAL), ATR (1.1 or 2.2 mg/kg, i.p.) or NAL (3.0 or 10.0 mg/kg, i.p.). Five min following pretreatment, animals were injected with SAL or soman (69 or 80 µg/kg, i.m.) and retested on HP 30 min later. Data were reported in terms of change from baseline HP latency (sec). Immediately after the second HP test animals were killed by focused microwave irradiation. ACh and Ch were analyzed in brainstem (B), cerebral cortex (C), hippocampus (H), midbrain (M), cerebellum (R), and striatum (S) by the gas chromatograph/mass spectrometric method (Psychopharmacology 78: 170, 1982). Soman (80 µg/kg) produced significant HP antinociception which was not antagonized by either dose of ATR but was facilitated by both doses of NAL. Neither ATR nor NAL treatment alone had any effect on HP latency scores. At an analgetic dose of soman (80 µg/kg), ACh was elevated in M (174%) and Ch in B and S (239% and 169%, respectively). Elevations of ACh and Ch produced by soman in these brain areas were not affected by any dose of ATR pretreatment. However, both doses of NAL significantly enhanced soman-produced elevation of Ch in S. Neither ATR nor NAL treatment alone had any effect on ACh or Ch in any of the brain areas studied. The results of the present study indicate that: (1) soman produces antinociception on HP, (2) this antinociception is facilitated by NAL pretreatment but is not affected by doses of ATR used in the present study, and (3) soman produces elevations of rat brain ACh and Ch levels which are not affected by ATR but Ch levels are potentiated by NAL, suggesting a possible relationship between production of antinociception on the one hand and changes in neurochemical substrate on the other. These data support previous findings that brain Ch levels are influenced by the presence of opiate compounds (Fed. Proc., 41, 1303, 1982) and that brain Ch levels may play a role in the modulation of HP antinociception (Comm. Psychopharm., 1, 519, 1977).

231.4 ACETYLCHOLINESTERASE (AChE) POSITIVE CELLS AT THE ORIGIN OF THE DORSOLATERAL FUNICULUS (DLF) IN THE RAT VENTRAL MEDULLA. J.N. Johannessen*, L.R. Watkins, F. Eckenstein* & D.J. Mayer, Lab. Clinical Science, NIMH, Bethesda, MD 20205 (JNJ), Dept. Physiol. Biophys., Med. Coll. Va./Va. Commonwealth Univ., Richmond, VA 23298 (LRW, DJM), Dept. Neurochem., Max Planck, Munich, Germany.

Destruction of the spinal cord dorsolateral funiculus attenuates or abolishes analgesia produced by opiates, brain stimulation or environmental manipulations. Yet little is known about the neurochemical makeup of descending pathways within the DLF. While spinal depletion of serotonin or norepinephrine does attenuate environmentally induced analgesia, cells containing these neurotransmitters do not constitute a significant portion of the cell population which descend via the DLF. Recently, analgesia induced by intense somatic stimulation has proved susceptible to muscarinic antagonists. This result, coupled with the similar distribution of cells exhibiting AChE activity and those which descend via the DLF, suggests that DLF projecting cells within the ventral medulla may be cholinergic or cholinoceptive.

To identify cholinergic or cholinoceptive bulbospinal DLF projecting cells, discrete unilateral placements of HRP gel were made in the cervical DLF. After perfusion and sectioning, the tissue was stained for retrograde HRP and either AChE activity or choline acetyltransferase (ChAT) immunoreactivity using a rabbit antibody directed against an immune-complex consisting of pig ChAT and a monoclonal antibody.

At the level of n. raphe magnus, considerable numbers of DLF projecting cells were found to contain AChE activity. In various sections, as little as 15% or as many as 70% of the DLF projecting cells were found to be double labelled. No particular patterns of double labelled cells were found. They intermingled with non-AChE containing DLF cells both medially and laterally.

In contrast, no DLF projecting cells were found to be positive for ChAT. In contrast to the cells of the facial nucleus (n. VII) which were darkly stained for ChAT, medial portions of the ventral medulla were devoid of staining.

Taken at face value, these results suggest that a portion of ventral medullary DLF projecting cells are cholinoceptive, but not cholinergic. Absolute validation of this conclusion must be confirmed by electron microscopic observation of HRP-AChE positive cells. However, these results do provide an anatomical basis for a cholinergic link, either spinal or supraspinal, in the production of analgesia. This work supported by PHS grant DA 00576 to DJM.

231.5 ACTIVATION OF A CHOLINOCEPTIVE PONTINE AREA CONTRIBUTES TO ENVIRONMENTALLY INDUCED NOCICEPTIVE SUPPRESSION. Y. Katayama*, L.R. Watkins, D.P. Becker, and R.L. Hayes (SPON: Daniel Bossut). Depts. Neurosurgery and Physiology & Biophysics (LRW), Med. Coll. VA/Virginia Commonwealth Univ., Richmond, VA 23298.

We have recently demonstrated that muscarinic cholinergic activation of the lateral part of the cholinoceptive pontine area (dorsal and ventral parabrachial region, PBR) produces non-opiate analgesia in the cat (Neurosci. Abstr., 8:619). In the present study, we have examined the possibility that PBR functions physiologically to modulate pain sensitivity.

This study involved two separate experiments. First, we investigated the effects of pharmacological manipulations of cholinergic systems in rats on footshock induced analgesia (FSIA), a previously described model of endogenous nociceptive suppression (Science, 216:1185). Analgesia (tail flick test) induced by brief hind-paw shock was found to be markedly attenuated ($p < .0001$) by systemic scopolamine (2 mg/kg, i.p.), a muscarinic antagonist, but not by intrathecal scopolamine (0.1 mg), systemic mecamylamine (2 mg/kg, i.p.) or systemic methylscopolamine (2 mg/kg, i.p.). Since this non-opiate FSIA is not affected by decerebration at the intercollicular level (Science, 216:1185), analgesias induced by brief hind-paw shock and cholinergic activation of PBR both involve non-opiate, muscarinic cholinergic mechanisms located in the brainstem. Secondly, we examined the effects of microinjection of the muscarinic antagonist atropine (4.0 µg in 1.0 µl, bilat.) into PBR on endogenous nociceptive suppression in the cat (tail flick and calibrated pinch tests). Animals not habituated to the novel testing environment commonly showed low pain responsivity (prehabituation nociceptive suppression, Pharmac. Biochem. Behav., 10: 481). This nociceptive suppression was significantly reduced ($p < .005$) by atropine microinjection into PBR but not by atropine microinjection into non-PBR sites or microinjection of vehicle alone into PBR. Atropine microinjection failed to reduce pain responsivity in the animals repeatedly habituated to the testing environment. However, presentation of novel auditory and visual stimuli reliably replicated low pain responsivity even in these animals. Atropine microinjection into PBR again reduced this nociceptive suppression ($p < .005$). In contrast, while we found that food-deprived animals reproducibly showed marked nociceptive suppression during consummatory behaviors, this form of nociceptive suppression was not significantly attenuated by atropine microinjection into PBR.

These data indicate that the lateral part of cholinoceptive pontine inhibitory area may function physiologically to inhibit nociception in response to novel environmental events. Supported by PHS Grant DA00576 and NIH Grant NS12587.

231.6 ENCEPHALOSPINAL ANALGESIA SYSTEMS: NORADRENERGIC COMPONENT DOES NOT DESCEND IN THE DORSOLATERAL FUNICULUS (DLF). E.F.S. Kaufman, R.M. Fay, J.N. Johannessen, L.R. Watkins, & D.J. Mayer. Dept. of Physiology, Medical College of Virginia, Richmond, VA 23298 and Laboratory of Clinical Science, NIMH, Bethesda, MD 20205.

Opiate analgesia following either morphine microinjection into the periaqueductal gray or brief front paw shock of rats utilize pathways descending in the DLF. Since both of these opiate analgesias are attenuated by spinal norepinephrine (NE) depletion, the question arises whether NE fibers descend the cord in the DLF.

Brainstem neurons which project down the DLF were identified by making discrete unilateral placements of HRP gels into the cervical DLF of male rats. After two days, rats were perfused with 4% paraformaldehyde; brains were sectioned at 20um and reacted with diaminobenzidene/nickel ammonium sulfate to form cytoplasmic black granules in HRP-filled cells. A standard peroxidase anti-peroxidase reaction using goat antibody (Ab) to bovine dopamine B hydroxylase, a precursor of NE, was utilized to stain NE containing cells a translucent brown. Double-labeled (DL) cells were indicative of NE cells descending the DLF.

Almost no DL cells were found. Retrogradely labeled cells generally exhibited a different distribution from Ab stained cells. As previously reported, retrogradely labeled cells were concentrated in the paralemniscal region and the nucleus raphe alatus. In contrast, over the same rostro-caudal extent, most Ab labeled cells appeared in the locus coeruleus (LC), A5, and A7. It is important to note that A7 cells are not contained whithin the paralemniscal group as previously hypothesized. Occasionally, cells from the two groups would intermingle in an intermediate zone. However, at most, one or two cells per section were DL in a population of about 40 single labeled cells. Control studies revealed that the Ab and retrograde methods did not alter the labeling patterns of one another. In contrast to discrete DLF placements, brainstems of rats in which whole cord HRP injections were made exhibited many DL cells in areas such as the LC and A5.

These results indicate that descending pathways utilizing NE lie outside the DLF. Similarly, descending serotonergic pathways appear to lie largely outside the DLF. Since analgesia can be attenuated by destruction of these encephalospinal monoaminergic neurons or by lesions of the DLF, it is obvious that simultaneous activation of pathways within and outside of the DLF are necessary for full analgesic effects.

231.7 FUNICULAR PROJECTIONS OF THE PONTINE CATECHOLAMINERGIC FIBERS INNERVATING THE LUMBAR SPINAL CORD OF THE CAT. R. T. Stevens, C. J. Hodge, Jr., and A. V. Apkarian. Dept. of Neurosurgery, Upstate Medical Center, Syracuse, NY 13210.

Stimulation of the dorsolateral pons (DLP) in areas thought to provide the primary catecholaminergic (CA) innervation to the lumbar spinal cord is capable of producing potent inhibition of cutaneous inputs onto dorsal horn interneurons. These DLP regions include the nucleus locus coeruleus (LC), subcoeruleus (SC), the parabrachial medialis (PBM), and the Kolliker-Fuse nucleus (KF), of which the Kolliker-Fuse nucleus is the primary source of CA innervation to the spinal cord of the cat. This study was performed to determine the funicular course of the CA fibers supplying the lumbar spinal cord.

Multiple unilateral injections of the retrogradely transported fluorescent dye, Evans Blue, were made throughout the lumbar enlargement of the cat following various thoracic cord lesions. The lesions included either bilateral dorsolateral quadrant (DLQ) lesions or bilateral ventrolateral quadrant (VLQ) lesions. After a 4 day survival period, brain stem tissue was processed with glyoxylic acid for CA histofluorescence and spinal injection sites were verified histologically. With this procedure retrogradely labeled cells (EB), CA containing cells (CA) and double labeled cells (CA-EB) could be identified in the same section and their funicular course at the thoracic level determined.

When VLQ's were spared, large numbers of CA-EB cells within LC and SC appeared near control levels with bilateral projection with an ipsilateral predominance. EB cells within LC and SC were fewer than control on both sides of the brain stem. Within the Kolliker-Fuse nucleus, the number of CA-EB cells appeared slightly reduced, bilaterally, when compared with control animals. As in the control, there are very few retrogradely labeled, non-CA containing cells within KF.

When only the DLQ was spared, no double labeled, CA-EB cells and few EB cells were observed within LC. In SC and KF a significant number of double labeled cells were identified primarily ipsilaterally. Throughout the DLP, the number of single labeled, EB cells was fewer than control. Within PBM and PBL there are few EB or CA-EB cells even in control animals, therefore, their funicular projections were not determined.

The results show that in the cat, CA containing cells in LC project solely through the ventral and ventrolateral quadrants, while CA containing cells in SC and KF project primarily within the VLQ, however, each has a significant projection through the DLQ as well. Non-CA, retrogradely labeled cells within the DLP travel throughout the lateral and ventrolateral funiculi.

231.8 DORSOLATERAL FUNICULUS PROJECTIONS IN THE MONKEY (M. fasicularis) AS DEMONSTRATED BY FLUORESCENT RETROGRADE TRANSPORT. S.M.Carlton*, J.M.Chung, W.D.Willis (SPON: G.Russell). Mar.Biomed.Inst.,Physiol. & Biophys. and Anatomy, Univ. TX Med. Br., Galveston, TX 77550.

Impulses descending in the dorsal quadrant of the lateral funiculus (DLF) can inhibit noxious input at the spinal level. Lesion experiments demonstrate that analgesia produced by morphine, electrical brain stimulation, vaginal stimulation and stress are all dependent on the integrity of the DLF. The anatomy of DLF-projecting systems has been reported in both rat and cat. However, cell bodies projecting to lumbar cord via the DLF have yet to be described in the monkey. The retrogradely transported fluorescent marker granular blue (GB) was used to label cells with DLF projections in the monkey, identifying neuronal populations which could mediate antinociceptive mechanisms.

To ensure discrete placement of GB within a cord funiculus, it was incorporated into a polyacrylamide gel (5% wt/vol). A laminectomy in L2-L3 region was performed in 3 monkeys, the DLF surgically cut, and a pellet of GB gel implanted. Following 8-13 days, the animals were perfused and the brainstems and cords immediately cut (35 and 50µm, respectively) and mounted. The sections were viewed with a microscope equipped for epifluorescence. Every 5th section was drawn with an X-Y plotter and all labeled cells mapped. Boundaries and landmarks were drawn in from corresponding cresyl violet stained sections.

Following unilateral DLF implants, an abundance of retrogradely labeled cells were observed on midline in n raphe (r) magnus and n r obscurus, mainly ipsilaterally in n medullae oblongatae centralis (CN) subventralis, n paragigantocellularis lateralis, mainly contralaterally in red n, and bilaterally in n reticularis (R) gigantocellularis. A fair number of labeled cells was observed mainly ipsilaterally in the lateral reticular n and Edinger-Westphal n; contralaterally in paralemniscal RF; bilaterally in locus coeruleus (LC), sub LC, caudal and medial pontine RF, paramedian medullary RF, dorsolateral to the facial n and in n r pallidus. Scattered labeling was present in the ipsilateral gracile and cuneate n, and Kolliker-Fuse n; contralaterally in lateral, medial and inferior vestibular n; bilaterally in CN subdorsalis, n solitary tract, in the area around the inferior olive, dorsal to the superior olive, n cuneiformis, midbrain tegmentum and n Darkschewitsch.

This information establishes possible anatomical substrates underlying descending nociceptive mechanisms in the primate. All of these nuclei have been previously described as having DLF projections in cat and rat, thus it can be inferred that manipulation of the DLF in monkey will result in sequelae similar to those seen in these lower species. (Supported by NIH grants NS 07062, NS 18830, NS 09743 and NS 11255 and a grant from The Moody Foundation.)

231.9 THE EFFECTS OF PENTOBARBITAL ON NALOXONE REVERSIBILITY OF RAPHE INHIBITION OF SPINAL DORSAL HORN NEURONS. Y.Hori*, K.Endo*, J.L. Steinman*, and W.D.Willis. Marine Biomed. Inst. & Depts. of Physiol. & Biophys. & Anatomy, Univ. TX Med. Branch, Galveston, TX 77550.

An interaction between the opiate antagonist naloxone and barbiturates has been reported by several authors (Doi et al., Neurosci. Ltrs. 32:81, 1982, etc.). The purpose of the present study was to investigate the effects of sodium pentobarbital on naloxone reversibility of raphe inhibition of spinal dorsal horn neurons.

In 15 unanesthetized cats decerebrated at a supracollicular level, the activity of single neurons backfired from an electrode placed at the C3 level was recorded from the lumbosacral spinal cord dorsal horn using glass microelectrodes containing a carbon microfilament. A monopolar stainless steel electrode was inserted into the medulla at 2.5-4.5 mm rostral from the obex and 4-7 mm deep to the surface of the IVth ventricle. Stimulation sites were marked by lesions that were checked histologically after the experiments. Stimulation in the NRM was by 500 ms trains of monophasic square wave pulses (duration: 0.1-0.5 ms; current strength: 25-200 μA; 333 Hz).

We observed that the responses to noxious stimuli (pinch with forceps applied to the receptive field) were inhibited by NRM stimulation in 13 neurons. In 12 cases, the inhibition was antagonized by naloxone (0.05 mg/kg, i.v.). The effects of naloxone on the NRM inhibition of the response to innocuous stimuli (brushing applied to the receptive field) were tested in 5 neurons; the inhibition was naloxone reversible in 2 cases.

In 4 cats, after recovery from the effects of naloxone (60-90 min. after injection of naloxone), sodium pentobarbital was administered intravenously in doses up to 10 mg/kg. The pentobarbital was infused slowly to prevent hypotension. After injection of pentobarbital, the effects of naloxone on NRM inhibition were retested. In 11 trials using different strengths of NRM stimulation on 4 neurons, naloxone reduced the percent inhibition produced by NRM stimulation from 65% to 47% before pentobarbital, but only from 62% to 61% after pentobarbital. The effects of naloxone were significantly smaller in the presence of pentobarbital as compared to before injection of pentobarbital ($p < 0.05$).

These findings seem to indicate that pentobarbital interferes with the action of naloxone in reversing NRM inhibition of nociceptive responses of dorsal horn neurons, although the mechanism for this effect is not clear.

(Supported by NIH grants NS 09743 and NS 11255 and a grant from The Moody Foundation.)

231.10 CHARACTERIZATION OF INHIBITION OF THE TAIL FLICK REFLEX BY STIMULATION IN THE MIDBRAIN AND MEDULLA IN THE PENTOBARBITAL-ANESTHETIZED RAT. J. Sandkühler* and G.F. Gebhart. (SPON: W. Kaelber). Dept. Pharmacology, Univ. Iowa, Iowa City, IA 52242.

Focal electrical stimulation (STIM) in the midbrain periaqueductal gray (PAG) and medullary nucleus raphe magnus (NRM) have been demonstrated to produce an antinociception in a variety of animals and analgesiometric tests. Only recently, however, have studies been performed examining the distribution of effective STIM sites medially and laterally in the midbrain and medulla. In this study, we examined and mapped STIM sites mediolaterally and dorsoventrally in both the midbrain and medulla in the anesthetized rat, employing inhibition of the spinal nociceptive tail flick (TF) reflex to evaluate the efficacy of STIM.

Rats were initially anesthetized with 50 mg/kg of pentobarbital ip for craniotomy and venous cannulation and subsequently maintained lightly anesthetized (corneal and flexion reflexes present) by iv infusion (.5-1.0 mg/kg/hr). TF latencies were significantly faster in the lightly anesthetized state (1.63 ± .01 vs 2.36 ± .04 sec awake), corresponding to tail skin temperatures of 39.2°C and 43.9°C respectively. Monopolar STIM was continuous 100 Hz constant current cathodal pulses of 100 μsec duration, started 10 sec before heat was applied to the tail. At some sites in the midbrain, STIM started 0, 2.5 or 5 sec before heating the tail had higher thresholds for inhibiting the TF reflex than did STIM started 10 sec before; at other midbrain sites and at medullary sites, STIM started 20 sec before heating the tail had higher thresholds. Strength-duration curves for thresholds of TF inhibition in the midbrain and medulla yielded chronaxies of 95 and 93.75 μsec, respectively, indicating that fibers of passage were likely affected by STIM. Electrode tracking through the midbrain revealed that the lowest thresholds for inhibition of the TF reflex were located in the reticular formation lateral to the PAG, extending ventrally and eventually to the midline at a point approx. 2 mm ventral to the ventral boundary of the PAG. Thresholds in the PAG or at its ventrolateral edge were higher. Thresholds for TF inhibition did not differ in the awake and anesthetized state, although some STIM sites effective in the anesthetized state were aversive at the same STIM intensities in the awake state. There was no clear differential distribution of such STIM sites in the PAG. In the medulla, the lowest thresholds for inhibition of the TF reflex were contained in a narrow band extending mediolaterally across the dorsal part of the NRM and through the nucleus reticularis gigantocellularis; thresholds were higher in the ventral 2/3 of the NRM and the nucleus reticularis paragigantocellularis. Supported by DA 02879.

231.11 LIDOCAINE BLOCKADE OF NUCLEUS RAPHE MAGNUS AND THE LATERAL MEDULLARY RETICULAR FORMATION INDICATES THE DESCENDING PATHWAYS FOR INHIBITION OF A SPINAL NOCICEPTIVE REFLEX FROM THE PAG ARE DIFFUSELY ORGANIZED IN THE RAT. G.F. Gebhart and J. Sandkühler*. Dept. Pharmacology, Univ. Iowa, Iowa City, IA 52242.

Last year at these meetings we reported that the descending pathways of inhibition of noxious-evoked dorsal horn neuronal activity in the cat produced by electrical stimulation in the periaqueductal gray (PAGS) were diffusely organized in the medulla. Lidocaine (LIDO) injected in either the nucleus raphe magnus (NRM) or the adjacent lateral medullary reticular formation (MRF) failed to affect the descending inhibition of spinal nociceptors by PAGS; LIDO blockade of both the NRM and MRF simultaneously was necessary to block the spinal inhibitory effect of PAGS (Neurosci. Abs. 8: 768). Employing an anesthetized rat preparation and inhibition of the spinal nociceptive tail flick (TF) reflex in these experiments, we first established the efficacy of PAGS to inhibit the TF reflex before systematically examining the effects of LIDO administered in the medulla on the efficacy of PAGS.

Rats were anesthetized with 50 mg/kg of pentobarbital ip and subsequently maintained lightly anesthetized by iv infusion (see Sandkühler and Gebhart, this volume). Monopolar brain stimulation (STIM) consisted of continuous 100 Hz constant current cathodal pulses (100 μsec) started 10 sec before the TF test.

The extent of the functional blockade produced by LIDO (4%, 0.5 μl) injected in the medulla revealed that the STIM threshold for inhibition of the TF reflex at the injection site in the medulla was elevated by 156% above control up to 60 min after LIDO microinjection. The STIM threshold for TF inhibition 0.5 mm distant from the site of LIDO injection was elevated 63% at the same time while the inhibitory STIM threshold had returned to control values by 30 min 1 mm distant from the LIDO injection site.

When the NRM alone or when the MRF bilaterally was blocked by LIDO, STIM thresholds for TF inhibition by PAGS were not significantly elevated (15.0 and 14.5%, respectively). When the NRM and MRF ipsilateral to the PAG electrode were blocked simultaneously by LIDO, the PAGS threshold for TF inhibition was increased 56.6%. When the NRM and MRF bilaterally were simultaneously blocked by LIDO, the PAGS threshold for inhibition of the TF reflex was increased 102.6%.

Thus, the descending pathways for inhibition of the spinal nociceptive TF reflex activated by STIM in the PAG are diffusely organized in the medulla, involving both the NRM and MRF. In the rat, unlike the cat, the contralateral MRF also appears to be involved. Supported by DA 02879.

231.12 **ROLE OF NEUROTENSIN IN THE INTERACTION BETWEEN THE PERIAQUEDUCTAL GRAY AND NUCLEUS RAPHE MAGNUS.** D. Haggard*, M.M. Behbehani, and F. Zemlan. (Spon: G. Khodadad) Dept. of Physiology, Univ. of Cincinnati Coll. of Med., Cincinnati, OH 45267

The periaqueductal gray (PAG) and the nucleus raphe magnus (NRM) are two essential components of a descending pain inhibitory system. Although the pharmacology of this system has been extensively studied, the neurotransmitter(s) that mediates the interaction between these sites remains unknown. Recent anatomical studies have shown that a significant number of neurotensin (NT) containing neurons that are located in the PAG have direct projection to the NRM. In this study we examined the possibility that NT may act as a neurotransmitter between these sites.

Male Sprague Dawley rats were anesthetized with 1-2g/kg urethane and were prepared for single unit recording from NRM (AP -12 to -12.5; L 0.0 to 0.1; D 8.9 with an electrode inserted at an angle of 20 degrees with respect to the vertical plane) using a double barrel electrode, and electrical stimulation of PAG (AP -5.8; D 5.5; L 0.8). NT was applied by pressure injection of 5 to 30 PSI. Activity of 61 neurons were recorded. As shown below, a significant number of neurons that responded to PAG stimulation did not respond to NT. Only 11 percent of NRM neurons were excited and 24 percent were inhibited by NT.

		RESPONSE TO PAG STIMULATION			
		EXC	INH	NR	TOTAL
RESPONSE TO NEUROTENSIN	EXC	5	0	2	7
	INH	7	4	4	15
	NR	24	2	13	39
	TOTAL	36	6	19	61

The result of this study indicates that NT has little effect on the activity of NRM neuron and is not the neurotransmitter between the PAG and NRM. It is possible that the neurotensinergic projection from PAG to NRM is involved in presynaptic modulation of afferents other than from the PAG to the NRM.

231.13 EFFECT OF MORPHINE MICROINJECTION INTO NUCLEUS RETICULARIS PARAGIGANTOCELLULARIS ON ACTIVITY OF NEURONS IN NUCLEUS RAPHE MAGNUS: COMPARISON OF SPONTANEOUS AND NOXIOUS-EVOKED ACTIVITY. Mary M. Heinricher and J. Peter Rosenfeld. Cresap Neuroscience Lab., Northwestern University, Evanston, IL 60201

The nucleus reticularis paragigantocellularis (PGC) of the ventral medulla has recently been implicated in the mechanisms of opiate analgesia. Electrical stimulation of, or opiate microinjection into, this region has antinociceptive effects in behaving animals. There is some evidence which suggests that this antinociceptive effect is mediated by nucleus raphe magnus (NRM) (Azami, et al., Pain, 1982). Recent studies in our laboratory have been designed to investigate the effect of PGC morphine microinjections on unit activity in NRM.

Rats were anesthetized with urethane (1.2 g/kg) and a 25 gauge guide cannula implanted above PGC. NRM unit activity was recorded using a glass micropipette. Cells responsive to noxious peripheral stimulation (noxious pinch with a toothed forceps and noxious heat delivered via a 10 ohm resistor applied to the skin) were chosen for study. Only one cell was recorded from in each animal. After the spontaneous firing rate and responses to noxious stimulation were determined, morphine sulfate (1 ug in 0.25 uL) was infused into PGC through a 31 gauge injector cannula over the course of 4 minutes. This dose was chosen because it reliably produces profound analgesia in awake animals. Following the microinjection, spontaneous firing rate and the responses to nociceptive stimulation were monitored for 30 to 60 minutes. When appropriate, morphine effects were challenged using naloxone (1 mg/kg, i.p.).

As we have recently reported (Heinricher and Rosenfeld, Brain Research, 1983), the predominant effect of PGC morphine microinjections on NRM spontaneous activity was suppression, and this effect was reversed by administration of naloxone. In contrast, preliminary findings indicate that the noxious-evoked excitation of these neurons is much less affected by PGC morphine microinjections. As a consequence, the response to noxious input relative to ongoing NRM activity is enhanced. These results suggest that the analgesic effect of PGC morphine microinjections may be mediated not by a tonic increase in descending inhibition from NRM, but by a relative increase in the nociceptive responsiveness of this system.

231.14 INHIBITION OF SPINAL DORSAL HORN NEURONS BY STIMULATION IN BASAL GANGLIA AND AMYGDALA. S. Pretel, M.J. Guinan*, S.N. Suberg & E. Carstens. Dept. Animal Physiol., Univ. Calif., Davis, CA 95616.

Electrical stimulation at ventromedial diencephalic and forebrain sites inhibited the responses of spinal dorsal horn neurons to noxious skin heating (Fraunhoffer et al., Soc. Neurosci. Abs. 8:767, 1982). We have continued this study to determine if spinal inhibition is produced by stimulation at more lateral sites in the basal ganglia (caudate n.= Cd; globus pallidus= GP; putamen= PU) and subjacent amygdala and prepiriform area.

Responses of single lumbar dorsal horn units to noxious heat stimuli (50^{o}C, 10 s) applied to glabrous footpad skin were recorded in 24 cats anesthetized with sodium pentobarbital and ventilated with 70% N_2O. Using a medio-lateral array of bipolar stimulating electrodes, effects of stimulation (100 msec pulse trains at 100 Hz, 3/s, 25-300 μA) at a variety of lateral diencephalic or forebrain sites were expressed as the magnitude of the unit response to heat during stimulation at each site as a % of the unit control heat-evoked response in the absence of brain stimulation.

Dorsal horn unit responses to heat were reproducibly and powerfully suppressed (to 50% of control or more) by stimulation in Cd, internal capsule, amygdala and prepiriform areas bilaterally. Inhibitory sites were distributed throughout the dorso-ventral and medio-lateral extent of the amygdala and prepiriform area at anterior levels +11 to +16, with no evidence of topographic organization. Inhibition was also generated at sites in PU and GP bilaterally, but this inhibition was weaker (51-80% of control) in some animals. Strong inhibition was frequently produced at sites along tracks passing through cortex lateral to the internal capsule.

Effects of stimulation at one effective amygdalar or prepiriform site on dorsal horn unit responses to graded noxious heat stimuli were tested in 20 cases. Unit responses increased in a linear manner with graded heat stimuli. The slope of the stimulus-response function was generally reduced, usually with minor changes in response threshold (but with threshold increases of up to 5^{o}C in a few cases) during stimulation at ipsilateral (N=9 units) or contralateral (N=11) sites. Similar effects were produced by contralateral Cd stimulation in 5 units to date.

The results indicate that stimulation in basal ganglia structures classically associated with the "extrapyramidal" motor system, and in amygdala and prepiriform areas associated with the limbic system, can strongly inhibit the spinal transmission of nociceptive information. We are investigating the possible role of medial brain stem structures in mediating inhibition from these areas.

231.15 FOREBRAIN ACTIVATION OF RAPHE-SPINAL NEURONS. M.J. Guinan*, S. Pretel, S.N. Suberg & E. Carstens. Dept. Animal Physiology, Univ. Calif., Davis, CA 95616. (SPON: M. McNamee).

Electrical stimulation at a variety of forebrain sites inhibited the responses of spinal dorsal horn neurons to noxious skin heating (Fraunhoffer et al., Soc. Neurosci. Abs. 8:767, 1982). Inhibition from some of these areas could be mediated via activation of an inhibitory raphe-spinal pathway. We therefore investigated the effects of stimulation at sites in the diencephalon and posterior telencephalon on single raphe-spinal neurons.

Antidromic responses of single units in the medullary nucleus raphe magnus to unilateral stimulation of the dorsolateral funiculus at an upper lumbar level were recorded in cats anesthetized with sodium pentobarbital and 70% N_2O. To date, 46 units gave constant-latency responses (range: 2.5-17.5 msec to yield conduction velocities of 15 to >100 m/sec) at high frequencies (>100 Hz) of cord stimulation, and 29 showed collision of the antidromic spike with orthodromic spikes elicited by forebrain stimulation. Most units gave orthodromic responses at latencies of 3-70 msec to single 0.1 msec forebrain stimuli, but some required repetitive stimuli (100 msec trains at 100 Hz, 3/sec, 25-500 μA) to be driven. Activity in 4 of the latter outlasted the period of brain stimulation by several seconds.

Maps of sites at which stimulation activated raphe-spinal units were constructed by systematically varying the medio-lateral and dorso-ventral position of the bipolar stimulating electrode at one anterior level (range: +9 to +15) in 12 cases. The current threshold for activating the unit, and/or the number of orthodromic spikes elicited by stimulation, were analyzed to compare the relative effectiveness of stimulation at each brain site. Units were typically activated from sites throughout the forebrain, with variations in the effectiveness of stimulation at different sites. The relative effectiveness of stimulation in a given structure varied from one unit to the next. Despite these inter-unit differences, the following sites were particularly effective in activating raphe-spinal units in nearly all experiments: amygdala, internal capsule and hypothalamic periventricular gray bilaterally. Less effective sites included the basal ganglia (caudate, putamen and globus pallidus), medial and lateral thalamic nuclei, and region of the optic tract.

The results indicate that stimulation at many sites in the forebrain known to inhibit spinal dorsal horn neurons can also activate raphe-spinal units. If the recorded raphe-spinal units are involved in spinal inhibitory mechanisms, they could mediate descending inhibition from more anterior areas.

231.16 RAPHE MAGNUS LESIONS BLOCK THE RESTRAINT POTENTIATION OF MORPHINE ANALGESIA. S. J. Kelly and K. B. J. Franklin. Department of Psychology, McGill University, Montreal, Quebec, H3A 1B1.

Rats which are restrained throughout tail flick testing have a different time course of morphine analgesia than rats which are left in their home cages between unrestrained tail flick tests. Restrained rats show a peak analgesic response 30 min after a subcutaneous (s.c.) injection of morphine. Unrestrained rats show a maximum analgesic response 60 minutes after a s.c. injection of morphine and the degree of morphine analgesia never reaches that of the peak analgesic response of restrained rats. The potentiation of morphine analgesia in restrained rats was shown to be dependent upon raised serotonin synthesis via increased uptake of brain tryptophan that results from restraint stress. Since the descending serotonergic projections of the nucleus raphe magnus (NRM) are known to be involved in morphine analgesia, the possibility that the NRM mediates the restraint potentiation of morphine analgesia was tested.

A group of male Long-Evans hooded rats received electrolytic lesions (1 mA, 10 sec) of the NRM. A second group received sham operations. Fourteen days after surgery, all rats were exposed to the laboratory for 90 min every day for 6 days. On the seventh day, the rats were brought into the laboratory and half of the lesioned and sham-operated rats were restrained in wire mesh restraining tubes. The rest of the rats were left in their home cage and manually held during each tail flick test. The tail flick test consisted of recording the latency with which the rat removed its tail from 55^{o}C water. All rats received one tail flick test, were then injected with morphine hydrochloride (5 mg/kg, s.c.), and tested every 15 min for 90 min after the injection.

Lesions of the NRM had very little effect on the time course of morphine analgesia in the unrestrained rats. Both lesioned and sham-operated unrestrained rats showed maximum analgesia 60 min after the morphine injection and the degree of analgesia never reached that of the 30 min peak analgesic response in the restrained sham-operated rats. NRM lesions in restrained rats greatly reduced the 30 min peak analgesic response and made the time course of analgesia in the restrained rats comparable to that of the unrestrained rats. These results suggest the NRM mediates the restraint potentiation of morphine analgesia but is not involved in morphine analgesia itself. (Supported by NSERC Grant No. A6303.)

231.17 RESTORATION OF FUNCTION OF THE DESCENDING FIBERS FROM THE NUCLEUS RAPHE MAGNUS BY 5-HYDROXYTRYPTOPHAN IN RATS ADDICTED TO MORPHINE. R. Emmers. Dept. of Physiol., Coll. of P & S, Columbia U., New York, N. Y. 10032.

Recent experiments (Physiologist 24:25) have indicated that during narcotic withdrawal the nociceptive system undergoes sensitization. Since the fibers descending from the nucleus raphe magnus (NRM) can block excitation of the spinothalamic tract (STT) by A-delta and C-fibers (J. Neurophysiol. 45:121), and thus modify pain, it appeared likely that narcotics alter the function of the NRM fibers. This possibility was investigated with 18 rats using electrophysiological methods. Twelve of them were addicted to morphine (80-120 mg/kg/day); 6 served as morphine-naive controls. Each rat received an i.p. injection of chloralose and urethane and was prepared for a stereotactic approach to neurons of the second somesthetic region (SII) of the thalamus. There a nociceptive neuron was identified by its unique spacing of spike potentials emitted in response to pricking the foot with a pin. Single-pulse stimulation of the sciatic nerve evoked the same response as pinpricks, but innocuous stimuli reorganized the spacing of the late spike potentials. Only neurons exhibiting this differential response were regarded as nociceptive; their response activity was accumulated on a digital computer to obtain post-stimulus time histograms. Similar to responses evoked in single STT neurons (J. Neurophysiol. 45:121), histograms of the thalamic neuron activity had peaks revealing the STT relay of the A-alpha, A-delta, and C-fiber input (Emmers, R. Pain: A Spike-Interval Coded Message in the Brain. Raven Press, 1981). With the control animals, the A-delta and C-fiber activity peaks were promptly suppressed by stimulation of the NRM (a 100-msec pulse train at 300/sec, 0.5 msec pulse width, terminated 20 msec before a single-pulse stimulation of the sciatic nerve, repeated at 2 sec intervals). With the addicted rats the A-delta and C-fiber activity peaks were dramatically elevated during naloxone precipitated narcotic withdrawal, and NRM stimulation diminished them only slightly. However, 5-HTP (3.5 mg/kg i.v.) promptly returned the augmented activity peaks to the control level and NRM-stimulation obliterated them. These results suggest that during morphine addiction the serotonin supply in the NRM fibers is gradually depleted, and, when naloxone lowers the spontaneous activity of the NRM pathway (unpublished observations), the blocking of the A-delta and C-fibers is lifted, resulting in sensitization of nociception. The serotonin precursor, 5-HTP, restores the synaptic function of the NRM descending fibers, reinstating the A-delta and C-fiber block. (Aided by grant DA-03292 from NIDA).

231.18 MICROINJECTION OF 6-OHDA IN THE REGION OF THE NUCLEUS TRACTUS SOLITARIUS DOES NOT ALTER PAIN THRESHOLD OR ANALGESIC EFFECTIVENESS OF SYSTEMIC MORPHINE INJECTIONS IN RATS.** N. Oley, J.D. Bronzino, and C. Siok*. Psychology and Engineering Departments, Trinity College, Hartford, CT 06106.

The nucleus tractus solitarius (NTS) is known to contain opiate receptors with pain-modulating functions (Oley et al., Brain Rsch., 236:511, 1982). This region also contains catecholaminergic (CA) neurons (Chiba & Kato, Brain Rsch, 1978) whose role in pain modulation is unknown. It has been suggested that central CA pathways are directly involved in pain modulation and may also mediate the analgesic effects of systemic opiates. The present study sought to determine whether the CA neurons in the region of the NTS play a role in pain modulation and/or opiate-induced analgesia.

Sprague-Dawley rats used as their own controls were first trained to perform a fixed-ratio liminal escape (LE) task (Bodnar et al., Neurosci. Biobeh. Rev., 1974). This complex operant task assesses both the sensory/discriminative and motivational aspects of the response to nociceptive stimuli. Once a stable operant baseline performance was established, subjects were given 17 daily LE tests. On day 1 a single 10 mg/kg, i.p., morphine sulphate injection was given 30" prior to LE testing. On day 8, after LE testing, subjects received 8 ug of the CA neurotoxin 6-OHDA in .15 ul of buffered Ringers + 0.1% ascorbic acid via a 33 ga cannula aimed at the NTS. Finally, on day 17, a second 10 mg/kg, i.p., injection of morphine was administered 30" prior to LE testing.

Destruction of CA neurons in the vicinity of the NTS did not alter sensitivity to footshock or the analgesic effectiveness of systemic morphine as measured by LE task. There was no evidence of morphine tolerance in control subjects that received only morphine, and 6- OHDA had no significant effects on the nociceptive response when injected outside the region of the NTS.

Thus, our preliminary results suggest that CA neurons in the NTS do not mediate the response to painful stimuli, and do not appear to interact significantly with the opiate-mediated pain-suppressive system in NTS or elsewhere.

231.19 DORSAL RAPHE STIMULATION, MORPHINE AND 5-HT IONTOPHORESIS EFFECTS ON MEDIAL THALAMIC UNITS FOLLOWING NOXIOUS AND NONNOXIOUS STIMULATION C. Reyes-Vázquez, B. Prieto-Gómez* and N. Dafny. Dept. Fisiol. Fac. Med. UNAM. México. and Neurobiol. Dept. UT Med. Sch. Houston Tx. 77025.

It has been shown that responsiveness to noxious stimuli can be reduced by focal electrical stimulation of selective brain loci. One explanation of this phenomenon is the existence of descending pain supressing mechanisms at the spinal cord level. Moreover, there is evidence that pain modulation also occurs at higher CNS levels, such as medial thalamus (MT). This work examines the possibility of ascending pain supression mechanisms by analyzing the effects of dorsal raphe stimulation (DRS) and microiontophoresed morphine (MOR) and 5-HT upon the activation of units in the MT of the rat, following noxious (NS) and nonnoxious stimulation (NNS). In urethane anesthetized rats a craniectomy was performed above the MT region and bipolar stimulating electrodes implanted within the DR. An array of 5 micropipettes was used for microiontophoresis containing: (1)MOR 0.045 M pH=4.5; (2)5-HT 0.01 M pH=5.0; (3)NaCl 2 M (used as balance barrel); (4)pontamine sky blue (used to mark the electrode location) and (5)recording electrode filled with NaCl 4 M. An aligator clip placed on the rat's tail or the immersion of the tail in a water bath (50°C) were used for NS. Stroking of the tail or extremities, light taps, brushing of the hair or puffs of air, were used as the NNS. The DR was stimulated from 0.1 to 0.6 mAmp with 10-15 HZ. After 5 min. of the spontaneous activity recording the effects of NS and NNS on each unit were recorded. After this, the effects of MOR and 5-HT microiontophoresis for 60 sec. with currents of 50 nA were recorded. Finally, simultaneously drug application with NS or NNS was tested. From 137 units exhibiting spontaneous activity only 79 were affected by NS, NNS or any of the drugs tested. 18/79 cells were affected only by MOR or 5-HT. In the 61/79 MT units it was possible to identify 3 different types of units accordingly to the responses following NS or NNS. Units excited exclusively by NS=11/61; units accelerated exclusively by NNS=15/61 and mixed units that responded both to NS and NNS=35/61. DRS elicited a decrease fire in 72% of 61 units analyzed. Similar effects could also be obtained by 5-HT and MOR microiontophoresis. MOR and 5-HT induced decreases mainly in MT units activated by NS, and had lesser effects in those units which were excited exclusively by NNS. DRS and 5-HT microiontophoresis decreased the acceleration induced by NS in 63% of noxious and mixed units, and only in 12% of the units affected exclusively by NNS. MOR was less effective in blocking these responses. This data suggest that DR and 5-HT are involved in the modulation of nociceptive responses of MT, and there are some similarities between the opiod effect and the serotonergic effects on the NS responses at the level of the MT.

232.1 SPINAL LEVEL ANALGETIC EFFECTS OF SEROTONIN AND SERTALINE IN A SUBSTANCE P-BASED PAIN MODEL, P.G. Cosgrove* and C.J. Pazoles, Central Research Division, Pfizer Inc., Groton, CT 06340.

Neuronal pathways which descend from the midbrain and medulla to the dorsal horn of the spinal cord appear to modulate the response to incoming nociceptive stimuli by direct inhibition of thalamic projection neurons and by activating enkephalinergic interneurons. Serotonin is present in some of these descending fibers and may play a role in their analgetic functions. When serotonin is injected into the lumbar subarachnoid space of several species, the animals exhibit a dose-dependent analgesia to noxious thermal stimuli (Yaksh and Wilson, J. Pharmac. Exp. Ther. 208:446, 1979). Furthermore, serotonin modulating drugs have been shown to influence analgesia. Indeed, amitriptyline and other antidepressant drugs that block monoamine reuptake have been used clinically in the treatment of certain painful conditions (eg. Watson, et al., Neurology (NY)31(part 2):68, 1981).

We examined the effects of serotonin and sertraline on substance P (SP) induced bite/scratch behavior in mice. SP (20 pmoles) injected intraspinally (i.s.) into the lumbar region causes a presumably nociceptive reaction characterized by vigorous biting and scratching at the abdomen. Coadministration of serotonin (0.2 pmoles, i.s.) inhibited the bite/scratch response by approximately 50%. The serotonin antagonist methysergide (2 ug, i.s.) blocked serotonin's analgetic effect. The effect was also reversed by peripherally administered naloxone (2 mg/kg), thus implicating the endogenous opiate system in the spinal level analgesia produced by serotonin. Sertraline (CP-51,974) is a highly selective serotonin reuptake blocker, 20 times more potent versus serotonin than norepinephrine reuptake. When subcutaneously administered one hour prior to SP administration, sertraline (10 mg/kg) significantly reduced the bite/scratch response (approximately 50%). As with serotonin, methysergide (2 ug, i.s.) reduced the analgetic effect of s.c. sertraline implicating serotonin reuptake blockade in the spinal cord as the mechanism of sertraline's action. When coadministered i.s. with SP, sertraline (1.9 nmoles) had no effect on the bite/scratch response, presumably because of the time necessary for serotonin accumulation following reuptake blockade.

These results demonstrate that serotonin is capable of modulating the pain-producing effects of SP at the spinal level, perhaps by activation of an endogenous opiate system. The ability of peripherally administered sertraline to produce spinal level analgesia suggests that this drug may be useful as a centrally acting analgetic.

232.2 LOCUS COERULEUS (LC) LESIONS INCREASE THE ANTINOCICEPTIVE POTENCY OF CLONIDINE GIVEN INTRATHECALLY BUT NOT MORPHINE GIVEN IN THE PAG. M.H. Ossipov and G.F. Gebhart. Dept. Pharmacology, Univ. Iowa, Iowa City, IA 52242.

Existing evidence indicates that the LC is a source of noradrenergic projections to the spinal cord and may be involved in descending inhibition and antinociception which appear to be mediated in part by spinal norepinephrine (NE). Clonidine exerts an antinociceptive effect directly at a spinal level by interacting with α_2-adrenergic receptor sites, and also modulates LC neuronal activity. To examine the role of the LC in antinociception, bilateral electrolytic LC lesions were made in male Sprague-Dawley rats. Tail-flick (TF) and hot plate (HP; 51 and 55°C) latencies were determined at days 0, 7, 13 and 14. No significant differences in response latencies between sham and lesion groups were observed in either test on any of the days tested. The antinociceptive efficacy of morphine administered in the periaqueductal gray (PAG) in doses of 2.5 and 5.0 µg (base) on days 7 and 14 was not different when compared between sham and lesion groups in either the TF or HP tests.

On day 13, clonidine was administered intrathecally in lightly anesthetized lesion and sham animals through an implanted cannula terminating at the lumbar enlargment of the spinal cord. In lesion rats, the dose required to elicit one half the maximal increase in TF latency (i.e., ED_{50} at 4 sec) was 0.32 µg (base), while 1.67 µg of clonidine was required to elicit a similar response in sham rats. Scatchard analyses of ^{3}H-clonidine binding in the lumbar cord obtained from rats sacrificed on day 15 revealed similar binding affinities between sham (K_d = 1.93 nM) and lesion (K_d = 2.72 nM) groups. B_{max} was 31.0 fmole/mg protein in sham and 44.3 fmole/mg protein in lesion rats, indicating increased α_2-adrenergic receptor numbers in the latter group. NE content of the lumbar spinal cord was greater in sham (0.765 ± .089 µg/gm tissue) than in lesion (0.631 ± .078 µg/gm tissue) rats. Serotonin and 5-hydroxyindoleacetic acid levels in lumbar cord were not different in sham and lesion animals.

The results indicate that spinal LC projections are not essential for expression of inhibition of a nociceptive spinal reflex by morphine administered in the PAG. However, spinal projections of the LC appear to be partly involved in α_2-adrenergic receptor mediated antinociception since lesions of the LC resulted in postsynaptic α_2-receptor supersensitivity as evidenced by increases in the antinociceptive potency of clonidine and B_{max}. Supported by DA 02879 and MH 15172.

232.3 REDUCTION OF AUTOANALGESIA FOLLOWING INJECTION OF 6-HYDROXYDOPAMINE INTO THE LOCUS COERULEUS OR CISTERNA MAGNA. William T. Chance and John C. Peters* (SPON: J.A. Rosecrans). Department of Surgery, Univ. Cincinnati Med. Ctr., Cincinnati, Ohio 45267.

Analgesia elicited by acute stress and classical conditioning procedures results from behavioral activation of descending antinociceptive mechanisms. Since dysfunction of these endogenous analgesia systems may result in chronic pain problems, specification of the neurochemical mediators of the analgesia is an important goal. Our previous research demonstrating the efficacy of yohimbine in antagonizing autoanalgesia and cross-tolerance of autoanalgesia to clonidine suggests a role of norepinephrine (NE) in mediating endogenous antinociception. To permit direct investigation of this hypothesis, acquisition of autoanalgesia was assessed in rats that had been treated with the catecholamine neurotoxin, 6-hydroxydopamine (6-OHDA). In one group of adult, male, Sprague-Dawley rats (n = 7) 6-OHDA HBr (30 ug/3 ul, free base) was injected bilaterally into the locus coeruleus (LC) through a 30 ga needle employing stereotaxic techniques. In another group of rats (n = 8) 6-OHDA HBr (200 ug/20 ul, free base) was injected into the cisterna magna (CM) through a 27 ga needle. Control rats (n = 14) were treated with all experimental procedures, except no injections were made into the LC. One week later basal tail-flick latencies were determined for all rats. The intensity of the heat source was adjusted to elicit basal response latencies of approximately 3 sec and an 8 sec cut-off criterion minimized tail-damage. All of the 6-OHDA-treated and half of the control rats were subjected to footshock (1 ma, 15 sec). Tail-flick latencies were determined again after (10 sec) the footshock on day 1 to reveal the analgesic response to acute stress. Across the next 6 days, tail-flick latencies continued to be measured prior to the administration of footshock to assess the analgesic response to classical conditioning procedures. Each animal was sacrificed and the brain and spinal cord were removed for biochemical analysis of amine neurotransmitters. Although tail-flick latencies acutely-following footshock were significantly ($p < 0.05$) reduced in 6-OHDA-treated rats as compared to shocked controls, both LC ($p < 0.01$) and CM ($p < 0.05$) groups exhibited significant analgesic responses. Similar intermediate responses were observed to the classical conditioning procedures in the 6-OHDA-treated rats, with both groups of rats being significantly ($p < 0.01$) different from shocked and nonshocked controls. These data continue to emphasize a role of NE in mediating autoanalgesic phenomena. The intermediate effects of 6-OHDA treatment may reflect partial depletion of NE (currently being measured) or the involvement of additional neurochemical mediators.

232.4 SPINAL 5-HT RECEPTOR SUBTYPES AND NOCICEPTION. F.P. Zemlan, M.M. Behbehani, L.-M. Kow Pfaff. Departments of Psychiatry and Physiology, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267.

The bulbospinal serotonin (5-HT) system is thought to suppress spinally organized nociceptive reflexes by raising nociceptive thresholds. The present study examined in the rat, four spinally organized nociceptive reflexes, freed from descending control due to spinal transection (T_{10}). Lumbar enlargement 5-HT receptors were stimulated by systemic administration of the centrally acting 5-HT agonists 5-MeO-dimethyltryptamine (0.1 to 2.0 mg/kg) and quipazine (5 to 20 mg/kg) during the initial two weeks after spinal transection. Unexpectedly, 5-HT agonists lowered nociceptive reflex thresholds and expanded reflex receptive field areas in a dose dependent manner. Both effects indicate a 5-HT induced facilitation of nociceptive input in the spinal preparation, rather than the 5-HT induced inhibition reported for the same reflexes in the intact animal. The facilitation of nociceptive spinal reflexes by centrally acting serotonin agonists observed in the present study, was blocked by the serotonin receptor blocker, metergoline (0.5 mg/kg), but not by the noradrenergic receptor blocker, phenoxybenzamine (20 mg/kg).

By postoperative Day 7 a clear shift to the left in the 5-HT agonist dose-response curves occurred indicating a functional supersensitivity. Receptor binding experiments investigated whether this 5-HT functional supersensitivity was correlated with a supersensitivity of spinal 5-HT_1 receptors labeled by ^{3}H-5-HT. A significant 37% increase in specific high affinity ^{3}H-5-HT binding was observed during the first week after transection. Scatchard analysis indicated that the increased ^{3}H-5-HT binding was due to an increased number of 5-HT_1 binding sites (Transected B_{max} = 199 + 19 f moles/mg, sham B_{max} = 107 + 15 f moles/mg), with no change observed in the apparent receptor affinity.

Literature is reviewed which suggests that the bulbospinal 5-HT system may differentially affect local spinal sensory input as opposed to ascending sensory input. The former system subserves local spinal nociceptive reflexes and is facilitated by the bulbospinal serotonin system while the latter relays nociceptive input centrally and is suppressed by the descending 5-HT system. Further, as the demonstrated functional and receptor supersensitivities were correlated, the present data suggest that the 5-HT facilitation of local spinal nociceptive reflexes is mediated by spinal 5-HT_1 receptors.

232.5 ANTAGONISM OF MICROSTIMULATION-PRODUCED ANALGESIA BY INTRATHECAL INJECTION OF METHYSERGIDE AND YOHIMBINE
N.M. Barbaro*, D.L. Hammond and H.L. Fields, Departments of Neurology, Physiology and Neurosurgery, University of California, San Francisco, CA 94143 and G.D. Searle & Co., Skokie, IL 60076.

Activation of bulbospinal serotonergic and noradrenergic fibers is postulated to mediate stimulation-produced analgesia (SPA) evoked from the nucleus raphe magnus (NRM) and nucleus reticularis paragigantocellularis (NRPG) respectively. Previous evaluation of this postulate has been hampered by the use of relatively high current intensities which do not permit anatomical resolution of effects produced by stimulation in these adjacent nuclei.

In the present study, Sprague-Dawley rats were acutely prepared with an intrathecal catheter and with two stimulating electrodes, one positioned in NRM, the other in NRPG. Baseline tail flick latencies (TFL) and paw pinch withdrawal thresholds (PWT) (Randall-Selitto test) were measured in these lightly anesthetized animals. The threshold current ($\leq$ 10 μA) required to evoke SPA was then determined for each site and test and then used throughout the experiment. Either the serotonergic antagonist methysergide (30 μg, 10 μl) or the noradrenergic antagonist yohimbine (30 μg, 10 μl) was then injected intrathecally. Fifteen minutes later, TFL and PWT were measured. NRM and NRPG were individually stimulated while TFL and PWT were measured. Then the other antagonist was added and the procedure was repeated. At completion of the study, the sites of stimulation and the position of the intrathecal catheter were verified histologically.

In agreement with previous work from this laboratory, threshold microstimulation in the NRM and NRPG produced a significant and quantal increase in TFL from a mean of 3.9 sec to above 10 sec (cut-off). Stimulation at the same sites also produced a significant and quantal increase in PWT from a mean of 216 g to above 800 g (cut-off). Intrathecal administration of either yohimbine or methysergide alone did not significantly antagonize the stimulation-produced increase in TFL or PWT evoked from either the NRM or NRPG. However, concomitant intrathecal administration of these two antagonists did antagonize the stimulation-produced increase in TFL and PWT from both nuclei. Intravenous administration of 30 μg of either drug or both was ineffective, as was intrathecal injection of saline.

These data indicate that both noradrenergic and serotonergic neurons projecting to the spinal cord mediate the descending inhibitory effects on nociceptive transmission exerted by NRM and NRPG in the rat.

232.6 FAILURE OF INTRATHECALLY ADMINISTERED THIP TO PRODUCE ANALGESIA.
D.L. Hammond and E.J. Drower*, Biological Research, G.D. Searle & Co., Skokie, IL 60077.

The analgesic properties of an isozaxole derivative of the GABA-mimetic muscimol, 4,5,6,7-tetrahydroisoxazolo[5,4-c]pyridin-3-ol (THIP), have recently been reported in the rodent following systemic administration. However, the site of action remains unknown. In the present study, THIP was administered intrathecally to determine if its analgesic activity was mediated by an effect exerted at the level of the spinal cord. Male Sprague-Dawley rats were prepared with an indwelling catheter in the spinal cord subarachnoid space. Seven days later, the animals' responsiveness to noxious thermal stimuli was determined using the tail flick and hot plate tests. After baseline tail flick latencies (TFL) and hot plate latencies (HPL) had been determined, the rats were injected intrathecally with either THIP (1-50 μg), muscimol (0.25-1 μg), or baclofen (1-10 μg). TFL and HPL were measured 10, 30 and 60 min later. Within 10 min of the intrathecal injection of THIP (5-50 μg), a marked dose-dependent flaccidity of the hindlimbs and tail occurred. The animals could not be tested on the tail flick or hot plate; however, they continued to vocalize to noxious pinch of the extremities. Intrathecal injection of lower doses of THIP that did not produce flaccidity (1-2 μg), did not increase TFL or HPL, or affect responsiveness to noxious pinch. Similarly, muscimol (0.5-1.0 μg) produced motor impairment and did not alter the animals' response to noxious pinch. Intrathecal injection of a lower dose that was without motor effects (0.25 μg) significantly increased TFL (3.3 $\pm$ 0.2 sec to 7.5 $\pm$ 1.6 sec), but did not alter HPL or decrease the response to noxious pinch. For comparison purposes, baclofen was also injected intrathecally. While 10 μg of baclofen produced motor incoordination, it also decreased responsiveness to noxious pinch. Intrathecal injection of 1 μg of baclofen did not produce motor impairment and significantly increased both TFL (2.5 $\pm$ 0.2 sec to 7.5 $\pm$ 1.8 sec) and HPL (7.8 $\pm$ 1.1 sec to 19.8 $\pm$ 5.3 sec), as reported previously. These data indicate that the site at which the GABA-mimetic THIP acts to produce analgesia does not involve the spinal cord.

232.7 RELEASE OF ENDOGENOUS NOREPINEPHRINE AND SEROTONIN INTO SPINAL CORD SUPERFUSATES FOLLOWING LOCAL INJECTION OF PHENTOLAMINE INTO THE NUCLEUS RAPHE MAGNUS.
H.K. Proudfit and J. Sagen. Dept. of Pharmacology, Univ. of Illinois at Chicago, Chicago, IL 60680.

Activation of neurons in the nucleus raphe magnus (NRM) produces hypoalgesia which most likely results from inhibition of spinal cord pain transmission pathways. Previous reports from this laboratory have demonstrated that blockade of the noradrenergic (NA) input to the NRM by microinjecting alpha-adrenergic antagonists produces hypoalgesia. These studies suggest that NA neurons inhibit the activity of NRM neurons. Subsequent studies have demonstrated that this hypoalgesia can be blocked by intrathecal injection of adrenergic or serotonergic antagonists as well as by depletion of spinal cord norepinephrine (NE) or serotonin (5-HT). These studies suggest that the hypoalgesia produced by injection of NA antagonists in the NRM is mediated by both bulbospinal NA neurons and raphe-spinal serotonergic neurons. The present studies were designed to directly measure the release of endogenous NE and 5-HT from the spinal cord following injection of the NA antagonist phentolamine (PTL) into the NRM.

Female rats (350 g) were anesthetized with urethane and fitted with inflow and outflow tubes for spinal cord superfusion. Three control samples, three ml each per 30 min period, were collected and then PTL was injected into the NRM. Three 30-minute samples were collected following PTL injection. The amount of NE and 5-HT released into the superfusates was determined by isolating the amines on a CG-50 column, lyophilizing the eluate, and quantitating the amount in each sample using HPLC and electrochemical detection. The injection site in each animal was verified histologically.

The average basal release of NE and 5-HT before the injection of PTL in the NRM was 0.27 +/- 0.04 and 0.31 +/- 0.11 ng/ml per 30 min., respectively. Within 30 min after the injection of PTL the NE concentration rose to 0.56 +/- 0.12 ng/ml and that of 5-HT rose to 0.80 +/- 0.32 ng/ml. The elevated amine concentrations in the superfusates returned to basal levels by 90 min. In contrast the injection of saline into the NRM did not affect the concentrations of NE or 5-HT in the superfusates. These studies support our proposal that the local injection of PTL into the NRM produces hypoalgesia which is mediated by the release of both 5-HT and NE in the spinal cord. 232.8 EVIDENCE FOR THE INVOLVEMENT OF DESCENDING NORADRENERGIC PATHWAYS IN THE ANALGESIC ACTION OF BACLOFEN.
J. Sawynok and C. Dickson*, Dept. of Pharmacology, Dalhousie Univ., Halifax, N. S., Canada, B3H 4H7

Noradrenergic systems originating in the brainstem appear to exert an inhibitory effect on the transmission of nociceptive information in the spinal cord (Fed. Proc. 40, 1981, p.278). The role of descending noradrenergic pathways in the analgesic action of baclofen was investigated because (a) microinjection of baclofen into lateral brainstem sites produces analgesia (Eur. J. Pharmacol. 57, 1979, p. 43) and (b) spinal transection reduces analgesia produced by systemic baclofen (Eur. J. Pharmacol. 47, 1978, p.159). Neurotoxins and receptor antagonists were administered intrathecally (i.t.) to rats implanted with chronic indwelling catheters, while baclofen was injected intraperitoneally (i.p.). Analgesia was assessed using the tail flick (baseline latency 2-3 sec) and hot plate (50°C) methods. 6-Hydroxydopamine (6-OHDA, 20 μg) significantly inhibited analagesia produced by baclofen, reducing the analgesic index (sum of latency minus baseline for 4 readings at 30 minute intervals following injection of baclofen) to 30-50% of control values in both tests 4, 7 and 13 days following i.t. administration. A higher dose (50 μg) injected intraspinally (i.s.) reduced the index to approximately 20% of control values 7 days after injection. 5,6-Dihydroxytryptamine (5,6-DHT, 20 and 100 μg) did not reduce analgesia, but increased it slightly in the tail flick test within two weeks of injection. Both 6-OHDA and 5,6-DHT produced hyperalgesia in the tail flick test during these time intervals when baseline latencies were increased to 6-8 seconds, an effect less reliably observed with the lower baseline latency and with the hot plate test. In other experiments, baclofen was injected i.p. while the alpha antagonists phentolamine and tolazoline were injected, i.t. 40 minutes later when the analgesic effect of baclofen was well developed. Phentolamine, 50 and 100 μg (but not 30 μg), produced a dose-related reduction in analgesia in the tail flick test, the higher dose reducing latencies to near baseline values. A similar reduction in analgesia was observed with tolazoline (100 μg). Phentolamine alone (50 and 100 μg) produced hyperalgesia when 6-8 second baseline tail flick latencies were used. These results suggest that a major component of the analgesic effect of systemically administered baclofen is mediated by descending noradrenergic pathways and subsequent activation of alpha receptors in the spinal cord. (Supported by MRC Canada).

232.9 INTRATHECAL SUBSTANCE P AND RELATED PEPTIDES:INHIBITION OF MORPHINE ANALGESIA AND HYPERALGESIA. S.M. Moochhala* and J. Sawynok, (SPON: F. S. LaBella), Dept. of Pharmacology, Dalhousie University, Halifax, N. S. Canada, B3H 4H7

Morphine (M) can produce analgesia by a local action in the spinal cord (Science 192, 1976, p. 1357). Substance P (SP) has been proposed as a primary afferent transmitter of nociceptive information, and the demonstrated ability of M to inhibit its release in vitro (Nature 268, 1977, p. 549) and in vivo (Nature 286, 1980, p. 155) may contribute to this spinal analgesic action. The objectives of this study were (a) to determine whether SP could inhibit the spinal analgesic action of M and to characterize the receptor subtype involved by comparing the effects of physalaemin (P) and eledoisin related peptide (ERP) to those of SP, and (b) to further examine the hyperalgesic effect of SP by determining dose-response characteristics, comparing the effects of P and ERP to those of SP and determining whether desensitization and cross-desensitization would occur. All drugs were administered intrathecally (i.t.) to rats implanted with chronic indwelling catheters. Analgesia was assessed using the tail flick (baseline latency 2-3 sec for interactions with M and 6-8 sec for hyperalgesia experiments) and hot plate (50°C) methods. Morphine (1.5-3.5 µg) produced dose-related analgesia in both tests. SP (5-15 µg) inhibited analgesia produced by 2.5 µg M in a dose-related manner, reducing the analgesic index (sum of latency minus baseline for 4 readings at 15 min intervals) to 60-70%, 35-50% and 10-20% of control values at 5 µg (4 nmole), 10 µg (7 nmole) and 15 µg (11 nmole) respectively. ERP (approx. 25 nmole) and P (approx. 5 nmole) reduced the analgesic index to 40-60% of control values, indicating a rank order of potency of P ≥ SP > ERP. In other experiments, SP (1.9-11 nmole) produced dose-related hyperalgesia as well as scratching and grooming behaviour. Both P and ERP also produced hyperalgesia with a rank order of potency similar to that observed previously. Desensitization to the hyperalgesic effect of SP was produced by 3 consecutive doses of 15 µg (11 nmole) SP. P and ERP did not produce hyperalgesia when rats were made insensitive to SP, suggesting an action on the same receptor. The observed inhibition of M analgesia by SP (via a physalaemin-type receptor) is consistent with the notion that this action may be due to an inhibition of SP release. However, less than specific effects may be involved because SP also inhibits the spinal analgesic action of noradrenaline and baclofen. (Supported by MRC Canada).

232.10 EVIDENCE FOR A CHOLECYSTOKININ (CCK)-LIKE ENDOGENOUS OPIATE ANTAGONIST. I.B. Kinscheck*, L.R. Watkins, E. Kaufman & D.J. Mayer (SPON: A. Szumski). Dept. Physiol. Biophys., Med. Coll. Va./Va. Commonwealth Univ., Richmond, VA 23298.

Exogenous CCK specifically antagonizes opiate analgesia via CCK/gastrin receptors, suggesting a physiological role for CCK in pain processing. The introduction of the specific CCK/gastrin antagonist, proglumide (PR, gift of A.H. Robins), provides a direct means of determining whether an endogenous CCK-like opiate antagonist exists. We therefore tested the effect of intrathecal (IT) PR on various opiate & nonopiate analgesias in rats as assessed by the tail flick (TF) test. Parameters were chosen so that each analgesic manipulation produced submaximal analgesia. IT PR alone (0, 0.02, 0.2, 0.6 µg) did not produce analgesia through 95 min after injection. A biphasic dose response curve was seen in response to 5 doses of IT PR tested against 1 µg IT morphine. Maximal potentiation was produced by .01 µg PR, which hastened the onset of analgesia without affecting peak analgesia, while 5 µg markedly attenuated analgesia through 95 min post-injection. The maximal potentiating dose, .01 µg, was subsequently tested against other analgesias. The opiate analgesias produced by periaqueductal gray morphine (3 µg) and by front paw shock (90 s, 1.6 mA rms) were also both significantly potentiated by this IT PR dose. Two independent forms of nonopiate analgesia, 10 µg IT norepinephrine bitartrate and 90 s, 1.6 mA rms hind paw shock of spinalized animals, were tested to assess specificity. Both analgesias were attenuated by .01 µg IT PR.

Thus CCK/gastrin appears to function as a specific opiate antagonist which is activated in response to acute opiate administration or release. As CCK does not bind to opiate receptors, a CCK receptor-opiate receptor interaction may occur which causes a decrease in opiate analgesic efficacy. Such a dynamic interaction would allow the animal to maintain nociceptive responsiveness via an opponent process mechanism.

We also tested whether this endogenous antagonist could play a role in the phenomenon of opiate tolerance. Rats were made tolerant via either 3 or 6 daily IT injections of 10 µg morphine & subsequently challenged with 5 µg IT morphine. Neither PR (1.8 µg) in the absence of morphine nor 5 µg morphine in the absence of PR produced analgesia. Animals receiving both PR & 5 µg morphine demonstrated analgesia in a dose-dependent manner. Animals exposed to the longer tolerance regimen required a higher dose of PR to induce analgesia. Maximal analgesia in these rats was produced by 1.8 µg PR plus 5 µg morphine. Thus CCK may be involved in a negative feedback system which attempts to maintain optimal nocisponsiveness, thus producing "tolerance." Supported by PHS grant DA 00576 to DJM.

232.11 CENTRAL NEUROTRANSMITTERS MODIFICATIONS AFTER EPIDURAL CORD STIMULATION IN THE RAT. E.A. Parati, G. Broggi*, B. Regi*, A. Franzini*, D. Servello*and M. Parenti. Neurological Inst. "C. Besta" and Dept. Pharmacology, Univ. of Milan, Sch. of Med., Milan, Italy.

The electrical stimulation of the dorsal cord (DCS) has been proved to be effective in the treatment of human incurable pain. However, the mechanisms underlying the therapeutic action of DCS are still unknown. In order to investigate the neurochemical correlates of DCS we used the rat as an experimental animal model. Monopolar electrodes were inserted epidurally at the level of the thoracic portion of the cord. Twenty four hours later, the animals, maintained freely moving in their cages, were stimulated electrically continuously for 6 hours at 1,000 Hz (the electrical parameters used were 1 mA, 1.5 Volts and 1 msec). At the end of this session the animals were killed and the cerebellum, brainstem, striatum and spinal cord removed for neurochemical measurements. Sham-operated animals were used as controls. The concentrations of serotonin (5-HT), 5-hydroxyindoleacetic acid (5-HIAA), dopamine and norepinephrine were then assayed using HPLC with electrochemical detection. While no significant alterations were detected in the catecholamine content of the different areas, a marked change in the indoleamine levels was found in the spinal cord, cerebellum and brainstem (see table). These results seem to be promising in view of the involvement of serotonergic system in pain modulation. Further studies are in progress to evaluate if opioid peptides and Substance P are altered after DCS.

232.12 THE RAT SPINAL CORD MET-ENKEPHALIN INCREASE, INDUCED BY LOCALIZED PAIN, IS MEDIATED BY AFFERENT FIBERS. M. Trabucchi, E. Faccini*, H. Uzumaki*, G. Pasinetti*, S. Govoni. Dept. of Pharmacology, University of Brescia, Italy.

Pharmacological and electrophysiological evidence indicates that endogenous opiates modulate pain transmission at spinal cord level. Met-enkephalin interneurons might represent the putative spinal gating control system and be regulated by a complex polysynaptic mechanism. In order to demonstrate whether met-enkephalin neuronal function is related to the activity of primary afferent fibers and thus to the incoming painful stimuli, the concentration of this endogenous opiate was measured in the cervical, thoracical and lumbar segments of the spinal cord after the injection of Freund's adjuvant either in the fore or in the hind paws of control or denervated rats. The results indicate that chronic localized pain induces a selective increase (+ 50%) in met-enkephalin immunoreactive material in the dorsal horn of the spinal cord segment which receives a direct projection from the inflamed paw. Denervation obtained by means of the sectioning of the plexus brachialis or of the sciatic nerve before inducing inflammation prevents the increase of spinal cord met-enkephalin content. In the same experimental conditions the injection of Freund's adjuvant in a paw significantly reduces the vocalization threshold in the paw pinch test. Moreover, denervated limbs were completely insensitive to any stimuli, although after Freund's adjuvant injection the degree of inflammation was comparable with that of controls. The data presented confirm the hypothesis that chronic pain induces a change in met-enkephalin content which is selective for the spinal cord segment receiving afferent fibers, the integrity of which is necessary for the activation of the spinal gating system made up of met-enkephalin interneurons.

232.13 AN AUTORADIOGRAPHIC DEOXYGLUCOSE STUDY OF SOME ACUPUNCTURE-PRODUCED METABOLIC CHANGES IN THE CENTRAL NERVOUS SYSTEM OF THE RAT. Peter J. Hand, Shyh-Chang Sheu* and Hongchien Ha*. Dept. of Animal Bio., Sch. of Vet. Med., Inst. of Neurol. Sci., Univ. of Penna., Phila., PA 19104 and Nat. Yang-Ming Med. Coll., Taiwan, R.O.C.

The quantitative (^{14}C) deoxyglucose (2DG) method was employed to study some central effects of acupuncture. 8 unanesthetized, restrained rats were pulse injected with 2DG and received either (1) intermittent noxious thermal stimulation (56°C water applied to the tail for 4 secs every 30 sec) during the 45 minute post injection period (N=1), (2) the same noxious stimulus and unilateral acupuncture of tsu-san-li point (proximal anterior tibial muscle) for 45 minutes (efficacy of acupuncture was determined by measuring tail flick response latencies=419-61%) (N=3), (3) unilateral tsu-san-li stimulation only for 45 minutes (N=3), or (4) non-noxious (40°C) thermal stimulation of the tail for 45 minutes (control; N=1). All rats were then prepared according to Sokoloff (J. Neurochem., 1977). Following noxious stimulation, a number of structures exhibited substantial increases (24-44% above control values) in local cerebral metabolic rates of glucose (LCMRG): medial medullary reticular formation; rostral medullary raphe, midbrain central gray and dorsal raphe; n. cuneiformis; n. reunie ns-central medianus complex of thalamus; intralaminar nuclei of thalamus; dorsomedial, rostromedial, dorsolateral, and lateral thalamus; and neocortex (particularly parietal areas). Following tsu-san-li stimulation alone, and with the exceptions of midbrain central gray and medullary raphe (LCMRG 26% above control values), the above structures exhibited small to moderate increases (7-19% above control values) in LCMRG. When noxious thermal and tsu-san-li stimuli were paired, LCMRG in the above regions either exhibited small increases (3-12%), no change (medullary reticular formation, n. reuniens-central medianus complex), or a small (3-7%) decrease (rostromedial, submedius nuclei of the thalamus) when compared to control values. Lower spinal cord segments are in the process of being examined in all of the above animals.

In conclusion, the data indicate that: (1) noxious thermal stimulation of the tail produces significant increases in 2DG labeling of a number of structures, some of which have been implicated in the conduction of noxious information and in the production of analgesia, (2) tsu-san-li stimulation alone produces moderately increased 2DG labeling of a number of the same brain structures examined in (1), and (3) the pairing of tsu-san-li and noxious thermal stimulation of the tail results in an interaction, which produces significantly less brain labeling than was present following noxious or acupuncture stimulation alone. Additional studies to determine the mechanisms of such an interaction are in progress. (Supported by grant NS-14935 and National Yang-Ming Medical College).

232.14 EFFECTS OF ELECTRO-ACUPUNCTURE AND NALOXONE ON CUTANEOUS PAIN THRESHOLDS AND PLASMA CONCENTRATIONS OF β-ENDORPHIN (β-EP) IMMUNOREACTIVITY IN SHEEP. D. F. B. Bossut*, M. W. Stromberg, and P. V. Malven. Departments of Vet. Anat. and Anim. Sci., Purdue University, West Lafayette, IN 47907.

Analgetic effectiveness of electro-acupuncture (EA) treatment and plasma concentrations of β-EP were measured in 26 male and female sheep. Cutaneous pain thresholds (PT) were quantified by scoring (0 to 9) the animal's reaction to cutaneous stimuli (pinprick, pinch, and contact heat) in the following 7 areas of the body: head, neck, thorax, forelimb, ventral abdomen, flank, and hindlimb. Control trials consisted of measuring PT and drawing blood samples every 8-10 min, but without any needle insertions. For EA trials, acupuncture needles were inserted in specific lumbosacral points (denoted YAO PANG in Chinese) or in specific points in one forelimb (denoted SAN YANG LU in Chinese). Stimulating voltage and frequency (Chinese-made stimulator SB-71-2) were increased gradually to levels just below those at which the animal reacted adversely and these settings were maintained throughout the remainder of the trial. EA treatment of both loci increased the cutaneous PT ($P<.01$) in all 7 body areas (i.e. EA caused cutaneous analgesia). The elevated PT following EA treatment of YAO PANG but not of SAN YANG LU, was partially but significantly ($P<.05$) antagonized by exogenous naloxone (1.1 mg/kg). Plasma concentrations of β-EP measured by radioimmunoassay were not increased by measurement of PT during control trials (remained between 0.3 and 0.4 ng/ml). Plasma β-EP increased significantly ($P<.05$) during EA treatment reaching a maximum after 15-30 min of EA stimulation. When plasma β-EP was analyzed on the basis of analgetic outcome of each trial, β-EP concentrations in trials with poor analgetic outcome were not increased over those concentrations during control procedures. In contrast, β-EP concentrations in trials with good analgetic outcome were increased 2- to 3-fold (0.7 to 0.9 ng/ml). Increases in β-EP during EA treatment of SAN YANG LU locus were slightly greater and of longer duration than those increases following YAO PANG stimulation. Plasma β-EP declined from peak levels even though EA treatment continued. In summary these results have demonstrated a positive correlation between EA-induced cutaneous analgesia and increases in plasma β-EP levels. However, naloxone-induced antagonism of analgesia resulting from YAO PANG stimulation, but not SAN YANG LU stimulation, when both showed a positive correlation between analgesia and β-EP is difficult to interpret. Although this finding raises some doubt about a cause-effect relationship between β-EP and cutaneous analgesia, the ineffectiveness of the present dosage of naloxone with SAN YANG LU stimulation might be due to the greater activation of β-EP during EA of that locus. Supported in part by grant DA 2661.

232.15 DIFFERENTIAL EFFECTS OF NALOXONE ON ANALGESIA AND VOCALIZATIONS INDUCED BY BRIEF DURATIONS OF PULSED FOOTSHOCK. J. Timothy Cannon, Nicholas Maro*, Bartholomew Telep* and Gerald Carty*. Dept. of Psychology, University of Scranton, Scranton, PA 18510.

It has recently been found that subjecting rats to relatively brief continuous footshock (all four paws) can result in opioid or non-opioid forms of stress-induced analgesia (Terman, Lewis and Liebeskind, this volume and personal communication). Differential activation of opioid or non-opioid mechanisms could be effected by varying the duration of shock exposure and/or the shock intensity.

The present research attempted to determine whether the pulsed shock pattern used by Lewis, Cannon and Liebeskind (1980) to produce an opioid form of analgesia after prolonged (20-30 min) stress could produce both the opioid and non-opioid effects that Terman et al. observed using brief exposures (4 min or less) to continuous shock. An additional advantage of having pulsed shock delivery was the potential for recording shock-elicited vocalizations during and between(vocalization after-discharge) shocks. Given the anatomical and pharmacological distinctions that have been demonstrated for these forms of vocalizations, it was hoped that the ability to observe such behaviors during the stress exposures might advance our understanding of the underlying mechanisms of stress-induced analgesia.

The subjects (adult, male, albino rats) were run during the dark phase of their 12-12 hr light-dark cycle. In three separate experiments the animals were exposed to either 2.2, 3 or 3.5 mA of scrambled footshock (1 sec pulse every 5 sec). Within each experiment, animals were divided into two groups (10 animals each) that received 1 cc/kg S.C. injections of either saline or naloxone (3 mg/kg) as indicated below. Each animal was exposed to 2 and 4 min of footshock in separate sessions one week apart. The animals were injected 5 min prior to baseline tail-flick testing (1 trial/min for 5 min). Footshock was begun 1-3 min thereafter. Tail-flick latencies were again recorded over a 15 min post-stress interval. The observers were blind in relation to the type of drug injection. Analgesia rarely lasted beyond 7 min post-stress, consequently, only this time interval was statistically analyzed using the .05 level of significance.

Our results are in general agreement with those of Terman et al., in that they suggest that manipulations of intensity and duration can result in either opioid or non-opioid forms of analgesia after brief footshock stress. Significant post-stress elevations of tail-flick latencies occured at all shock levels. Naloxone significantly reduced this effect only in animals that received 3 mA for 4 min. Naloxone also significantly increased vocalization after-discharges only in animals exposed to 3.5 mA of shock.

232.16 SUPRASPINAL OPIOID ANALGESIA IS PRODUCED BY LATERAL HYPOTHALAMIC STIMULATION. S. Uysal* and K. Carr. Dept. of Psychiatry, New York Univ. Med. Ctr., New York 10016.

Previous work has shown that stimulation in the lateral hypothalamus (LH) ameliorates supraspinally-elicited aversion (K. Carr and E. Coons, Science, 215:1516, 1982). The present study examined whether LH stimulation alters responses to peripheral pain stimuli applied via intracutaneous tail electrodes. A pain test developed by Carroll and Lim (Arch. int. Pharmacodyn., 125:383, 1960) allowing measurement of responses that reflect activity at different levels of the CNS was employed.

Rats were tested in a small chamber with a tail-stock at the rear. A test session consisted of four series of tail shocks. Each shock was a 1-sec train of 1.6 msec pulses at 125/sec. Shocks were separated by a 30-sec interval and voltage was increased in steps of 0.25V until thresholds were obtained for eliciting (1) forelimb locomotor movement, (2) vocalization, and (3) vocalization afterdischarge. On alternate series, LH stimulation was delivered concurrently with tail stimulation. LH stimulation was a 1-sec train of 0.1 msec pulses at 25/sec. An LH stimulation intensity that in preliminary testing elicited 1/3 the maximum rate of self-stimulation was used because such intensities produced asymptotic ameliorative effects in the studies of supraspinally-elicited aversion.

In the six rats tested, LH stimulation had no effect on threshold for the locomotor response (mean change: +8% ±7.9) or vocalization (+29% ±9.4). LH stimulation did elevate threshold for vocalization afterdischarge (+62% ±10.6; $p<.01$). Afterdischarge has been shown in transection studies to be organized at a higher level of the neuraxis than the other two responses and appears to reflect the "affective" dimension of pain. These results therefore support previous evidence that LH stimulation preferentially interacts with pain mechanisms at a supraspinal level to diminish the affective consequences of intense somatic stimulation.

When rats were injected with naltrexone (10.0 mg/kg, s.c.) 20 min prior to testing, the LH stimulation-produced elevation of threshold for vocalization afterdischarge was blocked ($p<.01$). This dose of naltrexone had no effect, in a later test, on intensity thresholds for eliciting self-stimulation through the same LH electrodes.

These results indicate that stimulation in the LH activates an opioid analgesic process which preferentially inhibits supraspinal activity associated with the affective dimension of pain. Moreover, as is true of the LH stimulation-produced amelioration of supraspinally-elicited aversion, this effect is dissociable from the self-stimulation reward process.

232.17 MORPHINE-INDUCED SUPPRESSION OF THE JAW-OPENING REFLEX IN RABBITS: A STUDY OF ELECTRICALLY STIMULATED DENTAL PULP PAIN. A.L. Curtis* and W.J. Anderson. Dept. Life Sciences, Indiana State Univ., Terre Haute, IN 47809 and Indiana Univ. Sch. Med., Terre Haute Ctr. Med. Ed., Terre Haute, IN 47809.

The purpose of this study was to clarify the electrical stimulus parameters and dose range requirements of the analgesic agent morphine sulphate (MOR) in order to obtain an effective suppression of the jaw-opening reflex in rabbits. The delineation of these conditions have indicated a differential morphine sensitivity in the trigeminal system. Statistically significant and similar response/time plots were obtained from the mandibular left incisor pulp stimulated at a high intensity stimulus (strength: four times the threshold for the response; frequency: twin pulse 0.1 ms duration, 0.8 ms delay at 1 Hz) over a dose range of 3, 6, and 12 mg/kg MOR as compared to the maxillary left incisor pulp stimulated at a low intensity stimulus (strength: three times the threshold for the response; frequency: single pulse 0.1 ms duration at 1 Hz) over a 6, 12, and 24 mg/kg MOR dose range. The pain stimulus was the electrical stimulation of the dental pulp. The pain response was the evoked jaw-opening reflex recorded from the left digastric muscle and indexed by the respectively averaged peak to peak measure of the electromyogram (EMG) and its latency (LAT). All morphine was administered via cannulated left carotid artery. The significant MOR-induced effects upon the pain response was the decrease of the EMG and the increase of the LAT, both of these divergencies being naloxone reversible. However, the high intensity stimulus applied to the maxillary left incisor pulp resulted in response/time plots that possessed no significant difference from control, even over a 6, 12, and 24 mg/kg MOR dose range. There is evidence of anatomical differences, beyond those dictated by somatotopy, between maxillary and mandibular dental pulp central projections in the spinal trigeminal nucleus. One such report by Westrum et al. (Exp. Neurol., 74: 787, 1981) indicates a greater number of horseradish peroxidase-labeled fibers and terminals for the maxillary canine over the mandibular canine in their cats as well as differences in their laminar distributions in rostral pars caudalis suggesting different synaptic input patterns. In concert with these anatomical differences, this study offers evidence of a physiological difference in the trigeminal system.

232.18 VOCALIZATIONS AS MEASURES OF PAIN AND HYPALGESIA IN THE STUMPTAIL MACAQUE. Cooper, Brian Y. and Vierck, C. J. Jr., Dept. of Neuroscience, Univ. of Florida, Gainesville, FL, 32610.

Stumptail macaques (macaca Speciosa), when trained to pull a bar to escape painful electrical stimulation, emit a large number of vocalizations. These vocalizations occur in reliable patterns, clustering 0-15 seconds following the shock-escape trial (the reactive period), but also appearing irregularly during the remainder of the intertrial interval (the waiting period). Spectrographic analysis of these vocalizations revealed that the predominant form of vocalization was the 'bridge scream' (Bertrand, 1965), which made up 80% of the total vocalization content. Other vocalizations, including grunts, whines and squeaks were observed, but these made up smaller percentages of the overall content and were highly individualized. Bridge screams were emitted most often in the reactive period but occurred throughout the intertrial intervals and were not related in frequency, duration, or amplitude to the intensity of preceeding trials.

Monkeys trained to pull a bar to receive a food reward also emit bridge screams. These vocalizations occur in similar patterns as for monkeys receiving electric shock. Also, following an extensive period of exposure to non-painful shock conditions (six weeks), monkeys previously exposed to painful shock continued to vocalize in similar patterns. Therefore, vocalizations in the macaque were not uniquely associated with pain in the experimental situation. Nevertheless, they were modulated by analgesics and other compounds with putative modulatory influences on pain sensations.

Following treatment with morphine (.25-3 mg/kg), the frequency of vocalizations rapidly decreased during the reactive and waiting periods. With small doses of morphine (.25-1 mg/kg), vocalization amplitudes typically decreased except during the immediate post-shock period. There was little evidence of changes in vocalization content (types of call) by morphine.

Attempts to block or enhance the effects of morphine by depletion of serotonin or noradrenaline produced effects that paralleled those found with measures of operant reactivity (bar pull force and latency of escape; Cooper & Vierck, 1980; Vierck, Cooper, Franzen, Ritz & Greenspan, 1983) - that is, weak blockade with PCPA and weak enhancement with Disulfiram. However, the inability to demonstrate that the frequency, intensity, duration, or content of vocalizations were reliably related to the intensity of painful stimuli suggests that these monoamine effects do not represent modulation of pain sensitivity or mediation of opiate hypalgesia.

232.19 LATERALITY OF ANALGESIA PRODUCED BY INTRAVENTRICULAR MORPHINE IN THE RAT. S.R. Cohen, F.V. Abbott, and R. Melzack*. Dept. of Psychology, McGill University, Montréal, P.Q., Canada.

The analgesic effect of morphine injected into the lateral ventricle of the rat was studied in two pain tests: the formalin test which assesses the behavioral response to tonic (continuous) pain generated in injured tissue, and the foot-flick test which examines phasic (brief) threshold-level pain. In the formalin test, morphine injected into the lateral ventricle produced analgesia when the ipsilateral hindpaw was injured but had no analgesic effect when the contralateral hindpaw was injured. In contrast, intraventricular morphine produced analgesia bilaterally in the foot-flick test. Analgesia was achieved with relatively low doses of morphine (2.5-10.0 μg) in the formalin test while very high doses (50-200 μg) were necessary to produce analgesia in the foot-flick test. In the formalin test, morphine's effect was as large during the first time block of testing (11-20 min after intraventricular injection) as at any other time. In the foot-flick test, morphine's effect reached a maximum at 30-45 min after intraventricular injection. These results add to other data indicating that different neural mechanisms underlie opiate analgesia in different types of pain. Moreover, they indicate that, in a test of tonic pain, the neural mechanisms of morphine analgesia are somatotopically organized and that forebrain structures are likely to be involved.

232.20 EFFECTS OF CONCOMITANT ADMINISTRATION OF MORPHINE AND d-AMPHETAMINE ON ESCAPE BEHAVIOR MAINTAINED BY AVERSIVE INTRACRANIAL STIMULATION. S. Sasson, E.M. Unterwald* and C. Kornetsky. Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118.

Several clinical reports suggest that the concomitant administration of morphine and d-amphetamine may be useful in the management of pain (e.g., Forrest et al., New Engl. J. Med., 296:712-715, 1977). We have found that morphine as well as other opioid analgesics will raise the threshold for escape from aversive electrical stimulation to the mesencephalic reticular formation (MRF) of the rat. The present study was conducted to determine if d-amphetamine would potentiate the analgesic action of morphine in this pain model.

Male albino rats (CDF - Charles River Laboratories) were stereotaxically implanted with bipolar stainless steel electrodes aimed at the MRF. Following recovery from surgery, animals were trained to turn a wheel manipulandum to escape from aversive electrical stimulation to this midbrain site. The threshold for escape was determined by varying the current intensity according to a modification of the psychophysical method of limits. d-Amphetamine (0.06-4.0 mg/kg, i.p.) had no effect or slightly lowered the escape threshold, depending on the animal. Morphine (1.0-16.0 mg/kg, i.p.), as in previous studies, caused a dose-related increase of the threshold. A dose of morphine, which by itself did not significantly raise the escape threshold, was then studied with concomitant administration of various doses of d-amphetamine.

This drug combination caused significant increases in the escape threshold which were directly related to the d-amphetamine dose. Recent work in our laboratory suggests that this effect is not due to actions on attentional or perceptual systems but are due to direct effects on a pain system. These data suggest the involvement of midbrain structures in the mediation of this drug effect and support findings from clinical studies which show that d-amphetamine potentiates the analgesic action of morphine.

232.21 OPIOID AND NONOPIOID FORMS OF STRESS-INDUCED ANALGESIA IN THE MOUSE: STRAIN COMPARISONS. A.S. Moskowitz, G.W. Terman and J.C. Liebeskind. Psychology Dept., UCLA, Los Angeles, CA 90024.

Recent work in rats has demonstrated that inescapable footshock elicits either opioid- or nonopioid-mediated analgesia depending on the shock parameters (Lewis et al., Science, 208: 623, 1980). Prolonged, intermittent footshock induces an opioid-mediated analgesia, whereas brief, continuous footshock induces analgesia not mediated by opioids.

In this study we compared opioid and nonopioid forms of stress-induced analgesia in two strains of female mice, C57BL/6BY and CXBK (Jackson Labs). The CXBK strain has been reported to have a lower number of whole brain opiate binding sites and is less sensitive to the analgesic effect of morphine than the C57 strain (Baran et al., Life Sci., 17: 633, 1975). Inescapable footshock (60-Hz sine waves) was delivered through a scrambler to a grid floor. The parameters necessary to induce the opioid and nonopioid forms of stress analgesia were ascertained using the criterion of naltrexone blockade (5 mg/kg, s.c.). Pain responsiveness was measured by the tail-flick method.

Opioid-mediated analgesia was induced by prolonged (10 min, 3.5 mA), intermittent (1 sec on, 4 sec off) footshock, whereas brief (4 min, 1.0 mA), continuous footshock was found to elicit a nonopioid form of stress analgesia. The CXBK strain showed significantly ($p < 0.05$) less of the opioid form of stress analgesia than the C57 strain, whereas the two strains did not differ in regard to nonopioid stress analgesia. Using in vitro autoradiography, the CXBK strain is also found to have a lower number of opiate binding sites than the C57 strain in brain and spinal cord areas associated with pain processing (Goodman et al., Soc. Neurosci. Abs., 8: 221, 1982). These findings support the hypothesis that separate opioid and nonopioid pain inhibitory systems exist and indicate that genetic factors influence the analgesic response to stress. (Supported by NIH grant NS07628 and by a gift from the Brotman Foundation. A.S.M. was supported by Mental Health Training Grant MH 15345.)

232.22 THE ROLE OF CURRENT INTENSITY IN OPIOID AND NONOPIOID STRESS-INDUCED ANALGESIA. G.W. Terman and J.C. Liebeskind. Dept. of Psychology, UCLA, Los Angeles, CA 90024.

The finding that exposure to certain forms of stress can produce potent analgesia has generated much research on the neurochemical and neuroanatomical substrates of this phenomenon. Such stress-induced analgesia has been shown to be multi-faceted, depending in some instances on opioid peptides and in others on extra-opioid mechanisms. The critical variables responsible for differential production of opioid- and nonopioid- stress analgesia have been investigated in several laboratories. We have demonstrated that the opioid or nonopioid nature of analgesia inescapable footshock depends on the temporal parameters of its administration. More specifically, whereas 1 or 2 min of continuous footshock produces analgesia sensitive to naltrexone antagonism (opioid), 3, 4 or 5 min of continuous footshock at the same intensity produces an equipotent analgesia not blocked by this drug (nonopioid). Others have reported a differential production of opioid and nonopioid stress analgesia as a function of body region shocked and number of shocks administered. We now show the importance of current intensity in determining the opioid or nonopioid nature of stress analgesia.

Eighty male Sprague-Dawley rats were assigned to one of ten groups. Twenty min before stress, five of the groups received naltrexone (5 mg/kg, s.c.), while the remaining animals received saline control injections. Immediately before stress, all animals were tested for baseline pain responsiveness using the tail-flick test. The naltrexone-treated and control animals were then exposed to 3 min of continuous footshock (60 Hz sine waves) at either 1.5, 2.0, 2.5, 3.0 and 3.5 mA. Beginning 1 min after footshock cessation, all animals were tail-flick tested at 1 min intervals for 10 min. Data were analyzed using separate two-way analyses of variance for each of the five current intensities.

Naltrexone significantly ($p<.05$) reduced stress analgesia at 1.5 and 2.0 mA without attenuating stress analgesia elicited by 2.5, 3.0, or 3.5 mA.

These data show the importance of current intensity in differentially producing opioid and nonopioid stress analgesia. Viewed in the light of our previous findings concerning a similar role for footshock duration, it seems that the interaction between duration and intensity determines which neurochemically discrete substrate of stress analgesia is activated. (Supported by NIH grant NS 07628 and a gift from the Brotman Foundation)

232.23 THE EFFECTS OF DECEREBRATION AND SPINAL TRANSECTION ON THREE DISCRETE FORMS OF STRESS-INDUCED ANALGESIA. M. V. Klein*, K.M. Lovaas*, G.W. Terman and J.C. Liebeskind. Dept. of Psychology, UCLA, Los Angeles, CA 90024.

Numerous stressors have been reported to reduce responsiveness to noxious stimuli. We have recently reported that three distinct forms of such stress-induced analgesia can be differentially produced by varying the temporal parameters of a 2.5 mA inescapable footshock. Specifically, 20 min of intermittent footshock produces an analgesia that appears to be mediated by opioid peptides and is dependent on the integrity of the adrenal gland. One min of continuous footshock, on the other hand, elicits an opioid-mediated analgesia that is independent of the pituitary-adrenal axis. Four min of continuous footshock produces a third, nonopioid, form of stress analgesia. In this series of experiments, we attempted to define the anatomical pathways underlying these three neurochemically distinct analgetic phenomena.

In Experiment 1, 24 male Sprague-Dawley rats were assigned to two equal groups and injected with pentobarbital (55 mg/kg, i.p.). One group was spinally transected (T1) whereas the remaining animals were sham operated and served as controls.

In Experiment 2, 30 male Sprague-Dawley rats were divided into two equal groups and either decerebrated at the mid-collicular level or sham operated, under pentobarbital anesthesia.

On three consecutive days starting two days after surgery, animals in both experiments were exposed in a counterbalanced fashion to the three footshock parameters described above. Poststress analgesia was measured at 1 min intervals for 10 min using the tail-flick test. Data for each experiment were analyzed using separate two-way analyses of variance for each stress paradigm.

In Experiment 1, spinal transection significantly ($p<.05$) reduced all three forms of stress analgesia, suggesting a role for descending controls from the brain in these phenomena. In Experiment 2, decerebration significantly attenuated only the adrenal-dependent opioid form of stress analgesia, indicating the independence of the other two forms of stress analgesia from control by supra-mesencephalic brain structures. (Supported by NIH grant NS07628 and a gift from the Brotman Foundation).

232.24 CONDITIONED TOLERANCE TO ANALGESIA PRODUCED BY ELECTRICAL STIMULATION OF THE PERIACQUEDUCTAL GRAY IN RATS. D.J. Paul* and A.G. Phillips. Dept. of Psychology, Univ. of British Columbia, Vancouver, Canada, V6T 1W5.

Stimulation of the periacqueductal gray (PAG) of the midbrain produces an analgesia that resembles opiate analgesia. There is considerable behavioral and physiological evidence to suggest a commonality in the underlying mechanism for stimulation produced analgesia (SPA) and opiate analgesia. Tolerance to the analgesic effect of opiate drugs has been shown to be subject to the laws of classical conditioning. Specifically, certain aspects of opiate tolerance have been related to a compensatory physiological response elicited by cues that reliably predict the drug effect.

Given the apparent similarity between SPA and opiate analgesia, the present experiments test the hypothesis that tolerance to SPA also should be subject to the laws of classical conditioning. Electrical stimulation of the PAG increased tail-flick latencies from a baseline score of 2.9 sec to 7.5 sec. Brain-stimulation was delivered for 5 min per day in the presence of distinctive environmental cues and tolerance to SPA developed over 7 daily sessions (tail-flick latency on day 7, $\bar{x} = 3.7$ sec.) Half of the rats (N=8) were then given 12 extinction trials which consisted of exposure to the environmental cues, without brain-stimulation. The remaining subjects stayed in their home cages throughout the period. When tested again with brain-stimulation in the experimental environment, animals in the extinction group displayed significant SPA (i.e. tail-flick latency, $\bar{x} = 5.8$). The home cage group remained tolerant with a mean tail-flick latency of 3.2 sec. Reaquisition of tolerance was observed in the extinction group.

A second experiment examined the specific hypothesis that tolerance to SPA should be accompanied by the development of a hyperalgesic response. Decreasing the temperature of the water bath from 52°C to 48.5°C elevated baseline tail-flick latencies to $\bar{x} = 8.2$ sec. PAG stimulation produced strong analgesia with complete tolerance developing over 7 daily sessions. On the eight session half of the animals (N=8) were tested without brain-stimulation and a hyperalgesic response was observed (i.e. tail-flick latency, $\bar{x} = 5.8$ sec., $p < 0.05$).

These results provide further confirmation of the conditioning theory of tolerance and suggest that opiate analgesia and SPA share a common mechanism.

233.1 REDUCTION OF HIBERNATION BOUT DURATION BY ICV INFUSION OF NALOXONE IN CITELLUS LATERALIS. Carmen Llados-Eckman* and Alexander L. Beckman. Alfred I. duPont Institute, Wilmington, DE 19899.

In previous work (Science 212:1527,1981), we demonstrated that opioid (morphine) physical dependence does not occur during deep hibernation. Others have shown that the CNS endogenous opioid system may be involved in the control of behavioral states and energy balance, two variables that are profoundly altered during hibernation. These findings raise the question as to whether the endogenous opioid system participates in controlling the state of hibernation. To explore this possibility, we attempted to interfere with the endogenous opioid system during hibernation by the constant intracerebroventricular (ICV) infusion of naloxone.

Hibernating ground squirrels (C. lateralis) of either sex were infused with naloxone hydrochloride, starting on the first day of the hibernation bout and lasting throughout the bout, by means of an osmotic minipump (Alza Corp.). The pump, immersed in a 0.9% NaCl bath, delivered naloxone through a length of PE 20 polyethylene tubing to a previously implanted cannula guide tube (21 ga.; 26 ga. injection tube) into the lateral cerebral ventricle. Doses infused were 1 µg/µl, 5 µg/µl, 7.5 µg/µl or 10 µg/µl at a flow rate of 1 µl/hr. Control animals were similarly infused with 0.9% NaCl. The length of each bout and the behavioral changes in the period immediately following arousal from hibernation were recorded.

In all animals, naloxone shortened the duration of the hibernation bout in relation to the immediately previous bout in a dose-dependent manner. Expressed as the percentage (± SEM) of bout shortening, the data were: 6.5 ± 4.4% (0.9% NaCl, control), 13.9 ± 4.2% (naloxone, 1 µg/hr), 47.7 ± 1.9% (naloxone, 5 µg/hr), and 62.3 ± 2.4% (naloxone, 7.5 µg/hr). The highest dose of naloxone (10 µg/hr), tested in only two animals, shortened the bout by an average of 47% and produced convulsions and abstinence-like signs in the arousal and post-arousal periods. One of these two animals died following arousal.

These data suggest that component neurons of the endogenous opioid system contribute to the maintenance of the hibernation state in C. lateralis. (Supported by NIDA grant DA-02254 and the A.I. duPont Institute).

233.2 TAIL SKIN TEMPERATURE: A SENSITIVE IN VIVO BIOASSAY FOR OPIATE RECEPTOR ANTAGONISTS. J.W. Simpkins*, I.C. Song*, M.J. Katovich*, N. Bodor* and R. Tuttle* (Spon: W.Millard) College of Pharmacy, University of Florida, Gainesville, FL 32610.

We have recently observed that in morphine-dependent rats, naloxone administration causes a prompt, dramatic elevation in tail skin temperature (Simpkins et al., Life Sciences 32: 1957, 1983). In the present study we evaluated this tail skin temperature (TST) response as a potential in vivo bioassay for narcotic antagonists. Morphine (MOR) dependency was produced by s.c. implantation of a single pellet containing 75 mg of MOR (freebase) followed 2 days later by 2 additional pellets. After a total of 4 days of exposure to MOR, animals were lightly restrained in wire-mesh cages and thermisters were attached to the dorsal surface of the tail. After a 30 min acclimation period, TST was recorded at 10 min intervals for 30 min to establish basal TST. Animals then received 1 of 5 doses of naloxone (NAL; 0, 0.01, 0.1, 0.5 or 1.0 mg/kg body weight, s.c.), naltrexone (NALT; 0, 0.001, 0.005, 0.01, 0.02, 0.1 mg/kg body weight, s.c.), a 6-spiro thiazolidine derivative of naltrexone (NALT-CYS; 0.001, 0.005, 0.01, 0.02 or 0.1 mg/kg body weight, s.c.) or nalmefene (JF-1; 0.001, 0.005, 0.01, 0.02, or 0.1 mg/kg body weight, s.c.). TST's were recorded at 5 min intervals for an additional 90 min following administration of the narcotic antagonist. Six different drug naive rats were used at each dose level for each of 4 narcotic antagonists studied.

Each of the narcotic antagonists caused a dose-dependent increase in TST. Peak TST were observed at 15 to 20 min and TST returned to the pre-injection baseline by 60 to 90 min after administration of the narcotic antagonists. For each drug evaluated, a linear relationship between the dose and the maximum change (Δ MAX) in TST was observed. A similar linear relationship was observed when drug dose and the area under the TST response curve was evaluated. The dose required to elevate TST to 50% of maximum (ED50) was 115 µg/kg for NAL, 30 µg/kg for NALT-CYS, 18 µg/kg for NALT and 8 µg/kg for JF-1. The relative estimate of potency of these narcotic antagonists obtained in this study is similar to that determined by other bioassay methods. In view of the ease of quantitation and the high sensitivity of the TST response to narcotic antagonists, this method could be readily applied to the evaluation of compounds with potential narcotic antagonist activity.

233.3 THE EFFECTS OF IN UTERO EXPOSURE TO MORPHINE ON POSTNATAL THYROID AXIS FUNCTION IN THE RAT. W.J. Litto* and J. Rabii. Dept. Biol. Sci. (Physiol.) and Bureau of Biol. Research, Rutgers Univ., Piscataway, NJ 08854.

Recent studies in our laboratory have indicated that opiates, in addition to their established acute actions, can produce long-lasting alterations in the development of neuroendocrine control of the pituitary. Results presented here are a continuation of these studies. We have examined the effects of injecting pregnant rats with morphine sulfate (MS) on days 5-12 of gestation, on the thyroid axis response of the offspring to changes in environmental temperature. Groups of MS- or vehicle-treated rats from 10 to 35 days of age were maintained at 22°C or exposed to 4°C or 37.5°C for 45 and 60 minute periods, respectively. At the end of each treatment trunk blood was collected and assayed for thyrotropin (TSH) and thyroxine (T_4) by RIA. In 10-day-old male and female pups both 4°C and 37.5°C temperature treatments inhibited TSH secretion as compared to 22°C controls, in prenatal saline treated animals. The opposite trend was observed in 10-day-old MS-treated pups, where 4°C and 37.5°C resulted in enhanced TSH secretion compared to room temperature. Exposure to 37.5°C produced an inhibition of TSH secretion, in male and female pups of both prenatal treatment groups, from 15 to 35 days of age. A more pronounced inhibition of TSH was observed in MS-treated male and female pups at 15, 20, and 35 days of age. Exposure to 4°C resulted in an enhancement of TSH secretion for pups of both sexes and both prenatal treatment groups from 15 to 35 days. Prenatal MS male and female pups showed a greater TSH response to cold at 15 and 25 days than their corresponding prenatal vehicle-treated groups, and a marked attenuation of this response at 20 and 35 days of age. Exposure to 37.5°C resulted in a marked increase in T_4 plasma levels in 10-day-old saline treated pups of both sexes. The opposite result occurred in the MS-treated animals where significantly lower T_4 levels were observed in heat-exposed pups of both sexes. Cold exposure had no significant effect on T_4 levels at 10 days in any of the prenatal treatment groups. Elevated T_4 levels were noted in cold-exposed 35-day-old saline-treated pups of both sexes. This pattern was not observed in 35-day-old male or female morphine treated pups. In conclusion, these results indicate that in utero exposure to MS can produce alterations in the thyroid axis response to changes in environmental temperature after birth.

233.4 LACK OF CORRELATION BETWEEN LUTROPIN (LH) AND FOLLITROPIN (FSH) SECRETORY PATTERNS UNDER PROLONGED BLOCKADE OF ENDOGENOUS OPIOID SYSTEMS IN NORMAL MEN. J. Ellingboe, J.D. Veldhuis*§, J.H. Mendelson, J.C. Kuehnle* and B. Andrews*. Alcohol & Drug Abuse Research Center, McLean Hospital-Harvard Medical School, Belmont, MA 02178; and §Department of Internal Medicine, University of Virginia School of Medicine, Charlottesville, VA 22908.

Blockade of endogenous opioid activity by naltrexone (NTX) has been shown to increase pulsatile LH secretion, but little is known about concomitant FSH release, which is believed to be controlled by the same hypothalamic factor, luliberin (LHRH).

Plasma gonadotropin levels were assessed on the day after placebo (P) and NTX administration in 2 groups (G1 and G2). G1 received P at 1800 h on Study Day 2, and 20-min serial integrated samples of blood were taken via intravenous catheter from 0900 h to 1520 h on Day 3. NTX (50 mg oral dose) was given at 1800 h on Day 4, and serial blood samples were collected again on Day 5. The order of P/NTX administration was reversed for G2. Plasma LH and FSH results are presented as ng LER-907 standard per ml ± SEM. FSH concentrations are shown in brackets.

Plasma LH after NTX was higher than after P in 14 of the 17 subjects for whom LH was analyzed, while FSH was higher after NTX in 16 of 21 subjects. G1 included 3 of the subjects with decreased LH after NTX and 4 subjects with no change or decreased FSH after NTX; but only one subject had decreases in both LH and FSH (ca.-4%). After P, LH [FSH] averaged 48±4 [549±53] for G1 and 43 ±3 [577±51] for G2. After NTX, LH [FSH] levels were 50±3 [572 ± 58] for G1, and 65±6 [565±55] for G2. Only in G2 did LH and FSH levels rise significantly above control levels after NTX treatment. LH was significantly higher in G2 than in G1 after NTX, but no significant differences in LH were found in G1 versus G2 after P, nor were there differences in FSH between G1 and G2 after NTX or P. The mean percent rise in LH from nadir to peak was greater after P than after NTX in G1 (87% versus 65%, p 0.05). Over the period of blood collection there were averages of 3.0 LH pulses and 2.0 FSH pulses, whether after P or NTX, or in G1 and G2. There was little coincidence between LH and FSH pulses; only one in six LH pulses occurred simultaneously with an FSH pulse, whether after P or after NTX. Interestingly, 3 days after NTX, LH pulses became markedly synchronized among subjects in G2, with a peak at 1230 h and nadirs at 0950 h and 1420 h.

Although the data indicate that endogenous opioids inhibit LHRH secretion, as suggested by prolonged increases of both LH and FSH after NTX, other factors must alter LH and FSH secretion differentially, perhaps at the pituitary level, with or without opioid blockade. Differences between the two experimental groups may reflect individual variation, or perhaps a sequence effect.

233.5 MEPTAZINOL: A UNIQUE MU_1 SELECTIVE OPIATE. K. Spiegel and G.W. Pasternak. Memorial Sloan-Kettering Cancer Center, New York, N.Y. 10021, USA.

Meptazinol, WY22811, is an unusual analgesic agent. Although its analgesic actions can be reversed with the antagonist naloxone, it displaces ^{3}H-opioid binding poorly. In an effort to address this problem, we have examined the binding, analgesic and respiratory depressant actions of meptazinol. As previously noted, meptazinol was not a potent inhibitor of ^{3}H-labeled opioid binding with IC_{50} values well over 50 nM for dihydromorphine, ethylketocyclazocine and SKF10047 and greater than 300 nM for D-ala^2-D-leu^5-enkephalin. However, detailed displacements were multiphasic, with meptazinol at concentrations under 10 nM inhibiting a portion of the binding for all ^{3}H-ligands. Blockade of mu_1 sites in vitro with naloxonazine eliminated this initial displacement. This selectivity of meptazinol for mu_1 sites was supported by the ability of meptazinol at 5 nM to selectively inhibit the high affinity, or mu_1 binding of ^{3}H-dihydromorphine in saturation experiments. Blockade of mu_1 sites in vivo with naloxonazine significantly attenuated meptazinol's analgesic actions. Naloxonazine shifted the dose-response curve for meptazinol in the writhing assay 2.6-fold (4.6 to 12 mg/kg). Similarly, the analgesic action of 10 mg/kg (i.v.) of meptazinol in the rat, which were equivalent to 3.5 mg/kg of morphine sulfate, were markedly attenuated by naloxonazine treatment. Previous work from our laboratory has suggested that spinal mechanisms for opioid analgesia in the mouse do not involv mu_1 sites. As expected, spinal transection eliminated meptazinol analgesia. Whereas the ED_{50} value in control mice was 44 mg/kg in the tail-flick assay, no analgesia was seen with doses of meptazinol of 40 and 60 mg/kg in spinalized mice. Mu_1 sites also appear not to mediate morphine's respiratory depression. Thus, it was not surprising that at an equianalgesic doses, meptazinol showed no respiratory depression whereas morphine significantly depressed pO_2 and pH and elevated pCO_2, as measured from arterial blood samples. These results suggest that meptazinol's pharmacological actions might result from selective interactions with mu_1 sites.

233.6 DEPRESSION OF ADENYLATE CYCLASE IN SYMPATHETIC PREGANGLIONIC NEURONS BY CLONIDINE AND BY OPIATES. Donald N. Franz, Parley W. Madsen, and Bradford D. Hare*. Departments of Pharmacology and Anesthesiology, University of Utah, Salt Lake City, Utah 84132.

The suppression of opiate-withdrawal symptoms by clonidine has been attributed to common effects of clonidine and opiates on central neurons having both alpha-2 adrenergic and opiate receptors. We have found that sympathetic preganglionic neurons (SPGNs) are depressed by both clonidine and opiates acting on their respective receptors and have suggested that these neurons are important sites for the antiwithdrawal effect of clonidine (Science 215:1643, 1982). Since clonidine appears to depress SPGNs by inhibiting adenylate cyclase and reducing cyclic AMP levels (Neurosci. Lett. 28:211, 1982; Soc. Neurosci. Abstr. 8:426, 1982), the possibility that opiates also depress SPGNs by inhibiting adenylate cyclase was investigated.

Sympathetic discharges recorded from upper thoracic preganglionic rami were evoked at 0.1 Hz by stimulation of descending excitatory pathways in the cervical dorsolateral funiculus of unanesthetized, spinal cats. Inhibition of cyclic AMP phosphodiesterase (PDE) by aminophylline (50 mg/kg), IBMX (1 mg/kg), or RO 20-1724 (1 mg/kg) enhanced intraspinal transmission to about 175% of control values within 10 min. Pretreatment with clonidine HCl (25 ug/kg) rapidly depressed transmission to about 20% of control and completely prevented enhancement by the PDE inhibitors. The alpha-2 receptor antagonists, yohimbine (0.5 mg/kg) or tolazoline (2.5 mg/kg), rapidly reversed the depression by clonidine and restored the ability of the PDE inhibitors to enhance transmission. Morphine (2 mg/kg) or methadone (1 mg/kg) also depressed transmission to 0-40% of control and almost completely suppressed enhancement by the PDE inhibitors. The opiate antagonists, naloxone or naltrexone (20-40 ug/kg), rapidly reversed the depression by the opiates and restored the ability of the PDE inhibitors to enhance transmission. These results support the proposal that clonidine and opiates depress SPGNs by activating alpha-2 and opiate receptors, both of which are negatively coupled to adenylate cyclase. Clonidine may suppress opiate withdrawal by substituting for opiates as an inhibitor of adenylate cyclase in SPGNs and in other central neurons.

233.7 CHANGES IN CORTICAL ADRENOCEPTOR FUNCTION FOLLOWING CHRONIC MORPHINE ADMINISTRATION IN RAT. H.C. Moises and C.B. Smith.*+ Dept. of Physiology and Dept. of Pharmacology,+ Univ. of Michigan, Ann Arbor, MI 48109.

Administration of opiates interferes with noradrenergic neurotransmission in the brain. In this study, radioligand binding techniques were used in conjunction with in vivo electrophysiological recording to determine whether changes occur in the density and/or sensitivity of central adrenergic receptors following long-term opiate treatment. The maximum number of specific binding sites (B_{max}) and dissociation constants (K_D) for ^{3}H-clonidine (CLON), an $alpha_2$ adrenoceptor agonist, and for ^{3}H-dihydroalprenolol (DHA), a beta receptor antagonist, were measured with neural membranes prepared from parietal cortex, hippocampus, and cerebellum of morphine- or saline-treated rats. Rats were injected with morphine or saline, i.p., every 8 hr for 14 days, with the dosage of the narcotic ranging from 10 mg/kg, t.i.d., on the first 3 days to 100 mg/kg, t.i.d., on the last 2 days. In control experiments, the B_{max}'s for specific binding of CLON and DHA, respectively, were (in fmoles/mg protein): parietal cortex, 130±4 and 71±5; hippocampus, 94±2 and 41±2; and cerebellum, 27±3 and 49±10. After chronic morphine treatment, the B_{max} for CLON was decreased significantly ($P<.05$) in parietal cortex (20%), but increased in cerebellum (27%, $p<.05$). Specific DHA binding showed a significant change ($p<.025$) only in parietal cortex, increasing by 24%. Morphine treatment did not alter the K_D's for either ligand.

Changes in sensitivity of postsynaptic adrenoceptors following chronic morphine were assessed by comparing the mean threshold current of iontophoretic norepinephrine (NE) (10 sec pulses, 250 mM conc.) required to inhibit the firing of cerebrocortical neurons recorded in drug-treated and saline control rats. In individual experiments, the same 5-barreled micropipet (3-8 MΩ) was used to alternately record single units from tandemly prepared, anesthetized control and morphine-treated animals. In tests on 26 cell pairs from 12 experiments, the mean threshold NE current required for depression of neurons in morphine-treated animals (20.6±3.8nA, S.D.) was significantly less ($p<.01$) than that of control cells (34.2±6.1nA, S.D.). Neurons recorded from morphine-treated rats displayed a similar increase in sensitivity to the inhibitory effects of isoproterenol (N=12 pairs). In comparison, no significant change in neuronal responsiveness to gamma aminobutyric acid was observed after chronic morphine treatment. Taken together, these findings suggest that changes in adrenoceptors in specific brain regions may be important in the development of narcotic

233.8 OPIATE INHIBITION OF CCK-8 RELEASE FROM HYPOTHALAMUS AND CORTEX OF ZUCKER LEAN AND OBESE RATS, IN VITRO. P. Micevych, T. Yaksh and V. L. W. Go*. Depts. of Neurosurgery and Gastroenterology, Mayo Foundation, Rochester, MN 55905.

Recent evidence has implicated both the endogenous opioid peptides and cholecystokinin octapeptide (CCK-8) in the regulation of feeding behavior. Opiates inhibit the stimulated release of CCK-8 from hypothalamus, in vitro, thus the opiate effects on feeding behavior may be modulated through a regulation of CCK-8 release in the hypothalamus. We speculated that obese Zucker rats (fa/-) which have an exaggerated stimulated release of CCK-8 may have an altered opiate modulation. Age-matched lean (200-270g) and obese (450-550g) Zucker rat littermates were decapitated and the hypothalamus and frontal cortex dissected out. Hypothalamic or cortical fragments were superfused with oxygenated KRB containing D-glucose and bacitracin. Samples were analyzed by RIA. Drug-free levels of release from lean rat hypothalamus were 1.15 ± 0.16 fmole CCK-8 equivalents/mg/10 min and from the obese rat 2.1 ± 0.19 fmole CCK-8 equivalents/mg/10 min. The percent inhibitions of stimulated (50mM K^+) CCK-8 release from lean rat hypothalamus with morphine (10nM) was 52% and with d-ala^2-d-leu^5-enkephalin (DADLE, 10nM) was 53%. The percent inhibition of stimulated CCK-8 release from obese rat hypothalamus was 77% with morphine (10nM) and 66% with DADLE (10nM). The cortical release of CCK-8 was 2.6 ± 0.35 from lean rats and 2.7 ± 0.41 fmole CCK-8 equivalents/mg/10 min from obese rats. Morphine and DADLE did not inhibit the stimulated cortical release of CCK-8. Equimolar concentrations of the specific opiate antagonist, naloxone, blocked the opiate inhibition of both morphine and DADLE in the lean and obese rats. Sephadex G-50 chromatography demonstrated that the immunoreactive CCK had a similar retention co-efficient to authentic sulfated CCK-8. These results indicate that the CCK-containing neurons of the hypothalamus of both lean and obese rats are sensitive to opiate inhibition of release while cortical CCK neurons are not. However, obese rats may have an altered degree of sensitivity to opiates, with respect to the release of CCK-8 which was not revealed in these experiments. The exaggerated release of CCK-8 from obese rat hypothalamus, in vitro thus may involve an altered "fine-tuning" within the hypothalamus.

233.9 DO OPIOIDS MODULATE NEURALLY MEDIATED ADRENAL OR PLASMA CATECHOLAMINE RELEASE? Karen L. Cochrane,* K. Bridget Brosnihan, Ph.D. and Carlos M. Ferrario, M.D. Cleveland State University and Research Division, Cleveland Clinic Foundation, Cleveland, Ohio 44106.

To delineate whether opioids modulate the neural release of adrenal catecholamines, we have stimulated the preganglionic splanchnic nerve before and after systemic administration of either an opiate agonist or an antagonist. Sixteen dogs were anesthetized with pentobarbital (30 mg/kg, IV) anesthesia. Adrenal secretion rate was assessed in situ. The preganglionic splanchnic nerve was stimulated at a fixed voltage and pulse duration (10V, 1 msec duration), and variable frequencies ranging from 0.3 to 10.0 Hz before and after administration of morphine (2 mg/kg IM) or naloxone (2 mg IV). Epinephrine and norepinephrine were measured by a radioenzymatic assay. Basal epinephrine secretion rates (22.7 ± 11.0 ng/min) and norepinephrine secretion rate (2.9 ± 1.1 ng/min) were unaffected by the administration of either drug. On the other hand, the dose stimulus response curve relating secretion rates of epinephrine and norepinephrine as a function of stimulus frequency was shifted to the left of the control curve by naloxone ($F = 7.52$, $p < 0.05$ and $F = 7.11$, $p < 0.05$, respectively). Morphine treatment was without effect on the neurally mediated release of adrenal catecholamines. We also observed that treatment with morphine reduced circulating plasma norepinephrine levels in both basal conditions and at the threshold frequency of stimulation, but markedly elevated plasma norepinephrine levels at higher frequencies of stimulation. These studies provide evidence for a role of endogenous opioid peptides tonically inhibiting the neurally mediated release of adrenal catecholamines in dogs anesthetized with pentobarbital. In addition, the potentiating effect of morphine on plasma norepinephrine level was unexpected but may be consistent with opioids acting at sites innervated by the splanchnic nerve other than the adrenal medulla although more indirect modes of action cannot be eliminated. (Supported in part by NHLBI grants HL-6835 and HL-24100).

233.10 CHRONIC OPIATE ADMINISTRATION INCREASES THE BINDING OF ^{3}H-CLONIDINE TO ALPHA-2-ADRENERGIC RECEPTORS IN CULTURED MURINE BRAIN AND CEREBRAL CORTEX. R. J. Plishka and J. H. Neale. The Department of Biology, Georgetown University, Washington, D. C. 20057.

Clonidine, a potent alpha-2-adrenergic receptor agonist, ameliorates the symptoms of opiate withdrawal. The mechanisms proposed for this action have focused upon the adrenergic neurons of the locus coeruleus, which possesses both opiate and alpha-2-adrenergic receptors. Chronic morphine administration is reported to increase alpha-2-adrenergic receptors in rat cerebral cortex in vivo.

We report here that chronic morphine administration to brain cell cultures (75 uM morphine sulfate; day 24 through day 30 in culture) caused a 24% increase in the binding of ^{3}H-clonidine. Cells from cerebral cortex which were grown in culture without benefit of adrenergic input also demonstrated a substantial increase in alpha-2-adrenergic receptor binding as a result of chronic morphine administration. In contrast, neither cell cultures prepared from brain without cortex nor the neuroblastoma-glioma hybrid cell line, NG108-15, which also possesses both opiate and alpha-2-adrenergic receptors, responded to chronic morphine administration with significant changes in ^{3}H-clonidine binding.

233.11 AN IN VIVO ELECTROCHEMICAL AND BEHAVIORAL STUDY OF THE EFFECT OF D-ALA^2-D-PRO^5-ENKEPHALINAMIDE ON DOPAMINE RELEASE FROM RAT TUBERCULUM OLFACTORIUM. F.A. Broderick, E.L. Gardner and H.M. van Praag*. Depts. of Psychiatry and Neurosci., Albert Einstein College of Medicine, Bronx, NY 10461

Rat tuberculum olfactorium is a mesolimbic brain area which has been shown to mediate, at least in part, the hyperactivity induced by amphetamine (Pijnenberg, et al, Eur. J. Pharm. 35:1976). Recent behavioral evidence has shown an enkephalinergic modulation of dopaminergic function in mediating mesolimbic components of amphetamine-induced locomotor activity (Broderick et al, Soc. Neurosci. Abstr. 8:1982). The purpose of the present study was to examine the effect of an enkephalin pentapeptide analog, D-Ala^2-D-Pro^5-enkephalinamide (DAP) (Wy 42,186), on the locomotor activity induced by d-amphetamine sulfate (AMP) and on dopamine release from the tuberculum olfactorium as measured by in vivo electrochemistry.

Male, Sprague-Dawley rats (350-450 g), group housed, fed and watered ad lib, were treated with DAP (5 mg/kg i.p.), followed one-half hour later with AMP (2.5 mg/kg i.p.). Testing for locomotor activity, as shown by the number of crossings into separate quadrants of the testing apparatus, began 15 min after AMP injection and continued for 2 min sessions every 20 min for 2 hours. The rats were isolated in a sound proof room and were observed through an adjoining one-way mirror. Semiderivative voltammograms were recorded every ten min at a scan rate of 10 mv/sec. Catecholamine sensitive electrodes (Blaha and Lane, Br. Res. Bull., in press, 1983) were stereotaxically implanted in the tuberculum olfactorium of chloral hydrate anesthetized rats, controlled for temperature changes. A Ag/AgCl reference electrode and a Pt auxiliary electrode were placed in contact with the cortex. After a stable, steady state dopamine signal was achieved, DAP (5 mg/kg i.p.) was administered. The effect of DAP on the dopamine signal was investigated for a period of one to two hours.

The results showed that DAP produced no significant alterations on dopamine release in rat tuberculum olfactorium, and produced no significant change in amphetamine-induced locomotor activity. Moreover, DAP was shown to significantly inhibit dopamine release from rat striatum and to have no effect on dopamine release from rat nucleus accumbens (Broderick et al, Biol. Psychiat., in press, 1983). These data further show a site specific enkephalinergic modulation of dopamine both behaviorally and biochemically. These results also suggest a correlation between mesolimbic dopaminergic function and locomotor activity induced by amphetamine. (Supported by USPHS Grant MH 15788).

233.12 CRF-INDUCED ACTH/β-END RELEASE IN STRESS. E.A. Young,* S. Watson, and H. Akil (SPON: G.C. Quarton). Mental Health Res. Inst., Univ. of Michigan, Ann Arbor, MI 48109.

The activation of the hypothalamo-pituitary-adrenal (HPA) axis in stress is a classic endocrinological finding. The adrenal steroids produced by this activation inhibit the further release of ACTH from the pituitary (feedback inhibition). Glucocortioids appear to be active at both the hypothalamus and pituitary to suppress release of both corticotropin releasing factor (CRF) and ACTH. The demonstration that an opioid peptide, β-endorphin (β-END) and ACTH are cosynthesized and co-released in pituitary suggests that β-END may also be released during stress.

Acute intermitent footshock has been demonstrated to produce analgesia in rats that is naloxone reversible. When this same shock is continued for 14 days, (chronic stress) the animals become tolerant to the analgesic effects of stress. Analgesia produced by footshock is attenuated by hypophysectomy and adrenalectomy, again suggesting the involvement of the HPA axis.

Since intermittent footshock has been well characterized, we were interested in studying the effects of these acute and chronic stress paradigms on the ability of the pituitary to respond to CRF and arginine vasopressin (another ACTH releaser). Pituitaries were removed from rats who had received either acute stress, chronic stress with the last stress occuring 24 hours prior to decapitation, and chronic stress followed by an acute stress immediately prior to decapitation, (chronic stress/acute stress). Pituitaries from naive, unstressed animals were used as the control group. After processing into single cell preparations, the pituitaries were incubated with varying doses of CRF (10^{-11} M to 10^{-9} M) and vasopressin (10^{-10} M to 10^{-8} M). Release of ACTH and β-END into the medium was measured by RIA. A clear response to both releasers was seen in control pituitary. In acute stress, a decreased responsivity to vasopressin and CRF is seen. This same blunted release is not seen in chronic stress, even if the animals are stressed immediately prior to decapitation. At the higher doses of CRF (10^{-9}M) an increased release of ACTH and β-END is seen in the chronically stressed rats. Thus it would appear that there is a loss of the normal steroid feedback inhibition on pituitary release of ACTH. In addition there may be changes in the ability of the pituitary to readily release ACTH (releasable pools) in chronic stress.

233.13 CHANGES IN β-ENDORPHIN CONCENTRATIONS IN THE MEDIAL PREOPTIC AREA DURING PREGNANCY IN THE RAT. R.S. Bridges and P.M. Ronsheim*. Department of Anatomy, Laboratory of Human Reproduction and Reproductive Biology, Harvard Medical School, Boston, MA 02115.

The expression of maternal behavior in the rat can be disrupted by the administration of the opiate morphine. Recently, we have reported that direct application of morphine to the medial preoptic area (mPOA), an area known to regulate maternal behavior in rats, interferes with ongoing maternal behavior. Based upon these findings and the reports of increased pain thresholds (Science 210:193, 1980) and elevated concentrations of β-endorphin (βE) in whole hypothalami (Brain Research 245:327, 1982) in pregnant rats, we have proposed that the onset of maternal behavior at parturition may result from a decline in endogenous opioid activity prepartum. In the present study we have addressed this possibility by measuring the content of the endogenous opiate, βE, during pregnancy in a region of the CNS identified with the control of maternal behavior, the mPOA, and in the medial basal hypothalamus (MBH). Tissue samples from the mPOA and MBH were obtained by macrodissection from pregnant rats (N = 6-7/group) between 1000 and 1400 h on days 6, 12, 18 and 22 of gestation. Samples were also collected from nonpregnant females on the morning of diestrus. Tissues were homogenized on ice in 0.2% HCl/1% formic acid, and the homogenates stored frozen at -20°C. Immediately prior to assay determinations of βE concentrations, each sample was thawed and an aliquot of the homogenate taken for protein determination (Bradford method). The remaining sample was microfuged at 8800 g and aliquots of the supernatant taken for βE measurement by radioimmunoassay. βE levels in the mPOA of 6, 12 and 18 day pregnant rats were higher than those found in diestrous rats. Concentrations of βE rose from a mean of 8.5 ng βE/mg protein on diestrus to 14.3 ng/mg on day 6 of gestation. Levels of βE remained elevated on days 12 and 18 of pregnancy; the average concentration of βE for days 6, 12 and 18 was 14.2 ± 1.3 ng/mg. βE content in the mPOA was significantly lower on day 22 ($\bar{X}$ ± SE = 9.0 ± 2.2 ng/mg) than during the other times of pregnancy. In contrast to the changes in βE in the mPOA found over the course of pregnancy, significant changes in βE concentrations were not detected in the MBH either over the course of pregnancy or as a function of the state of pregnancy. Mean βE levels in the MBH of pregnant and diestrous rats were approximately 22-24 ng/mg. Although the functional relationship of opioid concentrations to its activity is unproven, these findings are consonant with those indicating that a reduction in opioid concentrations/activity in the mPOA prepartum stimulates maternal behavior at parturition. (Supported by BOC Grant #5-311 from the March of Dimes Birth Defects Foundation and by NSF Grant BNS 80-14670 awarded to RSB.)

233.14 EFFECT OF ESTROGEN AND PROGESTERONE ON THE RAT BRAIN AND PITUITARY OPIOIDS. G.A. Tejwani, K.K. Vaswani,* J.C. Barbacci,* C.W. Richard III, and J.R. Bianchine. Dept. of Pharmacology, The Ohio State Univ. College of Medicine, Columbus, Ohio 43210

Morphine and endogenous opioids have been shown to decrease the release of gonadotropins in various species including rat. The opiate antagonist, naloxone, facilitates the release of pituitary gonadotropins. This effect of naloxone is blocked by estrogens suggesting that gonadal steroids influence the secretion of gonadotropins by altering the level of endogenous opioids. This prompted us to investigate the effect of progesterone in presence and absence of estradiol on the level of β-endorphin in rat pituitary, hypothalamus and striatum. Forty-eight female Sprague Dawley rats were divided in 2 equal groups for acute and chronic studies. Each group was further divided into 4 subgroups, each containing 6 animals. Each rat in the first control group received an inert pill (15 µg in 0.25 ml corn oil daily by gavage); in second group norethindrone (NE, progesterone, 15 µg MICRONOR); in third group 15 µg NE and 1 µg ethinyl estradiol (EE_2 MEDICON); in fourth group 10 times the dose of the third group was given. Rats were treated either acutely for 5 days or chronically for 7 weeks. β-endorphin was estimated by a sensitive and specific RIA procedure developed in this laboratory. The concentration of β-endorphin-like immunoreactivity (β-EI) in pituitary, hypothalamus and striatum of control rats was 459±31, 10±2 and 0.98±0.07 ng/mg protein, respectively. In acute study, NE alone did not change β-EI significantly in pituitary. NE and EE_2 together decreased β-EI by 37% (47% at 10x dose). In chronic study, NE had no significant effect on pituitary β-EI. However, NE and EE_2 together increased β-EI by 15%, but at 10x dose decreased it by 14%. In the hypothalamus, NE alone or in presence of EE_2 had no significant effect on β-EI but 10x dose of NE+EE_2 caused 50 and 76% decrease in β-EI in acute and chronic study. Striatum was the only tissue where NE alone caused a decrease of 82% in β-EI when given acutely and 52% when given chronically. EE_2 had some protective effect on this decrease since when given together (NE+EE_2) the decrease in β-EI was 21% in acute and 43% in chronic study. Thus our results, along with other studies on the regulation of gonadotropin levels by opioids, suggest that oral contraceptives alter the level of β-EI and in turn may regulate the release of gonadotropins. (Supported by a grant from the Weight Watchers Fdn., Inc; and by the Roessler Fdn. of The Ohio State Univ.)

233.15 INCREASE OF STRIATAL MET^5ENKEPHALIN-ARG^6-PHE^7 (ME-Arg-Phe) CONTENT ELICITED BY LONGTERM TREATMENT WITH HALOPERIDOL. J. Chou*, J. Tang*, H.-Y.T. Yang and E. Costa (SPON: J. Stevens). Lab. Preclinical Pharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032

The elevation of Met^5-enkephalin (ME) content in striatum of rats receiving a daily injection of haloperidol for 3 weeks has been reported from this laboratory (Hong et al., JPET 205:141-147, 1978). Since Met^5-Enk-Arg^6-Phe^7 (ME-Arg-Phe) is derived from the same preproenkephalin A as ME, we have studied the effect of haloperidol on the ME-Arg-Phe content of various rat brain structure. We have studied in detail its striatal content, the release and accumulation rate after inhibition of ME-Arg-Phe degradation in rats receiving saline or haloperidol. ME-Arg-Phe content in striatum was increased (from 1.32+0.15 to 2.11+0.19 pmol/mg protein) in rats receiving haloperidol once daily for 2-3 weeks, and this increase was dose dependent. The latency time for the ME-Arg-Phe increase is similar to that of ME. Following intraventricular injection captopril, an inhibitor of ME-Arg-Phe degrading enzyme, the rate of striatal ME-Arg-Phe accumulation was greater in haloperidol (570 fmol/mg protein/hr) than in saline (200 fmol/mg protein/hr) treated rats. A slower rate of ME-Arg-Phe release in halopeidol treated rats can be excluded as a cause for this drug-induced increase in ME-Arg-Phe content because the peptide is released by a similar concentration of K^+ and at a similar rate in striatal slices prepared from haloperidol and saline treated rats. The parallel increase of ME-Arg-Phe and ME content after chronic treatment with haloperidol suggests that haloperidol increases the biosynthesis of the specific mRNA for preproenkephalin A, which causes an increase in the content of both ME-Arg-Phe and ME.

233.16 EFFECT OF POSTNATAL PHENOBARBITURATE TREATMENT ON ENKEPHALIN, METABOLISM BY RAT BRAIN ANIMO-AND ENDOPEPTIDASES. S. Mousa* S. Tjioe and D. Couri* Department of Pharmacology, College of Medicine, Ohio State University, Columbus, Ohio 43210.

It has been shown that in vitro barbiturates inhibited the degradation of enkephalin by rat striatum membrane-associated endopeptidase (enkephalinase A) (Life Sci., 28: 185, 1981). The effect of postnatal administration of phenobarbital to male and female Wistar rats in a dose of 45 mg/kg subcutaneously daily from day 1 postnatally (birth = day 0) (4 litters) thru day 19 on enkephalin degrading enzymes was examined. Brains from saline and phenobarbital treated rats were used to prepare aminopeptidases (high speed supernatant) and enkephalinase A (synaptosomal membrane preparation). Incubation of methionine-enkephalin (ME) with rat brain aminopeptidases liberated tyrosine (T) while incubating with enkephalinase A resulted in the formation of tyrosylglycylglycine (T-G-G). The separation and quantitation of T, T-G-G and ME was performed using a high performance liquid chromatography coupled to electrochemical detector (J. Chromatography, 1983, in press). The phenobarbital treatment resulted in a significant inhibition of enkephalinase A and a slight activation of aminopeptidases. Phenobarbital protects ME from degradation an effect which may be due to its inhibitory effect on enkephalinase A. Further study is in progress to test other barbiturates. A preliminary experiment with secobarbital showed a highly significant inhibitory effect on enkephalinase A and the subsequent protection of ME.

Treatment	Aminopeptidase Activity		Enkephalinase A Activity	
	Unit*	% ME Degraded	Unit*	% ME Degraded
Saline	60.9 ± 2.6	75.9 ± 1.2	68.6 ± 2.5	42.6 ± 7.5
Phenobarbital	83.3 ± 8.4	71.9 ± 3.4	22.1 ± 2.0	20.7 ± 3.3
	p < 0.025	NS	p < 0.001	p < 0.06

234.1 INTERACTIONS OF DOPAMINERGIC NEURONS IN RAT RETINA WITH LIGHT: EFFECTS OF STIMULATION AND DEPRIVATION. E.Melamed,Y. Frucht*,M. Lemor* and J.Vidauri*. Lab. of Clin. Neurochemistry, Dept. of Neurology, Hadassah University Hospital, Jerusalem, Israel.

Dopamine (DA) turnover in retina is accelerated by photic stimulation.We investigated responses of rat retinal DA neurons to various effects of light exposure and deprivation.Rats,dark-adapted for 24hr, were killed in the dark or after being exposed to regular laboratory light for 5,15,30,60,or 120min. Retinal DA and DOPAC gradually increased up to 1hr with no further elevations thereafter.Groups of rats kept in a regular 12hr light-dark cyclic illumination (lights on at 6PM),were sacrificed at 2hr intervals begining at 6PM. Both,DA and DOPAC in retina markedly increased and remained elevated throughout the "lights-on" hours.They decreased and remained low during the"dark period".To determine whether the stimulatory effect of light on retinal DA neurons is mediated through photoreceptors, 24,35,or 70-day-old Royal College of Surgeons (RCS) rats with inherited progressive retinal dystrophy and age-matched controls were dark-adapted for 24hr and then exposed to light for 2hr. In controls,light exposure increased retinal DA and DOPAC levels in all age groups.Light stimulation enhanced retinal DA and DOPAC only in the 24-and 35-day-old RCS rats with functioning photoreceptors but not in the 70-day-old animals where all photoreceptors had been lost. Data suggest that intact photoreceptors are essential for light-induced activation of retinal DA neurons. To determine the effect of light deprivation on ontogenesis of retinal DA neurons,rats reared from birth in total darkness were killed in the dark 12,16,20,30,or 60 days postnatally.Age-matched controls kept in a regular light-dark cycle were killed at same ages after 24hr of dark adaptation.In controls,DA levels in retina increased up to 60 days after birth.In light-deprived rats, retinal DA levels failed to increase with age and were markedly smaller than those in controls.To determine the duration of postnatal light deprivation beyond which suppression of retinal DA levels becomes irreversible,rats were kept in total darkness for 16,20,or 30 days after birth and then transferred to normal light-dark conditions for periods up to 60 days.Controls were reared in normal lighting conditions or were totally light-deprived for 60 days postnatally.In rats grown in darkness and then changed to normal conditions, retinal DA levels were not lower but even higher as compared with controls.Sixty day-old rats raised from birth in a normal light-dark cycle were killed 7,14,30, or 60 days after being transferred to total darkness.Controls were killed after 24hr dark adaptation.In light-deprived rats, retinal DA gradually diminished and after 60 days was markedly lower than in controls.Findings suggest that postnatal light deprivation probably reduce synthesis and accumulation of DA and not the number of DA neurons in retina.

234.2 DOPAMINE AND EPINEPHRINE ARE CONTAINED IN SEPARATE AMACRINE CELLS IN RAT RETINA. M. Hadjiconstantinou*, A. Mariani*, P. Panula* and N.H. Neff. Lab. Preclinical Pharmacology, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032 and NEI, Lab. Vision Research, Bethesda, MD 20205.

There is now biochemical and pharmacological data supporting the presence of dopamine (DM)- and epinephrine (EPI)-containing neuronal elements in rat retina. We provide morphological evidence that they are contained in separate types of neuronal cells. Dopaminergic amacrine cells displaying bright, bluish-green fluorescence characteristic of catecholamines were seen in whole flat-mounts of the rat retina following fixation in an aqueous formaldehyde-glutaraldehyde (Faglu) mixture. After the systemic administration of pargyline, a monoamine oxidase inhibitor, some of the bright DM-containing cell dendrites in the inner plexiform layer were found to give rise to outwardly coursing processes which ramify in the outer plexiform layer indicating that some of the bright dopaminergic neurons are interplexiform cells. In addition, a third population of relatively weakly fluorescing amacrine cell bodies appeared. The color and intensity of their fluorophore suggested that they contain a catecholamine, perhaps EPI. This hypothesis was confirmed by the immunohistochemical localization of the EPI synthetic enzyme, phenylethanolamine-N-methyltransferase to amacrine cells. Our results indicate that three types of rat retinal neurons contain catecholamines. DM is present in a single type of amacrine cell and in interplexiform cells, EPI is contained in another type of amacrine cell.

234.3 RETINAL GABA NEURONS: IMMUNOCYTOCHEMICAL LOCALIZATION USING A NEW ANTISERUM AGAINST RABBIT BRAIN GLUTAMATE DECARBOXYLASE. Christopher Brandon. Department of Anatomy, Oregon Health Sciences University, Portland, Oregon 97201.

Much evidence exists to support the notion that γ-aminobutyric acid (GABA) is a neurotransmitter in at least some retinal neurons. One reliable method for identifying such cells is the immunocytochemical localization of glutamate decarboxylase (GAD), the enzyme responsible for the last step of GABA biosynthesis (see, e.g., Saito et al., PNAS 71, 269 (1974); Brandon et al., PNAS 76, 3557 (1979)). In order to examine such cells in detail with this method, a new antiserum has been produced against GAD from rabbit brain, and has been used for the localization of retinal GABA neurons in several species.

Rabbit brain GAD was partially purified by homogenisation and centrifugation, ion exchange and hydrophobic column chromatography, gel filtration, and gradient hydroxyapatite chromatography. This preparation, about 20% pure, was used for the immunization of several rabbits. One resulting multivalent antiserum was then used for the preparative immunoelectrophoretic production of a GAD immunoprecipitate according to Kroll and Andersen (J. Immunol. Methods 13, 125 (1976)). This GAD immunoprecipitate was then used in turn as an immunogen in a new rabbit. After several biweekly injections, an antiserum was obtained which formed a single precipitin arc on immunodiffusion or immunoelectrophoresis against a rabbit brain homogenate, and which precipitated GAD from crude homogenates (although it did not inhibit GAD enzymatic activity). By immunodiffusion, it cross-reacted with GAD from rabbit, rat, and goldfish.

This new antiserum has been used for the light-microscopic immunocytochemical localization of GABA neurons in the retinas of goldfish, catfish, turtle, chick, mouse, rat, rabbit, cat, monkey, and man. In all cases, GAD-immunoreactive processes were observed throughout the inner plexiform layer, although the patterns of lamination formed by these labeled processes were different in different species; in all species, some amacrine cell bodies were clearly labeled as well. In all non-mammalian retinas examined, sub-populations of horizontal cells were immunoreactive. Using this approach, the detailed synaptic connectivity of GABA neurons in the retinas of cat, rabbit, and monkey is currently under investigation.

234.4 DEVELOPMENT OF GLUCAGON-LIKE IMMUNOREACTIVITY IN THE CHICK RETINA. M.Cilluffo,* T.Yamada,* and N. Brecha.
Center for Ulcer Research and Education, VA Wadsworth Medical Center and UCLA School of Medicine, Los Angeles, CA 90073

Previously we reported the presence of pancreatic type glucagon in the vertebrate retina. In our present studies we have examined the distribution of glucagon-like immunoreactivity (GLI) in developing and mature chick retina.

Retinas from staged chick embryos and young and adult chicks were immersion fixed in paraformaldehyde and processed according to standard immunohistochemical techniques. Using antisera against porcine pancreatic glucagon (N211 and GVI), GLI was found in at least 3 distinct populations of amacrine cells. The majority of cells present in all retinal regions had small, round somata and processes which primarily ramified in lamina 1 of the IPL. A second cell type had large, round somata and a single, short, thick primary process oriented parallel to the IPL. This primary process gave rise to multiple fine secondary processes extending to laminae 1, 3 and 5 of the IPL as well as to a single process that coursed to the ora serrata where it joined a fascicle of GLI processes. Medium sized cells were observed in peripheral retina and they gave rise to processes which joined the GLI fibers in the ora serrata. In the stage 39 (day 13) chick embryo retina, GLI was observed within "immature-appearing" somata lacking processes located in central retinal regions of the proximal INL. GLI containing processes were first observed in lamina 1 of the IPL at stage 40. By stage 43 (day 17), GLI was observed in all retinal regions and processes were observed in the ora serrata and laminae 1, 3 and 5 of the IPL as in the adult retina.

Radioimmunoassay of acid-ethanol extracts of retinas using pancreatic glucagon specific antiserum 30K revealed GLI concentration of 2.0pmol/g wet weight from stages 32 to 38. From stages 39 to 46 (hatching), retinal GLI rapidly increased from 2.6pmol/g ±1.6 to 15.3pmol/g±3.9. GLI peaked at day 1 (26.0pmol/g±6.1) and dropped to adult levels (14.9pmol/g±4.1) by day 3. Retinal extracts at stages 42, 46 and days 1, 2, 60, 90 were chromatographed on Sephadex G50. GLI was found to co-elute in a similar position to chicken pancreatic glucagon and synthetic porcine glucagon (Lilly).

These studies demonstrate that retinal GLI is present in distinct cell types which appear to develop simultaneously in the embryo. Tissue content of GLI matches the appearance of immunoreactive somata and processes. These studies suggest that the marked changes in retinal GLI at hatching is associated with changes in cellular GLI content and not the changes in numbers of GLI cells.

234.5 POSSIBLE CIRCADIAN VARIATION IN A PUTATIVE RETINAL NEUROTRANSMITTER. K.T. Keyser*, H.J. Karten, V.M. Cassone and M.Menaker.(Spon:J. Kleinschmidt). Dept. of Psychiatry, S.U.N.Y.at Stony Brook, N.Y. 11794, Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

The identification of putative transmitters and an understanding of their distributions and physiological roles in vivo remain central problems in neurobiology. The current wide availability of antisera directed against a variety of neuropeptides, enzymes and traditional transmitter candidates has greatly encouraged such studies.

The bird retina contains numerous classes of morphologically-distinct amacrine cells, many of which have recently been shown to be immunohistochemically distinct. For example, cells exhibiting Substance P-like reactivity in the pigeon retina are essentially identical to a cell type described by Cajal (Brecha & Karten, 1980).

We have begun investigation of the changes in levels of putative transmitters in amacrine cells of the pigeon as a function of time of day. Birds maintained on a 12:12 light-dark cycle were anesthetized and decapitated, the eyes infused with fixative, rapidly removed from the skull and the retinae processed for indirect immunoflorescence. Retinae from birds sacrificed at midnight showed dramatically increased staining of some amacrine cell types when compared to retinae from birds sacrificed twelve hours earlier. These included cells exhibiting enkephalin-like immunoreactivity (ELI), tyrosine hydroxylase-LI (THLI), and serotonin-LI (5-HT LI). In all three cases the cell bodies seemed more numerous and more extensive arboriztions were visible.

In some experiments, birds to be sacrificed at midnight were given a one hour exposure to room light before decapit ation and "noon"birds were kept in the dark for one hour. The retinae from these midnight birds again exhibited more intense staining in all three of the categories listed above. In addition to the enhanced 5-HTLI in amacrine cells of the midnight birds,there is a population of bipolar cells which was affected. The 5-HTLI bipolars appeared more numerous and their processes seemed more intensely stained in the midnight cases.

Preliminary biochemical data from chickens indicates about a twofold increase in measurable serotonin in the retinae of midnight birds (124pg/mg compared to 72pg/mg).

These observations raise the question as to whether these changes in levels and staining of putative transmitters are due to an actual cicadian rhythm. Experiments are currently being designed to test this hypothesis by using "free running" (i.e. under constant light or dark conditions) animals to determine whether or not the variation persists. Supported by EY 04796 to H.J.K. and AM 26972 to M.M.

234.6 ASPARTATE AMINOTRANSFERASE-LIKE IMMUNOREACTIVITY AS A MARKER FOR ASPARTATE/GLUTAMATE IN THE MONKEY RETINA. Judith L. Mosinger* (SPON: J. Erichsen). Dept. of Cellular & Developmental Biology, Harvard University, Cambridge, MA 02138.

Aspartate and/or glutamate have been proposed as transmitters in the vertebrate retina. The enzyme, aspartate aminotransferase (AAT), is involved in the metabolism of aspartate and glutamate. Previous studies have suggested that the antibody to AAT may serve as a marker for aspartergic/glutaminergic neurons (Altschuler, et al., PNAS, 78:6553, 1981). Peroxidase-antiperoxidase techniques were used for light and electron microscopic localization of AAT-like immunoreactivity in the cynamolgus monkey retina.

At the light microscopical level, a band of immunoreactivity is seen in the outer plexiform layer. This band is thick in the peripheral retina and sparse in the central retina, disappearing entirely near the foveal region. Electron microscopical analysis shows reaction product is localized to rod spherules, consistent with the gross regional distribution of AAT in the retina.

Two types of labeled cells are seen in the inner nuclear layer (INL): numerous somata in the position of bipolar cells and approximately 10-15% of the neurons on the proximal edge of the INL. AAT-like immunoreactivity is seen in both amacrine and bipolar terminals in the electron microscope. Labeled bipolar terminals are seen exclusively in the proximal half of the inner plexiform layer. They synapse mainly onto unlabeled and occasionally labeled amacrine processes. Labeled amacrine processes synapse upon and receive input from other amacrine processes and bipolar terminals.

A few large neurons in the ganglion cell layer also show AAT-like immunoreactivity in the light microscope. Their identity as ganglion cells or displaced amacrine cells is uncertain.

These results differ from those of similar experiments in guinea pig retina where cone and amacrine endings show AAT-like immunoreactivity but rod and bipolar terminals do not (ARVO Abstract, 22:247, 1982). These results support the hypothesis that aspartate and/or glutamate is a neurotransmitter in rods and a subpopulation of amacrine and bipolar cells in the cynamolgus retina.

234.7 EFFECTS OF DOPAMINE, FORSKOLIN, L-GLUTAMATE, Mg^{2+}, AND PYROGLUTAMATE ON GABA RELEASE FROM THE TELEOST RETINA. D. R. O'Brien* and J. E. Dowling. (SPON: M. Karnovsky), The Biological Laboratories, Harvard University, Cambridge, MA 02138.

We examined the rate of release of ^{3}H-GABA from intact carp and goldfish retinas using a "static perfusion" technique. Small, significant increases in the rate of GABA release were observed when the retinas were exposed to dopamine (DA) (10-100 µM); however, when free Ca^{++} was removed from the medium, the basal rate of GABA release was increased and DA became inhibitory. Forskolin, a non-specific stimulator of adenylate cyclase in intact cells, also inhibited GABA release in the absence of Ca^{++}. There was no significant effect of forskolin in the presence of Ca^{++}. L-glutamic acid (L-Glu) (1-10 mM) caused up to a 10-fold increase in GABA release. This effect of L-Glu was not significantly altered by removing Ca^{++} from the medium. In the presence of Ca^{++} DA did not significantly alter the effects of L-Glu; however in the absence of Ca^{++} a significant inhibition of the effects of L-Glu by DA was observed. These results suggest to us a model wherein DA stimulates Ca^{++}-dependent GABA release from one site and inhibits Ca^{++}-independent GABA release from another site via a cAMP mediated event.

Yazulla earlier reported (Invest. Ophth. Vis. Sci. 24 (Suppl): 40, 1983)that the effects of L-Glu in stimulating GABA release were significantly inhibited by 1 mM Mg^{++}. We have confirmed these observations. However, low concentrations of pyro-glutamate (pGlu) (10 µM) also inhibited the effects of L-Glu to the same extent as did Mg^{++}. Since neither pyroglutamate nor Mg^{2+} affected the basal rate of GABA release, these data raise the possibility that a retinal glutamic acid cyclotransferase converts Glu to pGlu in the presence of Mg^{++}. Such Mg^{++}-dependent cyclotransferase activity has been observed in a number of tissues, including CNS (Orlowski & Meister, The Enzymes 4: 123, 1971).

234.8 MONOCLONAL ANTIBODIES ASSOCIATED WITH H1 HORIZONTAL CELLS IN THE CARP RETINA. L. H. Y. Young* and J. E. Dowling. The Biological Laboratories, Harvard University, Cambridge, MA 02138.

Horizontal cells in the teleost retina have been classified into four subtypes with respect to their shape, location in the outer plexiform layer, specificity of synaptic connections and electrophysiological responses. The possibility that in addition to these differences there are distinct patterns of surface molecules among horizontal cell subtypes prompted our use of monoclonal antibodies as probes to further enhance our understanding of the cell surface properties of horizontal cells.

Balb c mice were injected with either carp retinal cell mixtures (approximately 10% horizontal cells) or purified horizontal cells obtained through velocity sedimentation Ficol gradients. Four hybridomas secreting antibodies specific to the outer plexiform layer in the carp have been raised. These hybridomas originated from 2 separate fusions, one from fusion of SP2/0 myeloma cells with spleen cells from a mouse immunized against gradient isolated horizontal cells and the other three from a mouse immunized against retinal cell mixture. All four monoclonal antibodies produce a very similar immunofluorescent staining pattern in the frozen sections of carp retina at the light microscopy level. The staining extends all along the outer plexiform layer and appears to be related only to the external (H1) horizontal cells. Of particular interest is the observation that the staining pattern is very similar to the outer plexiform layer dopamine fluorescence obtained with the Falck-Hillarp method. However, the staining is unaltered following 6-hydroxydopamine treatment which selectively destroys the terminals of the dopaminergic interplexiform cells. Our results thus suggest that the antibodies may be recognizing an element postsynaptic to the interplexiform cell terminals or some nearby molecule on the H1 horizontal cells.

234.9 ^{3}H-DOPAMINE RELEASE FROM THE INTACT CARP RETINA: EFFECTS OF K^{+}-IONS, 5HT AND (-)-3PPP. S. J. Dorison*, K. J. Watling* and J. E. Dowling (SPON: E. M. LASATER). Biological Laboratories., Harvard University, Cambridge, MA 02138.

The effects of K^{+}-ions, 5HT and (-)-3PPP have been investigated on ^{3}H-dopamine (DA) release from the dopaminergic interplexiform cells present in the carp retina. Dark-adapted carp retinas were removed and incubated for 15 min. in oxygenated Ringer's (pH 7.4) containing 0.2 µM ^{3}H-DA. Following a 10 min. rinse in DA-free Ringer's, retinas were placed, receptor side up, in a perfusion apparatus, such that each retina received a constant drip of Ringer's at a flow rate of ~2 ml./min. Samples of Ringer's were collected every minute and the ^{3}H-DA efflux determined by scintillation counting. Autoradiographic techniques, performed on pieces of retina processed according to the above protocol, revealed the presence of extensive labelling surrounding the horizontal cells in the outer plexiform layer (OPL), consistent with the uptake of ^{3}H-DA by the DA-ergic interplexiform cell terminals. Perfusion of retinal pieces with 1 min. pulses of Ringer's containing high concentrations of K^{+}-ions resulted in a large, dose-dependent efflux of ^{3}H-DA, with 30 mM K^{+}-ions evoking a 2-4 fold increase over basal ^{3}H-DA release. This response did not occur in Ca^{++}-free Ringer's, or in fish that had previously received intraocular injections of 6-hydroxydopamine, a treatment known to destroy selectively DA-ergic nerve terminals in the OPL. In agreement with the data of Kato et al. (J. Neurochem. 39, 493-498, 1982), both 5-hydroxytryptamine (5HT) and tryptamine induced a dose-dependent (1-300 µM) increase in ^{3}H-DA release when added to the perfusion Ringer's. However, contrary to the findings of the above workers, this response was neither Ca^{++}-dependent, nor blocked by 5HT antagonists, including cyproheptadine, methysergide and spiroperidol. These data raise the possibility that this 5HT effect is not mediated through a receptor specific mechanism located on DA-ergic terminals, but rather via an exchange mechanism. In contrast, (-)-3-(3-hydroxyphenyl)-N-n-propylpiperidine ((-)-3PPP), a putative presynaptic dopamine receptor agonist, did evoke a dose-related, Ca^{++}-dependent increase in ^{3}H-DA release. Furthermore, 100 µM (-)-3PPP greatly enhanced the response to 30 mM K^{+}-ions. These data raise the possibility that presynaptic dopamine receptors may modulate dopamine release in the carp retina. Various other retinal neurotransmitter candidates, including GABA, glycine, glutamate, aspartate, acetylcholine, enkephalin, thyrotropin releasing hormone and vasoactive intestinal peptide were all without effect either on basal or K^{+}-ion stimulated ^{3}H-DA release.

234.10 LIGHT MICROSCOPIC IMMUNOCYTOCHEMISTRY OF SOMATOSTATIN IN THE RAT RETINA. S.M. Sagar, P.E. Marshall* and D.M.D. Landis. Neurology Service, Massachusetts General Hospital, Boston, MA 02114.

Following paraformaldehyde fixation, Vibratome cross sections of rat retina were reacted with a commercially obtained antibody raised in rabbit to somatostatin-14 conjugated to bovine serum albumin. Triton-X100 was used to aid antibody penetration. The primary antibody was visualized using biotinylated second antibody and avidin-biotin-peroxidase complex. Control sections, incubated in primary antiserum preadsorbed with 10 ng/ml somatostatin-14, showed no selective staining of fibers or cell bodies.

Specifically stained cell bodies were found at the inner margin of the inner nuclear layer, some of which were seen to give off one or two thick processes passing into deep layers of the innner plexiform layer. In addition, a meshwork of fine, varicose somatostatin-reactive fibers was seen at the outer border of the inner plexiform layer. Occasionally, stained varicose fibers were seen running horizontally at the approximate midpoint of the inner plexiform layer as well as in deeper sublamina of that layer. Of particular note were extremely fine, varicose immunoreactive fibers which were seen to pass vertically or obliquely through the inner nuclear layer and bifurcate at its outer margin. Some of these fibers were continuous with short segments of immunoreactive, varicose fibers which were observed to run horizontally in the outer plexiform layer. Rare stained cell bodies in the ganglion cell layer with processes entering the inner plexiform layer were visualized, but their significance is uncertain in view of the high background staining of the ganglion cell layer.

These observations are consistent with rat retinal somatostatin being contained within diffuse amacrine cells. Some or all of these somatostatin-reactive cells are interplexiform cells. A cell type in the ganglion cell layer may also contain somatostatin. Recent immunocytochemical studies have localized tyrosine hydroxylase to interplexiform cells of the rat retina (Nguyen-Legos et al., Neuroscience Letters, 27 (1981) 255-259). The possibility of cohabitation of somatostatin and dopamine within the rat retina is therefore being investigated.

234.11 THE ORGANIZATION OF THE GANGLION CELL DENDRITIC GRIDS IN THE RETINA OF Astronotus. Roger P. Zimmerman, Departments of Neurological Sciences and Physiology, Rush University, Chicago, IL 60612.

The inner plexiform layer (IPL) of the retina of the cichlid fish Astronotus ocellatus exhibits two repeating anatomical patterns. The three-dimensional structure of these patterns has been studied using electron microscopy in combination with Golgi, Bodian, and horseradish peroxidase (HRP) labeling techniques.

The radial processes of the Müller glial cells form a roughly square array (nearest neighbor distance of 11.7 $\pm$ 0.2 micrometers, mean $\pm$ S.E.M.) in the plane of the retina.

The other repeating pattern is composed of ganglion cell dendrites, which form two gridworks of fibers that divide the thickness of the IPL into roughly equal thirds. These grids form two square lattices within the plane of the retina with a repeat distance of approximately 12 µm between nodes. The proximal (vitread) grid is rotated 45 degrees with respect to the distal (sclerad) grid.

Retrograde labeling of ganglion cell dendrites with HRP reveals that each grid has a substructure in the radial dimension. The distal grid extends from 20 - 45% of the inner plexiform layer thickness (roughly Cajal's sublamina 2), and the proximal grid extends from 55 - 85% of the IPL (sublamina 4 plus the adjacent halves of sublaminae 3 and 5). Both grids consist of two dense sublaminae rich in ganglion cell dendrites which surround a layer relatively poor in ganglion cell dendrites.

The majority of the individual ganglion cells which contribute dendrites to the grids have cell bodies (12 - 20 µm in diameter) in the ganglion cell layer, and multistratified dendritic arborizations which extend into both grids. In addition, there are large wide-field displaced ganglion cells which participate only in the distal grid.

The synaptic relationships of the ganglion cell dendrites within the grids and the relationship of the dendritic grid to the radial Müller processes will be discussed.

Supported by EY 03189, BRSG grant SO 7RR0547, and grants from Rush University.

234.12 EXPRESSION OF SUBSTANCE P- AND VIP-LIKE IMMUNOREACTIVITY BY RAT RETINAL NEURONS IN CELL CULTURE. M. Fukuda*, H.H. Yeh and D.G. Puro (Spon: H.H. Hess). Laboratory of Vision Research, National Eye Institute, NIH, Bethesda, Maryland 20205.

Both substance P and VIP have been localized by immunohistochemistry to amacrine cells of the vertebrate retina. Despite knowledge of their localization, much remains to be learned about the retinal cells which contain these neuropeptides. Since cell culture provides a potentially useful approach to the study of neuropeptide-containing nerve cells, retinal cells of perinatal rats were maintained in cell culture and examined for immunoreactivity.

Cultures containing dissociated retinal cells were prepared as previously described (Puro et al., 1982). At various times after the plating of the retinal cells, the cultures were initially incubated for 24 hr at room temperature with substance P or VIP antiserum at dilution of 1:500-1:1000. The cultures were then incubated for 1 hr at 37^{o} C with FITC-labeled antiserum diluted 1:100. Cultures were examined using phase contrast and fluorescence microscopy.

Substance P- and VIP-like immunoreactivity was detected within two weeks of culture. Both substance P- and VIP-positive cells had somas of 7 to 10 µm in diameter and could be of a variety of morphological types. Neurons staining for substance P- or VIP-like immunoreactivity were usually in close proximity to non-staining retinal cells. Only a relatively small percent of the neurons in our cultures displayed either substance P- or VIP-like immunoreactivity.

The results suggest that substance P and VIP are present in a number of morphological subtypes of retinal neurons in our cultures. This cell culture system should be useful in further studies of the role of substance P and VIP in the mammalian retina.

234.13 SPECIFIC TYPES OF HORIZONTAL AND GANGLION CELL IN CAT RETINA STAINED BY ANTISERUM RAISED AGAINST ALPHA-MSH. R. Stone, A. Laties and P. Sterling. (Spon: T.L. Davis). Depts. of Anat. & Ophthalmol., Univ. of Penna. Sch. of Med., Phila., PA 19104.

The cat retina contains two morphological forms of horizontal cell and 23 morphological forms of ganglion cell. Each form studied so far has a characteristic cytology, set of connections, and physiological properties, but no characteristic chemical features have been identified. We report here that an antigen identified by its immunoreactivity with antiserum raised against alpha-MSH is present in horizontal and ganglion cells of particular types. Retinas from adult cats fixed by perfusion with 4% paraformaldehyde solution, 0.1 M lysine HCl and 0.01 M Na periodate in 0.1 M phosphate buffer, were sectioned radially and tangentially at 10um on a cryostat. Antibody to alpha-MSH (Immunonuclear) was applied in dilutions 1:250 and visualized by means of FITC fluorescence and by HRP reaction product (avidin-biotin method). One-third of all horizontal cells stained. The neurons had thick dendrites and the appearance in tangential section of starfish; they formed a regular array with an average nearest neighbor distance of 66±14 um. Stained horizontal cells observed in the electron microscope had indented nuclei and clusters of clear vesicles that formed halos around a few smaller, dense-core vesicles. These neurons correspond in form, ctyology and distribution to the type A horizontal cell described by Boycott, Wassle, Kolb, et al. A subpopulation of the largest ganglion cells was also stained. These had radiating dendrites restricted to sublamina a of the inner plexiform layer suggesting that they are alpha (Y)-off ganglion cells. Consistent with this, we observed large axons stained in the optic tract and stained terminal arborizations in the lateral geniculate A-laminae and in the superficial gray layer of the superior colliculus. Some small ganglion cells with various morphologies also were stained. All had dendrites arborizing in sublamina a, suggesting they represent several types of off cell. Staining was not observed when the antiserum had been preincubated with 50um synthetic alpha-MSH. We have observed neuronal staining in the retina of many vertebrate species using this antiserum, but other well-characterized anti-α-MSH antisera have yielded negative histochemical or radioimmunassay results when applied to these retinas (unpublished observations). Whether the antigen identified in the current experiments is actually alpha-MSH or a cross-reacting molecule is uncertain. It does seem clear, however, that the antigen is contained in the A and not the B horizontal cells and in the alpha (Y)-off and not the alpha (Y)-on ganglion cell. This specific chemical feature thus contributes further to the definition of these cells as fundamental types in cat retina.

234.14 MONOCLONAL ANTIBODIES MARK SPECIFIC TYPES OF AMACRINE VARICOSITY IN CAT RETINA. P. Sterling and L.A. Lampson. Dept. of Anatomy, Univ. of Penna. Sch. of Med., Phila., PA 19104.

The neural processes belonging to 56 types of neuron (23 ganglion, 22 amacrine, 10 bipolar, 1 interplexiform) are intermingled in the inner plexiform layer (IPL) of the cat retina. Each process lies within microns of all the other 55 types but makes synaptic contact at specific loci with only a small subset of these. One way to account for this extraordinary specificity is to postulate the presence of synapse-specific "recognition molecules" on neuronal membranes at sites of synaptic contact. Here we describe 3 monoclonal antibodies whose binding in the IPL is restricted to specific populations of amacrine synaptic varicosity. A panel of monoclonal antibodies (MoAbs) was raised against homogenates of adult cat retina and screened, using the PAP technique, against 50um Vibratome sections of cat retina fixed by perfusion with 2% paraformaldehyde-2% glutaraldehyde. Of 41 cultures screened, 19 stained neurons and none stained Muller cells or glia. Many of the MoAbs stained the somas of amacrines, bipolars, and ganglion cells in different proportions. There was no Golgi-like staining of their arborizations in the IPL, such as observed with antibodies to peptides; instead there was intense staining of certain varicose structures in the IPL. The varicosities stained by three different MoAbs were studied by electron microscopy of serial sections. The varicosities were stained in both membrane and cytoplasm and proved to be the synaptic structures of amacrine processes. Ganglion cell dendrites, bipolar axons and the strands interconnecting amacrine varicosities were unstained. In sublamina b of the IPL, which we analyzed in detail, the stained varicosities made reciprocal contact with the rod bipolar axon at about half of the dyads. The AII amacrine process, which is the other member of the dyad, was never stained, nor were the non-reciprocal amacrines presynaptic to the rod bipolar at sites other than the dyad. The reciprocal varicosities belong to two types of GABA-accumulating amacrine (A_{13} and A_{17}). It is probable, since each antibody stained the reciprocal element at only about half the dyads, that each stains the varicosities of only one amacrine type. Whether or not the determinants recognized by these MoAbs belong to "recognition molecules", it does appear that the synaptic membrane of one specific neuron type can be distinguished immunologically in the presence of many others. Supported by NEI EY00828 and NINCDS NS16552.

234.15 GANGLION CELL MORPHOLOGY OBSERVED BY RETROGRADE HRP-FILLING IN FLAT MOUNTED RETINA. F.Scalia and V. Arango*. Dept. of Anatomy and Cell Biology, Downstate Medical Center, Brooklyn, N.Y. 11203.

The axons, dendrites and somata of retinal ganglion cells were selectively impregnated by a HRP-reaction product in flat mounted retinas of the frog, Rana pipiens, following application of the tracer to limited incisions in the intraorbital segment of the optic nerve. The small size of the nerve incisions permit the dendritic morphology of relatively isolated ganglion cells to be examined, and to be correlated with soma size, axon diameter and retinal locus. Preliminary observations indicate the presence of cells resembling the α, β and γ cells of the cat retina by virtue of their dendritic morphology, without reference to size. Most cells have roughly circular dendritic fields, although many α cells show strongly elliptical field contours, and apparent γ cells can be found having nearly linear arborizations. Soma diameters vary from 6-20 μm, and dendritic fields vary from 45-900 μm in the current sample. Further quantitation will be provided. (Supported by NSF grant BNS 79-23788.)

234.16 CELL DIFFERENTIATION IN THE RETINA OF THE SEA LAMPREY, PETROMYZON MARINUS. K. Rubinson and H. Cain.* Dept. Physiol. and Biophysics, NYU Med. Ctr., New York, NY 10016.

Our earlier report ('77) indicated that the central zone of the larval retina was histologically differentiated with disc-bearing outer segments. However, no evidence of a photolabile pigment or of an ERG could be demonstrated until the peripheral retina showed a similar differentiation late in transformation. This report describes that histological development of the peripheral retina using Golgi and toluidine-blue methods.

The youngest lamprey (Group I larvae) have only a narrow rim of peripheral retina surrounding the central zone and this is composed of a dense lamina of neuroblastic cells, each with cytoplasmic extensions to the inner and outer limiting membranes. Group II larvae show the beginning of a cell-sparse lamina between the dense lamina and the vitreal surface and the enlargement of the retinal surface area of the peripheral retina. Ganglion cells can be identified within the cell-sparse lamina and Muller cells within the neuroblastic mass.

In Group III, the cell-sparse lamina extends almost to the rim of the retina with the ganglion cells lying within the inner plexiform layer and vitread to the layer of optic nerve fibers. The cell-dense lamina has separated into a darkly-stained outer portion and a predominantly lightly-stained inner portion. Based upon Golgi impregnations, the inner portion contains Muller cells, amacrine cells, ganglion cells and, in its outer limits, immature horizontal cells. Undifferentiated neurons, corresponding in location to the darkly-staining cells, characterize the outer portion and a lamina within the inner portion.

As the animals enter transformation, the eye enlarges markedly (Stage I of Manion and Stauffer, '70). Although the histological appearance of the peripheral retina is similar to that in Group III, its area also increases markedly while the extent of the central zone is unchanged.

Later transformers and adults differ from the above description in the appearance of photoreceptors with inner and outer segments and an outer plexiform layer. Although the outer segments may be short at first and the retinal histology is similar to that attained by the central zone years before, this development seems to be correlated with the appearance of the ERG and manifestation of a photolabile pigment.

Supported, in part, by NS15252.

234.17 **SIX-HYDROXYDOPAMINE-INDUCED DOPAMINE DEPLETION IN FROG RETINA**
L. Erinoff, M.C. Citron, N. Brecha, D. Rickman*. Neurology Res., Childrens Hospital of Los Angeles, Los Angeles, CA 90054 and CURE, VA Wadsworth Medical Center, Los Angeles, CA 90073.

In order to selectively destroy dopaminergic amacrine cells in the frog retina (Rana pipiens), 6-hydroxydopamine (6-HDA), 100µg in 5µl saline-ascorbate, was injected intravitreally into one eye; vehicle injection into the other eye served as control. After two weeks eyes were excised and ERGs were recorded from an eyecup preparation. Following recording, retinal dopamine (DA) and serotonin (5HT) concentrations were determined by HPLC with electrochemical detection.

DA content of the treated retinas was reduced by 91% (6-HDA treated 1.44±0.51 ng/mg protein, vehicle control 16.06±1.99 ng/mg) while 5HT levels were unchanged (treated 76.12±10.14 ng/mg protein, control 67.44±7.30 ng/mg). The ERG b-wave of the treated retinas showed an increased latency of 49.25±23.7 msec ($p < .025$) relative to the vehicle control.

An additional group of retinas was studied immunohistochemically for both tyrosine hydroxylase-like (TH) and 5HT-like immunoreactivity seven days after 6-HDA treatment. Normal, 6-HDA treated, and vehicle control retinas were fixed in 4% paraformaldehyde in 0.1M phosphate buffer, washed, and processed simultaneously according to standard immunohistochemical procedures. No TH-like immunoreactive staining was observed in retinas treated with 6-HDA, while 5HT-like immunoreactivity remained unchanged. In both normal and vehicle control retinas, the majority of TH-like immunoreactive somata were located in the inner nuclear layer (INL) at the border of the INL and inner plexiform layer (IPL); an occasional somata was also located in the ganglion cell layer. A dense, continuous band of varicose processes was located in lamina 1 of the IPL adjacent to the INL. A second discontinuous band of processes was present in lamina 5 of the IPL. Scattered processes were also present in laminae 2-4 of the IPL. TH-like immunoreactivity was not observed within the ganglion cell axon layer, distal INL, outer plexiform layer, or outer nuclear layer. Serotonin-like immunoreactivity was observed in a seemingly distinct amacrine cell population; 5HT immunoreactive somata were distributed in the INL at the IPL border and their processes were distributed to all laminae of the IPL.

Our results demonstrate biochemically and histochemically that it is possible to deplete dopaminergic amacrine cells selectively in the frog retina. Removal of these cells is correlated with an increased latency in the b-wave of the ERG.

Supported in part by NIH grants EY04711, EY04304, and EY04067.

234.18 NEUROTENSIN CONTAINING AMACRINE CELLS IN THE RETINA OF A TURTLE (PSEUDEMYS SCRIPTA): AN ULTRASTRUCTURAL AND BIOCHEMICAL STUDY.
W.D. Eldred and R.E. Carraway*
Dept. of Biology, Boston University, Boston, MA 02215
Dept. of Physiology, University of Massachusetts Medical School, Worcester, MA 01605

Antisera directed against immunoreactive neurotensin (INT) were used to specifically label two amacrine cell types in the turtle retina, both of which arborized within strata 3 and 4 of the inner plexiform layer. One of these cell types with INT had large elongated cell bodies which gave rise to several long tapering processes. Using peroxidase techniques at the ultrastructural level, the immunoreactivity was primarily confined to 1000 A vesicles, with little diffuse cytoplasmic reaction product. These large neurons received both conventional and ribbon synaptic contacts, and made conventional synaptic contacts containing unlabeled synaptic vesicles (525 A in diameter) onto other cells. The second cell type with INT had smaller rounded cell bodies which gave rise to a few short delicate branching cell processes. The cytoplasmic reaction product in these cells was very intense and obscured much of the intracellular detail. This cell type also received both conventional and ribbon synaptic contacts, and made conventional synaptic contacts containing unlabeled synaptic vesicles (600 A in diameter) onto other cells.

Biochemical studies were done to determine the identity of the INT localized in the ultrastructural studies. Isolated retinas were sonicated in 10 volumes of 0.1 N HCl on ice, and the extracts were examined for the presence of INT using four region-specific antisera. The results indicated the presence of substances (8-10 pMoles/g) resembling the C-terminal region of neurotensin, but differing at the N-terminal portion. During HPLC on micro-Bondapak C18 two major peaks of INT were obtained, one of which chromatographed near the position of turtle neurotensin obtained from the small intestine.

The combination of the ultrastructural and biochemical results suggests that a peptide, which closely resembles neurotensin found in gut, coexists with another neurotransmitter within these amacrine cells.

234.19 NEUROTRANSMITTER LOCALIZATION IN THE SKATE RETINA.
B. Ehinger, A. Bruun* and V.M. Sytsma*. Department of Ophthalmology, University of Lund, Lund, Sweden.

The retina of the skate (Raja clavata, R. radiata, and R. oscellata) was studied by autoradiography following intraocular injections or incubations with (^{3}H)-GABA, (^{3}H)-isoguvacine, (^{3}H)-glycine, (^{3}H)-dopamine or (^{3}H)-5-hydroxytryptamine. Fluorescence immunohistochemistry was also used to demonstrate the endogenous content, accumulation, and retention of 5-hydroxytryptamine.

The (^{3}H)-GABA was taken up by glia, and (^{3}H)-isoguvacine failed to appreciably label any neurons. (^{3}H)-Glycine was accumulated by amacrine cells, possibly of two subtypes. The (^{3}H)-dopamine was taken up by some few amacrine cells. Both autoradiography and immunohistochemistry showed 5-hydroxytryptamine to be efficiently accumulated by two types of cells in the inner nuclear layer: ON bipolar cells and some amacrine cells. The bipolar cells contained far less endogenous 5-hydroxytryptamine than the amacrine cells did.

The results show the localization of presumed glycinergic, dopaminergic and indoleaminergic neurons. They also show that there are two fundamentally distinct types of indoleamine neurons, a bipolar cell type with a low and an amacrine cell type with a high content of 5-hydroxytryptamine.

234.20 CYTOCHEMICAL LOCALISATION OF 5'-NUCLEOTIDASE IN THE RAT RETINA.
G.W. Kreutzberg and S.T. Hussain*. Max Planck Institute for Psychiatry, D-8000 Munich, F.R. Germany.

We have previously described the activity of 5'-nucleotidase (E.C.3.1.3.5.) in the brain to be associated predominantly with plasma membranes of glial cells (Kreutzberg et al., 1978, Brain Res. 158: 247). When studying the distribution of this enzyme in the retina of the rat we similarly found the enzyme to be very prominent on the glial cells of the Müller type. There is, however, an asymmetric distribution of this ecto-enzyme insofar as only those Müller cell processes extending into the external layers show 5'-nucleotidase activity (Kreutzberg and Hussain, 1982, J. Neurocytol. 11: 53). Further studies have revealed activity in the clefts of the complex synapses formed by the rod spherules, the horizontal and the bipolar cell terminals. In this location no glial elements are present. Thus, the enzyme must be of neural origin. Activity is also seen as an ectoenzyme on the axolemma of receptor fibers. In the rod inner segment strong reaction product is located intracellularly. In the rod outer segment the enzyme appears to be located only on the cytoplasmic side of the disc membrane and not intradiscally. Retinal pigment cells are rich in 5'-nucleotidase. Their microvilli accompany the tips of the receptor cells and show enzyme activity in an ecto position. A role for 5'-nucleotidase is possible in the metabolism of guanylate and adenylate nucleotides both of which are important for visual transduction processes.

234.21 ISOLATED, ARTERIALLY PERFUSED HUMAN EYE. M.L. Anderson, R.L. Purple, D. Burkhardt, J. Wirtschafter and T. Kraft. U of Mn. Med. Sch., Depts. of Physiology, Ophthalmology and Psychology.

Preliminary experiments have shown that ERGs recorded from brain dead, potential, multiorgan donors, are almost always indicative of a viable eye, despite absence of blood flow to brain tissue and lack of any brain stem reflexes, as prescribed by the U. of Mn. Dept. of Neurosurgery's definition of clinical brain death. Two of these potential organ donors actually had normal ERG's despite having been clinically brain dead and on a respirator, for more than 3 days.

Necessary approval for harvesting one eye for physiological research from such organ donors has been made through the U. of Mn. Human Subjects Volunteer Committee, the U. of Mn. Hospitals, and the Depts. of Ophthalmology, Neurosurgery, Surgery, and the Multiple Organ Donor Program. A portable perfusion apparatus has been constructed and tested successfully on cat eyes.

Initial results have been obtained from one human eye which was successfully perfused for over 5 hours. Due to other surgical procedures done on the donor, blood pressure had fallen to zero before surgical removal of the eye began. Artificial perfusion with an enriched tissue culture perfusion medium was established through cannulation of the ophthalmic artery approximately 40 minutes after blood pressure had fallen to zero. Initially, only a small a-wave could be recorded. Within 3-4 hours, at a perfusion rate of 4 ml/mn, the scotopic ERG had recovered to normal amplitudes (a-waves, b-waves and b-wave oscillations). These initial results indicate a rather remarkable ability of the eye to recover from prolonged anoxia. They also indicate the potential feasibility for direct research on the human eye.

This study has been supported by the Minnesota Medical Foundation and by the Minnesota Lions Eye Bank and Children's Fund. We thank Jane VanHook and the Multiple Organ Donor Program for their cooperation.

234.22 THE INVOLVEMENT OF CHLORIDE IONS IN HORIZONTAL CELL FUNCTIONING IN FISH RETINA. M.B.A. Djamgoz and P.J. Laming*. Dept of Pure and Applied Biology, Imperial College, London SW7 2BB, UK.

Intracellular measurements of chloride activity in fish and amphibian retinae showed that luminosity type horizontal cells (HC's) contain higher levels of Cl^- than necessary for passive distribution i.e. the chloride equilibrium potential, $E_{Cl} > E_m$, the membrane potential in the dark (Djamgoz and Laming, 1983; Miller and Dacheux, 1983). This raises the possibility that Cl^- are involved at an excitatory synaptic input to HC's, and in the mudpuppy retina, Miller and Dacheux (1983) suggested that Cl^- are indeed the ions responsible for generating the photoreceptor-driven, light-evoked hyperpolarizing responses of HC's. In cyprinid fish retina HC's receive excitatory synaptic inputs from the photoreceptors (PC's) and the interplexiform cells (IC's). Since the latter are known to use dopamine as their transmitter (Dowling and Ehinger, 1975), we tested the possibility that Cl^- are gated by dopamine at the IC → HC synapse.

The intracellular choride activities (a^i_{Cl}'s) and membrane potentials of 41 L_1(H1) type HC's (8 retinae) were measured simultaneously using double-barreled Cl^--sensitive microelectrodes employing the Corning exchanger 477315 in the isolated retinae of a common cyprinid fish, roach, *Rutilus rutilus*. Retinae were specifically not superfused with artificial salines so 'normal' ionic activities could be measured; 10 μM dopamine and 1 mM sodium ascorbate were applied from an atomizer system (Djamgoz, 1983). In control retinae $E_{Cl} - E_m$ had an average value of + 12 ± 2 mV. Following treatment with dopamine, however, HC's depolarized by an average of 20 mV, and the $E_{Cl} - E_m$ difference was reduced to − 0.7 ± 0.3 mV. All values are given as means ± SE's.

Thus, for HC's treated with dopamine, $E_{Cl} \simeq E_m$ thereby suggesting that Cl^- can permeate through dopamine-sensitive channels, presumably at the IC → HC synapse. If so, sodium ions, which are also required for generating light-evoked HC responses in fish retinae (Kaneko and Shimazaki, 1975), are probably involved at the PC → HC synapse.

234.23 WAVELENGTH DEPENDENCE OF RESPONSES AND LIGHT ADAPTATION OF GOLDFISH H1 HORIZONTAL CELLS. R.P. Malchow and S. Yazulla. Department of Neurobiology and Behavior, SUNY Stony Brook, NY 11794.

Anatomical studies reveal that H1 horizontal cells of the goldfish retina contact all three types of cones. Proposed models suggest that H1 cells receive input from red cones and feed back onto red, blue and green cones. Electrophysiological evidence suggests that, while red cones dominate the response of H1 cell, they do not constitute its only input. We wished to study this question in greater detail, and to examine the effects of steady monochromatic backgrounds on the response properties of this cell.

Intracellular recordings were obtained from H1 cells in the isolated retina. Full field 651nm and 501nm stimuli produced responses which had different waveforms at equivalent response amplitudes. Dim 651nm stimuli produced very square responses which returned quickly to the dark adapted resting potentials at light offset. 501nm stimuli resulted in responses which reached a peak, then slowly decayed towards the dark resting potential despite the continued presence of the light. Light offset often resulted in a depolarizing overshoot which took several seconds to return to the dark resting potential. 651nm and 501nm stimuli also produced response vs. intensity (RvI) curves which differed in shape.

RvI curves for dark adapted H1 cells were broad, even when stimuli were short in duration. For .1sec 651nm stimuli, these cells spanned 4.6 log units of intensity in going from 1% to 99% of their maximal response (Vmax). Using a substitution paradigm, light adaptation with steady 651nm backgrounds produced a narrowing of the RvI curves leaving Vmax unaltered: a background of 13.6 log photons/sec.cm^2 resulted in an RvI curve spanning only 2.5 log units of intensity. Backgrounds produced a shift of the RvI curves to the right along the intensity axis. 501nm backgrounds resulted in enhanced responses to .1sec 651nm test flashes, as well as increasing Vmax and narrowing the RvI curves. These effects could be seen even when the 501nm background had small effects on the steady state potential of the cell. The potentiating effect was the same regardless of whether the 651nm test stimulus was presented as a 2mm spot, a 2mm i.d. x 3mm o.d. annulus, or a full field flash. This indicates that the effect of 501nm light is not mediated by the dopaminergic interplexiform cell, since the addition of dopamine reduces the receptive field size of H1 cells.

These data support the contention that H1 horizontal cells have inputs besides red cones and dopaminergic interplexiform cells. This input is unlikely to be due to rods, for the effects of 501nm stimuli begin at an intensity at which the rods saturate.

234.25 A POWER LAW INTENSITY-RESPONSE RELATIONSHIP IN TURTLE CONES. V. Pluvinage* and D.G. Green, Univ. of Michigan, Ann Arbor, MI.

Using eyecup preparations, we recorded intracellularly the voltage response of red cones in Pseudemys scripta turtle retinae to a slit (width=5 um) or a spot (diam.=7 um) of light (λ=650 nm) flashed (dur.=20 msec) at different positions in the receptive field. The intensities used ranged from 10^4 to 10^7 photons/um^2·sec.

In a first experiment, the responses due to two small stimuli, one centered on the cone and the other one 30 um away, were analyzed using a method of excitation summation similar to the one first introduced by Easter in 1968. First, the intensity of the centered stimulus was adjusted so that it gave the same response amplitude as the displaced stimulus. Then they were flashed together, and the amplitude of the combined response was measured. The intensity of the centered stimulus was increased so that the central response was equal in amplitude to the combined response. This process was repeated for different intensities of the displaced spot to determine the intensity coding for the central stimulus. This was a power function with an exponent 0.48 (0.46 to 0.5, N=5) over a range of 2 log units. In a second experiment, we measured the receptive field in two different ways. For each position of the slit in the receptive field, we determined 1) the response amplitude to a fixed intensity and 2) the light intensity needed to elicit a fixed response amplitude. Both response amplitude and sensitivity decayed exponentially with distance from the impaled cone. Surprisingly, the two space constants were very different (29 um and 15.1 um respectively, N=4). The average ratio was 1.92. For one cone, the receptive field was asymmetrical: on one side the response space constant was 37 um, on the other 24 um. The sensitivity space constants were 18.5 um and 12.6 um respectively, so that, on each side, their ratio was close to 2:1. These and other experiments are consistent with a response of the form: $V(x,I) = c \cdot I^{\frac{1}{2}} \cdot \exp(-x/L)$, where c is a constant, I is the light intensity, x is distance and L is the response space constant.

This finding may be related to experiments on ganglion cells in goldfish and cat that suggested the existence of a power law relation with an exponent of 0.5 between light intensity and some early stage of signal processing in the retina (Easter, 1968; Levine and Abramov, 1975; Enroth-Cugell & Harding, 1980). We now have evidence that such a relationship exists in a coupled cone in an intact retina. We will discuss a possible explanation of this result.

234.26 AN ON-OFF AMACRINE CELL TYPE IN THE CAT RETINA. Helga Kolb and Ralph Nelson*. Department of Physiology, University of Utah School of Medicine, Salt Lake City, Utah 84108, and Laboratory of Vision Research, National Eye Institute, Bethesda, Maryland 20205.

Intracellular recording and staining with horseradish peroxidase (HRP) has revealed a new amacrine response type in the cat retina. Although common in lower vertebrate retinas, the ON-OFF response type is rarely encountered in the cat retina, where most amacrine cells give either a sustained depolarization or a sustained hyperpolarization (A13, A17, A4, A6). Transient ON (AII) and transient OFF (A8) types have also been observed. It was, thus, of extreme interest to discover an amacrine cell in this species that responded to a broad-field stimulus with a transient depolarization at both light onset and offset.

In whole-mount view, the HRP injected cell exhibited the morphology of the A19 cell described in our Golgi study (Kolb et al., 1981). The cell has a large cell body (12 x 14 um) and a large monostratified dendritic tree covering an area of 600 x 750 um. Two major dendrites leave the cell body, descend to S2 of the IPL and there arborize into a radiate dendritic tree of linear, sparsely-branching dendrites. The major dendrites are of large caliber, intermittently varicose or beaded and bear a few small spines and appendages. Electron microscopy of the HRP stained example indicates that the major input to the linear dendrites is from amacrine cells while amacrine and cone bipolar cell input occurs onto the spines and appendages. In cross section the larger primary dendrites are seen to be filled with neurotubules thereby giving A19 cells a characteristic and recognisable cytoarchitecture within the IPL. In fact neurotubule-filled profiles of similar dimensions and synaptic characteristics have been seen to make gap junctions with like amacrine profiles. These in turn are presynaptic to another amacrine cell type, A17, known to be involved in the rod system of the cat retina.

In lower vertebrate retinas (e.g. fish and amphibia) it has been suggested that ON-OFF amacrines are bistratified and aquire their ON and OFF input from the differently signed responses of bipolar cells branching in the two sublaminae of the IPL. The ON-OFF A19 amacrine of the cat retina receives input primarily from other amacrines. The only bipolar input is from cone bipolars of sublamina a known to be OFF center. Based on our present knowledge then, amacrine cells will have to be invoked to explain the ON-OFF response of the A19 cell of the cat retina.

234.27 SPATIAL DISTRIBUTION OF INPUT FROM DEPOLARIZING CONE BIPOLARS TO DENDRITIC TREE OF ON-CENTER ALPHA GANGLION CELL M. A. Freed and P. Sterling. Dept. of Anat., Sch. of Med., U. of Pa., Phila.,Pa., 19104

Excitation at light on is conveyed to the the on-center beta (X) ganglion cell of the cat retina by bipolars of type CBb_1. Type CBb_1 is apparently depolarizing and excitatory with a narrow field and an antagonistic surround. Each of three CBb_1s contacts the beta cell at least 50 times, ending on dendrites of all orders spread widely over the dendritic tree. The distribution of CBb_1 inputs to the on-center alpha (Y) ganglion cell showed a pattern that was strikingly different.

An on-center alpha cell within 2 degrees of the center of the area centralis was filled by retrograde transport of HRP injected into the optic disk. The cell, stained in a Golgi-like manner by reaction with DAB, was cut into a series of 420 tangential sections each 90 nm thick. We have reconstructed about 10% of the dendritic tree, an area 30 um wide that extended 60 um from the soma. Included were two primary dendrites and all daughter branches out to the sixth order.

Ten CBb_1s were found in the area studied. These formed a regular array, with an average nearest neighbor distance between axonal stalks of 10±1 um. The bipolars made an average of four contacts to the alpha cell dendritic shafts and to thin (.3 um) spines, which often invaginated the bipolar axon terminal.

The contacts from each CBb_1 were localized on the alpha dendrites to one side of the nearest branch point, sometimes contacting two daughter branches that resulted from a bifurcation. In such cases the parent dendrite was not contacted by the same bipolar. Thus, contacts from each CBb_1 were restricted to a single order of dendrite. Contacts from one CBb_1 were never interpolated with those of another.

Two other types of cone bipolar contacted the alpha cell, mostly on proximal dendrites. One possessed large diameter (3 um) dark varicosities in stratum 5. The other type had moderately dark, smaller swellings in stratum 4. Five rod bipolars contributed one contact each; these were on spines and dendritic shafts of the first to the fourth order.

We extrapolate from the area studied that the whole alpha cell receives input from about 100 cone bipolars of type CBb_1, each contributing about four inputs at a distinct electrotonic distance from the soma. The on alpha (Y) cell dendritic field is known to be cospatial with the on center of the receptive field. Apparently, excitation evoked by stimulation of the receptive field center comes from an array of CBb_1 bipolars, arranged such that excitation at progressively more peripheral loci in the receptive field is from bipolars at progressively greater electrotonic distances from the soma.

234.28 CHANGES IN THE RECEPTIVE FIELD PROPERTIES OF GANGLION CELLS IN THE RABBIT RETINA WITH DOPAMINE ANTAGONISTS. R. J. Jensen* and N. W. Daw (SPON: Y. Fukami). Dept. of Physiology and Biophysics, Washington Univ. Sch. of Med., St. Louis, MO 63110.

Much evidence has accumulated implicating dopamine as a neurotransmitter in the retina. Very little is known however of the functional role of dopamine in visual processing, particularly in the mammalian retina. We decided therefore to investigate the effects of dopamine antagonists on the receptive field properties of retinal ganglion cells in the intact, anesthetized rabbit. Extracellular recordings were taken of ganglion cell responses to spots and annuli of light before, during and after drug infusion of a dopamine antagonist in the arterial system supplying the eye.

Dopamine antagonists haloperidol, fluphenazine, and cis(Z)-flupenthixol were used and found to produce similar changes in the receptive field properties of ganglion cells. All OFF-center brisk cells showed reduced spontaneous activity and reduced surround ON responses upon infusion of a dopamine antagonist. The drug effect on ON-center brisk cells depended upon the specific cell type. ON-center brisk-sustained cells showed a marked increase in spontaneous activity and a change in the center-surround balance in favor of the surround, whereas ON-center brisk-transient cells showed little change in spontaneous activity and a change in the center-surround balance in favor of the center. ON-OFF directionally selective cells showed reduced ON responses to spots of light and reduced leading-edge responses to moving bars of light. In addition, the dopamine antagonists delayed ON or OFF light-evoked responses of ganglion cells frequently by tens of milliseconds. Recovery from the drug effects took 1-3 hours.

In addition to D-1 (adenylate cyclase linked) receptors, the rabbit retina appears to have D-2 receptors (Dubocovich, M. L. and Weiner, N., J. Pharmacol. Exp. Ther., 219:701, 1981). The effects described above appear to be due to blockage of D-1 receptors rather than D-2 receptors since neither metoclopramide nor S-sulpiride, two specific D-2 antagonists, had much effect.

Supported by NIH Grants EY07057 and EY00053.

234.29 DISTRIBUTION OF GANGLION CELLS IN THE RETINA OF THE THIRTEEN-LINED GROUND SQUIRREL. A. Flores and E. Kicliter. Lab. of Neurobiology and Dept. of Anatomy, Univ. of Puerto Rico Sch. of Med., San Juan, PR 00901.

The distribution of retinal ganglion cells of the thirteen-lined ground squirrel (Spermophilus tridecemlineatus) was studied in Nissl-stained and horseradish peroxidase-labeled wholemount preparations (Stone, The Wholemount Handbook, 1981; de Olmos and Heimer, Neurosci. Lett. 6: 107-114, 1977). Ganglion cells were measured and counted from camera lucida drawings. Maps of the retinas showing isodensity contours of ganglion cell distribution were prepared. The overall distribution of ganglion cells included a visual streak below the linear optic nerve head and a preponderance of cells in the inferior retina. Ganglion cell densities ranged from 10,000 cells/mm^2 in the visual streak to 2,000 cells/mm^2 in the periphery of the retina.

Frequency/cell size histograms were made for retinas of six animals. The distribution of ganglion cells according to soma size was studied in various regions of the retinas. Ganglion cells ranged in size from 6 to 20 um in diameter. The average ganglion cell soma size increased with eccentricity from the visual streak and large cells were more numerous toward the retinal periphery. Medium-sized (10-14 um diameter) cells were present throughout the retina and together with the small cells were abundant in the visual streak.

Approximately 80% of the cells labeled after injection of horseradish peroxidase into the optic nerve correspond to the cells defined as ganglion cells in the Nissl preparations. The 20% remaining are likely displaced ganglion cells which were not classified as such in the Nissl preparations. These cells were more numerous in the periphery of the retina.

Our findings indicate that the inferior retina, corresponding to the superior visual field, is most critical for vision in this species. Further, as in most mammals, small and medium-sized ganglion cells are abundant in retinal areas associated with acute vision.

Supported, in part, by USPHS Grant NS-07464.

234.30 RETINAL GLIAL CELL ENDFEET HAVE HIGH K^+ CONDUCTANCE. Eric A. Newman . Eye Research Inst. of Retina Fdn., Boston, MA 02114.

Previous investigations have suggested that the endfoot process of retinal Müller cells has high K^+ conductance. I have tested this proposal in two ways, by measuring Müller cell impedance in retinal slices and by monitoring Müller cell depolarization evoked by local extracellular ejection of K^+ in dissociated Müller cells. Recordings were made from cells of the frog, Rana pipiens and the turtle, Pseudemys scripta . Müller cell impedance was measured by passing lnA current pulses through an intracellular electrode and a bridge circuit in a perfused retinal slice preparation. When cells were impaled in their cell bodies (inner nuclear layer) the measured resistance was 8.4 +/- 4.9 MΩ . On the other hand, when cells were penetrated in their endfeet (optic fiber layer), the resistance was 4.9 +/- 3.9 MΩ . This result demonstrates that the Müller cell has a significant cytoplasmic resistance (the cell is not isopotential) and that the conductance of the endfoot region is at least twice the conductance of the cell body region. (The measured conductance ratio between the two regions is less than the actual ratio due to resistive coupling between the regions.)

Local Müller cell membrane K^+ conductance was assessed by recording intracellular responses to local increases in extracellular K^+ concentration ($[K^+]_o$) produced by pressure ejecting a KCl solution from an extracellular pipette. Responses were recorded from the cell bodies of single, enzymatically dissociated cells. $[K^+]_o$ increases near the endfoot region of the cell elicited significantly greater depolarization than did increases near other regions of the cell. Depolarizations evoked by a 10 ms pressure pulse of 117 mM KCl typically had amplitudes of 20 to 30 mV for ejections near the endfoot and 1 to 5 mV for ejections near the stalk, cell body and distal end of the cell. Response latencies and waveforms were similar for K^+ ejections near all cell regions. These results are most easily explained by postulating that the K^+ conductance of the Müller cell endfoot is significantly greater than the conductance of other regions of the cell.

A high endfoot membrane conductance would have an important influence on the magnitude and path followed by currents generated by Müller cell depolarization (as may occur in electroretinogram generation). This membrane specialization might also function as part of a passive glial cell $[K^+]_o$ buffering system; K^+ flowing into Müller cells in regions of increased $[K^+]_o$ would exit through the high conductance endfoot process of these cells, directly into the vitreous. (Supported by NIH grant EY04077.)

234.31 RESPONSE OF RETINAL GANGLION CELLS TO BRIEF LASER EXPOSURES. Randolph D. Glickman, William R. Elliott III*, and David Schafer*, Life Sciences Division, Technology Incorporated, San Antonio, TX.

Brief (<1 msec) flashes of light result in longer dark adaptation times and longer-persisting afterimages than would be predicted from the amount of visual pigment bleached (Rushton, W.A.H. & H.D. Baker, Nature, 200:421, 1963), possibly due to the production of desensitizing photoproducts. Because Q-switched lasers produce light pulses of pico- or nanosecond duration, the effect of these emissions on the retina might be to produce even longer-lasting afterimages. Ganglion cell activity should reflect the presence of afterimages, thereby providing a physiological measure of the degree of flashblindness induced by the laser exposure. In addition the effects of beam size and light scatter within the eye could be evaluated.

Ganglion cell recordings from feline and rhesus monkey retinae were made during exposure of the receptive fields of these cells to laser light. Pulses of light of 530 nm wavelength and 20 nsec duration were obtained from the doubled output of a Q-switched, Nd-glass laser and presented along with white or colored light from a xenon-arc lamp in Maxwellian view to the animal. The intensity of the exposures was adjusted to 0.1 to 1.0 times the Maximum Permissible Exposure (ANSI standard Z136.1, 1980). In the cat retina, a single pulse of laser light, ranging in diameter at the retina from 0.25 to 2.0 deg of visual angle, elicited in ganglion cells a characteristic response: first a brief discharge at the time of exposure, followed by a silent period lasting less than 0.5 sec, and then a maintained after-discharge of spikes at a relatively constant frequency. This after-discharge lasted up to 5 min, although it was briefer in cells more than 10 deg from the area centralis in the cat, possibly due to the Stiles-Crawford effect. During the after-discharge, the threshold for light sensitivity was elevated by up to 4 log units, with recovery completed by the end of the after-discharge.

Similar patterns of response were observed in monkey retinal ganglion cells, except that recovery was faster and was generally complete in about 30 sec. Immediately following the laser exposure, the visual threshold was elevated by up to 2 log units. Recovery of sensitivity occurred shortly before the episode of spontaneous firing ended. These effects were observed even when the laser beam fell 3-5 deg from the receptive field. These single unit responses to laser exposures have similarities to attributes of psychophysical flashblindness, i.e. the persistence of an afterimage and the elevation of the visual threshold.

234.32 PROTECTIVE EFFECT OF TAURINE ON PEROXIDATION REACTIONS IN PHOTORECEPTORS. (SPON A. Feria) Herminia Pasantes-Morales and Carlos Cruz. Centro de Investigaciones en Fisiología Celular, Universidad Nacional Autónoma de México.

Lipid peroxidation has been implicated in the destruction of rod outer segments (ROS) in light-damaged retinas. Experimental models of retinal degeneration produced by intravitreal injection of ferrous sulfate have shown a relationship between lipid peroxidation and alterations in the membranous structure of frog ROS in vivo (Wiegand et al., ARVO Abst. p. 183).

Disturbances produced by constant illumination or by exposure to ferrous sulfate on ROS structure may be reproduced in vitro in isolated frog ROS. In these two experimental models we observed a characteristic alteration of the ordered membranous structure of ROS, accompanied by an increase in malondialdehyde formation. ROS appear swollen, enlarged, showing distention of discs and vesiculation.

The presence of the sulfonic amino acid taurine, in the incubation medium protects against the disturbing effects of light or ferrous sulfate. Taurine protective action is dose-dependent, being maximal at 25 mM. The physiological concentration of taurine inside photoreceptors is about 20-40 mM. For protection of ferrous sulfate-induced damage, zinc should be also present in the incubation medium, although zinc has no protective action by itself. Taurine has no effect on malondialdehyde formation suggesting that its protective effect is not related to a direct action preventing lipid peroxidation. A suggested mechanism for taurine protective action is an effect on ion permeability on ROS membranes. Both, illumination and ferrous sulfate induced damage require sodium chloride and bicarbonate to exert their disturbing action. Therefore, an alteration of membrane permeability allowing ion entry accompanied by water, may be a secondary effect of lipid peroxidation, leading to swelling and structure disruption. Taurine effects on membrane permeability have been described in excitable tissues as well as on isolated ROS. Therefore, taurine protective action may be related to a restoration of membrane permeability altered by peroxidative conditions.

234.33 MONENSIN, A CARBOXYLIC IONOPHORE, STIMULATES CALCIUM UPTAKE IN THE RAT RETINA IN THE PRESENCE OF ATP AND ATP PLUS TAURINE. J.B. Lombardini. Department of Pharmacology, Texas Tech University Health Sciences Center, Lubbock, TX. 79430.

It has been demonstrated by biochemical and autoradiographic techniques that taurine is the most abundant amino acid in the retina, attaining concentrations as high as 80 mM in the photoreceptor layer (Orr et al., J. Neurochem. 26: 609-611, 1976). However, the precise function of taurine in the retina is unknown, although it has been postulated that taurine has a role as an inhibitory neurotransmitter or as a modulator in the retina. Recent information suggests that taurine has an effect on calcium uptake in excitable tissues. It has been demonstrated that taurine produces an increase in ATP-dependent calcium uptake in retinal preparations either positively or negatively depending upon the calcium ion concentration (Lopez-Colome and Pasantes-Morales, Exp. Eye Res., 32: 771-780, 1981).

Previously it has been reported from our laboratory that at low calcium ion concentration (10 μM) valinomycin, a neutral ionophore, inhibits the taurine-stimulated ATP-dependent calcium ion uptake in rat retinal membrane preparations (Lombardini, Invest. Ophthalmol. Vis. Sci. 24: 161, 1983). The inhibitory effect of valinomycin on calcium ion uptake was observed only when potassium ions were present in the incubation media; this was an expected result since valinomycin is considered to be a potassium ionophore with an equilibrium selectivity for potassium ions over sodium ions of approximately 10,000:1.

Present studies have demonstrated that monensin (MNS), a carboxylic ionophore which has an equilibrium selectivity ratio of 10:1 for sodium ions over potassium ions, stimulated the uptake of calcium ions by rat retinal membrane preparations. Replacement of the sodium salts in the buffer with potassium salts did not lessen the stimulatory effects of monensin.

Condition	Control	ATP (1.2 mM)	ATP (1.2 mM) + Taurine (20 mM)
Na^+ buffer	0.10 ± 0.02	0.50 ± 0.14	2.03 ± 0.36
Na^+ buffer + MNS	0.21 ± 0.08	1.47 ± 0.26[a]	3.16 ± 0.35[a]
K^+ buffer	0.23 ± 0.08	0.91 ± 0.11	1.85 ± 0.14
K^+ buffer + MNS	0.35 ± 0.11	1.93 ± 0.45[a]	4.09 ± 0.80[a]

Na^+ buffer = bicarbonate buffer containing sodium salts.
K^+ buffer = bicarbonate buffer containing potassium salts.
N = 4; [a] $P < 0.05$, Duncan's multiple-range test.

234.34 EFFECTS OF GUANIDINOETHYL SULFONATE (GES), A TAURINE DEPLETOR IN THE ADULT RAT RETINA. Norma Lake and Sue Cocker*, Departments of Physiology and Opthalmology, McGill University, Montréal, Canada.

The rat retina contains high levels of the sulfur-containing amino acid, taurine, which may be rapidly depleted by in vivo treatment with a taurine analogue, GES, (Lake, Life Sci. 1981, 29: 445). The present experiments indicate that GES is an antagonist of high affinity taurine uptake in the isolated retina in vitro. Taurine concentration was 10 μM, and a range of GES concentrations gave the following inhibitions of uptake:

GES conc'n (μM)	Uptake (%control)	n	t-test
125	94	16	n.s.
500	61	16	p<.001
1000	49	16	p<.001

Extracellular space and binding corrections were estimated using labelled mannitol or 3°C incubations. In addition, the presence of GES did not accelerate the efflux of previously accumulated taurine. The biosynthetic capacity for taurine of the retina is low as estimated from enzymic activities. Thus it would appear that the taurine-depleting effects of GES observed in vivo arise mainly due to antagonism of taurine transport across the blood-retinal barrier.

Electroretinographic studies (ERG's) were carried out on male rats (Sprague Dawley, 260g at start) who were recorded for several weeks to establish control values before being placed on the GES treatment (1% in drinking water). Analyses of averaged potentials to full field white or coloured flash stimuli over a range of intensities were made to determine a and b wave latencies, implicit times and amplitudes, and the relationship between these quantities and stimulus intensity. Treatment with GES led to significant changes in 4 weeks: b wave amplitudes decreased by 21-42% and the slope of b wave amplitude versus intensity decreased by 31-52% compared to control. These effects were partially reversible (amplitudes recovered to 85-96% of control) by 3 weeks after discontinuing GES treatment. These studies indicate the functional importance of taurine in retinal activity.

234.35 **EFFECTS OF SOME NEUROTRANSMITTER CANDIDATES ON THE RESPONSES OF SKATE (RAJA ERINACEA) GANGLION CELLS.** **J. Cohen. Dept. of Ophthalmology, New York Univ. Med. Ctr., New York, 10016.**

Immunocytochemical studies (Brunken, Karten and Witkovsky, 1983) have demonstrated the presence of the neurotransmitters GABA and serotonin in the retina of the skate Raja erinacea. In addition we will present autoradiographic evidence for the presence of glycine-accumulating cells. We therefore wanted to determine the physiological action of these transmitter candidates on the responses of ganglion cells in the retina of the skate.

Extracellular recordings were made from the dark-adapted, superfused eyecup preparation using platinum-iridum electrodes. The majority of cells recorded from was of the ON-center variety. The action of glycine, in doses as low as 500 μm, was to inhibit the light-evoked responses. This action was blocked by addition of 100 μm strychnine to the glycine-containing superfusate. Those cells that were inhibited by glycine were not affected by GABA. However, GABA, in doses as low as 500 μm inhibited the on discharge of other ON-center ganglion cells which in turn were not affected by glycine. Area-sensitivity curves were determined for all these cells by finding a threshold response to spots of increasing diameter. The resulting curves could be described by a power function with slopes ranging from 1.43 to 1.82. The integrating area for the cells inhibited by glycine was smaller than for those affected by GABA. Preliminary data suggest that serotonin had an excitatory action on ganglion cell responses.

234.36 CONTROL OF DARK-INDUCED RELEASE OF ^{3}H-GABA FROM GOLDFISH RETINAL HORIZONTAL CELLS. S. Yazulla and K. Studholme*. Dept. of Neurobiology and Behavior, S.U.N.Y. Stony Brook, NY 11794.

H1 horizontal cells of goldfish retina probably are GABAergic. They receive synaptic inputs from red cone photoreceptors which may use glutamate or aspartate as their transmitter, and from dopaminergic interplexiform cells (DA-IPC). H1 cells are synaptically excited by red cones in the dark and should release GABA in this condition. DA-IPCs appear to be inhibitory since the application of dopamine reduces the receptive field size of H1 cells. D-aspartate has been found to potentiate the depolarizing action of L-glutamate on H1 cells, presumably by blocking the uptake of L-glutamate. If D-aspartate were to block the uptake of the red cone transmitter, then H1 cell excitation should be enhanced resulting in increased and hopefully detectable ^{3}H-GABA release. This study was designed to detect release of ^{3}H-GABA from H1 cells by a physiological stimulus (darkness) in order to obtain information regarding the identity of the red cone transmitter and on the action of DA-IPCs on the synaptic release of GABA by H1 cells.

The release of ^{3}H-GABA was studied by biochemical analysis of perfused isolated retinas. Retinas were isolated from goldfish which were light adapted in very dim room light for 2 hrs. Retinas were incubated in dim red light for 20 min in 0.72 μM ^{3}H-GABA, placed in a perfusion chamber (flow rate-1 ml/min), rinsed for 30 min in dim red light and subjected to darkness under a variety of conditions. Radioactivity in the perfusate was determined by liquid scintillation spectroscopy. The findings are: 1. both L-glutamate and L-aspartate cause a dose-dependent release of ^{3}H-GABA from H1 cells which is independent of extracellular calcium, 2. inclusion of 3.2 mM D-aspartate in the perfusion medium potentiates the effect of L-glutamate and totally inhibits L-aspartate, 3. retinas perfused in the standard Ringer without D-aspartate do not show increased ^{3}H-GABA efflux when placed in the dark, 4. when 3.2 mM D-aspartate is included in the perfusion medium, there is significant dark-induced ^{3}H-GABA release at a rate of 0.65 nmoles [3-H] GABA/retina/min. This is only about 10% of the release rate induced by 1 mM L-glutamate, 5. 100 μM dopamine reversibly inhibits the dark-induced release of ^{3}H-GABA. These results show that release of ^{3}H-GABA from H1 cells can be detected under physiological conditions strongly supporting the hypothesis that H1 cells are GABAergic and, in addition, are subject to antagonistic inputs from red cones and DA-IPCs. Furthermore, since D-aspartate potentiates ^{3}H-GABA release evoked by L-glutamate and inhibits L-aspartate, and, is required for the detection of dark-induced release of ^{3}H-GABA, the transmitter for red cones more likely is L-glutamate rather than L-aspartate.

234.37 KAINIC ACID STIMULATES THE RELEASE OF ENDOGENOUS AMINO ACIDS FROM CHICK RETINA IN VITRO. P. Campochiaro*, J.W. Ferkany and J.T. Coyle. Depts. of Opthalmology, Psychiatry, Neuroscience, Pharmacology, Div. of Child Psychiatry. Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

The spontaneous and evoked release of amino acids from isolated chick retinas was studied by means of a sensitive precolumn derivitization HPLC technique. Retinas were dissected from chick eyes, placed in perfusion chambers, and superfused at 0.5 ml/min with Krebs bicarbonate buffer bubbled with O_2:CO_2(95:5) and maintained at 37°C. After one hour perfusion, spontaneous release of taurine (Tau), glycine (Gly) and glutamine (Gln) were found to be > ten-fold greater than that of aspartate (Asp), glutamate (Glu) and GABA. Increasing concentrations of KCl substituted for NaCl caused a dose-dependent release of all six amino acids although maximal response for Gln was only 23±4% (N=6;p<0.05). The EC_{50} values for release of Tau (+235±25%), Gly (+70±8%) and Glu (+50±8%) were approximately 30 mM KCl whereas the EC_{50} for GABA release (+215±40%) was 50 mM KCl. Notably, whereas the KCl-evoked release of Glu, Gly and GABA peaked within 4 min, the KCl-release of Tau was gradual and peaked 8-12 min after stimulus onset. Ca^{++}-free buffer containing 2mM EGTA inhibited 30 mM KCl evoked release of Glu, GABA and Gly by >90% whereas Tau release was inhibited by only 55±5% and Asp by 67±7%.

Kainic acid (KA;100 uM) was quite effective in evoking release of Tau (+477±130%), Gly (624±58%) and GABA (1258±240%) but not Gln, Asp or Glu in contrast to the effects of KA on perfused brain slices (Ferkany et al, Nature 298:757,1982). The EC_{50} of KA was 30 uM for Gly, 36 uM for GABA and 50 uM for Tau. Intravitreal injection of 125 nmoles of KA results in a severe loss of cells in the inner nuclear layer but spares the outer nuclear layer and the ganglion cells. This lesion reduced the receptor specific binding of [^{3}H]-KA(25nM) to retinal homogenates to 29±4% of control (N=6;p<0.01). The KA lesion markedly decreased 100 uM KA evoked release of Gly (-86±1%), Tau (-99±4%) and GABA (-97±1%). The 30 mM KCl evoked release from KA lesioned retina was also markedly reduced for Gly (-85±4%) and GABA (-97±3%); however, the release of Tau (120±10%) and Glu (67±15%) did not differ significantly from that of intact retinas.

The results are consistent with a direct, receptor mediated release of Gly and GABA by KA; in contrast, the effects of KA on release of Tau appear to be indirect and may involve a different pool than that evoked by 30 mM KCl. (Supported by a fellowship from Fight for Sight of New York and USPHS grant NS 13584).

235.1 MORPHOLOGICAL DIFFERENCES IN RETINAL GANGLION CELLS PROJECTING TO DIFFERENT LAYERS OF THE DORSAL LATERAL GENICULATE NUCLEUS IN THE TREE SHREW. E. J. DeBruyn* and V. A. Casagrande (SPON: J. K. Brunso-Bechtold). Depts. of Anatomy and Psychology, Vanderbilt Univ., Nashville, TN 37232.

Previous studies of the dorsal lateral geniculate nucleus (LGN) of the tree shrew have shown that this nucleus contains 6 well defined layers, two of which receive uncrossed retinal input (1,5) and four of which receive crossed input (2,3,4 and 6). These layers can also be distinguished on the basis of cytology, cortical projections and physiology. Layers 1 and 2 have medium and large spindle shaped cells that project to the upper tier of layer IV of striate cortex; layers 4 and 5 contain medium and large sized darkly staining cells that project to the lower tier of layer IV; and layers 3 and 6 contain smaller, pale staining cells that project to the supragranular cortical layers. Physiological studies have shown that layers 1 and 2 contain ON center cells, layers 4 and 5 contain OFF-center cells and layers 3 and 6 contain OFF-center (layer 3) or ON-OFF-center (layer 6) cells.

In light of the above, we were interested to see if retinal ganglion cells (RGCs) projecting to different layers of the LGN formed anatomically distinct populations. Iontophoretic injections of HRP were made into single or multiple laminae of the LGN in 10 tree shrews using evoked potentials to determine laminar boundaries. Following a two day survival, the animals were perfused and the retinae were processed with Hanker-Yates reagent, whole mounted and stained with cresyl violet. The areas of labeled and unlabeled RGC somas were measured at 1000X and the level of dendritic ramification within the inner plexiform layer (IPL) was noted for well-filled cells. Results show the following: RGCs projecting to layer 3 have small (1st-35th %tile of local cell sizes) somas, while those projecting to layer 6 are primarily small with a few medium (36th-70th %tile) and large (71st-99th %tile) cells also. RGCs projecting to layers 1,2,4 and 5 are medium and large sized and can be further distinguished in terms of the level of dendritic ramification within the IPL. Those projecting to layers 1 and 2 ramify in the superficial IPL and those projecting to layers 4 and 5 ramify in the deep part of this layer. Taken together with earlier studies, these results suggest that the RGCs projecting to different LGN laminae are morphologica ly distinct and that the information they carry ends in different cortical sublaminae Further, it suggests that ON and OFF center information reaches cortex via separate channels in this species Support by EY01778; 1K04-EY00223; MH 08472; RR 05424

235.2 PROJECTIONS OF THE INTERNAL OPTIC TRACT: RETINAL PROJECTIONS WHICH SURVIVE SUPERFICIAL THALAMIC LESIONS IN HAMSTERS. G.E.Schneider and S.Jhaveri* (SPON: J.Delatizky). Department of Psychology & Research Lab. of Electronics, Massachusetts Institute of Technology, Cambridge, MA 02139.

Retinal ganglion cell axons cross at the chiasm and form a broad ribbon as they traverse the external surface of the cerebral peduncle. Many of these axons remain on the thalamic surface as they course over the lateral geniculate body (LGB) and continue caudally to the superior colliculus (SC). Collaterals from these surface axons dive into the LGB and terminate along characteristic lines of projection. However, a fair number of retinofugal axons leave the surface optic tract and penetrate the ventral nucleus of the LGB, immediately dorsal to the peduncle. These axons, running parallel to the superficial fibers, travel in tight fascicles through the LGB, the lateral-posterior nucleus (LP) and the pretectum forming what we will refer to as the internal optic tract (IOT).

To study the projections of the IOT in adult Syrian hamsters, the dorsal thalamus was exposed and shallow knife cuts were made across the optic tract, confined in some cases to the outer 1/5 of the LGB. After survival periods of up to 4 weeks, the contralateral eye was injected with a solution of WGA-HRP and/or ^{3}H-amino acids. Animals were sacrificed after a further survival of 24-36 hours and the brains treated according to the TMB procedure for visualization of the transported enzyme; appropriate cases were prepared for standard autoradiography.

IOT axons can be traced through the deeper portions of LGB and LP, with little evidence of dense arborization until they reach the pretectal olivary nucleus, where they show heavy termination even when only the deepest IOT axons are spared by the initial lesion. The nucleus of the optic tract is, at best, only sparsely innervated by the IOT, whereas the posterior pretectal nucleus receives axons from its more superficial portions. In the rostral SC, the IOT does not contribute to the dense fascicles of the stratum opticum; it appears to retain its deeper-lying position. Caudally this separation becomes obscured. In the superficial gray layer (SGS), the deepest axons of the IOT appear not to terminate near the tectal borders, in the representation of the peripheral retina. Even when most of the IOT is spared, the central portions of the SGS are more densely labelled than the margins The IOT axons also appear to terminate in the intermediate gray layer along their trajectories.

These findings have implications for studies of optic tract development and plasticity, as well as for studies of visual system function.

235.3 HUMAN PATTERN EVOKED RETINAL CORTICAL AND RESPONSE: EFFECTS OF SPATIAL AND TEMPORAL ADAPTATION, J. Vernon Odom. Department of Ophthalmology, West Virginia University, Morgantown, WV 26506.

If the optic nerves of humans and cats are severed unilaterally and the eye on the ipsilaterial side is stimulated with pattern reversal or luminance increments, the response to luminance remains normal while the response to pattern is extinguished suggesting that retinal potentials elicited by pattern reversal stimulation originate in retinal ganglion cells (Maffei and Fiorentini, 1981; Dawson et al, 1982). Use of pattern evoked retinal responses in humans appears then to represent a means of examining the population behavior of human retinal ganglion cells Comparisons of retinal and cortical response may aid our understanding the retinal role in determining cortical responses.

In three experiments the effects of adaptation on retinal and cortical responses were examined. Sinusoidal gratings of 30% contrast were alternated at 4 Hz (8 alt/sec). In the first experiment subjects were adapted for two minutes either to an unpatterned field of the same mean luminance as the test field or a pattern of the same spatial (1 cpd) and temporal frequency (4 Hz; 8 alt/sec). In a second experiment test patterns of 30% were alternated at 4 or 16 Hz (8 or 16 alt/sec) following 2 min. adaptation to 50% contrast patterns of the same temporal but varying spatial frequencies. The bandwidth of spatial frequency channels may be defined by the half-amplitude points of the adaptation induced amplitude reduction. In the third experiment patterns of 30% contrast alternated at 4 and 16 Hz were presented following two minutes of adaptation to whole field flicker and to patterns of the same spatial frequency and 50% contrast alternated at varying temporal frequencies, providing an indication of the bandwidth of temporal channels.

235.4 RETINAL EFFERENTS AND AFFERENTS IN A CICHLID FISH. A.D. Springer and A.S. Mednick. Department of Anatomy, New York Medical College, Valhalla, NY 10595.

Cobaltous-lysine was applied to the severed optic nerve of oscars (Astronatus ocellatus) and they were allowed to survive for 24 hr at 18°C. Thereafter, the cobalt was precipitated and paraffin sections were intensified with silver. Retinal fibers terminate bilaterally in a ventral preoptic region between the base of the third ventricle and the genu of the horizontal commissure and among periventricular cells along the sides of the third ventricle. Other fibers innervate the tuberal region of the hypothalamus anterior to the infundibulum. Targets innervated in the pretectum include: nucleus lateralis geniculatus and dorsal, medial and ventral pretectal nuclei. Two targets in the dorsal (nucleus opticus dorsolateralis and nucleus opticus commissurae posterior) and one in the ventral thalamus (nucleus opticus ventrolateralis) are innervated by fibers that leave the medial edge of the dorsal optic tract, while two targets in the ventral thalamus (basal optic nucleus and accessory optic nucleus) are innervated by fibers from the ventral optic tract.

Retinal fibers in the ventral optic tract innervate the ventral tectum, but not rostrally. Fibers in the dorsal optic tract innervate the entire rostro-caudal extent of the dorsal tectum and, in addition, the rostral pole of the ventral tectum. Thus, the axons of retinal ganglion cells from dorsal and ventral hemiretinas are not completely segregated in the optic tracts since the axons of dorsotemporal retinal ganglion cells are located in the dorsal optic tract.

Efferents to the retina originate in two nuclei and both project contralaterally. The first is the nucleus olfactoretinalis which is located ventrally between the olfactory lobe and forebrain, and consists of about 200 cells. Most of the cells are 11-13 um in diameter, with a few cells having a 20 um diameter The second, nucleus thalamoretinalis, is an arched and diffuse system of 200 cells extending from anterodorsal to posteroventral thalamus. Most of the cells are 8-10 um in diameter, but a few cells are 20 um in diameter. Cobalt-filled cells were not observed in either tectal lobe.

235.5 EXCITATORY AND INHIBITORY RECEPTIVE FIELD ORGANIZATIONS OF RETINAL GANGLION CELLS IN TURTLE. J.E. Fulbrook**, J.H. Maxwell, and A.M. Granda. Inst. for Neuroscience, Univ. of Delaware, Newark, DE. **U.S. Army Aeromedical Research Lab., Ft. Rucker, AL.

Excitatory (ERF) and inhibitory (IRF) receptive fields (RFs) were investigated with single-unit, extracellular recordings taken from retinal ganglion cell (RGC) axons responding to moving and/or flashing light spots in the curarized, anesthetized turtle, Pseudemys. The RF organization of most RGCs was complex, usually asymmetric, and frequently mutable to changes in adaptation level, stimulus wavelength, and stimulus velocity. All of the units were particularly sensitive to moving stimuli. 40% of the units were directionally-sensitive (DS).

In turtle, most RFs have ERF and IRF regions but IRF regions are usually silent, not giving well-defined, robust responses to moving or flashed stimuli. Also, the spontaneous activity in these units was very low (less than one spike/sec) or even non-existent, especially when light-adapted. IRF regions in these units could still be studied by mapping RFs with a moving stimulus while a supplementary flashing stimulus was used to drive the cells. This technique only works with slow-adapting cells; however, from these units several complex ERF-IRF organizations were revealed. DS cells showed ERF and IRF regions in the preferred direction of stimulus movement, but had only an IRF region in the null direction, overlapping the ERF-IRF region seen in the preferred-direction RF map. At least four ERF-IRF organizations were described for DS and bar-shaped (orientation-sensitive) cells.

Directionally-preferring (DP) cells were found that differed from DS cells in that DP cells had their strongest ERF and IRF regions in the preferred direction but had weak ERF-IRF regions in the null direction. In effect, DP cells had opposite IRF-strength vectors from DS cells, and possibly represent a separate cell class.

Rest assured, not all turtle RGC RFs are complex and unusual. Some units were studied which had relatively simple center-surround ERF-IRF organizations and at least one of these will be shown.

Summary: In the number and variety of complex RF types described at the RGC level, the turtle possesses one of the most complex retinal integrative capacities recognized in vertebrates.

235.6 TIME DEPENDENCE OF ACTIVITY IN FROG RETINAL GANGLION CELLS, M. Stiles,* K. P. Unnikrishnan* and E. Harth. Physics Dept., Syracuse Univ., Syracuse, N.Y. 13210.

Neural activity was recorded from neighboring retinal ganglion cells in frog (Rana pipiens) optic tectum, using extracellular tungsten microelectrodes. Action potentials were labeled on-line according to arrival time and waveform, and stored on flexible disk. Photic stimulation by cathode ray tube consisted of rectangles of chosen size, contrast and position within the previously determined receptive field. The post-stimulus time histogram of the accumulated responses showed a high degree of reproducibility. About 70% of the recordings show bursts lasting several hundred milliseconds, often with a marked periodic pattern.

Inter-burst intervals change regularly with stimulus contrast, size and position. In some cases, delayed burst responses appear several hundred milliseconds following a very brief (17 msec.) stimulus.

We have investigated the interactions between the temporal patterns produced by temporally or spatially separated stimuli on the supposition that temporal coding of ongoing activity describes complex visual events.

(Supported in part by BRSG Grant SO7 RR077068-17, NIH)

235.7 A DOSE-RESPONSE ANALYSIS OF THE EFFECTS OF ANTIBODIES TO LARGE GANGLION CELLS ON THE CAT'S RETINOGENICULATE PATHWAYS. John W. Crabtree*, Peter D. Spear, Lillian Tong, Kim R. Jones and Steven E. Kornguth. Depts. of Psychology and Neurology, Univ. of Wisconsin, Madison, WI 53706.

Antibodies were produced against large ganglion cells derived from ox retinae. These immunoglobulins were injected into the vitreal chamber of one or both eyes in adult cats. Antibody concentration ranged from 333-1000 ug/0.1 cc injection volume and the animals were studied after at least a 3 week postinjection period.

Evoked potentials to optic chiasm shock were recorded from the optic nerve head of 22 eyes. With increasing antibody concentration the ratios of the Y- to X-wave amplitudes decreased monotonically from 0.71 to 0.05. Relative to evoked potentials obtained from noninjected and control eyes, those from injected eyes showed a substantial reduction in both X- and Y-wave absolute amplitudes for all concentrations used. However, with increasing concentration the amplitude of the X-wave remained constant while that of the Y-wave steadily declined. In fact, 3 of 6 eyes injected with the 1000 ug concentration showed an absence of the Y-wave.

In 8 cats monocularly injected (1000 ug concentration), single cells were recorded from either the retinal ganglion soma layer or laminae A and A1 of lateral geniculate nucleus (LGN). While the injected-eye sampling density for retinal W-cells (13.8%) was unaffected, the densities for X- and Y-cells (8.6% and 1.5% respectively) were significantly lower than the noninjected-eye densities (17.3% and 12.7% respectively). These effects are in contrast to the lack of retinal effects reported for cats monocularly injected with 333 ug antibody concentration (Spear et al., 1982).

From some of the above cats retinal wholemounts were prepared and stained with cresyl violet. Thus far, cell counts have revealed an average of 93.5% fewer alpha cells (presumed Y-cells) in the injected eye than in the noninjected fellow eye. This average is a 3-fold greater loss of alpha cells than the average following injections of 333 ug concentration (Kornguth et al., 1982).

In LGN laminae receiving input from the injected eye, only 2% of the encountered cells (1/50) were Y-cells; the proportion of encountered X-cells (61.6%) was normal. The proportion of Y-cells was significantly lower than the 29.6% Y-cells (14/47) encountered in LGN laminae receiving input from the noninjected eye. This difference represents a 93% loss of Y-cells in injected-eye laminae, which is greater than the 77% Y-cell loss in such laminae in cats that received concentrations of 333 ug (Spear et al., 1982).

These findings show that the effects of antibodies on retinofugal pathways in the cat are dose-dependent. Furthermore, by using a sufficiently high antibody concentration, a nearly complete loss of the Y-cell pathway is possible with only a partial loss of X-cell and no loss of W-cell pathways. (EY01916, EY02545)

235.8 SPECIALIZATIONS IN THE VISUAL SYSTEM OF PANTODON BUCHHOLZI (Teleostei, Osteoglossiformes). William M. Saidel and Mark R. Braford, Jr., Dept. of Anatomy, Georgetown University Medical School, Washington, D.C. 20007

The visual system of P. buchholzi exhibits several atypical features. The retina is divided along a horizontal axis into two parts by an elaborated falciform process. We show that the ventral hemiretina views through the water-air interface while the dorsal part of the retina views the aquatic environment. The two parts of this retina are different in various aspects of the neuronal architecture. The ventral hemiretina is more complex in all features that were compared.

We have investigated the central connections of the retina as a whole and of the dorsal and ventral hemiretinas individually using autoradiographic, degeneration, and HRP histochemical techniques. The dorsal and ventral hemiretinas each contribute a separate fascicle to the optic nerve (ON). The two fascicles fuse outside the sclera into the ON. At the chiasm, an ON almost completely decussates, with most fibers entering the contralateral optic tract (OT). The OT continues along the lateral margin of the diencephalon to form the Marginal OT (MaOT). Two fascicles leave the MaOT to innervate the Superchiasmatic Nucleus. Further caudal, the MaOT divides into medial (MOT), lateral (LOT), and dorsal (DOT) optic tracts. The MOT terminates in several midline nuclei including the Anterior, Intermediate, and Ventrolateral Thalamic nuclei. The tract continues into a periventricular pretectal nucleus (PP), with fibers terminating and others crossing to the ipsilateral PP. Some of the crossed fibers continue rostrally within the ipsilateral MOT. At the rostral pole of the optic tectum (OpT), fibers from the LOT terminate in the Superficial Pretectal nucleus, pars parvocellularis, in a pretectal complex, and in an accessory optic complex. Fibers from the DOT also innervate the pretectal complex, but the bulk of fibers from both the DOT and LOT terminate in the OpT, primarily deep to the marginal layer and adjacent to the Periventricular Cell Layer (PV). The PV layer exhibits a discontinuity about midway between the medial and lateral margins of the OpT. By tracing the fibers from the ventral or dorsal hemiretina alone, we determined that this discontinuity marks the boundary between terminations from the two hemiretinas. Optic tract fibers that do not cross in the chiasm, travel in the LOT, and terminate only in the lateral OpT, interdigitating with fibers from the dorsal hemiretina only.

This visual system thus exhibits peripheral and central structural differences that parallel differences in visual environments. (Supported by a BRSG grant from GU, and grants from NSF and NIH.)

235.9 THE EFFECTS OF AMBIENT ILLUMINATION ON CONTRAST SENSITIVITY AND DYNAMICS OF THE CAT RETINA AND LGN. R.M.Shapley*, E.Kaplan* and D. Tranchina*† (SPON: F.Ratliff). Laboratory of Biophysics, Rockefeller University, New York, N.Y. 10021 and †Courant Institute, New York, N.Y. 10012.

Regulation of visual contrast sensitivity is one of the main functions of the retina. We have studied this process by recording from optic tract fibers and LGN cells in lightly anesthetized cats and by stimulating the retina with modulated patterns of light over a wide range of mean retinal illumination. The contrast sensitivity (impulse/sec per unit contrast) of retinal ganglion cells and LGN cells increased greatly from the lowest light level we used, approximately 10^3 quanta/(deg^2 sec), up to a mean illumination of 10^8 q/(deg^2 sec). These levels of illumination extend from the low scotopic to the mesopic range of vision for the cat. In several but not all cells, the contrast sensitivity actually declined between 10^8 and 10^9 q/(deg^2 sec) mean retinal illumination (corresponding to luminances of between 10 and 100 cd/m^2 respectively). This drop in contrast sensitivity may be associated with the shift from scotopic to photopic visual function in cat retinal ganglion and LGN cells.

The effect of mean light level in the dynamics of response was determined by measuring the temporal frequency response of each cell over the same range of backgrounds as above, with a small centrally placed spot modulated sinusoidally in time around the mean level. There was a differential effect of mean level on responses at low temporal frequencies versus high temporal frequencies. At low temporal frequencies the gain (impulses/quantum) was approximately 1/(mean level), while at high temporal frequencies the gain was approximately constant, i.e. unaffected by mean level. The phases of the responses were affected in a consistent fashion: phases of the responses to low frequencies were advanced by increasing mean level, while phases of the responses to high frequencies were relatively unaffected by variations in the mean level of illumination. These results suggest that the retinal processes which control gain and dynamics modulate the strength of negative feedback rather than causing a multiplicative attenuation of retinal responses to light.

235.10 MORPHOLOGY OF NORTH AMERICAN OPOSSUM RETINAL GANGLION CELLS. P. D. Wilson and G. J. Condo, Dept. of Psychology, Univ. of California, Riverside, Riverside, CA 92521.

Previous studies of retinal ganglion cells (RGC) in the North American opossum (Didelphis virginana) have suggested three or possibly four classes of RGC based on soma size distributions (Rapaport, et al., JCN, 199: 465, 1981), conduction velocity groups (Rowe, et al., JCN, 199: 481, 1981), and pattern of central projection (Rapaport and Wilson, JCN, 213: 74, 1983). In order to further investigate the anatomical characteristics of opossum RGC, we have examined in retinal wholemounts the dendritic morphology of RGC filled with HRP from injections in either the optic nerve or tract. Retinae were dissected and reacted with either cobalt or cobalt-nickel intensified DAB, and counterstained with cresyl violet. Four distinct types of RGC dendritic morphology were identified. Type 1 RGC are characterized by large dendritic fields (200-375μm) with radiate organization and a relatively complex branching pattern steming from 3-5 primary dendrites (soma diameter:21-32μm). Type 1 RGC in the opossum are similar in dendritic morphology to RGC termed Type 1 in the rat, Class I in the rabbit, and alpha cells in the cat. Type 2 RGC in the opossum are characterized by small to medium dendritic fields (64-202μm), a complex pattern of dendritic branching issuing from 1-2 primary dendrites, and dendritic arborizations displaced from the cell body (17-28μm). These Type 2 RGC are similar in morphology to beta RGC in the cat. Type 3 RGC are characterized by medium size dendritic fields (131-252μm) with bipolar dendritic arborizations from 2-4 opposing primary dendrites and a sparse branching pattern (soma size: 10-27μm). Type 4 RGC are characterized by medium size dendritic fields (134-265μm) with sparse dendritic branching arising from 2-4 primary dendrites..The dendritic branching of Type 4 RGC is in a radiate pattern in contrast to the bipolar pattern of Type 3 RGC. Type 4 RGC are morphologically similar to gamma-epsilon RGC in the cat retina. The present material indicates that there is a significant overlap in soma diameter for morphological classes of RGC in the opossum. It is of interest that for none of the proposed classes was there a systematic change in dendritic morphology with increasing eccentricity from the area centralis. (Supported by NSF grant BNS-8021602 to PDW).

235.11 MORPHOLOGY OF DORSAL LATERAL GENICULATE NUCLEUS RELAY CELLS OF THE NORTH AMERICAN OPOSSUM. G. J. Condo and P. D. Wilson, Dept. of Psychology, Univ. of California, Riverside, Riverside, CA 92521.

The dorsal lateral geniculate nucleus (dLGN) of the North American opossum (Didelphis virginana) is not cytoarchitecturally laminated, but termination of retinal projections show some degree of afferent lamination within the dLGN. The cells in the opossum dLGN (formalin fixed tissue) have a unimodal soma size distribution (11-19μm, mode: 15μm) with little variation through the nucleus. We have investigated the morphological differentiation of dLGN relay cells in the opossum using Golgi-Cox impregnated material and cells filled with HRP retrogradely from visual cortical areas. Both Golgi-Cox and HRP materials was serially sectioned at 120 and 100μm coronally; HRP sections were reacted with either cobalt or cobalt-nickel intensified DAB, and counterstained with cresyl violet. Three cell types have been identified on the basis of soma shape, dendritic morphology, and the orientation of the dendritic arborization. Type 1 relay cells are characterized by round somata (15-18μm in diameter with HRP and 12-26μm in diameter with Golgi-Cox), radial dendritic arborizations issuing from 4-6 primary dendrites, and a dendritic field mean diameter of 200-398μm. Type 2 relay cells have relatively round somata (13-19μm in diameter with HRP, and 13-22μm in diameter with Golgi-Cox), 3-5 primary dendrites giving rise to a vertically elongated dendritic arbor (150-400μm in mean diameter) oriented dorso-ventrally within the nucleus. Type 3 relay cells have relatively fusiform somata (14-16μm in diameter with HRP, and 19-22μm in diameter with Golgi-Cox) 3-5 primary dendrites giving rise to a horizontally elongated dendritic arbor (150-430μm in mean diameter) oriented medio-laterally within the nucleus. All three morphological types of relay cells have been identified throughout the anterior-posterior extent of the dLGN. Thus while there is a unimodal distribution of cells in the opossum dLGN there are three distinct morphological types of relay cells, and there are morphological similarities between Type 1 and Type 2 relay cells in the opossum and Class 1 and Class 2 relay cells in the cat dLGN. (Supported by NSF grant BNS8021602 to PDW).

235.12 AN ELECTRON MICROSCOPIC STUDY OF SYNAPTIC TERMINAL MORPHOLOGY IN THE CHICKEN VENTRAL LATERAL GENICULATE NUCLEUS. R.M. KRAEMER* AND W.J. CROSSLAND (SPON: R. Pourcho). Dept. of Anatomy, Wayne State Univ. School Medicine, Detroit, MI 48201

The neuropil lamina of the chicken ventral lateral geniculate nucleus (GLv) receives projections contralaterally from the retina and ipsilaterally from the visual wulst and optic tectum. We have examined this lamina using the electron microscope to determine qualitatively the morphological categories of synaptic terminals present in order to relate them subsequently to the three sources of afferents.

Four major types of synaptic terminals have been found. (I) An irregularly shaped terminal containing large round synaptic vesicles in a matrix of medium electron density. These terminals contain pale staining mitochondria with poorly defined cristae and a relatively large space between the inner and outer mitochondrial membranes. In newly hatched chicks, the terminals contain inclusions resembling beta glycogen. The terminals form asymmetric synapses on small dendrites, spine-like profiles, and small vesicle containing profiles (VCPs) but rarely contact medium or large dendrites or cell bodies. This terminal usually occurs in a cluster of small profiles resembling the "glomerular" synaptic arrays seen in the cat and monkey thalamus, although it lacks a clearly defined glial wrapping. (II) A rounded terminal containing mainly round (a few pleomorphic) vesicles (smaller in diameter than the vesicles in type I terminals) in an electron lucent background matrix. The terminal makes asymmetric synapses, most frequently on dendritic shafts, less commonly on small dendrites and spine-like processes. Type II terminals frequently are covered on three sides by a glial wrapping. (III) A terminal similar in shape to type II but containing predominantly pleomorphic vesicles in an electron lucent matrix and making symmetrical synaptic contacts with dendritic shafts and small dendritic processes. (IV) VCPs have a few scattered pleomorphic vesicles in an electron lucent matrix and contain medium staining mitochondria with poorly defined cristae. VCPs have not been seen forming presynaptic relationships with other profiles but are commonly post-synaptic to type I and III terminals.

Following eye removal, type I terminals degenerate. We conclude that the chicken has retinal synaptic terminals resembling those found in the visual pathways of other types of vertebrates including the cat and monkey.

235.13 LIGHT ADAPTATION IN THE TURTLE RETINA AND THE ROLE OF NEGATIVE FEEDBACK. D.Tranchina*[1,2], J. Gordon[1] and R.M.Shapley*[1]. Laboratory of Biophysics, Rockefeller University, New York, N.Y. 10021 and [2]Courant Institute of Mathematical Sciences, New York, N.Y. 10012.

We measured temporal frequency transfer functions of horizontal cell responses to modulations of retinal illuminance superimposed on various steady background levels. These levels spanned the range of $2 \cdot 10^{9}$ - $2 \cdot 10^{12}$ effective quanta sec^{-1} cm^{-2} at 630 nm on the retina. The time to peak of the impulse response to a superimposed flash decreased from 211 msec at the dimmest background to 74 msec at the brightest background. The incremental sensitivity of the response to a low frequency of modulation decreased as the background illuminance increased. Over a range of high background levels, the amplitude of the response to a low frequency stimulus depended only on its contrast and was independent of background. On the other hand, the incremental sensitivity of the response to a high frequency of modulation was independent of background; the amplitude of a high-frequency response was proportional to the absolute amplitude of light modulation, and the phase of the response was also independent of background. Consequently, as the background level is increased, the gain (mV/photon) of the response at high frequencies approaches that at low frequencies, and in this way the response dynamics speed up. These findings can be accounted for quantitatively by a subtractive-feedback model in which there is a linear feed-forward pathway and a feedback pathway whose gain is proportional to the mean level of retinal illuminance.

A family of temporal transfer functions measured at various backgrounds can be fit by an equation of the form

$$H(f,I_o) = A(f)/\{1 + I_o \cdot B(f)\},$$

where $H(f,I_o)$ is the value of the horizontal cell's temporal transfer function (mV/light modulation amplitude) evaluated at frequency f and mean retinal illuminance I_o; A(f) is the transfer function of the feed-forward pathway; and $I_o \cdot B(f)$ is the open-loop gain of the feedback loop.

235.14 INFLUENCES OF GRATING CONTRAST AND DURATION ON THE RESPONSES OF CAT RETINAL GANGLION CELLS. Kenneth E. Kratz and James G. May* Louisiana State University Medical Center and University of New Orleans, New Orleans, Louisiana.

In a previous investigation we reported the results of manipulating duration and spatial frequency of a pattern appearance sinewave grating on the responses of cat retinal ganglion cells.[1] Holding contrast constant we found that the latency of the initial excitatory response (time between stimulus onset and response onset) increased with increasing spatial frequency for both X and Y cells, and Y cells had shorter latencies than X cells at low spatial frequencies (<.5 c/d). Latency however, was unaffected by stimulus duration while response duration (time between response onset and response offset) increased with increasing stimulus duration. Also, persistence (time between stimulus offset and response offset) decreased with increasing stimulus duration. In the present study we report the effects on these same measures of manipulating grating contrast while holding stimulus duration constant. We recorded extracellularly the responses of single, optic tract axons in normal cats to the presentation of sinewave gratings of varying spatial frequency (.25,.5,1.0 c/d) and contrast value (.6,.33,.15,.10). A constant space average luminance of 30 cd/m^2 was maintained across the CRT. The gratings were presented for 100 msec at a rate of 2hz and were positioned to evoke the maximal excitatory onset response. Post-stimulus time histograms were obtained for 500 msec following stimulus onset. Average response latencies for both X and Y cells increased with decreasing grating contrast at all spatial frequencies. Also for both X and Y cells, response duration and persistence decreased with decreasing grating contrast. In addition, we determined contrast thresholds for X and Y cells to the presentation of gratings of varying spatial frequency and stimulus duration (25-300msec). These latter measures (determined auditorally) provided estimates of temporal integration for these two classes of retinal ganglion cells. These plots indicate that the critical durations for X and Y cells differ in that the average critical duration for X cells remains constant across spatial frequency but for Y cells increases with increasing spatial frequency.

235.15 COMPARISON OF PROTEINS TRANSPORTED IN RETINOFUGAL PATHWAYS OF NORMAL ADULT CATS AND RABBITS. A. S. Kelly* and S. A. Schemel*. Div. of Neurobiology, Univ. Calif. San Francisco, S.F., CA 94143.

We have compared the proteins transported via fast transport in the retinofugal pathways of normal adult cats and dutch-belted rabbits, using a combination of axonal transport of [^{35}S] methionine and two-dimensional gel electrophoresis techniques. In initial studies we determined the amount of radioactivity present in optic nerve and tract segments and in target nuclei, the lateral geniculate nucleus (LGN) and superior colliculus (SC), as a function of survival time. The initial wave of radioactivity had arrived at target nuclei with 8 hours of survival in the rabbit, and with 24 hours of survival in the cat. Two-dimensional electrophoresis of nerve, tract and target tissues at these survival times revealed that over 70% of the proteins between 10,000 and 100,000 Daltons and between 3.5 and 7 isoelectric point present in these tissues are the same in the cat and the rabbit. Autoradiograms of these gels indicate which proteins were transported to these loci from the retina, given appropriate controls for blood-borne label and leakage at the target sites (Wagner et al., 1978). Over 75% of the labelled proteins identified in cat tissue were also present in rabbit tissue. In particular, the 3 most heavily labelled proteins described previously in rabbit tissue (Kelly et al., 1980) were common to both species. One of these exhibits microheterogeniety in both species, and is more basic in SC tissue than in LGN tissue, and more acidic in optic tissue than in LGN tissue, in both species. The isoelectric point of this protein does not change as a function of time, and is very reproducible. The differences reported were observed in 17 of 18 rabbits and in 6 of 6 cats. We do not as yet know where this portion is located in axons or their terminals, or what the functional role of such a protein modification in mammalian central visual pathways may be.

235.16 LABELLING OF RETINAL PROJECTIONS IN THE MORMYRID FISH,GNATHONEMUS. G. Làzàr°, S. Libouban° and T. Szabo° (SPON: R.L. Thompson). Dept. Neurophysiologie Sensorielle, Lab. Physiologie Nerveuse, CNRS, 91190 Gif sur Yvette, France.

It was stated by several authors (Lissmann, H.W., J.exp.Biol., 35:156, 1958; McEwan, M.R., Acta Zool., 19:427, 1938; Teyssèdre,C. & Moller, P., Z.Tierpsychol., 60:306, 1982) that weakly electric fish e.g. mormyrids may have a poorly developed visual capacity obviously compensated by an electric sense, specific to these fish. Therefore, the retinal projections were studied in G.petersii using Fink-Heimer, HRP and cobalt-lysin labelling techniques. HRP labelled retinal axons and terminals were visualized by the Hanker-Yates technique, while the cobalt procedure was used according to Làzàr et al., (J.comp.Neurol., 215:108, 1983). The cobalt method always gave a more complete filling of fibers and projections.

The optic nerves do not cross completely in the chiasma. The crossed fibres form a lateral and medial tract. The former covers the lateral surface of the diencephalon and splits into a ventral and a dorsal branch at the rostral end of the tectum opticum. The medial tract is composed of loosely arranged fascicles of axons coursing laterally and dorsally to the lateral forebrain bundle. Its most medial part gives rise to the fasciculus dorsomedialis tractus optici. On the contralateral side optic fibers terminate in five areas, 1. hypothalamus,nucl. suprachiasmaticus (= hypothalamic optic nucl. or preoptic nucl. of other authors), 2. thalamus,nc. opticus dorsolateralis, and nc.geniculatus lateralis, 3. praetectal area: nc. corticalis, nc. comm. post. and nc.pretectalis. The densest projection is found in the nucl. corticalis, whereas only few fibers are seen in the lateral part of the nc. praetectalis, 4. Tectum opticum where the fibers terminate in the stratum fibrosum and griseum superficiale. A few slender fascicles reach this layer also through the str. marginale and str.opticum. 5. Accessory optic nuclei identified in the rostral tegmentum mesencephali. A telencephalic projection through the lateral forebrain bundle was also detected although its terminal field has not yet been determined.

A relatively large ipsilateral optic bundle enters the nc. suprachiasmaticus ventro-medially. Few retinal fibers could be followed into all ipsilateral optic centers except the nc.gen.lat. and the nc.pretectalis.

It may be concluded that the general organization of the visual system in Gnathonemus is similar to that of other teleosts, although identification of the nc.geniculatus lat. and the accessory optic nc. remains uncertain. The less developed projections in comparison to diurnal teleosts may reflect the restrained visual capacity of this fish.

235.17 THE ON CHANNEL AND VISUAL FUNCTION. P. H. Schiller*, J. H. Sandell, and J. H. R. Maunsell. (SPON: B. M. Dawson). Dept. of Psychology, M.I.T., Cambridge, MA 02139

The effects of reversibly blocking the retinal ON channel were examined for several visual functions. 2-amino-4-phosphonobutyric acid (APB) was injected into one eye of rhesus monkeys to produce vitreal concentrations of 200-600uM APB. Concentrations in excess of 400uM effectively blocked the ON channel for 8 to 24 hours as determined by ERG, evoked potential or single unit recordings. Absolute threshold, spatial and temporal contrast, acuity, flicker, color discrimination and visually guided eye movements were examined using either a staircase method or the method of constant stimuli. Each trial was initiated with the appearance of a fixation spot, and the stimuli to be detected or discriminated appeared to either side of this spot. Animals were required either to touch the correct stimulus (detected on a touch panel) or to saccade to it (as assessed with a scleral search coil). Response accuracy and reaction time measures were taken.

Our results show that APB had little effect on high-contrast acuity, critical flicker frequency and color discrimination. Absolute threshold for light increment in the light and dark adapted animal was elevated by 1 and 2 log units, respectively. Spatial and temporal contrast sensitivities were significantly elevated. Saccadic eye movement accuracy to visual targets was unaltered, but there was a significant increase in saccadic reaction time.

The ON and OFF channels originating in the retina make it possible to signal both light increment and light decrement with an excitatory process to the central nervous system. Our results suggest that these two systems (1) provide for high spatial and temporal contrast sensitivity and (2) improve the speed of information processing.

This research was supported by the following grants: NIH EY00676, NSF BNS8019714, and NIH EY02621.

SUBCORTICAL VISUAL PATHWAYS I

236.1 RETINOTOPIC ORGANIZATION OF THE MEDIAL INTERLAMINAR NUCLEUS OF THE CAT. C. Lee*, J. G. Malpeli, H. D. Schwark and T. G. Weyand. Dept. of Psychology, University of Illinois, Champaign, IL 61820.

The purpose of this experiment was to obtain a total map of the medial interlaminar nucleus (MIN) at a level of detail sufficient to resolve the lamination pattern and to allow estimation of the entire range of visual fields represented in each layer. Rather than assembling a map from partial studies, the MIN of a single cat was exhaustively and systematically mapped.

The cat was held in a stereotaxic frame modified to leave the visual field unobstructed. The direction of gaze was determined precisely for each eye by comparing the whole-mounted retinae with the pattern of blood vessels projected onto the screen during the experiment. Electrode passes were made in a rectilinear array, spaced 400 microns antero-posteriorly and 200 microns medio-laterally, spanning the MIN in all directions. Data were taken every 100 microns along each pass. A total of 1568 points were mapped in 102 passes. Of these, 480 points in 65 passes were within the MIN as determined by physiological and histological criteria. Computer reconstructions of these data allowed analysis of the visual field map in coronal, horizontal, and parasagittal planes, and aided in assigning each point to one of the 3 MIN layers following the terminology of Guillery et al. (J. Comp. Neurol., 194: 117-142, 1980).

We confirm physiologically the trilaminar structure of the MIN previously revealed by anatomical methods (Hayhow, W.R., J. Comp. Neurol., 110: 1-64, 1958), as well as the general form of the retinotopic map described by others. Generally, the lowest elevations are found anteriorly, the highest elevations posteriorly, and extreme azimuths ventrally. The representation of the vertical meridian is adjacent to the lateral border of layer A of the LGN. The ipsilateral hemifield representation in layer 3 extends 25 degrees from the vertical meridian. Neither any single layer nor the MIN as a whole represents an entire hemifield. All layers have a very strong bias for the lower visual field. Overall, 68% of the volume of the MIN is devoted to the lower visual field. One striking feature of this map is the absence of significant naso-temporal overlap in any given layer. The range of nasotemporal overlap for the 3 layers is 0-0.5 degrees with an uncertainty of 0.5 degrees.

(Supported by grants NIH RO1 EY02695, NIH KO4 EY00229, NIH T32 EY07005, PHS ST32 GM7143, and grants from the University of Illinois Research Board and Biomedical Research Support Committee.)

236.2 RELATIONSHIPS BETWEEN CELL BODY SIZE AND AXON TERMINAL FIELDS IN SINGLE X- AND Y-CELLS OF THE RETINA AND LATERAL GENICULATE NUCLEUS. A.L. Humphrey, M. Sur and S.M. Sherman, Dept. of Neurobiology & Behavior, SUNY at Stony Brook, NY 11794.

We are using the technique of intracellular injection of horseradish peroxidase to visualize the somata and axon terminal fields of single, physiologically identified X- and Y-cells within the retinogeniculate and geniculocortical pathways of the cat. We hope to determine what relationships exist among such parameters as cell soma size, volume of axon terminal field, and receptive field eccentricity. Another goal is to determine whether X- and Y-cells differ in any of these relationships.

Single axons of LGN cells were recorded in the optic radiations below areas 17 and 18 using HRP-filled micropipettes. Retinal ganglion cell axons were recorded in the LGN or in the optic tract just below the LGN. After each axon was identified extracellularly as X or Y, it was impaled intracellularly and HRP was iontophoresed into it. Post-injection survival time extended from 15-30 hrs. to allow transport of the HRP anterogradely through the axon terminal field and retrogradely to the cell body.

We have analyzed the soma/axon pairs of 10 retinal ganglion cells and 10 cells from the LGN. No clear relationship was seen between soma size and terminal field volume for the X- or the Y-cells. However, among retinal and LGN neurons, there is a moderately strong relationship between a cell's soma size and the number of boutons in its terminal field (r=0.74 and 0.77, respectively). This relationship appears to be stronger for Y-cells at both locations than for X-cells, but more neurons are needed to confirm this. The mean soma size of labeled retinal X- and Y-cells is roughly twice that of those in the LGN, but the LGN cells contain 2-3 times more boutons in their axon terminal fields than do the retinal neurons. Thus, while the number of terminals is related to soma size among cells in the retina and in the LGN, the absolute relationships differ between the two regions. Y-cells of the LGN that project to area 17 exhibit larger terminal field volumes (r=0.9) and greater numbers of boutons (r=0.9) with increasing receptive field eccentricity. The density of synaptic boutons in this group of Y-cells is roughly constant with retinal eccentricity (r=0.9). Geniculate X-cells that project to area 17 and Y-cells that do so to area 18 also show increased terminal field volumes with eccentricity, but it is not yet clear whether their density of boutons remains constant or decreases with increasing eccentricity. Retinal Y-cells, but not X-cells, show an eccentricity-related increase in terminal field volume within the LGN.

Supported by USPHS Grants EY04091 and EY03038.

236.3 THE ULTRASTRUCTURAL SUBSTRATES FOR SYNAPTIC CIRCUITRY OF AN X RETINOGENICULATE AXON. J.E. Hamos, D. Raczkowski, S.C. Van Horn* and S.M. Sherman. Dept. of Neurobiology & Behavior, SUNY at Stony Brook, NY 11794.

We have begun to investigate the ultrastructure of connections made by a single optic tract axon in the LGN. We intracellularly recorded and electrophysiologically identified an axon from a retinal X-cell in the optic tract and iontophoresed HRP into that axon. We then perfused the animal and processed the LGN for electron microscopy. We serially sectioned tissue containing the axon's terminal field, and we reconstructed neurons which were postsynaptic to the labeled terminals from the injected axon.

We have found remarkable selectivity in the contacts from the injected axon. Labeled synaptic terminals repeatedly contact dendrites of some neurons while totally avoiding those of others. However, the pattern of contacts by the X-axon varies on the postsynaptic partner as seen to date in three examples: Cell 1 receives numerous labeled (41%) and unlabeled (59%) retinal inputs, both on its main dendritic shafts and on dendritic appendages. Also, the labeled terminals are preferentially located near the cell body so that labeled inputs form 76% of the retinal terminals within 25μm of the cell body and 29% of those further than 50μm away. Therefore, not only has the injected axon selectively innervated this cell, but it has also selected a particular region of this neuron to contact. Cell 2 receives only unlabeled retinal terminals on its dendrites in the region in which LGN relay cells typically receive retinal input (i.e., within 100μm of the cell body). However, in a secondary retinal recipient zone (150-200μm from the cell body) 29% of the retinal terminals are labeled. Once again, the injected axon has selectively innervated a neuron in a specific region. Cell 3 has several dendritic regions that contain "grape-like clusters" characteristic of certain geniculate cells. In several cases, the injected axon is the sole retinal input to the region. For example, in a cluster of 12 multilobed appendages, there are 16 labeled retinal inputs to the spine or its adjacent dendrite and no unlabeled retinal inputs. These clusters thus seem to be a focal point for retinal input from a single axon.

We have thus far found three distinctly different patterns of input from a single retinal axon. We also found differences in the relationship of nonretinal inputs to these same cells. Further analysis of this and other injected axons will allow us to begin to define the structural details of retinogeniculate circuitry.

236.4 A COMPARISON OF A-LAMINAE AND C-LAMINA Y-CELLS IN THE DORSAL LATERAL GENICULATE NUCLEUS OF THE CAT. Joseph Frascella* and Stephen Lehmkuhle* (SPON: Charles Elbaum). Department of Psychology, Brown University, Providence, RI 02912

We recorded extracellularly from isolated Y-cells in the A-laminae and the upper C-lamina of the dorsal lateral geniculate nucleus of the cat and compared their responses to several sine wave grating presentations. Both spatial and temporal contrast sensitivity functions were determined for these cells as well as suprathreshold response functions with 20 and 40% contrast levels using 2 Hz sine wave counterphasing gratings at a number of spatial frequencies.

The results from the spatial contrast sensitivity show that the C-lamina Y-cells were much more sensitive than A-laminae Y-cells at the lowest (0.175 and 0.25 cycles/degree) and highest (3.00 and 4.00 cycles/degree) spatial frequencies and only slightly more sensitive at intermediate spatial frequences. Temporal contrast sensitivity functions revealed that C-lamina Y-cells were more sensitive than A-laminae Y-cells across all temporal frequencies tested. The fundamental response amplitudes of both groups of Y-cells were similar across all spatial frequencies for both suprathreshold contrast levels; however, the second harmonic responses were different. At both 20 and 40% contrast, the C-lamina Y-cells gave larger second harmonic responses across all spatial frequencies with the largest differences at 40% contrast. The second harmonic amplitudes were the greatest at the intermediate spatial frequencies for both populations of cells.

These results indicate clear response differences between A-laminae Y-cells when compared to those in the C-lamina. The largest difference occurs in the second harmonic measures thereby revealing a difference between these populations of Y-cells in subunit contribution. Preliminary analysis of the data has shown a possible difference in response properties of lamina A and A1 Y-cells.

236.5 RESPONSE PROBABILITY OF X- AND Y-CELLS IN THE LATERAL GENICULATE NUCLEUS (LGN) OF THE CAT. A. K. Sestokas and S. W. Lehmkuhle* Dept. of Psychology, Brown University, Providence, RI 02912.

The discharge patterns of LGN neurons vary during repeated presentations of a visual stimulus. We have begun to investigate this variability by studying the effects of stimulus grating contrast and spatial frequency on response probability. Specifically, we analyzed the discharge patterns of LGN X- and Y-cells in anaesthetized, paralyzed cats during repeated 100-msec stimulus presentations. Neurons were tested with vertical, sinusoidal gratings of fixed spatial frequency at 6 values of contrast between 5 and 40 percent, and with gratings of fixed contrast at 6 values of spatial frequency between .17 and 2.0 cycles/degree. Each stimulus was presented 20 times at a rate of 1 presentation per second. A 450-msec period preceding stimulus onset was defined as the baseline period for each stimulus trial. A neural response was defined to have occurred after stimulus onset if 2 criteria were met. First, instantaneous spike frequency had to exceed the mean baseline neural response by at least 2 standard deviations (SD) of the mean baseline instantaneous frequency within 200 msec of stimulus onset. Second, the instantaneous frequency had to remain above this 2 SD window at least 50% longer than it maximally did during the preceding baseline period. The proportion of trials in which a response occurred was then calculated for each stimulus condition tested. The results show that both the spatial frequency and contrast of stimulus gratings influenced the probability of response occurrence. X-cells were more likely to respond at intermediate spatial frequencies than at low or high spatial frequencies. Y-cells were more likely to respond at low than at high spatial frequencies. Moreover, at low spatial frequencies Y-cells were more likely to respond than X-cells, whereas at high spatial frequencies this result was reversed. Finally, response probability increased with increases in stimulus contrast equally for both X- and Y-cells.

The peak responses in these stimulus conditions were measured in 2 ways. First, when peak responses were determined from peristimulus histograms based on the original raw data, a similar pattern of results was obtained for X- and Y-cells as a function of spatial frequency and contrast as that observed for response probability. Second, when peak responses were determined from traces of instantaneous spike frequency, the peak responses of Y-cells generally exceeded those of X-cells for all stimuli tested. These results suggest that response amplitude estimated from conventional peristimulus histograms may be significantly influenced by response probability, which varies as a function of cell type and stimulus condition.

236.6 DIFFERENTIAL CYTOCHROME OXIDASE STAINING OF OFF- AND ON-CENTER VISUAL CHANNELS IN RETINA AND LATERAL GENICULATE NUCLEUS OF FERRET AND MONKEY. G.H. Kageyama* and M. Wong-Riley (SPON: C. Brown). U. of Calif. San Fran. CA 94143 and Med. Coll. of Wisconsin, Milwaukee, WI 53226.

In certain species of mammals, the functional segregation of OFF-center (OFF) and ON-center (ON) visual channels in the retina (Nelson et al. '78) is preserved within the lateral geniculate nucleus (LGN) as well (Schiller & Malpeli '78; LeVay & McConnell '82). In order to determine whether the ON and OFF visual pathways have different levels of oxidative metabolic activity, sections of retina and LGN from normal ferrets, macaque and squirrel monkeys were reacted histochemically for cytochrome oxidase (C.O.). In the ferret LGN, each of the A laminae is subdivided into inner (A, A1) and outer (A', A1') leaflets (Linden et al. '81), which respectively contain a higher percentage of ON-center and OFF-center geniculate neurons (Zahs & Stryker, personal communication). The outer (OFF) leaflets were notably more reactive for C.O. than the inner (ON) leaflets. Similarly, in the inner plexiform layer (IPL) of the ferret retina, sublamina a (IPL-a; presumed OFF) was more reactive than sublamina b (IPL-b; presumed ON). In the macaque LGN, the dorsal laminae (6 & 5) contain predominantly ON cells, and the middle laminae (3 & 4) contain mainly OFF cells (Schiller & Malpeli '78). While the primate magnocellular laminae (1 & 2) may be the most reactive (Kageyama & Wong-Riley '82), the ON parvocellular laminae (5 & 6) were more reactive than the OFF laminae (3 & 4). The corresponding IPL-b (presumed ON) in the retina was usually more reactive than IPL-a (presumed OFF). These results demonstrate that ON and OFF channels may exhibit different levels of activity. While the OFF channel appears to be metabolically more active in the ferret, the converse seems to be true in the monkey.

In all species studied (see also Kageyama & Wong-Riley '82), the large (presumed Y or Y-like) retinal ganglion cells and LGN neurons tended to be more darkly reactive than medium and small neurons in the same region. Thus, our findings suggest that, in addition to ON- and OFF-channel differences, the Y or Y-like systems may, in general, be metabolically more active than the X/X-like or W/W-like systems.

236.7 ULTRASTRUCTURAL IDENTIFICATION OF SATELLITE INTERNEURONS IN THE RAT DORSAL LATERAL GENICULATE NUCLEUS: AN EM-HRP STUDY. V. M. Montero and G. L. Scott*. Dept. Neurophysiology, Waisman Center, Univ. of Wisconsin, Madison, WI 53706.

Multiple injections of horseradish peroxidase (HRP) were placed in the occipital cortex of rats, including all striate and extrastriate visual areas, to examine with the electron microscope the population of retrogradely labeled and unlabeled cells in the dorsal lateral geniculate nucleus (LGN), for the purpose of ultrastructurally identifying geniculate interneurons. O-tolidine was used as chromogen in the histochemical procedure. EM analysis of LGN showed dense HRP reaction products diffusely distributed in the cytoplasm of virtually all large and medium size geniculate cells, identifying the geniculo-cortical relay cells. The classes of unlabeled cells distinguished in this study are oligodendrocytes, astrocytes, and other small cells whose glial or neural nature is difficult to assess in light microscopic semithin sections. In serial ultrathin sections, these small cells were seen to be presynaptic in somato-somatic synapses with relay cells, and to give origin to presynaptic dendrites. These neurons are cytologically identifiable by their small size, scant cytoplasm, characteristic chromatin clumps in nuclei that are not indented, and by having extended contracts with the cytologically different relay cells. We conclude that these neurons were not retrogradely labeled because of their intrinsic nature in LGN and, because of their common contacts with relay cells, we term them "satellite interneurons".

236.8 FUNCTIONAL CHANGES IN THALAMIC LATERAL GENICULATE NEURONS DURING OSCILLATIONS OF THE SPONTANEOUS RETINAL INPUT FREQUENCY IN CHRONIC CATS. A. Fourment*, J.C. Hirsch* and M.E. Marc* (SPON: M.C. CALVET). INSERM U3, 91 Bd de l'Hôpital, 75634 Paris cedex 13 France.

In lateral geniculate (LGN) relay cells of cats, the maintained discharge of retinal ganglion cells determines monosynaptic composite EPSPs (S potentials of BISHOP et al, 1962: S-pot), subthreshold or generating spikes. Since in adult cats chronic deafferentation causes intense neuronal reorganization, we investigated if the naturally occurring pseudo periodical pauses in retinal discharges changed post synaptic LGN activities during the sleep wake cycle. This was performed by using potassium citrate filled micropipettes to record juxta- and intracellularly S-pot and spikes in chronic cats adapted to head restraint.

During quiet wake and slow wave sleep uncorrelated to any obvious alteration in the behavioral state, transient reductions in frequency of spontaneous subthreshold S-pot occurred for periods lasting 3 to 30 sec. There was a concomitant decreased firing during which bursts predominated but no change in spike height. During these S-pot poor periods the cell membrane was hyperpolarized by 2 to 15 mV, and a depression or reversal of synaptically evoked IPSPs was observed.

Concurrently the characteristics of spontaneous S-pot varied: control subthreshold S-pot displayed an abrupt rising slope, less than 500 µsec, followed by a slow (40 msec) rounded depolarization; control suprathreshold S-pot generated after a few msec one to three spikes which often regained the amplitude of the rounded depolarization; subsequent subthreshold S-pot arising from the rounded depolarization or from a synaptically evoked IPSP yielded a decrease in the amplitude of both the fast rise and the slow return, suggesting an underlying increased conductance. In sharp contrast, during S-pot poor periods most of the few remaining S-pot generated spikes after a delay shorter than 1 msec. Moreover, the amplitude of the fast rising initial phase of the S-pot increased by 18 to 25%, as it did during artificial membrane hyperpolarization applied during control periods. Simultaneously the amplitude and half-width of the rounded depolarization decreased significantly in comparison with control periods and with membrane hyperpolarization elicited during that time.

Thus a transient fall in the number of monosynaptic retinal input triggers a tonic membrane hyperpolarization which enhances the efficiency of the few remaining S-pot to elicit spikes while reducing the amplitude of the slow post depolarization.

236.9 SPATIAL RELATIONSHIPS OF THE COLLICULAR INFLUENCE UPON LATERAL GENICULATE CELL ACTIVITY IN RABBITS. S. Molotchnikoff, D. Delaunais*, C. Casanova and F. Tremblay*. Département de Sciences biologiques, Université de Montréal, Montréal, P.Q. Canada H3C 3J7.

It is now established that the Superior Colliculus (SC) is involved in the mechanisms of goal-directed movements. For instance, the saccadic intregative model (spatial models[1]) is based on the peculiar organization of the SC which allows for a point-to-point activation of deep saccadic-related neurons by overlying visual cells. This is possible because the dorsal layers of the SC receive retinotopic afferents while the ventral layers seem to correspond with an eye movement map [1]. It also has been shown that the dorsal layers of the SC send fibers to the lateral geniculate nucleus (LGN). Thus, it may be expected that the influence of the SC on the LGN [2] exhibits spatial relationships. The proposed investigations were aimed at confronting this latter hypothesis. In anesthetized and paralyzed rabbits, glass micropipettes filled with 2M NaCl were used to record lateral geniculate cell responses to localized stimuli presented within its receptive field (RF). Stimuli delivered to the geniculate (Flashed spots, LED, bars sweeping across the RF in various directions) were presented in a random sequence. The SC was manipulated in two fashions: a) cells of the SC were excited with an appropriate stimulus positioned within their RF (dual stimulation) or b) collicular cells were inactivated with a microinjection of $CoCl_2$ or Xylocaïne (100 nanol.). The geniculate responses were compared prior to and following collicular excitation or inhibition. To be considered for analysis the variations of the geniculate responses must be greater than 20%. So far the results can be summarized in the following manner. Collicular inactivation with cobalt produced a decrease of all tested geniculate OFF-cells (5). By contrast all ON and ON-OFF cells (6) had their responses enhanced. The dual stimulation protocole resulted in a decrease of only two OFF cells, whereas (16) ON and ON-OFF cells had their discharges diminished. Finally, the influence of the SC upon LGN ON and ON-OFF units declined as the distance between the collicular and the geniculate RF increased. This latter trend seems to indicate that the collicular impact upon geniculate activity is stronger when both RFsare in register.

236.10 DISINHIBITION OF DORSAL LATERAL GENICULATE NEURONS FOLLOWING LESION OF THE THALAMIC RETICULAR NUCLEUS. G. A. Marks, A. Stabrowski* and H. P. Roffwarg. Dept. of Psychiatry, University of Texas Health Science Center, Dallas, TX 75235.

The excitability of relay cells in the rat dorsal lateral geniculate nucleus (dLGN) is depressed following a shock to the optic tract (OT). Paired shocks less than 100 msec apart will fail to elicit a response to the second shock. Electrophysiological and anatomical evidence strongly implicate the visually responsive cells of the thalamic reticular nucleus (TRN) as the responsible mechanism acting through feed-back or feed-forward inhibition of dLGN relay cells. Sumitomo et al[1] have reported the results obtained from one rat showing that electrolytic lesion of the visually responsive TRN shortens the post-excitatory recovery of relay cells as measured by double-shock OT stimulation. In confirmation of these results, we report that electrolytic destruction of the caudal pole of the TRN leads to a disinhibition of neuronal elements in the dLGN in response to the second of a paired shock to the OT.

Long Evans hooded rats under chloral hydrate anesthesia were bilaterally implanted with 122.5 um nichrome wire in the dLGN and wire with 1.0 mm of insulation removed in the caudal TRN. A bipolar stimulating electrode was placed near the OT at the level of the chiasm. A double shock, 100 msec apart, delivered to the OT would always elicit a short latency multiple unit response to the first shock and never to the second. Increasing amounts of RF current was passed to the TRN electrode until either a response to the second shock would appear or activity was lost in the dLGN. Utilizing this method, success at eliciting a response to the second shock is greater than 50% and in all successful experiments histology revealed the lesion to have destroyed the caudal pole of the TRN.

Figure: Oscilloscope tracings of activity recorded from the dLGN. Large amplitude stimulus artifact indicates 2v shock to OT. Shocks are 100 msec apart. 1. pre-lesion, no response to second shock. 2. post-lesion, response to both shocks.

These data support the role of the visually responsive cells of the TRN in the post-excitatory inhibition of dLGN relay cells.

236.11 THE RELAY OF INFORMATION FROM DORSAL LATERAL GENICULATE NUCLEUS (LGNd) TO VISUAL CORTEX IN THE AWAKE RABBIT. H. A. Swadlow and T. G. Weyand. Dept. Psychology, Univ. Conn., Storrs, CT 06268

The inherent stability of the rabbit eye was exploited to enable receptive field analysis of LGNd neurons and optic tract axons in the awake, unparalyzed state. Axonal properties were also studied. The eye monitoring system we generally used was accurate to 1/3° (early experiments) or 1/5° (later experiments). In some experiments, however, we reflected a low intensity laser off of a mirror cemented to the eye. Using this system (accurate ± 2 min.) to test eye stability, we commonly observed eye position to remain within a range of 1.0° for 4-5 minutes and, in some cases, for periods in excess of 10 minutes. Such stability is comparable to that seen in awake monkeys trained to fixate.

The receptive fields of approximately 85% of LGNd neurons were concentrically organized. This is a higher value than previously reported in this species and we argue that many of the uniform cells previously described in rabbit LGNd show, in our experimental situation, a clear surround mechanism. Most of the remaining neurons were either directionally selective (7%) or motion/uniform (7%). Concentric sustained cells were found predominently near the representation of the visual streak while concentric transient cells were more common in the upper visual field. In the region of the visual streak, receptive field diameters of sustained cells were somewhat smaller (median = 1.7°) than those of transient cells (median = 2.3°). Both sustained and transient cells showed primarily non-linear spatial summation. As reported previously (Swadlow, H. A. and Weyand, T. G., Neurosci Abstracts, 8: 207, 1982), non-visual sensory stimuli that resulted in EEG arousal had a profound effect on the duration of the response of most sustained concentric neurons. Such arousing stimuli usually had little or no effect on the spontaneous firing level of the cell in the absence of visual stimulation. Arousing stimuli had no effect on the response of sustained, concentric optic tract axons.

Approximately 77% of LGNd neurons tested (127/165) were antidromically activated following electrical stimulation of the visual cortex. All receptive field classes of LGNd neurons projected axons to the visual cortex. Thus, no evidence for a separate class of intrinsic interneuron was obtained. While concentric sustained neurons conducted somewhat more slowly than did transient neurons, antidromic latencies were quite similar for all classes of cells studied.

236.12 FUNCTIONAL CHARACTERISTICS OF PRE- AND POSTSYNAPTIC FIELD POTENTIAL RESPONSES IN THE RETINOGENICULOSTRIATE PATHWAY OF HOODED RAT. D. Impelman*, C.L. Lear*, R. Wilson* and D.A. Fox. Coll. of Optometry, Univ. Houston and Div. Tox., UTMSH, Houston, TX.

Previously we examined the effects of lead on field potential responses in the retinogeniculostriate pathway of hooded rat (Neurosci. Abs. 8:81,1982). Differences in chronaxies and conduction velocities for the high (H) and middle (M) conduction groups and a depression of geniculostriate recovery cycle (RC) were found. Therefore we further characterized the functional properties of pre- and postsynaptic components as a tool to assess X and Y population responses in rat visual system. Optic nerve fibers in H and M groups project to fast and slow P cells in dLGN which project to cortical areas 17 and 18 and are probably correlates of X and Y cells in cat (J. Physiol. 315:69,1981). Presynaptic responses of H and M were recorded from the optic tract in response to stimulation of optic chiasm (OX) and were identified by their response latencies, chronaxies, frequency following and antidromic responses. Orthodromic RCs for H and M groups were characterized by their refractory, supernormal and subnormal periods. The minimal ISI at which a conduction group was recorded for group I was 0.52-0.71 ms and 0.69-0.95 ms for groupII. Standard plots of stimulus intensity functions showed that maximal response amplitudes for H and M functions were reached at approx. 6.4-8.0 times threshold for group I and 13.3-17.3 times threshold for group II. Stimulus intensity and RCs for geniculate responses differ from their presynaptic inputs mainly in their inhibitory interactions which produce a prolonged and sometimes cyclic recovery for both fast and slow P cells. In our recordings of responses in area 17 to OX stimulation, the pre- and postsynaptic components of P cell input characterize the early part of the waveform. Postsynaptic responses to fast and slow fiber input are identified by their response latencies, frequency following and RC responses. The late P cell discharge, at 150-200 ms in fast P cells and at 250-400 ms in slow P cells, occurs as a characteristic increase in excitability in their postsynaptic RC responses. The early depression of postsynaptic RC responses occurs in absence of any correlated changes in presynaptic RC and suggests that cortical depression may be mediated by postsynaptic inhibition as in cat (Exp. Neurol. 21:424,1968). Although the functional characteristics of retinostriate projections of the two conduction groups are more similar in rat than cat (J. Physiol. 121:415,1953 and 150:214,1960) their differences are characteristic. Further information concerning their cortical interactions in area 17 and 18 are the subject of present investigation. Supported by ES 07090 and ES 03183 (DAF).

236.13 CYTOARCHITECTURE AND AFFERENT CONNECTIONS OF NUCLEUS LATERALIS POSTERIOR IN GROUND SQUIRREL. N. Lugo-García and E. Kicliter. Lab. of Neurobiology and Dept. of Anatomy, Univ. of Puerto Rico Sch. of Med., San Juan, PR 00901.

Nucleus lateralis posterior (LP) of the ground squirrel (Spermophilus tridecemlineatus) is a large, wedge-shaped structure considered to be homologous, in part, to the primate pulvinar. We were interested in determining whether LP contains subdivisions, as it does in related species. Our methods included study of LP's cytoarchitecture and connections.

The cytoarchitecture was studied in Nissl-stained sections. Differences were found in the soma sizes and distribution of neurons in rostral and caudal sectors of the nucleus. The rostral portion of LP was observed to consist of medium-sized (5-10 um diameter) cells often grouped in clusters. The caudal sector contained larger neurons (10-17 um diameter) which were more evenly distributed.

Afferent projections to LP were determined by making small iontophoretic injections of horseradish peroxidase into various parts of the nucleus. After 24 or 48 hour survival times the animals were perfused intracardially with aldehydes and brain sections were processed histochemically according to the method of de Olmos and Heimer (J. Comp. Neur. 181: 213-244, 1977). On the basis of connections with the superior colliculus and visual cortex, LP of this species consists of three subdivisions. The rostral portion can be subdivided into rostrolateral and rostromedial sectors. The caudal portion cannot be further subdivided on the basis of connections. Only the rostrolateral and caudal sectors of the nucleus received projections from the superior colliculus. These projections originated in the lower half of the stratum griseum superficiale. On the other hand, all three subdivisions of LP received visual cortical input. Rostrolateral LP received projections from areas 17, 18, 19 and temporal cortex; rostromedial LP from areas 17, 18 and 19; and caudal LP from area 19 and temporal cortex. The cell bodies of all visual cortical afferents were located in lamina V and the upper part of lamina VI.

Thus, differences in cytoarchitecture and afferents evidence the existence of three subdivisions of ground squirrel LP. The organization of ground squirrel LP is similar to that reported for grey squirrels (Robson and Hall, J. Comp. Neur., 173: 355-388, 1977), golden hamsters (Crain and Hall, J. Comp. Neur., 193: 351-370, 1980) and the Chilean rodent Octodon degus (Kuljis and Fernández, Brain Res., 234: 189-204, 1982). The present and previous results further suggest that LP has more than a single role in the processing of visual information.

Supported, in part, by USPHS Grants NS-07464 and GM-07718.

236.14 MECHANISMS FOR RESPONSES TO MOVEMENT-IN-DEPTH IN THE LATERAL PULVINAR OF THE MACAQUE. D. Burman, L.A. Benevento and G. Felsten. Dept. of Anatomy, Univ. of Illinois at Chicago, Health Sciences Center, 808 S. Wood, Chicago, IL 60612

Our previous work has shown that some units in the lateral pulvinar of paralyzed macaques respond to movement in depth, and also to expanding and contracting discs on a tangent screen. The possible bases for these responses have been studied in greater detail. Monocular responses indicate that binocular interaction is not necessary to evoke a response to movement in-depth. Disparity tuning curves, however, suggest that a unit which responds best to an approaching object gives a maximum response to an object in front of the plane of focus. Careful analysis of receptive field organization indicates that the location in the visual field and the sign of response (i.e., excitation or inhibition) to a tangentially moving bar or an expanding circle in the plane of focus, correspond well with the size and location of the expanding or contracting solid spot (disc) that evokes maximum response. Use of radial moving bars seldom if ever increased the magnitude of response. Stimulus intensity was also an important factor. Changes in whole-field intensity or that of discrete spots of light evoked a response that was intensity-dependent, but consistent with the response to movement in-depth or an expanding/contracting disc. For example, a unit which responded to an approaching object (or a dark expanding disc) might respond with excitation to a flash of dim light and inhibition to a flash of bright light; it might also respond to a stationary stimulus changing intensity. The size of the stimulus was also important; for example, a flashing large dark spot would evoke a larger response than a flashing small spot. It therefore appears that at least some pulvinar units detect 3-dimensional movement in-depth by translating information from several 2-dimensional stimulus cues, such as location, size, and brightness, as well as using 3-dimensional cues such as disparity. In this way, monocular as well as binocular cues could give the animal information about movement in-depth. (Supported by EY 2940)

237.1 EVIDENCE FOR PROJECTIONS TO THE SUPERIOR COLLICULUS FROM THE HYPOTHALAMUS AND ZONA INCERTA IN THE CAT. R.W. Rieck and J.T. Weber. Dept. of Anatomy, Tulane University Medical School, New Orleans, LA. 70112

Previous studies have suggested that the hypothalamus and zona incerta project to the superior colliculus (Harting et. al., '79; Edwards et. al., '79). The present study determines the specific origin of this hypothalamotectal projection using the retrograde transport of a lectin bound peroxidase tracer (WGA-HRP). Electrophoretic injections of WGA-HRP were placed unilaterally within the superior colliculus. Animals survived 48 hours, after which they were processed for routine HRP histochemistry. Following large injections of WGA-HRP that include the stratum griseum superficiale (SGS), the stratum opticum (SO) and the stratum griseum intermediale (SGI), extensive retrograde labeling is localized within the zona incerta and the dorsal hypothalamic area (DHA). Scattered cell labeling also is noticed within the lateral hypothalamic area (LHA) and the medial hypothalamic nuclei of the tuberal region, including the dorsomedial nucleus (DM). Labeled neurons within the zona incerta are observed to be medium and large fusiform cells. The labeled neurons within DHA are exclusively small spherical cells that routinely form relatively densely packed clusters that are directly dorsolateral to the apex of the third ventricle. In contrast, the retrogradely labeled neurons within the LHA and medial hypothalamus include widely dispersed small spherical cells and medium sized multipolar neurons. These latter neurons are not apparently restricted to specific nuclear boundaries, however, there appears to be larger numbers of labeled neurons within the medial hypothalamic nuclei. In contrast to the results obtained with large injections, restricted injections of WGA-HRP within either the SGS or the SO result in negligible labeling in either the zona incerta or the hypothalamus. This finding is interpreted to suggest that the SGS and the SO are not the major tectal recipient layers of the projections that arise in the hypothalamus or zona incerta. In conclusion, these results suggest that the zona incerta and hypothalamic projections to the superior colliculus arise from uniquely different groups of neurons, and further, that the hypothalamotectal projection has a preferential termination within SGI as indicated previously by anterograde techniques (Harting et. al., '79).

237.2 'TEMPORAL CODING' FOR PATTERN VELOCITY BY MOVEMENT SENSITIVE VISUAL CELLS IN CAT SUPERIOR COLLICULUS. G. Mandl. Aviation Medical Research Unit, Dept. of Physiology, McGill Univ., Montreal, Canada H3G 1Y6.

This study attempted to relate the temporal characteristics of unit discharge patterns, to the presence or absence of moving visual stimuli within unit receptive fields. METHODS. Spike data were recorded extracellularly from the superficial and intermediate layers of the superior colliculi of unanaesthetized paralyzed pretrigeminal cat preparations. Visual stimuli consisted of small luminous bars (1-4° x 0.2-0.8°) moving under computer control at uniform velocities (2-160°/s) across a CRT screen. Interval histograms, plotted from data acquired at sampling times of 0.2-1 ms, were used to estimate the probability distributions of interspike intervals RESULTS. Spike activities in all tested cells were characterized by two dominant statistical processes: (1) A fast process (FP), consisting of brief irregular high-frequency spike bursts, whose intraburst interval distributions suggested a truncated Poisson process with dead-time (refractory period) and a long 'tail' decaying exponentially from a short (<4 ms) modal interval. (2) A slow process (SP), with periods of near-regular firing (noisy pacemaker), characterized by approximately bell-shaped interval distributions with longer modal intervals (15-50 ms). By relating the interplay of these two processes to external stimulus conditions, each cell could be assigned to one of three functional groups: Group A. Unstimulated activity was dominated by SP. Stimulation with moving pattern caused emergence of FP. An increase in pattern velocity was accompanied by a progressive increase in the FP/SP ratio, without significant changes in the duration of the two respective modal intervals. At one given ('optimal') pattern velocity, cell activity became dominated by FP. Group B. Unstimulated activity was dominated by FP. Stimulation with moving pattern caused complete switch to SP whose modal interval length then varied inversely with pattern velocity. Group C. For all conditions, FP and SP co-existed (double-humped interval distribution). The length of SP modal interval was inversely related to pattern velocity. The length of FP modal interval remained fixed for all pattern velocities, but the time constant of FP exponential decay frequently varied inversely with pattern velocity. Thus, the dominant response of collicular cells to pattern movement does not seem to consist of simple frequency modulation of 'spontaneous' carrier-type 'background' activity. Rather, the present observations suggest that different collicular cells encode the presence, and the velocity, of moving visual stimuli by switching and combining a number of characteristic, stereotyped temporal patterns of discharge.

237.3 TIME COURSE OF MULTIMODAL RESPONSE ENHANCEMENT IN CAT SUPERIOR COLLICULUS NEURONS, J.W. Nemitz, M.A. Meredith and B.E. Stein, Dept. of Physiol.& Biophys., Med. Coll. Va., Richmond, VA 23298.

Visual, auditory and somatosensory inputs converge on cells in the intermediate and deep laminae of the superior colliculus (SC). These cells respond to combinations of sensory stimuli (combined-modality tests) in a manner that may not be predictable on the basis of their responses to each stimulus individually (separate-modality tests). The 'multimodal interactions' fall into two functional categories: response enhancement and response depression. The present investigation examined the time course of response enhancement.

Experiments were conducted on 14 cats chronically prepared for extracellular recording. Each animal was anesthetized with Ketamine HCl, paralyzed and then artificially respired with a mixture of 75% N_2O and 25% O_2. Visual stimuli consisted of flashed or moving bars of light and auditory stimuli consisted of white noise bursts lasting 100-300 msecs. Each cell was first presented with a series of separate-modality tests consisting of 16 repetitions of each sensory stimulus. These same stimuli were then paired and presented simultaneously 16 times. A multimodal interaction was considered to have occurred if there was a significant ($p<.05$) increase in the number of impulses elicited (this enhancement effect varied from a 28-900% increase in the number of impulses evoked). The durations of the response trains evoked in each cell was normalized so that the duration of the response to the most effective separate-modality stimulus represented a value of 100%. Thus, the time course of the responses among different cells to separate- and combined-modality tests could be compared.

A total of 49 multimodal neurons was identified, of which 22 exhibited enhanced responses when visual and auditory stimuli were presented simultaneously. Typically a cell responded to either stimulus presented alone with a brief burst of discharges at the onset of the discharge train and discharge rate decayed rapidly thereafter. When the stimuli were combined a similar pattern occurred, but clearly the discharge rate was higher throughout most of the discharge train. Unexpectedly, however, the greatest percentage of response enhancement did not correspond to the period in which the maximal response rate was evoked. Rather the greatest increase in discharge frequency produced by combining stimuli occurred only after approximately 40% of the discharge train had already elapsed and response rate would normally have decreased markedly to either stimulus alone. Apparently response enhancement is limited during the period in which optimal response rates normally occur to either stimulus alone.

237.4 Descending Efferents of the Superior Colliculus Relay Integrated Multimodal Information, M.A. Meredith and B.E. Stein, Dept. of Physiol. & Biophys., Med. Coll. Va., Richmond, VA 23298.

Activity in the superior colliculus (SC) is related to the orienting of sensory receptors (eyes, pinnae, head) toward a sensory stimulus. Cells in the deeper SC laminae are known to connect with brainstem motor and premotor areas which are involved in the generation of these movements. While many of the efferent SC fibers projecting to these regions are carried in the Lateral Efferent Tract (LET) or Medial Efferent Bundle (MEB), little is known concerning the sensory properties of efferent colliculus neurons. The present study was initiated to determine the responses of such cells to sensory stimuli.

Stimulating electrodes were stereotaxically placed in the LET and MEB of each of 7 cats. Routine paralysis, respiration and recording techniques were used. Cells in the SC were identified by their spontaneous activity or by their responses to visual, auditory and/or tactile stimuli. Once isolated, a cell was tested for antidromic activation from either set of stimulating electrodes (70-300 uA, 0.1 ms pulse). Criteria for antidromic activation: 1) < 0.2 ms latency variation, 2) following frequency > 300 Hz, and 3) threshold current < 300 uA. Whether antidromically activated or not, all cells were evaluated for their responses to separate-modality and combined-modality stimulation.

Of the 115 cells identified in the deeper SC laminae, 48.7% (n=56) were antidromically activated by one (LET=10; MEB=33) or both (LET+MEB=13) sets of stimulating electrodes. The vast majority of these antidromically activated cells (51/56; 91%) were responsive to sensory stimuli (visual=48.3%; auditory=31.5%; tactile =20.2%) and the majority (32/51; 62.7%) received multimodal inputs. Often, the multimodal nature of a cell could only be determined by its response to combined-modality stimulation. No differences between responses to separate-modality and combined-modality tests were apparent in 77.9% (n=46) of the neurons unresponsive to efferent tract stimulation (n=59). The remaining non-efferent cells (n=13) were unaffected by sensory stimuli. Neurons identified as efferents occurred with similar frequency in the intermediate and the deep laminae; and there was no apparent laminar segregation with regard to multimodal properties.

Since these efferent tracts connect the SC to premotor areas of the brainstem, multimodal convergence on efferent SC cells appears to constitute the neural mechanism by which sensory information influences the motor behaviors dependent upon the SC.

237.5 VISUAL DESYNCHRONISATION OF EEG IMPAIRED BY LESIONS OF SUPERIOR COLLICULUS IN RAT. P. Dean, P. Redgrave* and L. Molton*. Dept. of Psychology, Sheffield Univ., Sheffield, S10 2TN, U.K.

Rats with lesions of the superior colliculus fail to orient to novel visual stimuli in the peripheral field. It is unclear whether this deficit arises because the animals have difficulty in producing specific orienting movements, or because they fail to detect or notice the stimuli. We therefore examined the effects of collicular lesions on a response to a novel stimulus that did not involve specific movements, namely desynchronisation of the cortical EEG.

Hooded Lister rats were tested in a small isolated chamber with an overhead mounted 6w fluorescent tube. Their EEGs were recorded with bipolar surface-to-depth electrodes, implanted into frontal and visual cortex. On-line analysis of EEG was used to present stimuli upon the appearance of continuous (15 sec) high-amplitude low-frequency activity. Light flashes of increasing duration (from 20 msec in 40 msec steps) were presented until either the EEG desynchronised for at least 5 sec, or flash duration reached 380 msec.

Irrespective of electrode location, both normal animals and animals with control lesions of cerebral cortex overlying the superior colliculus showed EEG desynchronisation to stimuli within the range studied (12 electrodes in 6 animals, median duration = 60 msec). In contrast, at 13 of 14 electrodes tested in 7 animals with lesions of the superior colliculus, desynchronisation was not observed even for the 380 msec flash, although in a subsequent test some evidence of desynchronisation was observed to a 1 sec flash from a high intensity floodlight. The collicular impairment was not the result of: (1) eyelid closure, because a 380 msec flash, delivered only when an observer close to the animal was certain the eyes were open, failed to desynchronise the EEG; (2) a nonspecific deficit in arousal, because no comparable collicular deficit was found with 20-100 msec bursts of overhead white noise; (3) failure to produce observable orienting movements, because no such movements were apparent when the EEGs of control animals desynchronised.

These results support the view that lesions of the superior colliculus in rats do not merely affect specific orienting movements, but rather impair the ability to detect or notice certain kinds of novel visual stimulus. The results also suggest, in conjunction with the observation that low intensity electrical stimulation of the superior colliculus can desynchronise the EEG (Olds and Peretz, EEG Clin. Neurophysiol., 12:445, 1960), that the superior colliculus may be directly involved in alerting cerebral cortex to such stimuli.

237.7 VISUAL ORIENTING RESPONSES FOLLOWING SELECTIVE REDUCTION OF OPTIC INPUT TO AOS AND/OR OPTIC TECTUM IN FROG. K.V. Fite, D. Hayden*, N. Montgomery & L. Bengston*. University of Massachusetts, Amherst, Massachusetts, 01003.

Recent neuroanatomical studies in anurans have revealed a rich complexity of interconnections among mesencephalic visual areas. For example, the nucleus of the basal optic root (nBOR) is the retinorecipient nucleus of the accessory optic system (AOS) and projects primarily to the pretectal nucleus, which is reciprocally connected with the optic tectum. In addition, nBOR has interconnections with the adjacent, medial tegmental region (peri-nBOR), the oculomotor complex, and nMLF and brainstem nuclei. Contrary to earlier reports, we have demonstrated that nBOR plays a relatively minor role in horizontal optokinetic nystagmus (hOKN), while the pretectal nucleus appears to be more crucially involved in mediating hOKN in frog, as in other vetebrate species.

C. J. Herrick (1948) was among the first to suggest that retinal excitation via the largest myelinated optic fibers may produce a "generalized nonspecific effect" which comes to motor expression, first, through the basal optic tract (BOR). Reduction or removal of retinal input to nBOR might thus be expected to alter the timing of certain visually guided behaviors, such as the rapid visual orientation to live prey seen in many anurans. In order to evaluate this hypothesis, either partial-to-complete transections of BOR, direct lesions of nBOR, or localized retinal deafferentation of the optic tectum were produced in Rana pipiens. Extensive pre- and post-surgical visual orientation response-latency functions (VORLs) were obtained using live prey presented randomly at each of 8 equidistant, circumferential locations around the subject's body. The location and extent of optic deafferentation was subsequently evaluated using anterograde transport of HRP. The results indicate that complete BOR transection or nBOR lesions produce consistent, large increases in VORLs at all prey locations, with the largest latency increases occurring for the lateral, monocular and posterior visual field positions. Localized deafferentation of optic tectum and/or partial transection of BOR yielded much smaller latency increases. Prey-catching behaviors were otherwise unaltered and virtually indistinguishable from normal. These data suggest that the AOS conveys an important aspect of visual information which may serve a unique priming or alerting function in those mesencephalic visuomotor circuits which mediate rapid orienting responses in anurans. Whether or not other visuomotor behaviors are also affected by AOS deafferentation remains to be determined. (Supported by NSF BNS-8209026).

237.8 ANATOMICAL AND ELECTROPHYSIOLOGICAL CHARACTERISTICS OF THE NEURONS IN THE FROG TECTUM RECEIVING OPTIC INPUTS. R.A. McCrea and P. Grobstein, Dept. of Pharm. & Physiol. Sciences, Univ. of Chicago, Chicago, IL. 60637

We have begun a study of tectal organization based on intracellular recording and HRP injection in Rana pipiens. Animals were anesthetized with tricaine and had stimulating electrodes placed on the optic nerve. The field potential evoked in superficial tectal layers in response to optic nerve stimulation consisted of 2 negative peaks with latencies of approximately 2 and 5 msec., and two broader positive peaks of latencies approximately 10-12 and 20-30 msec. Spikes recorded from large diameter optic axons had latencies of 2-5 msec. In addition to a local area of dense terminals in the tectum, the axons collateralized in the pretectal nucleus as well as along the course of their trajectory through the tectum.

The earliest synaptic potentials evoked in tectal cells had latencies ranging from 2 to 40 milliseconds. Short latency EPSP's (less than 10 msec.) were more frequently seen in recordings above layer 6 than below. In and below layer 6, we encountered cells which either had no observable synaptic response or in which the earliest response was a long latency IPSP (40 msec. or more). Some deep cells and virtually all superficial cells responded to optic stimulation with EPSP's at 40 msec. or less.

We injected cells having excitatory synaptic inputs with latencies of 40 msec. or less. To date we have recovered such cells in layers 2, 5, 6, 7, 8, and 9. All cells had processes in retinal recipient layers: the arborizations were in some cases quite restricted both horizontally and vertically and in other cases quite widespread. Many cells appeared to lack clear axons or had axons ramifying only locally. Other cells, including cells both above and below layer 7 had axons which left the tectum. Many of these axons collateralized significantly along the course of their way out of the tectum.

While all cells had dendrites in retinal recipient layers, there was substantial variation among cells in synaptic latency. This almost certainly reflects both heterogeneity in optic fiber input and processing within the tectum. The more frequent recording of short latency inputs above layer 6 as well as the reduced frequency of observed excitatory inputs below layer 6 indicates that a functional subdivision into superficial and deep tectal layers may characterize tectal processing in anurans as in mammals. Finally the frequent collateralization observed along axon trajectories suggests that substantial horizontal as well as vertical interactions characterize tectal organization.

237.9 DENDRITIC AND AXONAL MORPHOLOGY OF TECTAL-PROJECTING NEURONS IN THE ISTHMUS REGION OF A TURTLE, PSEUDEMYS SCRIPTA. M. Sereno. Committee on Neurobiology, Univ. of Chicago, Chicago, IL 60637.

The tectum receives a well-known topographic retinal input to its superficial layers. Relatively little, however, is known about the cellular morphology of other inputs. Therefore, the dendritic and axonal morphology of tectal-projecting neurons in two isthmus region nuclei was examined using HRP injections and serial-section reconstruction techniques.

As in other vertebrates, there is in turtles a retinotopically organized nucleus (magnocellular nucleus isthmi caudalis, Imc) at the caudolateral pole of the tectum. Imc neurons have restricted dendritic fields and are arranged on a shell-shaped map surface. Their dendrites bear fine filamentous appendages with leafy, en passage varicosities. Cases with two punctate HRP injections in the tectum show that Imc neurons projecting to different tectal loci have non-overlapping dendritic fields. The putative axons of Imc neurons travel just below the superficial gray and turn upwards, giving off cylindrical, vertically-oriented arbors of several thousand boutons. Single arbors are about 100 μm in diameter and extend from the central gray (where strings of large boutons have a reticular appearance) up into the superficial gray (where strings of medium-sized boutons appear in vertical arrays that turn horizontally just below the stratum opticum) and finally into the stratum opticum (where less dense vertical arrays reappear). Each arbor covers less than 0.1% of the tectal surface.

Just rostral to Imc is the magnocellular nucleus isthmi rostralis (Imr) which, unlike Imc, has a non-topographic tectal input and a non-topographic projection back to the tectum. Back-labeled Imr neurons have robust dendrites that arborize in the stream of axons that leave the tectum in the ventral tectobulbar path. Their dendritic fields are large relative to the nucleus and their dendrites bear no appendages. Imr axons are emitted ventrally and then turn up into the tectum where they course under the superficial gray, emitting strings of large boutons. In contrast to Imc axons, Imr axons cover a much larger area (10 - 40%) of the tectum with a much less dense, but patchy, terminal distribution.

These results suggest that the superficial and central layers of the tectum both participate in topographic as well as non-topographic feedback loops with structures outside the tectum. (Supported by PHS Grant NS 12518).

237.10 CHANGES IN RECEPTIVE FIELD ORGANIZATION AND VELOCITY TUNING IN TURTLE TECTAL NEURONS FOLLOWING LASER IRRADIATION. Robbins, D.O., Westgate, T.M.*, Zwick, H.*, Bloom, K.R.* and Schuschereba, S.T.* Department of Psychology, Ohio Wesleyan University, Delaware, OH 43015 and Division of Biorheology, Letterman Army Institute of Research, San Francisco, CA 94925.

The receptive field organization of cells in the turtle optic tectum are organized in a complex manner without clear evidence of traditional center-surround relationships. Exposure of these cells to low level laser irradiation (514 and 633 nm) did not produce obvious spectrally selective losses. The overall effect was to uniformly reduce the cell's sensitivity across its entire visible spectrum. Generally, the more intense the exposure, the stronger its effect on the responsiveness of the cell.

Laser irradiation of the center only, periphery only or the entire receptive field produced a similar overall constriction of the field. With intense irradiation, the entire field would constrict until the cell was no longer responsive to light stimulation. With less intense laser exposures, the initial response of the cell was an expansion followed in time by a gradual reduction of the field diameter.

When receptive fields were mapped with moving targets of varying velocities (0 to 100 deg/sec), receptive field expansion was noted for fields plotted with faster moving stimuli. In the long end of the spectrum this effect was monotonic with velocity but with intermediate wavelength stimuli, the effect was much more nonlinear. As velocity was increased, peaks in the intermediate spectrum became more pronounced. Repeated exposure to visible laser light reduced receptive field size across the spectrum when moving as well as stationary targets were used. Maximum effects, however, were found for fields mapped with higher velocity stimuli, suggesting perhaps involvement of neural processing beyond the receptor level.

At the light microscopy level, minimal alteration of retina tissue was observed with even the maximum dosage level used. The observed laser effects suggest that either the coherency or the narrow bandwidth of laser light may artificially elicit activity not commonly observed with more traditional incoherent light sources and may overdrive the neural transmission system.

237.11 POSSIBLE NEURONAL CIRCUITS IN THE PIGEON'S OPTIC TECTUM : AN INTRACELLULAR RECORDING AND LABELING STUDY. O. HARDY*, N. LERESCHE* and D. JASSIK-GERSCHENFELD*(SPON : European Neuroscience Association). Lab. de Psychophysiologie Sensorielle, Université Pierre et Marie Curie. Paris, France.

Excitatory and/or inhibitory effects from the optic nerve have been described in the pigeon's optic tectum by early extracellular studies (Holden, A.L., J. Physiol., 194:91, 1968 ; Robert, F. and Cuenod, M., Exp. Brain Res., 9:123, 1969 ; Bagnoli, P., Franchesconi, W., Magni , F., Brain, Behav. Evol., 16:19, 1979). In order to identify the neuronal circuits involved on such effects, intracellular recordings were obtained from 65 tectal cells using micropipettes filled with Horseradish peroxidase (HRP). The contralateral optic nerve (ON) was electrically stimulated. In addition, the visual telencephalon or wulst (W) and the opposite optic tectum (OT) were also stimulated. Most tectal neurons responded to ON stimulation either with an EPSP or with an EPSP-IPSP sequence ; few cells responded with a pure IPSP. The polarity of the IPSPs was easily reversed by small intracellular hyperpolarizing currents or by intracellular injection of Cl^- ions. IPSPs were also obtained from W and OT stimulation. Latency measurements show that IPSPs to ON are not due to the transynaptic activation of either W or OT ; most likely such IPSPs are transmitted via intratectal inhibitory circuits of both feedback and feedforward type.

After being intracellularly studied 20 cells were labeled by iontophoretic injection of HRP. Pure EPSPs to ON were recorded from different cell types, i.e., radial, stellate and horizontal cells. The bodies of such cells were located in sublayers IIb, c, i, j. EPSP-IPSP sequences were recorded from radial cells whose bodies were distributed in sublayers IIg, i and also from multipolar neurones of Layer III. Pure IPSPs were obtained from ganglionic type neurons having their bodies located in Layer III. Radial cells have apical and basal dendrites. The apical dendrites of EPSP-IPSP cells terminate or give off prominent laterally spreading branches within sublayer IIe, f while those of EPSP cells distribute more superficially in sublayers IIa-d. Autoradiographic studies (Hunt, S.P. and Kunzle, H., J. Comp. Neurol., 15:173, 1976) have shown the presence of 3H-GABA accumulating axon collaterals in sublayer IIf. Our data suggest that EPSP-IPSP cells may receive their inhibitory input by way of such GABA related system.

237.12 THE ANURAN NUCLEUS PRETECTALIS II: LAMINAR ORGANIZATION OF AFFERENT TERMINALS. Neil M. Montgomery & Katherine V. Fite, University of Massachusetts, Amherst, Massachusetts 01003

The anuran nucleus pretectalis (nPt) receives afferents from the central retina and is substantially involved in the neural circuitry underlying optokinetic nystagmus (Montgomery, et al., 1982a,b). The geometry of afferent terminations in nPt was investigated using both HRP and autoradiographic techniques.

Bilateral optic nerve transections soaked with HRP saturated gelfoam showed dense labelling of optic terminals throughout nPt. With unilateral optic nerve soaks however, the contralateral nPt showed a restricted dense-core of HRP label in the superficial portion of the nucleus with sparcer HRP label occurring in the surround. Ipsilateral retinal afferents arborize throughout nPt except the dense-core region. Thus a central contralateral-core, ipsilateral-surround configuration exists for retinal afferents.

Afferents from the accessory optic system (AOS) arborize only in the dense-core region, following restricted HRP injections of nBOR. Afferents from the nucleus of the posterior commissure arborize in all parts of nPt except the dense-core, while afferents from the tectum and anterior thalamus appeared to arborize throughout the nucleus without discernible pattern.

This lamination of afferent terminals in nPt was correlated with cytoarchitectural material in which the somata of the large neurons of the nucleus cluster around the dense-core region. This specific population of large cells should thus receive inputs from both the contralateral retina and AOS near their somata and afferents from the nucleus of the posterior commissure along their outer dendritic extensions.

Similar laminated projections to the pretectal nucleus of the optic tract have been reported from the retina in opossum (Linden & Rocha-Miranda, 1981) and from the AOS in rat (Blanks et al., 1982).

237.13 FUNCTIONAL ANALYSIS OF LMmc AND nBOR OF PIGEON ACCESSORY OPTIC SYSTEM. B. Morgan*, B. J. Frost, P. Ramm*, and J. Chown*. Dept. of Psychology, Queen's University, Kingston, Ontario, Canada. K7L 3N6

We have used unit recordings and ^{14}C-2-Deoxyglucose (^{14}C-DG) autoradiography to specify responses of the pigeon accessory optic system (AOS) to whole field visual stimulation. The AOS is a visual pathway processing information required for control of stabilizing eye movements during motion of the entire visual array. It includes the nucleus of the basal optic root (nBOR), and, possibly, the nucleus lentiformis mesencephali, pars magnocellularis (LMmc). Cells in nBOR respond preferentially to large stimuli moving slowly in an upward, or downward and anterior direction. We now report that cells in LMmc respond preferentially to horizontal motion.

Pigeons were monocularly exposed to stimuli consisting of a large random visual noise pattern, moving slowly (2-4 deg/sec) in a horizontal direction. Single unit responses were recorded from the LMmc of 34 birds. Other birds (n=14) received injections of ^{14}C-2-DG while viewing the random noise pattern moved in either a horizontal or vertical direction.

Responses of LMmc cells were essentially similar to those of nBOR cells, except in their preferred stimulus direction. Both LMmc and nBOR cells responded optimally to very large, slowly moving random noise patterns, were spontaneously active, and showed no adaptation to continued stimulation. However, LMmc cells preferred temporal to nasal horizontal motion, while nBOR cells preferred upward, or downward and anterior movement.

Autoradiographic optic densities (OD), were read from components of the AOS. Ratios were constructed comparing ODs in structures ipsilateral to the exposed eye, to those contralateral to the exposed eye. Ratios <1 indicated increased functional activity in the contralateral structure. The LMmc was selectively activated by horizontal movement (mean I/C=0.78), and nBOR by vertical movement (mean I/C=0.84).

The autoradiographic and unit data converge to suggest that LMmc processes horizontal whole-field motion, and nBOR processes vertical whole-field motion. Thus LMmc and nBOR, components of the AOS, are well adapted to detect retinal slip produced by self-induced motion in three planes.

This research was supported by NSERC grant A0353 and MRC grant MA7244 to B.J.F.

237.14 ULTRASTRUCTURAL CHARACTERIZATION OF A PRETECTAL NUCLEUS, THE LENTIFORM NUCLEUS OF THE MESENCEPHALON (LM). M.D. Gottlieb and O.C. McKenna. Biol. Dept., City College of CUNY, New York, N. Y. 10031.

The avian LM is a pretectal retinorecipient nucleus that is considered to be homologous to the nucleus of the optic tract (NOT) in mammals. Both the LM and NOT have been shown to respond preferentially to slow horizontal movement of the visual world and are thought to signal horizontal optokinetic eye movements.

We examined the fine structure of the LM in four week old chicks using routine methods for electron microscopy. The LM contains two types of neurons that differ in size, one approximately 15 um x 25 um and the other approximately 15 um x 15 um. The somatic profiles of both have a pyramidal shape, evidence a smooth nuclear envelope, and are filled with cytoplasmic organelles, in cluding abundant rough endoplasmic reticulum. These neurons receive axosomatic input from several types of synapses which can be distinguished from one another on the basis of the shape of the synaptic vesicles found in the presynaptic terminals; they contain either round, flat, or a mixture of round and flat vesicles. In all types of axosomatic synapses rough endoplasmic reticulum or cisterna is commonly found subadjacent to the postsynaptic membrane. In the neuropil two types of axodendritic synapses are found. By far the most frequently encountered type contains large round vesicles 40-50 nm in diameter which are clustered at the presynaptic membrane adjacent to the synaptic cleft. The cytoplasmic surface of the postsynaptic membrane displays a marked density. The area of the presynaptic profiles varies; the larger ones usually make several synapses onto one or more dendrites while several of the smaller ones may make individual synapses onto a single dendrite. The presynaptic profile of the second type of axodendritic synapse, which is less frequently seen, contains a mixture of small flat and round vesicles, often clumped near the presynaptic membrane. These profiles participate in axodendritic synapses but as a rule do not make multiple synapses. Unlike the first type of synapse, these do not have a marked postsynaptic density.

In order to identify terminals of retinal origin, HRP-WGA was injected intravitreally and the LM reacted with DAB. HRP reaction product is seen in presynaptic profiles containing large round vesicles indicating that these terminals are of retinal origin. In addition, label is seen in postsynaptic profiles suggesting that transsynaptic transport has occurred.

This study indicates that the most frequently encountered axonal terminal is retinal in origin. The presence of other axonal elements implies that retinal information may be modified at the level of the LM. We are currently investigating the origin of these other terminals. (Supported by NIH EY 03613)

237.15 VISUAL DEPRIVATION DISTURBS POSTNATAL DEVELOPMENT OF THE ACCESSORY OPTIC SYSTEM AND OPTOKINETIC BEHAVIOR. Olivia C. McKenna, Jose Velez*, Bradford Taylor* and Josh Wallman. Dept. of Biology, City College of the City Univ. of N.Y., New York, N.Y. 10031

Retinal slip signals, which provide the input for optokinetic responses, are largely transmitted through the accessory optic system. In birds, the principal nucleus of this system is the nucleus of the basal optic root (nBOR). A previous metabolic mapping study using 2-deoxyglucose (2DG) in 3 week or older chicks has shown that upward movement of the visual world results in labeling in the dorsal portion of the nBOR (nBORd) whereas downward and anterior movement of the visual world results in labeling in the nBOR proper. In chicks less than 1 week old this functional separation is not seen; instead, both divisions of the nBOR are equally labeled whether upward or downward motion is used as the visual stimulus. Furthermore, when optokinetic nystagmus (OKN) is measured in non-horizontal (vertical, torsional and intermediate) directions, the best OKN gain is different in hatchlings than in older birds. Together these results suggest that a postnatal reorganization of the nBOR occurs which, in turn, affects optokinetic eye movements. In the present study we tested whether lack of visual experience during the first three postnatal weeks influences the development of this system.

At hatching both eyes of chicks were covered with translucent occluders which were kept in place for 3 weeks. For the metabolic mapping studies animals were injected with ^{14}C-2DG and positioned in a rotating drum with both eyes open so that one eye viewed upward motion and the other eye viewed downward motion; since the visual pathways in chicks are essentially crossed, differential stimulation of the two eyes results in differential labeling of the two sides of the brain. Autoradiograms of the brains did not show the functional separation of the nBOR usually seen in 3 week old chicks; instead, the label was uniformly distributed within the nBORd and nBOR proper whether the corresponding eye viewed upward or downward motion. For the OKN experiments eye movements of animals were measured in a variety of directions. Preliminary findings show that visual deprivation impairs OKN in non-horizontal stimulus directions much more severely than in horizontal directions.

Together these results suggest that postnatal reorganization of the nBOR and the consequent optokinetic response system require visual experience to develop normally.

VISUAL CORTEX: INTRINSIC ORGANIZATION III

238.1 CONVERGENCE ON NEURONS IN LAYER IV (CAT AREA 17) OF LATERAL GENICULATE TERMINALS CONTAINING ROUND OR PLEOMORPHIC VESICLES. G.Einstein, T.L. Davis, and P. Sterling. Dept. of Anat., Univ. of Pennsylvania, Phila., PA 19104.

We observed that terminals from the lateral geniculate nucleus (LGN) labeled by anterograde transport of radioactive amino acids are of two morphological types: one contains round vesicles and forms an asymmetric synaptic contact; the other contains pleomorphic vesicles and forms a symmetric synaptic contact(ARVO, 1983). The LGN terminals with round vesicles are distributed throughout the depth of layer IV; those with pleomorphic vesicles are distributed in IVc and deep IVab. We believe that the terminals with pleomorphic vesicles arise from the small LGN neurons (Guillery type III) that accumulate GABA and stain with antibody to GAD. Some of these apparently GABA-ergic neurons have been shown physiologically to be X-cells and to project to area 17. Cortical neurons in IVc and deep IVab might therefore receive convergent input from excitatory (Guillery type II) X-cells and inhibitory (Guillery type III) X-cells . We examined neurons in this region for evidence of such convergence.

Six neurons were partially reconstructed from electron micrographs of 138 serial autoradiograms in which LGN terminals had been labeled by transport of 3H-proline and leucine. Consistent with the observations of others, LGN terminals with round vesicles were presynaptic to dendrites, somas, and spines; LGN terminals with pleomorphic vesicles were presynaptic to dendrites and somas but not to spines. Five of the reconstructed neurons were in IVc. They had medium somas (13-15μ) with pale cytoplasm, and each contained a cytoplasmic laminated body (CLB). Synaptic contacts were distributed to the somas at a density of 19-33/100μm^2. Most somatic contacts were made by terminals that contained pleomorphic vesicles, their ratio to those with round vesicles (F/R) ranging from 4-7. LGN input to the soma and proximal dendrites of these cells was sparse, representing only about 3% of all contacts; however, both types of LGN terminal were represented on each neuron. One reconstructed neuron was from the border of IVab/IVc. It had a medium soma (15μ) with dark cytoplasm and a folded nucleus. Synaptic contacts were distributed to its soma at a density of 34/100$\mu m^2$and LGN input to the soma was heavy, representing 21% of all contacts. LGN terminals of both types were represented roughly equally on the soma (13, pleomorphic; 15, round). In summary, of the six cortical neurons studied, all received LGN input. Whether the distribution from the LGN to these neurons was sparse or dense, both types of terminal were about equally represented. This suggests that the receptive field properties of cortical neurons deep in layer IVab and in IVc may be influenced by inhibitory input as well as excitatory input from X-cells in the LGN. Supported by NEI EY00828.

238.2 THE ORGANIZATION OF MACAQUE GENICULOSTRIATE TERMINALS VISUALIZED AFTER INTRAVITREAL INJECTION AND THE TRANSNEURONAL TRANSPORT OF WGA-HRP. S.K. Itaya, P.W. Itaya* and G.W.Van Hoesen. Depts. of Anatomy and Neurology, Univ. of Iowa, Iowa City, IA 52242.

In previous research we demonstrated that wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP) can be used as a transneuronal marker of visual pathways (Itaya & Van Hoesen, 1982). To study monkey geniculostriate terminals, we made intravitreal injections of WGA-HRP, then processed coronal brain sections for TMB histochemistry (Mesulam, 1978). All labeling in visual cortex was terminal labeling; no WGA-HRP labeled cell bodies were observed, and few labeled intracortical axons were seen. Cortical layers in area 17 were numbered according to Lund (1973). A small amount of reaction product was observed in layer I, mainly in the calcarine fissure and usually above labeled patches in II and III. Lightly labeled patches occurred in II and III throughout the striate cortex, usually over ocular dominance columns in IVC. In IVA, terminal labeling in tangential sections clearly showed a honeycomb pattern in patches which usually corresponded to ocular dominance columns in IVC. In IVC there was a clear pattern of ocular dominance column labeling; additionally, intercolumnar labeling was also obvious. The ocular dominance columns themselves showed a range of shapes and sizes. Generally, IVCβ was more heavily labeled than IVCα, but in a small number of instances, this pattern was reversed. We also found examples where labeling was continuous between ocular dominance columns, either in IVCα, IVCβ, or in a thin layer comprising the lower one-third of IVCβ. Layer VI labeling was patchy, and usually coincident with ocular dominance columns in IVC. When bilateral injections of WGA-HRP were compared with semiserial sections stained for cytochrome oxidase (Wong-Riley, 1979), the labeling patterns from both techniques were similar with patches in II and III, honeycombs in IVA, a band in IVC, and patches in VI.

Several conclusions may be drawn from our results. 1) WGA-HRP is transported only in an anterograde-anterograde direction; all of our evidence to date also supports the hypothesis that WGA-HRP is transsynaptically transported in the visual system. 2) The transneuronal WGA-HRP technique confirms the known anatomy of geniculostriate terminals but, in addition, suggests the following: 3) Left and right retinogeniculostriate terminals are not completely segregated in the ocular dominance columns. 4) Retinogeniculostriate input occurs in patches in II and III. 5) The labeling of retinogeniculostriate terminals in IVC suggests a suborganization within the ocular dominance slabs. 6) Cytochrome oxidase staining coincides with geniculostriate terminals. 238.3 PYRAMIDAL AND STELLATE NEURONS IN MONKEY VISUAL CORTEX LABEL FOR DIFFERENT PEPTIDES. Anita Hendrickson. Dept. Ophthalmology RJ10, University of Washington, Seattle WA 98195.

The peptides somatostatin (SOM), alpha melanocyte stimulating hormone (aMSH) and avian pancreatic polypeptide (APP) have been localized in Macaca monkey visual cortex using immunocytochemical techniques at the light and electron microscopic level. Animals were perfused with 4% paraformaldehyde containing 0.34% lysine and 0.005% periodate; some animals had received intracortical injections of 15ug/ul colchicine 24hrs before sacrifice. For LM frozen sections were reacted using standard methods for the peroxidase-antiperoxidase method of Sternberger. For EM the same method was used for vibratome sections, only the times in antisera and amount of Triton was reduced to provide better tissue preservation.

The two peptides SOM and APP labeled similar cell populations, but with different intensities. The most common cell was found in the white matter just under layer 6, and was seen throughout the occipital pole with no difference noted among visual areas. These horizontally oriented neurons have curved dendrites which send rising branches up into layer 6 and above. A single straight process, presumably the axon, arises from the cell body or primary dendrite and travels upward through all layers, finally ending in an extensive tuft in layer 1. SOM or APP neurons are less common within visual cortex; most are stellate neurons with multiple dendrites and a complex, beaded locally-ramifying axon. They occur most often in layers 2 and 3 in both primary and secondary visual cortex. APP processes form an extensive network in layers 3, 4B, and 5A, but are almost absent in 4C of striate. SOM neurons are more difficult to stain than APP and may be less frequent.

aMSH labels mainly pyramidal neurons; preabsorption of diluted antiserum with 10uM aMSH completely abolishes this staining. Without colchicine the large pyramids of layers 5 and 6 in striate and layer 3 of prestriate are heavily labeled. With colchicine all pyramids label, especially the small cells in layers 2 and 3 which appear almost Golgi-like with dendritic spines and axon delineated. Bundles of axons in cortex and white matter are also labeled by aMSH. In all visual areas the granule cell layer of 4 contains very few stained cell bodies. At the EM level the immunocytochemical stain is found throughout the cytoplasm, especially around microtubules. Asymmetric synaptic terminals are sometimes stained as are all other regions of the pyramidal neuron.

The role for these peptides in visual processing must await neuropharmacological and neurophysiological testing.

238.4 THE FINE STRUCTURE AND INTRACORTICAL CONNECTIONS OF SMALL, LAYER IV, SPINOUS STELLATE NEURONS IN MONKEY STRIATE CORTEX. R. L. Saint Marie and A. Peters. Dept. of Anatomy, Boston Univ. Sch. of Med., Boston, MA 02118.

Several varieties of spinous stellate neuron have been described in layer IV of monkey primary visual cortex (Lund, J.S., J. Comp. Neurol., 147: 455-496, 1973). Of these, only the smallest have axons that routinely impregnate with the rapid Golgi and Golgi-Kopsch procedures. The fine structure and intracortical connections of these neurons are examined using the gold-toning EM procedure of Fairén et al. (J. Neurocytol., 6: 311-337, 1977).

Small, spinous stellate neurons have rounded cell bodies (7.5-10 um, diam.). The nucleus is also round, slightly eccentric and nearly fills the cell body. Rough ER is sparse and dispersed within the perikaryon with no well-developed Nissl bodies present. Few synapses occur on the cell body and these synapses are symmetric. As few as three primary dendrites may emerge from the cell and bifurcate 3-4 times. The resulting dendritic field is approximately spherical. Dendritic spines frequently terminate as a rounded head connected to the dendrite by a long thin stalk. Synapses on these spines are asymmetric almost exclusively whereas axo-dendritic synapses may be either symmetric or asymmetric.

The axons of small, spinous stellate neurons descend either from the cell body directly or, rarely, from the base of a primary dendrite. The initial segment possesses no prominent axo-axonal synapses. The descending axons of some small, spinous stellate neurons branch to form several recurrent collaterals which ascend vertically through the dendritic field as far as layer III. The recurrent axons of others ascend obliquely within layer IV. The axons of still other spinous stellates emit long, horizontal collaterals which terminate in a secondary plexus within layer IV. Synapses formed by the axons of all small, spinous stellate neurons are asymmetric and these synapses occur on dendritic spines for the most part, as well as on dendrite shafts. Light-microscopic examination of groups of well-impregnated neurons suggest that the axons of small, spinous stellate cells make synaptic contact with the dendrites of other spinous and non-spinous stellate neurons, with the apical dendrites of infragranular pyramids and their secondary branches, with the dendrites of layer III and IVA-B pyramidal neurons, and with the dendrites of the parent cell (autapses). Some of these synaptic contacts have been confirmed ultrastructurally.

238.5 THERE ARE INTERINDIVIDUAL DIFFERENCES IN THE NUMERICAL DENSITY OF FLAT-SYMMETRICAL (BUT NOT OF ROUND-ASYMMETRICAL) SYNAPSES IN AREA 17 OF CAT. C. Beaulieu* and M. Colonnier. Department of Anatomy, Laval University, Québec, Que. G1K 7P4.

The numerical density (Nv) of synapses has been estimated in individual laminae of the binocular and monocular regions of cat area 17, using a method of size-frequency distribution. Separate estimates were obtained for asymmetrical synapses with round vesicles (RA synapses) and for symmetrical synapses with flat vesicles (FS synapses). Five adult animals have been studied to date. For the total cortical thickness, the Nv of synapses was not significantly different for the two regions, being in the order of 180 million/mm^3 in the binocular and 175 million/mm^3 in the monocular region. Of these, approximately 84% were of the RA type and 12% were of the FS type (the remaining 4% could not be clearly classified as one or the other). There was no significant difference in Nv between binocular and monocular regions, for either of the two types. In contrast the total number of synapses under 1 mm^2 of cortical surface was 40% higher ($p < 0.005$) in the binocular region (310 million), than in the monocular region (225 million). This difference is due mainly to the greater thickness of the binocular region.

Although there was no significant difference between the number of RA and FS synapses per mm^3 of tissue in the binocular and monocular regions, the standard deviations in both regions were much higher for FS (~40% of the mean) than for RA (<10% of the mean) synapses. In an individual animal if the Nv of FS synapses was either high or low in the binocular region, it was correspondingly high or low in the monocular region. The animals, however, were very different from each other (as low as 13 million and as high as 38 million FS synapses/mm^3 of cortical tissue). For this reason, the two-way analysis of variance comparing the Nv of FS synapses in the binocular and monocular regions of the five animals which showed that there was no difference between the two regions for these animals, did demonstrate a significant difference between the animals ($p = 0.01$). This was not the case for the RA synapses, were the Nv was quite similar for both regions and for all animals. The interindividual differences for the FS synapses may be due to differences in age, breed or to environmental factors. In cortex, FS synapses are largely GABAergic and inhibitory (Riback '78, J. Neurocytol: 7,461). On the basis of the evidence presented by Leventhal and Hirsch ('80, J. Neurophysiol: 43,1111) that inhibitory connections may be particularly dependent on visual experience, we suggest that the interindividual differences are mainly due to the (unknown, and probably varied) rearing conditions of the animals used in the present study.

238.6 ACTIVITY LABELLING OF THE VISUAL SYSTEM FOLLOWING INACTIVATION OF THE RETINAL "ON" CHANNEL WITH 2-AMINO-4-PHOSPHONOBUTYRIC ACID (APB). J.H. Sandell and P.H. Schiller*. Psychology Dept., M.I.T. Cambridge, MA 02139.

2-amino-4-phosphonobutyric acid (APB) selectively inactivates ON center bipolar cells when applied to the retina of the rhesus monkey (Schiller, 1982). As an adjunct to neurophysiological and behavioral studies using APB, we have begun to study the changes in the biochemical anatomy of the visual system which accompany chronic APB administration.

One rhesus monkey received six 0.075cc injections of 14mM APB into the vitreous of one eye (est. conc. = 525μM) over a 15 day period. The effectiveness of the APB was monitored by sampling LGN unit activity following the first and fourth injections and just prior to sacrifice. The ON response of LGN units in the injected eye laminae was abolished by this chronic injection procedure, although OFF responses remained plentiful. Serial sections from the striate cortex and the LGN were processed for AChE, BuChE and cytochrome oxidase activity, together with sections from a monkey which had been monocularly enucleated for 15 days.

The lateral geniculate nuclei from the APB treated animal contained normal AChE and BuChE activity and moderately decreased cytochrome oxidase activity in the injected eye laminae. As expected, the LGN of the enucleated animal had moderate reductions in AChE and BuChE activity in accordance with Graybiel and Ragsdale (1982), and dramatically decreased cytochrome oxidase activity in the deprived eye laminae.

The enucleated animal's striate cortex revealed the prominent AChE and BuChE stripes described by Graybiel and Ragsdale (1982). The cortex of the simultaneously processed APB treated animal showed no such stripes. By contrast, cytochrome oxidase stripes in layer 4c were well defined in the cortex of both animals, although those of the APB treated animal were somewhat fainter. The cytochrome oxidase patches above and below layer 4 were essentially normal in the APB treated animal; they did not have the obvious alternating rows of darkly and faintly labelled patches seen in the enucleated animal. These findings show that the changes in cortical activity produced by blocking the ON system for 15 days can produce clear modulation of cytochrome oxidase activity but not AChE or BuChE activity in the rhesus monkey. 238.7 HOW IMPORTANT ARE INHIBITORY SUBREGIONS FOR THE VELOCITY UPPER CUT-OFF IN THE CAT VISUAL SYSTEM ? J. Duysens, G.A. Orban, H. Maes* and J. Cremieux*. Laboratorium voor Neuro- en Psychofysiologie, K.U.L., Campus Gasthuisberg, B-3000 Leuven (Belgium).

In theory, the absence of responses to a fast moving light bar could be related to interactions between excitatory and inhibitory regions in the visual field of geniculate or cortical neurons. This may be due to retro-active inhibition, elicited by the entry of the light bar into a short-latency inhibitory zone after crossing the discharge region (Goodwin and Henry, J. Physiol.(Lond.), 277, 467, 1978). Or it may be due to pre-active inhibition, in which the excitatory effects, caused by the crossing of the discharge zone, are neutralized by the lingering inhibitory effects caused by the preceding entry into an inhibitory region.

The contribution of these two mechanisms was explored in 94 cells (15 from LGN, 59 from area 17 and 20 from area 18) by testing the effect of masking of these inhibitory zones on velocity sensitivity. Cells which rely on inhibitory zones for their velocity upper cut-off were expected to have a higher cut-off when the inhibitory zones were masked.

In the LGN two X-ON cells were found to respond to much higher velocities when only the most sensitive part of the center was stimulated. The latency of the inhibition was not shorter than the latency of the excitation so that pre-active inhibition is the most likely explanation for the velocity upper cut-off of these cells.

At the level of the cortex, the most dramatic effect of limiting the exposed receptive field was an overall decrease in response level. Since such decrease was not apparent in the LGN material it follows that the need for spatial summation increases steeply at the cortical level. Cortical cells were divided into an ON and OFF group depending on the presence of dominant ON or OFF subregions. When ON cells were tested with a light bar and OFF cells with a dark bar it was found that most cells showed a slight shift of their velocity upper cut-off to lower velocities as a result of the mask induced reduction in response levels. In a few cases the cut-off shifted to higher velocities and evidence for retro-active inhibition was obtained for some of these cells. When OFF cells were tested with a light bar then shifts of the cut-off to higher velocities occurred more frequently and this seems largely due to the masking of pre-active inhibition.

It is concluded that inhibitory interactions between different parts of the RF play only a secondary role in the generation of a velocity upper cut-off in most cells of areas 17 and 18.

An alternative mechanism, based on the temporal integration characteristics of cortical cells, is likely to be of more importance in this respect (Duysens et al., Soc. Neurosci. Abstr., 8, 677, 1982).

238.8 CELLS ENCODING FOR RED, YELLOW, GREEN, AND BLUE IN LAYER 4 OF STRIATE CORTEX IN THE AWAKE MONKEY. R.G. Vautin* and B.M. Dow (SPON: C.J. Smith). Neurobiology Division, Physiology Department, School of Medicine, SUNY, Buffalo, NY 14226.

Complete color tuning curves have been obtained for 218 cells in foveal striate cortex of alert, behaving macaques. Each cell was tested with its optimal spatial stimulus. Test colors, provided by 14 interference filters and four gelatin filters (purple) matched for human photopic luminosity, were presented at luminance levels sufficient to evoke vigorous responding from individual cells. Data were plotted as percent maximal response, and a tuning index (1-the area under the curve) obtained for each cell.

Cross-correlations of 183 tuning curves having a tuning index of at least .25 revealed 132 which correlated at a level of .9 or better with at least one other tuning curve. Sixty-four tuning curves fell into the six largest cross-correlation groups, containing 15, 14, 14, 9, 6, and 6 cells. Mean tuning curve peaks for these six groups were at 450, 656, 656, 506, 506 and 577 nm, respectively. The more broadly tuned 656 and 506 nm groups were excluded from further analysis. Mean tuning curves for the other four groups suggest an opponent relationship between 656 and 506 nm cells (red vs. green) and between 577 and 450 nm cells (yellow vs. blue). Cone inputs to the four groups, estimated from Smith and Pokorny's human cone sensitivity functions (Boynton, Human Color Vision, 1979) by means of a curve-fitting procedure, also suggest opponent pairs, with cortical red and green cells receiving input from long vs. middle wavelength cones, and cortical yellow and blue cells receiving input from long plus middle vs. short wavelength cones.

Microdrive depth readings and histological lesion sites suggest that red, yellow, green, and blue cells are concentrated in layer 4 of striate cortex, whereas cells responding optimally to other colors (e.g., orange, cyan, purple) are located more typically in upper and lower layers. Combining the mean curves of red (r), yellow (y), green (g), and blue (b) cells according to Hurvich and Jameson's (J. Opt. Soc. Amer. 45:602-616, 1955) opponent hue model, gives a curve similar in most regards to those obtained from human observers by means of either hue cancellation or hue naming techniques (Werner and Wooten, Percept. Psychophys. 23:371-374, 1979). The red, yellow, green, and blue cells found in layer 4 of the monkey's striate cortex may therefore constitute the striate cortical correlate of the 4 primary colors of the Hering-Hurvich-Jameson opponent-colors theory.

238.9 THE NEURONAL CODING OF ROTATING BAR STIMULI IN PRIMARY VISUAL CORTEX OF CAT. J.C. Pearson*, Dept. of Physics; D.M. Diamond*, Dept. of Psychobiology; T.M. McKenna, Dept. of Psychobiology; P.C. Rinaldi, Dept. of Neurosurgery; G.L. Shaw, Dept. of Physics; N.M. Weinberger, Dept. of Psychobiology, Univ. of Calif. Irvine, Irvine, Calif. 92717

Investigations of the functional organization of area 17 have revealed that cells having a common optimal bar orientation are arranged in minicolumns. These studies usually have employed stimuli whose orientations were fixed during a given presentation. However, such simple "isolated" stimuli may not have revealed the full extent of the information processing capacity of visual cortical cells. This issue has been addressed by Shaw, et. al., (Exp. Neurol., 77:324, 1982) in a proposal to investigate dynamic interactions between minicolumns. Specifically, it was suggested that the responses to rotating bar stimuli would involve interactions between minicolumns, and reflect additional processing capacities.

Single unit activity was recorded from chronically prepared cats under neuromuscular blockade to insure constancy at the periphery. The stimuli consisted of a bar of light, (approximately 3° by 0.25°) "rotating" about its center, which is a fixed point in the visual field. The "rotation" consists of sequential presentation of the bar at 4-8 equally spaced angles. This sequential stimulation is predicted to involve interactions between minicolumns within a given ocular dominance column, hence, the response to a bar of a given orientation should depend on the sequence it is in. We have investigated dynamic stimulus parameters evoking neuronal discharge patterns which can not be explained simply as a composite of the responses to the "isolated" stimuli. Previously, we have reported such complex sequence-dependent responses in multiple-unit recordings (Shaw, et. al., Exp. Neurol.,79:293,1983). We have extended this inquiry to the discharges of single neurons and have found three sequence-dependent effects to date: (1) a significant difference between responses to a given orientation of a bar as a function of the direction of rotation, i.e., clockwise vs. counter-clockwise; (2) differences in response to identical sequential stimuli presented at slightly differing rates (1.0 Hz vs. 1.2 Hz.) -- there were no differences in response to identical isolated single bars presented at these same rates; (3) replacing one orientation in a clockwise sequence by a blank (no bar) of equal duration resulted in no change in the response to the next orientation -- in contrast, the responses to the other orientations were doubled. Such single neuron response properties appear to reflect network dynamics.

238.10 ORIENTATION AND SPATIAL FREQUENCY DISCRIMINATION: CAT SINGLE CELLS AND HUMAN PSYCHOPHYSICS B.C. Skottun*, A. Bradley* and I. Ohzawa* (SPON: T. Cohn) School of Optometry, University of California, Berkeley, CA 94720

The spatial selectivity of single neurons in the visual cortex suggests an important role for these units in mediating spatial vision. Quantitative comparisons between behaviorally determined properties of spatial vision and response characteristics of single cells must incorporate not only the selectivity but also the variability of the neuronal responses. In this study we compare the performance limits of single cells in the cat's visual cortex (area 17) with the psychophysically determined orientation and spatial frequency discrimination limits of human observers, using techniques that take both factors into account while requiring few assumptions to be made.

All experiments were performed with sinusoidal luminance gratings. Human psychometric functions were obtained with a temporal-two-alternative-forced-choice method of constant stimuli. "Neurometric" functions for individual cells plot the probability of an increase in firing rate for stimulus changes of different magnitudes. The probabilities were estimated, using Receiver Operator Characteristic (ROC) analysis, by comparing firing rate distributions from two conditions out of a series of orientations (or spatial frequencies) that were presented in a randomly interleaved sequence.

For both single units and human observers a 75 % threshold criterion was adopted. The mean thresholds for 6 human observers were 0.56 deg and 3.6 % for orientation and spatial frequency, respectively. For the single neurons large inter-unit variability was evident with thresholds ranging from under 2 to more than 16 deg, and from about 4 to 48 % for orientation and spatial frequency, respectively. In our sample (N= 15 for orientation and N= 11 for spatial frequency) the "best cells" had orientation and spatial frequency discrimination thresholds of 1.85 deg and 3.95 %, respectively.

The similarity in resolution of single cells and human observers suggests that the information contained in the firing rate of individual neurons can be close to the level required to attain the performance measured behaviorally.
(We are indebted to G. Solar for preparing the cats for recording.)

238.11 A SEARCH FOR FUNCTIONAL BINOCULARITY IN THE PIGEON. B. J. Frost, M. A. Goodale, and J. D. Pettigrew. National Vision Research Institute, Carlton, Victoria, Australia 3053.

Although there is behavioral evidence to suggest that the pigeon uses stereopsis to make depth judgements, a neural substrate for stereoscopic vision has not been demonstrated in this species. One candidate for the necessary binocular integration is the visual Wulst which receives both ipsilateral and contralateral projections from the optic nuclei of the thalamus. In the owl, units have been recorded in the Wulst that are well-tuned for different retinal disparities, and accumulating anatomical and electrophysiological evidence suggests that the thalamic projections to the avian Wulst may be a functional analogue of the geniculostriate system in the mammal.

The present study was designed (1) to determine whether functional binocular interaction exists at the single-unit level in the pigeon's visual Wulst, and (2) to measure the amount of functional binocular overlap by combining eye position recording with visual field measurements derived from electrophysiology and ophthalmoscopy.

Electrophysiological recordings were made with glass-coated tungsten microelectrodes under Ketalar/Rompun anesthesia. Retinal landmarks (the pecten and ora terminalis) of each eye were plotted with a reversible ophthalmoscope. The position of the eyes was measured in alert birds with subconjunctival search coils. Single-unit recordings in the pigeon's Wulst showed two distinct retinotopically organized maps of visual space, one lying subjacent to the other in the hyperstriatum accessorium. A much larger proportion of the map was devoted to that part of the visual field immediately in front of the beak, and most cells with receptive fields in this area responded best to stimuli presented within 10 to 15 cm from the eye (in contrast, to units in the nucleus rotundus which responded to stimuli more than 200 cm from the eye). Despite the over-representation of the field in front of the beak, only a few binocular cells were encountered. Measurements derived from the eye position recordings and the retinal landmark plots indicated that when the pigeon's eyes were in the primary position (at rest and under anesthesia), the area centralis of each eye coincided with the ora terminalis of the other providing about 22^{o} of binocular overlap. Eye movements occurred in the alert bird, however, which were up to 20^{o} convergent of the primary position so that the areae centrales lined up and binocular overlap doubled to over 40^{o}. The failure to find many binocular units in the Wulst may therefore be due, either to the fact that monocular processing is favoured at times of divergent oculomotor activity, or to the technical difficulties associated with stimulating binocular units when the receptive fields would be divergent by some 20^{o}.

238.12 ANALYSIS OF INTRINSIC CONNECTIVITY IN CAT VISUAL CORTEX USING INTRACELLULAR DYE INJECTIONS IN VITRO. L. C. Katz* (SPON: A. J. Hudspeth). Div. of Biology 216-76, Caltech, Pasadena, CA 91125.

Intracellular, in vivo injection of horseradish peroxidase into neurons in cat area 17 has illustrated the previously unsuspected complexity of the intrinsic axonal arborizations of these cells (Gilbert, C. D., Weisel, T. N., Nature 280:120, 1982). However, since obtaining well filled cells, or cells in specific laminae is technically difficult in vivo, an in vitro brain slice preparation of cat area 17 has been devised. Intracellular staining of cortical neurons in vitro reveals detailed axonal arborizations whose extent and appearance are similar to those described in vivo.

350 µm slices were cut from the visual cortex of Nembutal-anesthetized adult cats, maintained in vitro with standard mammalian brain slice techniques, and intracellularly injected using lucifer yellow. Laminar borders were clearly visible. In experiments on six cats, 150 cells (mostly pyramidal) were intracellularly injected in layers II/III. The pyramidal cells had a stereotyped pattern of arborization. Collaterals which emerged from the cell body in the vicinity of the basal dendrites ascended and branched within the upper reaches of layer II and within layer I. Within layer I, the terminals often formed discrete clusters, as described in vivo. A number of long horizontal collaterals (extending over 1 mm) emerged from the main axon at the III/IV border. Often these collaterals sent vertically ascending branches back into layer II/III. No collateral branching was seen in layer IV. Another profuse collateral arborization (also extending for up to 1 mm) was observed within layer V. Smaller branches were observed in layer VI.

The electrical excitability of neurons in slices was apparently normal. Action potentials of filled cells averaged 50 mV amplitude and less than 1 msec duration at half height. Spontaneous EPSP's and IPSP's were frequently observed. Intracellular penetrations remained stable for over an hour, and the slices were viable for up to 12 hours.

I have used this preparation to determine whether the efferent connectivity of area 17 cells correlated with a specific pattern of intrinsic axonal arborization. A new fluorescent retrograde tracer (latex microspheres) was injected into the corpus callosum in vivo followed by preparation of brain slices and intracellular lucifer yellow injections in vitro. At least one double labelled cell at the lamina III/IV border was clearly a spiny stellate cell with some axon collaterals running horizontally along the III/IV border and with others ascending into lamina III. This confirms the observation (Innocenti, G. M., Fiore, L., Neurosci. Lett. 2:245, 1976) that some stellate cells can make long distance efferent connections.

238.PO **A MODEL OF A CORTICAL AREA BASED ON A GENERALIZED MORPHOLOGY OF THE NEOCORTEX.** W. von Seelen*, G. Krone*. Institut für Zoologie, Saarstr. 21, D-6500,Mainz, FRG. (SPON: K. Behrend)

The visual cortex of the cat comprises at least 13 areas each with a topographical representation of the visual field. One method of studying such a system is to lesion one area after the other and compare the performances of the animals in specific behavioral tasks. The outcome of such experiments has shown that there is a considerable degree of functional interaction between the areas.

To investigate principles of interaction we constructed a model of an area based on a generalized morphology. The model comprises six layers of pyramidal and stellate cells. Neurons are described by their dendritic and axonal density which is synonymous with afferent and efferent connectivity. As a rule, the afferent area of pyramidal cells increases from layer II to layer VI. Input to layer I is considered to be of cortical origin, input to layer to be of thalamic origin with no restrictions with no restriction to quality.

As a first step, we simulated the response of neurons in layers II to VI to an input to either layer I or IV, or to both of them. Despite the rigid and uniform design of elements and connections, the response profiles in space and time of the different layers show a surprizing variety which includes those of the known neurophysiological cell types from "simple" to "hypercomplex". The second step will be to simulate two such model areas and to investigate the effects of their interaction.

239.1 PHYSIOLOGICAL DISTRIBUTION OF PIRACETAM IN RATS. M.T. Tacconi* and R.J. Wurtman (SPON: A.L. McCall). Laboratory of Neuroendocrine Regulation, MIT, Cambridge, MA, 02139, USA.

Although previous studies suggest that levels of piracetam (2-oxo-1-pyrrolidine acetamide, Nootropil R , the prototype of nootropic drugs, are higher in brain (especially rat cortex), than in blood several hours after its administration, few data are available on its overall physiological disposition in experimental animals. We examined the distribution and fate of piracetam in rats given 100 or 1000 mg/kg of the compound by gavage, with or without the addition of ^{3}H piracetam as a tracer. Peak levels in serum were obtained after about 60 minutes; thereafter levels decayed following a two exponential curve, with a short (2 hours) and a longer (3.5 hours) half life. Brain levels equaled those of serum at about 4 hours, after which brain levels fell exponentially but more slowly, so that the drug's concentration was about 2 fold higher in brain than in serum. No evidence could be obtained for significant metabolism of the drug, either after its oral administration or when it was incubated with liver homogenates. Brainstem piracetam levels after a single dose were lower (by 30-40%) than those in olfactory bulb, superior colliculi or cortex. After its oral administration piracetam accumulated in the cytosol of subcellular preparations of liver and brain, showing low (2-3%) binding to particulate organelles. Repeated doses (100 mg/kg, 7 days) of piracetam failed to elevate brain levels beyond those observed after single doses. These data suggest that piracetam probably distributes within two metabolic compartments, a central compartment, including the plasma and easily-diffusible tissues, with a high elimination rate; and a compartment with a lower diffusion rate. Since piracetam has a Chloroform/water partition coefficient of 0.04, the drug might meet some resistance in crossing the blood brain barrier in both directions so that its clearance from the brain is retarded in comparison to that of the serum.

239.2 MEMORY PROTECTIVE AND ENHANCING EFFECTS OF ANIRACETAM (Ro 13-5057) IN MICE TESTED IN AVOIDANCE PROCEDURES. G. Vincent*, A. Verderese*, and E. Gamzu (SPON: L.M. Bartoshuk). Dept. Pharmacology I, Hoffmann-La Roche Inc., Nutley, NJ 07110.

Previous reports from our laboratories have shown that the nootropic agent aniracetam, a piracetam analog (1-anisoyl-2-pyrrolidinone), protected against a non-convulsant electrobrain shock (EBS)-induced disruption of retrieval in a one-way shuttle avoidance procedure (Gamzu et al., Soc Neurosci Abstr 7:525, 1981; Cumin et al., Psychopharm 78:104-111 1982).

We have developed an automated platform-jump avoidance procedure using mice, which allowed for manipulation of acquisition and retention of the avoidance behavior. Mice are trained on Day 1 to avoid a grid shock by jumping onto a drop platform. This training consisted of 2 separate 5-trial sessions spaced 4 hours apart. Testing occurred 24 hours later using a 10-trial session.

In aniracetam pretreated mice (at 10, 30, and 100 mg/kg) EBS applied prior to testing did not disrupt the avoidance response. Thus, aniracetam was protective against memory retrieval corroborating our earlier observations in the shuttle avoidance. Low avoidance behavior can be produced by eliminating the second training session. In this test, aniracetam up to 100 mg/kg, administered immediately after a single training session, failed to effect memory consolidation in normal mice. This result suggests that normal mice may be responding close to an optimal level in this test. Consequently the next two experiments focused on the poor learners - i.e. mice that failed to successfully escape the shock in the first training session. In these mice, aniracetam (100 and 300 mg/kg), given one hour before or immediately after the second training session, produced a significant improvement in avoidance performance compared to vehicle-treated animals. This post-training paradigm suggests that part of the performance can be attributed to improved consolidation of memory. Our findings confirm the memory-protective effects of aniracetam. Furthermore, experimental evaluation of nootropic drugs might be expanded to include situations involving experimentally impaired learning and memory or animals with learning/memory deficits.

239.3 A RAPIDLY ACQUIRED, APPETITIVELY MOTIVATED, SERIAL SPATIAL DISCRMINIATION REVERSAL IN RATS FOR EVALUATING MANIPULATIONS OF LEARNING AND MEMORY. E. Gamzu, E. Boff*, M. Zolcinski*, G. Vincent*, and T. Verderese*, Pharmacology I, Hoffmann-La Roche Inc., Nutley, NJ 07110

Animal tests for evaluating manipulations of learning and memory range from simple one-trial procedures to complex learning situations requiring long periods of training. We have developed an automated procedure in which over 90% of naive rats can be trained in a single 1 hour session. A spontaneous food-seeking response to a feeding device is reinforced on a schedule that eventually requires 10 responses for each food pellet (FR10). 24 hours later the rats can obtain 5 reinforcements for 20 responses (i.e., an FR4) from one of two adjacent feeding devices. Responses to the second device are not rewarded and are counted as errors. This unsignalled spatial discrimination is then reversed 13 times in a single session (1 hour maximum). Errors and qualitative measures of performance are analyzed in each discrimination component. Control rats show the expected high error rate during the first few reversals followed by a gradual improvement in performance. Repeated exposure to such test sessions continue to improve performance for at least 8 sessions.

Eighteen compounds, chosen on the basis of clinical use for treating cognitive deficits, or efficacy in animal "learning" procedures were administered prior to a single test session. Only piracetam (1000 mg/kg p.o.) and diphenylhydantoin (10 mg/kg p.o.) significantly improved performance, but these effects could not be replicated.

Aniracetam (Ro 13-5057) and piracetam were administered daily prior to 4 successive test sessions. Aniracetam (10 and 30 mg/kg i.p.) significantly improved performance on the second test session. Piracetam had no effect on any measure.

This test has also been useful in demonstrating deficits and strain differences in learning. Rats with lesions of the magnocellular nuclei of the basal forebrain learned this task significantly more slowly than appropriate controls (see Lerer et al., this meeting). In addition, spontaneously hypertensive rats were superior to Wistar-Kyoto normotensive rats (Vincent et al., Fed. Proc. 1983, 42:1347). Finally, we demonstrated that mature (12-month-old) rats made significantly more errors than 51-day-old rats.

239.4 EFFECTS OF ANIRACETAM (RO 13-5057) AND DIPHENYLHYDANTOIN ON HIPPOCAMPAL AFTERDISCHARGE IN RATS. S.A. Stwertka, D.A. MacNeil, and E. Gamzu, Dept. of Pharmacology I, Hoffmann-La Roche Inc., Nutley, New Jersey 07110.

Transcorneally administered subconvulsant electrobrain shock (EBS) disrupts the memory retrieval of mice in an avoidance procedure. Protection against this EBS-induced disruption can be produced by a variety of pharmacological agents used to treat cognitive deficits in patients (Gamzu & Perrone, Soc. Neurosci. Abstr. 1981, 7:525). We now report that in mice with bipolar electrodes implanted in the hippocampus, those EBS parameters that lead to memory disruption in an avoidance procedure also produce a hippocampal afterdischarge (AD). Moreover, the current threshold for producing this AD correlates highly with the threshold necessary to produce a memory disruption. This suggests that the previously reported pharmacological protection might be the result of a direct change in hippocampal reactivity to the EBS.

To test this possibility, we determined the effects of aniracetam (Ro 13-5057), diphenylhydantoin (DPH), phenobarbital (PHE), and chloral hydrate (CH) on electrically-evoked hippocampal AD activity in Sprague-Dawley male rats with chronic bilaterally implanted electrodes in the dorsal hippocampi. Following one to two days recovery, the animals were paralyzed with Flaxedil (80 mg/kg i.p.) and placed on a respirator during stimulation and recording. Constant current stimulation consisted of 2 second trains of 80 Hz biphasic square pulses of 4 msec duration delivered to one of the electrodes. Thresholds to evoke an AD were established over a period of three consecutive ADs at 15-20 minute intervals at the same current intensity. All drugs were administered i.v. through a lateral tail vein and were tested for effects on AD threshold, duration, and spread (to the contralateral electrode). PHE and CH significantly raised the threshold for evoking an AD. In contrast, DPH (50 mg/kg i.v.) suppressed the duration and spread of the AD, but had no detectable effect on the AD threshold. Aniracetam (1-100 mg/kg i.v.) had no effect on the threshold, spread, or duration of the AD. Thus, while it is possible that the protective effect of DPH against EBS-induced memory disruption is related to its ability to suppress the spread of AD activity in the hippocampus, the memory protective effects of aniracetam are most reasonably attributed to some other as yet unknown mechanism of action.

239.5 HOE 175: ITS EFFECT ON DIFFERENT LEARNING TASKS IN MICE. F. J. Hock and J. L. McGaugh. HOECHST AG, D-6230 Frankfurt/M. 80, Germany and Department of Psychobiology, University of California, Irvine, CA 92717.

Hoe 175, 3,8-dimethyl-4-phenyl-5,6,7,8-tetrahydropyrazolo (3, 4-b) (1,5)diazepine-1H,4H-5,7-dione, is a new compound with marked effects for nootropic activity. Though it is a pyrazolodiazepine the compound produced a slight effect in classical anxiolytic tests. We investigated the effect of Hoe 175 on (1) acquisition and retention in an one-trial passive (inhibitory) avoidance task and on (2) retention of an active avoidance task in mice. The apparatus used for the experiments consisted of a light (L) and a dark (D) compartment, connected by a guillotine door.

(1) Passive (Inhibitory) Avoidance. During the acquisition trial an unavoidable footshock (1 mA, 1.0 sec) was delivered immediately after entering D, followed by a maximal electroconvulsive shock (15 mA, 0.2 sec). Retention (the latency for entering D) was tested 24 hrs later. Hoe 175 was administered orally 90 min prior to both acquisition and retention. At doses from 3.0 - 12.0 mg/kg Hoe 175-treated mice had retention latencies significantly higher than those of controls.

(2) Active Avoidance. Animals were trained (8 trials) on the first day to avoid a footshock in D by moving to L. Each trial consisted of 10 sec to avoid the footshock followed by 20 sec footshock (350 μA) after which there was a 20 sec intertrial interval in L. The retention test trial was run 24 hrs later under the same parameters. During training and testing the time for entering L and the avoidance numbers were measured. Hoe 175 was administered intraperitoneally immediately after the last trial on training day. In comparison with controls, Hoe 175 in the dose range of 1.0 - 25.0 mg/kg significantly increased avoidances on the retention test.

239.6 REVERSAL LEARNING OF A SPATIAL-MEMORY TASK IS FACILITATED BY MEDIAL SEPTAL INJECTIONS OF 6-HYDROXY-DOPAMINE. L.E. Harrell, T.S. Barlow*, M. Miller*, J. Haring and J.N. Davis. Department of Neurology, Univ. Alabama, Birmingham, AL and Departments of Medicine (Neurology) and Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Electrolytic lesions of the medial septal region result in depletion of some hippocampal neurotransmitters including acetylcholine, norepinephrine (NE), serotonin, and Substance P. Behaviorally, medial septal lesions produce disruption of spatial and memory tasks. To determine whether a specific neurotransmitter might be responsible for dysfunction, we selectively depleted hippocampal NE and studied acquisition and performance of rats on a radial 8 arm maze.

Adult male Sprague-Dawley rats were trained to approach 4 baited arms and ignore 4 unbaited arms of an eight arm maze. Daily testing was performed and criterion of learning was defined as selection of 4 baited arms out of the first 5 arm choices on each of 5 consecutive days. Rats were assigned to either an acquisition (A) or performance (P) group. Group A rats were treated either with vehicle or 8 ug of 6-hydroxydopamine in the medial septal region prior to training, while rats in Group P were treated after mastery of the task. After attainment of either initial criterion (Group A) or after reaching a second criterion (Group P) all animals underwent a reversal procedure in which baited and unbaited arms were exchanged.

Treatment with 6-hydroxy-dopamine either prior to (Group A) or after mastering of the task (Group P) did not effect animal's ability to either learn or perform in this particular paradigm. Reversal performance was, however, significantly enhanced in all treated animals. These animals required approximately 25 trials to achieve criteria versus 40 trials in controls.

Our data suggest that hippocampal NE is not necessary for initially learning or maintenance of behavior in this particular spatial/memory task. Unexpectedly, we found that loss of hippocampal NE facilitated reversal learning. This finding may be important to understanding mechanisms of attention and interference since others have proposed a major role for the NE containing dorsal bundle in these behaviors.

239.7 AMPHETAMINE REVERSES LEARNING DEFICITS IN DOPAMINE DEPLETED RAT PUPS. R. S. Wool*, B. A. Shaywitz, M. H. Teicher, G. A. Anderson*, D. J. Cohen*, and D. A. Weldon. Dept. of Ped. and Neuro., Yale Univ. Sch. Med., New Haven, CT 06510 and Dept. of Psychology, Hamilton College, Clinton, NY 13323.

Depletion of brain dopamine in neonatal rats produces a constellation of changes in behavior that includes transient hyperactivity, deficits in habituation, and learning impairments in avoidance and escape tasks. We have recently found that dopamine depleted rat pups show deficits in appetitive learning performance as early as 8 days of age, and that these impairments can be reversed by treatment with the dopamine agonist apomorphine before conditioning (Weldon et al., Pharmac. Biochem. Behav. 1982, 17, 1281). The purpose of the present experiment was to determine whether administration of amphetamine would also produce a reversal of the performance deficits.

Selective depletions of brain dopamine were produced in 5 day old rat pups by administration of desmethylimipramine (20 mg/kg, i.p.) followed by intracisternal 6-hydroxydopamine (100 μg in 20 μL of saline). The next day each animal received an intratongue cannula while anesthetized with ether, and on day 7 each pup was conditioned by the presentation of licorice odor paired with the presentation of infant formula. Animals were tested the next day in a rectangular apparatus with a wire screen floor. Licorice extract was placed under one half of the floor, and learning performance was determined by measuring the percentage of a 5-min period that the animal spent over the side with the conditioned stimulus. Animals received injections of amphetamine (0.5 mg/kg, i.p.) prior to conditioning and testing.

In animals treated with saline before both conditioning and testing, control pups spent 85% of the time and depleted pups spent 40% of the time over the conditioned stimulus. Amphetamine administration prior to conditioning (but not testing) produced a significant improvement in the performance of depleted animals. In controls, amphetamine treatment prior to either conditioning or testing produced an impairment in performance. These results are consistent with our previous investigation of apomorphine effects in this task and support the hypothesis that dopamine plays an important role in learning in young animals.

239.8 RETENTION DEFICIT AFTER D-AMPHETAMINE TREATMENT: MEMORY DEFECT OR PERFORMANCE CHANGE? W. W. Beatty. Dept. of Psychology, North Dakota State Univ., Fargo, ND 58105.

Psychomotor stimulants such as amphetamine often facilitate long-term memory, either by enhancing consolidation or promoting retrieval. By contrast, these agents disrupt short-term memory (STM) in a variety of different tests. Kesner, et al. (1981) have interpreted these latter effects as support for the idea that arousal accelerates the loss of information from STM. But since amphetamine causes numerous changes in performance, alternative explanations of the deficit are also plausible. In an attempt to separate drug effects on memory from those on performance, the effects of d-amphetamine sulfate on spatial memory in the radial maze were studied in rats. The unusually long span of accurate STM in this setting permits drug administration within the retention interval as well as prior to the to-be-remembered event. (TBRE). In rats tested at a 5-hr retention interval (imposed between choices 4 and 5 in an 8 arm maze), 1 mg/kg d-amphetamine disrupted retention only when given 0.5 hr before the retention test. A higher dose (2 mg/kg) interfered with retention if given 0.5 hr before the TBRE or 0.5 hr before the retention test. Neither dose altered retention when given 0 or 2 hr after or 3 hr before the TBRE. At a 5 hr retention interval 3 mg/kg d-amphetamine impaired performance if given 2 hr after the TBRE, but not when given 0 hr after or 3 hr before the TBRE. However, when the retention interval was lengthened to 7 hr, administering 3 mg/kg d-amphetamine 2 hr after the TBRE did not degrade retention. The effects of d-amphetamine on spatial memory are best explained in terms of the well known effects of the drug on motor activity and appetite. Similar changes in performance may account for the "memory" impairments observed after amphetamine treatment in other tasks that measure STM.

239.9 EFFECTS OF PHYSOSTIGMINE ON MEMORY DEFICITS INDUCED BY PRETRAINING ELECTRICAL STIMULATION OF THE DORSAL HIPPOCAMPUS IN MICE. J. MICHEAU*, C. DESTRADE* and R. JAFFARD* (SPON: M. CAUDARELLA). Lab. Psychophysiologie, Univ. Bordeaux I, 33405 TALENCE FRANCE

Previous experiments based on mouse-strain comparisons have suggested that differences in long-term memory formation as well as facilitatory effects of posttraining hippocampal electrical stimulation on retention might be related to differences in hippocampal choline acetyltransferase activity (ChAT)(JAFFARD et al., Brain Res., 133 , 277-289, 1977). In subsequent experiments we have shown that pretraining electrical stimulation of the hippocampus led to a decrease of this enzymatic activity, with a latency of 6 hrs, in BALB/c mice and that this delayed decrease was paralleled by long-term memory deficits (JAFFARD et al., Physiol. Behav., 22 , 1093-1096, 1979). Consequently, it was suggested that a positive correlation exists between hippocampal ChAT activity at the time of training and the effectiveness of memory consolidation (JAFFARD and DESTRADE, in The Genetics of the Brain, I. LIEBLICH, Ed., 299-322, 1982). Though the activity of ChAT is an essential factor in acetylcholine synthesis, it is not clear if in physiological conditions the enzyme functions with saturating concentrations of substrate and thus if it can be considered a limiting factor for acetylcholine synthesis.

The aim of the present experiments was to test the validity of our hypothesis that presynaptic cholinergic activity may have a functional significance for memory formation. The results show that pretraining electrical stimulation of the dorsal hippocampus in BALB/c mice, which induces a decrease of about 40% of hippocampal ChAT activity at the time of learning, results in deficits in retention scores in two appetitive learning tasks (operant conditioning in the Skinner box or a spatial-memory task using a 4-hole board). In both behavioral tasks the intraventricular injection of 1 µg of physostigmine 20 min before the acquisition session reverses the disruptive effect of pretraining hippocampal stimulation.

Our results seem to indicate that the memory deficits induced by pretraining electrical stimulation of the hippocampus result from both a decrease of ChAT activity and a reduction of acetylcholine availability in the hippocampal formation.

239.10 EFFECTS OF SCOPOLAMINE ON RECOGNITION MEMORY IN MONKEYS AFTER IBOTENIC ACID INJECTIONS INTO THE NUCLEUS BASALIS OF MEYNERT. T. Aigner*, J. Aggleton, S. Mitchell, D. Price, M. DeLong & M. Mishkin. Laboratory of Neuropsychology, NIMH, Bethesda, MD 20205 and Depts. of Neurology and Neuroscience, Johns Hopkins Medical School, Baltimore, MD 21205.

Alzheimer's disease (AD) is accompanied by degeneration of neuronal cell bodies in the nucleus basalis of Meynert (nbM), the major source of cholinergic projections to widespread areas of the neocortex. This abnormality has been suggested as one explanation for the memory impairment in AD. To test this hypothesis in the monkey, we trained three experimental (E) and two control (C) cynomolgus macaques on a delayed nonmatching-to-sample task with trial-unique objects in a Wisconsin General Testing Apparatus. The animals were required to distinguish a sample object, presented 10 sec earlier, from a novel object. The animals were given 20 trials each day until they reached a criterion of 90 correct choices in 100 trials. In the E monkeys, the region of the nbM was identified electrophysiologically and bilateral injections were made of ibotenic acid (IA), a neurotoxin previously shown to destroy neurons in this region. Two weeks later, behavioral testing was resumed. Two of the E monkeys relearned the task in the minimal number of trials (100), while the third required an additional 20 trials. The monkeys were then given a series of performance tests involving delays of 30, 60, and 120 sec and lists of 3, 5, and 10 objects to be remembered. Each condition was tested for 5 consecutive days. The E group showed no impairment on these tasks when compared to the C group (92.1% vs 93.5% correct, respectively). In order to challenge the damaged cholinergic system further, the task was made more difficult (2 lists of 20 items to be remembered per session), and a dose-response curve was determined for scopolamine hydrobromide (Scop) by injecting .3,1,3,5.6,10, or 17.8 mg/kg i.m. 20 min before the session. The drug session was preceded by at least one drug-free control session (no injection or saline). Each dose of Scop was tested twice in a nonsystematic order. Scop produced a dose-related decrease in the number of objects correctly remembered by both groups of monkeys. However, at each dose tested, the E group made more errors than the C group. Linear regression analysis was used to compare the relative potency of Scop in the two groups. The dose of Scop which reduced correct responses to 80% of control values was 5.0 mg/kg for the E group and 12.4 mg/kg for the C group.

Our data indicate that although monkeys can still perform a recognition memory task normally after IA injections into the nbM, their performance is more easily disrupted than that of normals when challenged with Scop. These results add support to the view that the nbM cholinergic system plays a role in memory.

239.11 BEHAVIORAL TOLERANCE TO SCOPOLAMINE IN THE RAT USING A WORKING MEMORY TASK. W.S. Messer, Jr.*, G.J. Thomas and W.P. Hoss. Center for Brain Research, University of Rochester School of Medicine, Rochester, New York 14642.

In order to examine further the known role of the cholinergic septo-hippocampal system in working memory, male hooded rats of the Long-Evans strain were trained to perform a delayed alternation task in a T-maze. After rats demonstrated proficiency (100% correct for three consecutive sessions), guide cannulae aimed at the CA3 region of each hippocampus were surgically implanted. After recovery from surgery, animals were retested, injecting physiological saline (0.5 µL) before each session until proficiency was attained again. Rats were then assigned to one of two groups, receiving 0.5 µL injections of either scopolamine hydrobromide (60 mg/mL) or saline bilaterally.

Whereas saline injections had no effect on performance, the initial dose of scopolamine caused a significant impairment of working memory. Usually this impairment was manifest as a reduction to chance in the number of correct choices. Occasionally, however, a rat would choose correctly but show a marked increase in choice time. Animals regained their ability to alternate within two days following the initial injection. A second injection of the same dose of scopolamine two days after recovery did not cause an impairment in either the percent of correct choices or choice time.

These experiments suggest that the hippocampus has a functional capacity to overcome the effects of muscarinic receptor blockade. A number of mechanisms could be responsible for the development of tolerance to scopolamine, including an increase in the sensitivity of muscarinic receptors. This possibility will be explored using autoradiographic localization of muscarinic receptors within the hippocampus.

This work was supported in part by NIH research grant DA 01851 and NIH training grant 5T32 GMO 7136-08.

239.12 NICOTINE TOLERANCE AND LEARNING IN MICE. S. J. Jackson, M. J. Marks* and A. C. Collins*. Institute for Behavioral Genetics, University of Colorado, Boulder, CO 80309.

The involvement of the cholinergic system in learning and memory is well documented. The prevailing attitude is that this phenomenon involves effects at the level of the receptor. If cholinergic receptors could be manipulated prior to a learning experience, evidence for direct involvement of that receptor in learning might be obtained.

It has been demonstrated that muscarinic receptors can be down-regulated by chronic treatment with anticholinesterases and up-regulated by chronic treatment with muscarinic antagonists. Conversely, nicotine, a cholinergic agonist, produces up-regulation of nicotinic receptors in response to chronic administration. Chronic exposure to these drugs also results in various behavioral and physiological changes in response to a challenge dose of the same drug.

C57BL and C3H mice either were injected with 2.0 mg/kg nicotine 3X/day for 3 days or were chronically infused for 3 days with 2.0 mg/kg/hr nicotine. Subsequent to chronic exposure, the mice were challenged either with saline or with 1.0 or 2.0 mg/kg nicotine and were trained daily for 4 consecutive days on a Rotarod or in a successive discrimination maze. The nicotinic receptors in the various groups were assayed to determine if changes in these receptors were correlated with changes in the rate of learning.

The results indicate that behaviorally tolerant C57BL mice, trained on the Rotarod, learn at a faster rate than do saline controls or naive subjects. This finding suggests the possibility of a direct role for nicotinic receptors in the learning process.

239.13 EFFECTS OF PHOSPHATIDYLSERINE ON MEMORY AND PSYCHOMOTOR PERFORMANCE IN AGED RATS. R.L.Dean[1], J.Corwin[2], D.L.Watkins[1], J.P. Rotrosen[2,3], and R.T.Bartus [1,3]. Med.Res.Div., American Cyanamid Co., Lederle Labs, Pearl River, NY, [2]Manhattan V.A. Med. Center, NY, NY, [3]NYU Med. Center, NY, NY.

One of the most serious neurobehavioral dysfunctions associated with old age is loss of memory. Biochemical, pharmacological and electrophysiological evidence suggests that dysfunctions in central cholinergic mechanisms may play a critical role in this impairment (Bartus, et al., Sci., 1982). This age-related impairment can be partially reversed with cholinomimetic agents. In addition to cognitive deficits, deleterious effects of age are also observed on tasks designed to measure psychomotor coordination and muscle strength. Recent research by Marshall and Berrios (Sci., 1979) and Joseph, et al. (Neurobiol.Aging, 1980) suggests that these dysfunctions might be reduced by pharmacologically compensating for age-related alterations in dopamine function.

Phosphatidylserine (PS), a major phospholipid, has been reported to increase brain levels of glucose and cAMP and to enhance turnover and release of dopamine and acetycholine when administered to rats peripherally. Thus, one approach to compensate for age-related dysfunctions might be to enhance dopaminergic and cholinergic function with PS. Preliminary data reported by Drago, et al.(Neurobiol.Aging, 1981) indicated that PS improved acquisition and retention of passive and active avoidance tasks in aged rats.

Previous work in our lab and others has shown that aged rats demonstrate: 1)severe retention impairments on a single trial step-through passive avoidance task and 2)severe impairments on a battery of psychomotor tasks designed to measure muscle strength and tone, equilibrium, and psychomotor coordination. Using these tasks we tested the effects of PS in aged Fischer 344 rats(22 mo. of age). PS (12.5-50 mg/kg) was administered ip., 30 min prior to the behavioral tasks.

All doses of PS produced a significant increase in retention latencies (measure of memory) over control scores in a dose-related manner. This improvement could not be explained on the basis of changes in locomotor activity or foot-shock sensitivity. PS did not have any significant effect in psychomotor performance at any of the doses tested.

239.14 FACILITATION OF RETRIEVAL BY PRE-TEST ADMINISTRATION OF OXOTREMORINE IN MICE. H. J. Altman Lafayette Clinic, Detroit, MI 48207

Stimulation of the cholinergic nervous system with the potent and highly selective muscarinic cholinergic agonist oxotremorine (OXO) has been shown to facilitate retention of a one-trial inhibitory avoidance response in mice, when this compound was administered immediately following training (Baratti et.al., 1979; Huygen et.al. 1980). It was, therefore, suggested that stimulation of post-synaptic muscarinic receptors immediately following training enhanced the process(s) of memory consolidation and/or storage.

The purpose of the present series of experiments was to determine what effects, if any, direct muscarinic cholinergic receptor stimulation would have on the retention of a previously acquired aversive habit if OXO were administered prior to the retention test.

The behavioral task used was a modification of the standard one-trial inhibitory avoidance paradigm (Quartermain and Altman, 1982), in which thirsty mice were trained to drink from a tube in an experimental chamber and 24 hrs. later, following an initial period of drinking, were shocked (via the tongue), each time they touched the drinking spout (0.75mA/3shock max). Retention was measured as the latency to complete 5 sec. of drinking 48 hrs. later (under extinction conditions).

The results indicate that peripheral administration of OXO 30 min. prior to retention testing results in a significantly elevated suppression of drinking compared to saline injected controls ($t=2.34; P<0.05$). The facilitation by OXO was both dose and time dependent and blocked by pretreatment with scopolamine·HBr.

The longer latencies exhibited by the animals treated with OXO was not likely to have been due to non-specific effects of the drug on behavior in general, as the latencies of an independent group of non-contingently (NCS) shocked mice, (Quartermain and Altman, 1982), were very short ($t-4.86; P<.001$). That is, had the administration of OXO resulted in illness, a reduction in thirst or reduced locomotor activity the NCS trained animals, would have had long latencies. Since the latency scores of the animals in this group were short, the results suggest that OXO is enhancing the memory of the original avoidance habit.

The results of the present series of experiments suggest, therefore, that OXO can also facilitate retrival processes.

239.15 THE ROLE OF AMYGDALAR CHOLINERGIC ACTIVITY IN TASTE-POTENTIATED ODOR AVERSION LEARNING. F. Bermudez-Rattoni, F. Chavez-Alamanza* K. Coburn* and J. Garcia*. Department of Psychology, Mental Retardation Research Center, UCLA, Los Angeles, California 90024.

Previous reports have shown that odor and taste stimuli may be affected by different temporal parameters during toxiphobic conditioning. Odor must be followed immediately by poison, while taste alone is effective even with delayed poison. However, when odor plus taste is followed by delayed illness, odor becomes aversive as if it has been potentiated by taste. Our interest was in the neural mechanism involved in the potentiation of odor by taste. It has been shown that "reversible lesions" of the amygdaloid complex (using procaine) disrupt potentiated odor aversions, but not taste aversions. Also, it has been shown that cholinergic activity is highly involved in retention of learned aversion tasks. Thus, it is highly likely that cholinergic activity is involved in the gating of the odor into the taste system. The purpose of this experiment was to learn the role of the cholinergic mechanisms of the amygdala in potentiated odor aversions.

Rats implanted with bilateral cannulae in the amygdala received physiostigmine (phys; 9µg/3µL), scopolamine (scop;30µg/3µL) or saline (sal; 3µL) infused over 3 min. Almond odor and .1% saccharine were the CSs and .15M LiCl (190 mg/kg) was the US. One group of rats received the drugs before acquisition and another group received the same drugs before the test. During acquisition the drugs were given 30 min before the presentation of odor and taste (CSs) and were followed by delayed illness (US). Then the animals were tested with odor or taste alone in separate test days with water days in between. The rest of the animals received the same drugs 30 min before the presentation of odor or taste during the test days in a counterbalanced order.

Results of the manipulations showed that when given prior to acquisition, phys significantly decreased the odor aversion, while scop produced a nonsignificant increase. Taste aversions were unaffected. Administered prior to testing, scop increased odor aversion but not taste aversion; phys increased taste aversion and tended to decrase odor aversion. The general trend of these results is toward an inverse relationship between cholinergic activation in taste potentiated odor aversion learning.

239.16 NON-CONTINGENT ACTION OF NATURAL REINFORCERS ON MEMORY. Claude Messier and Norman M. White. Department of Psychology, McGill University, 1205 Dr. Penfield Ave., Montreal, Canada, H3A 1B1.

Previous studies have shown that retention of a learned behavior is improved by a post-training and non-contingent session of self-stimulation (Coulombe & White, Physiol. Behav., 25 :267-272, 1980; Can. J. Psychol., 36 :57-66, 1982). The facilitative effect of self-stimulation was interpreted as a non-contingent strenghtening action of that reinforcer on the previously formed association. Although the self-stimulation technique has proved useful in helping to understand the neural basis of reinforcement, it is a highly artificial event. Therefore, the present experiments sought to replicate the self-stimulation findings using laboratory versions of "natural reinforcers": sweet solutions of sucrose and saccharin.

Preference curves were generated by testing 14 concentrations each of sucrose and saccharin in a 20-minute test in which rats were presented with a choice of a sweet solution and water. Three concentrations of each substance (the most prefered and one higher and one lower concentration) were chosen for further study. In the memory test, training consisted of pairings of a tone and a shock. The animals were allowed to drink one of the solutions after training. The next day, the tendency of the tone to suppress drinking was tested.

Post-training ingestion of the sucrose solutions but not of the saccharin solutions retroactively and non-contingently improved retention of the previously formed, classically conditioned tone-shock association. This suggests that the sweet taste of the solutions was not the cause of the improvement in retention. The hypothesis that some post-ingestional effects of sucrose caused the effect was supported by the observation of improved retention with post-training subcutaneous (sub-q) injection of glucose (1 ml of a 30g/100 ml solution). An equivalent or doubled amount of fructose (a sugar that does not cross the blood brain barrier but is metabolized in the liver) had no effect when injected sub-q. This suggest that some central action of glucose may cause the improved memory.However, intraventricular injections of glucose (5 ul of a 30g/100 ml solution) also had no effect on retention.

This series of experiments parallels previous findings obtained with self-stimulation as the reinforcer. The results support the hypothesis that reinforcers produce a non-contingent, retroactive enhancement of retention of previously formed association. Further investigation will be necessary to discover the route by which glucose has this effect.

239.17 LEUPEPTIN, AN INHIBITOR OF CALCIUM ACTIVATED PROTEINASES, SELECTIVELY DISRUPTS MEMORY. U. Staubli*, M. Baudry and G. Lynch. (SPON: J. Conway). Department of Psychobiology, Univ. of California, Irvine, CA 92717.

Biochemical studies have indicated that the number of glutamate receptors in membranes isolated from mammalian forebrain is irreversibly increased by the activation of a calcium sensitive proteinase ("calpain"). It has been suggested that this process is involved in the formation of those types of memory that require hippocampus and neocortex.

To test this idea, we measured the effects of leupeptin, a potent inhibitor of the proteinase, on several memory tasks in rats. Leupeptin or saline was injected into the lateral ventricle with implanted osmotic minipumps at the rate of 10 µg/hr over a period of 14 days. The drug caused no apparent changes in food and water intake or in body temperature. However, leupeptin treated rats (n=8) committed many more errors than did controls (n=7) in a 8 arm radial maze task that involved a 15 minute delay between the 4th and 5th choices ($p < 0.001$).

Separate groups of rats were also tested on a Y maze problem. In this, the animals choose one of two arms for a food reward and are then removed to a holding cage for 15 min to 2 hours. They are returned to the start box with the reward placed in the arm not entered on the first trial. Leupeptin treated rats (n=5) performed in an essentially random fashion on the second trial while controls (n=5) almost invariably made the correct response. Leupeptin did not disrupt all memory-related behaviors. Drug treated animals could be trained to go to a single arm of an eight arm maze for food reward over a period of several trials; moreover, they retained information about the task for at least 24 hours. Animals injected with leupeptin (n=5) were also indistinguishable from controls (n=5) in learning to escape from a mild shock and were only slightly slower in acquiring an avoidance response.

These results satisfy the prediction that inhibition of calcium activated proteases will interfere with certain types of memory. However, leupeptin blocks proteolytic enzymes other than calpain and it is possible that this effect contributed to certain of the results reported here. Behavioral experiments involving additional manipulations of the calcium proteinase are now in progress. (Supported by NIMH grant 197939-12 and NIA grant AG-00538. LEARNING AND MEMORY: PHARMACOLOGY OF CONDITIONING

240.1 NALOXONE ENHANCEMENT OF MEMORY PROCESSES: DEPENDENCE ON INTACT NOREPINEPHRINE FUNCTION. P.R. Rapp and M. Gallagher. Dept. of Psychology, Univ. of North Carolina, Chapel Hill, NC 27514.

Opiate receptor mechanisms in both the soma-dendritic and terminal regions of norepinephrine (NE) neurons are capable of inhibiting NE function. The present research investigated the possibility that such interactions contribute to regulating memory processes. Numerous studies, including our own, have demonstrated that opiate agonists such as morphine can impair retention of recent learning. It is also well documented that interference with opiate receptor activation by administration of opiate antagonists can improve retention when comparable testing procedures are used. The effect of opiate antagonists on memory processes may be due to release of NE neurons from inhibition by opioid peptides. This suggestion has received some support from the finding that opiate antagonist enhancement of memory in rats can be prevented by administration of the β-adrenergic antagonist propranolol (Izquierdo and Graudenz, Psychopharmacology 67: 265, 1980). The present investigation examined whether the effects of opiate antagonists on memory processes might be altered by denervation of brain NE systems.

Three weeks prior to behavioral testing Sprague-Dawley rats received 6-hydroxydopamine (6-OHDA) or vehicle alone injected into the dorsal noradrenergic bundle. During behavioral testing rats received one-trial step-through passive avoidance training. Intraperitorial administration of the opiate antagonist naloxone or saline vehicle occured immediately after training. Retention for the training experience was conducted 24 hrs later. Animals were sacrificed 1 week following behavioral testing and brain catecholamine levels were assessed via radioenzymatic assay.

In agreement with previous reports post-training naloxone administration was observed to facilitate retention of passive avoidance training. Depletion of forebrain NE via 6-OHDA administration, however, blocked the enhancing effects of the opiate antagonist. Further evidence that the effects obtained in this investigation reflected dependence on NE activity is suggested by the observation that partial protection of brain NE neurons via desimpramine injection prior to 6-OHDA administration restored the memory enhancing effects of naloxone administration.

The results of the present investigation provide further support for the proposal that opiate receptor mechanisms may, at least in part, alter memory processes by regulating brain NE function. Further experiments are being conducted to investigate whether significant NE/opiate interactions occur within the amygdala, a brain site which has been demonstrated to be sensitive to NE and opiate treatments on memory processes. Supported by NIMH Grant MH35554 and NIMH Research Scientist Development Award to M.G.

240.2 EFFECTS OF MORPHINE, ETHYLKETOCYCLAZOCINE AND N-ALLYNORMETAZOCINE ON ACQUISITION OF THE CLASSICALLY CONDITIONED NICTITATING MEMBRANE RESPONSE. C. W. Schindler*, M. R. Lamb*, I. Gormezano* and J. A. Harvey. Departments of Psychology and Pharmacology, The University of Iowa, Iowa City, IA 52242.

Based on studies in the chronic spinal dog, Gilbert and Martin (J. Pharmacol. Exp. Ther. 197:517, 1976) proposed a three receptor model for the action of morphine and morphine-like drugs. Morphine, ketocyclazocine and ethylketocyclazocine (EKC), and N-allynormetazocine (NANM) were proposed to interact with the mu, kapa and sigma receptors respectively. Previous work in our laboratory has shown that morphine will profoundly retard the acquisition of the classically conditioned rabbit nictitating membrane response (NMR). Therefore the purpose of the present study was to determine the effects of the proposed kappa and sigma receptor agonists EKC and NANM on the acquisition of classically conditioned responses.

Classical conditioning of the rabbit NMR involved the presentation of tone and light conditioned stimuli (CS) for 800 msec before delivery of the unconditioned stimulus (UCS), consisting of a 100 msec msec electric shock to the skin over the paraorbital region of the head. Both 1 mg/kg (i.v.) EKC and 5 mg/kg morphine injected just prior to each conditioning session significantly retarded the acquisition of conditioned responses across 10 conditioning sessions of 60 CS-UCS pairings each. Both tone and light CSs were affected equally. The retardation produced by EKC and morphine was evident in measures of percent conditioned responses, average response latency and percentage of rabbits reaching a criterion of 10 consecutive conditioned responses. The retarded acquisition of conditioned responses produced by EKC and morphine could still be detected when the rabbits were tested five days after cessation of drug injections, suggesting that EKC and morphine were affecting acquisition and not performance of conditioned responses.

We have previously shown that 1 mg/kg naloxone has no effect on the acquisition of conditioned responses and the present results indicated that NANM and naloxone + NANM have only a small retardation effect on acquisition. However, both naloxone and NANM will block the retardant effects of either EKC or morphine on acquisition. These results suggest that the retardant effects of both EKC and morphine are due to an action at a single receptor site. This site could be the mu receptor proposed by Gilbert and Martin since both naloxone and NANM are mu recpetor antagonists. This suggests that EKC is a partial mu agonist as well as a kappa agonist.

240.3 SEPARATE ROLES FOR NUCLEUS ACCUMBENS AND CAUDATE IN ACQUISITION AND PERFORMANCE OF AVOIDANCE BEHAVIOR. A. G. Phillips, J. MacCrea* and H. C. Fibiger. Departments of Psychology and Psychiatry, University of British Columbia, Vancouver, Canada.

Lesions of the ascending forebrain dopamine pathways or blockade of dopamine receptors with neuroleptic drugs prevent the acquisition of one-way avoidance behavior (Fibiger, Phillips and Zis, 1974; Fibiger, Zis and Phillips, 1975). However, these treatments do not disrupt the performance of this response in overtrained rats. The question remains as to whether response acquisition is dependent upon the integrity of the nigrostriatal and/or mesolimbic dopamine pathways. Temporary blockade of each of these pathways was produced by local microinjection of haloperidol (0.5, 5.0 µg) bilaterally into either the caudate nucleus or nucleus accumbens. In half of the experimental subjects, the drug injections were made prior to training in a one-way avoidance shuttlebox. A 10 sec tone signalled a subsequent foot shock (1.0 mA) and trials continued to a criteria of 8/10 avoidance responses or a 40 trial cutoff. On the second test session, those animals trained after vehicle injections now received haloperidol and the animals previously treated with haloperidol received the vehicle. Acquisition was blocked by microinjection of haloperidol (5µg) into either the caudate or accumbens. In contrast, a similar caudate injection had no effect on the second test session after acquisition of avoidance behavior. Accumbens injections did disrupt behavior on the second session despite successful acquisition on the preceding day. Ventricular injections of haloperidol (5µg) disrupted acquisition but not performance thereby replicating the pattern seen with caudate injections. Together, these data suggest that the dopaminergic input to the caudate is necessary for the acquisition of avoidance behavior but not the subsequent performance of this response. Integrity of the dopaminergic innervation of the accumbens appears to be important for the initiation of motor activity related to both the acquisition and performance of a voluntary avoidance response.

240.4 ENHANCEMENT OF MOTOR CONDITIONED INHIBITION BY MICROINJECTIONS OF APOMORPHINE IN THE CAUDATE NUCLEI OF CATS. C. Barajas-López*, C. Reyes-Vázquez and H. Brust-Carmona. Depto. de Fisiología. Fac. de Medicina, Div. de Investigación, UNAM, México, D.F., México.

Dopamine (DA) microinjected into the Caudate Nuclei (CN) enhances the acquisition of an inhibitory motor conditioned response (IMCR), whereas haloperidol diminishes it. Furthermore, depletion of catecholamines, produced by the application of high doses of 6-OHDA into both CN, impairs this learned response. It has been suggested that the IMCR depends upon the functional integrity of the CN's aminergic systems. Hence, Apomorphine (AP), which might be a dopaminergic agonist, should facilitate IMCR. Cats were trained to press a lever (MCR) to obtain 0.5 ml of milk while a small light was on during 60 s; no reinforcement was given when it was off and paired to a sound during 20 s (IMSR), i.e., the animals had to learn to suppress the MCR. This paradigm was repeated 12 times in one session per day. After 3-5 sessions, under pentobarbital anesthesia we implanted stereotaxically a cannula into each CN at coordinates A 16, L 4.5, and H +4. After 4 retraining sessions, each animal received 5 bilateral microinjections (MI) of 10 or 20 µg of AP, one per session, alternated with sham microinjections. Both manipulations were performed 10 min before the sessions in an adjoining laboratory. A third group of cats -control- was only conditioned and tested at the same days as the treated animals. At the end of the experiments, under deep anesthesia the brains were perfused, and later on, histological sections (100 µm width) were made to localize the cannulae's position. During the IMCR, the average lever pressing tends to diminish in the control cats after repeating the sessions. In those treated with 10 µg of AP, the average lever pressing diminishes clearly with the first three MIs. After the 3rd MI the average lever pressing stays below the control level during the following sessions, being the difference statistically significant at $P<0.05$ (Mann Whitney U Test). In the group treated with 20 µg of AP, the average lever pressing diminishes very clearly during the first 4 microinjections, reaching s significant difference at $P<0.05$ (Mann Whitney U Test), but returns to the initial level during the sham microinjections. During the MCR, the average lever pressing of the control group tends to increase while repeating the conditioning sessions; whereas it diminished in the treated animals after the AP microinjections. Similar effects were described for DA microinjections into CN, except for the diminution during MCR. These findings further support the postulation that catecholamines in the CN have a behavioral inhibitory action upon a motor conditioned response.

240.5 EFFECTS OF CHOLINE INJECTIONS INTO THE CAUDATE NUCLEUS ON ACTIVE AVOIDANCE. R. A. Prado-Alcala, G. Cepeda*, L. Verduzco*, A. Jimenez* and E. Vargas*. Sch. of Medicine, Nat. Univ. of Mexico, Mexico 20, D.F. and Sch. of Psych., Anahuac Univ., Mexico.

Injections of acetylcholine-receptor blockers into the caudate nucleus (CN) significantly impair the acquisition and maintenance of instrumental behaviors. In line with these findings are those showing that small doses of choline injected into the CN improve the performance of lever pressing and passive avoidance behaviors. Some authors have reported, however, that cholinergic activation of the caudate disrupts avoidance performance. The present experiment was designed to test the idea that injections of a small dose of choline into the CN can facilitate active avoidance performance. During training male Wistar rats were put inside a shuttle box, and after 10 sec a tone and a light were turned on; if the rat jumped to the opposite compartment within 20 sec an avoidance response was computed; if the rat did not jump in 20 sec a 2.0 mA scrambled footshock was presented and remained on until the rat escaped to the opposite compartment. There were 10 training sessions of 40 trials each. To avoid a "ceiling effect" only rats with less than 50% avoidance responses during the last three training sessions were studied. After training cannulae were bilaterally implanted in the dorsal-anterior CN or in the dorsal-posterior CN. An additional 10 sessions were programmed. Bilateral injections of choline (15 ug/3 uL) were given to the implanted rats, and 100 mg/kg of choline (I.P.) to an unoperated group, 6 and 40 min before sessions 13 and 19, respectively. Saline solution (NaCl) was injected intracranially or I.P. 6 or 40 min before the 16th session. It was found that choline injections into the posterior CN significantly improved active avoidance performance relative to all other groups and treatments; the injection of choline into the anterior CN induced a better performance than intracranial injections of NaCl and I.P. injections of choline or NaCl. These results further support the hypothesis that cholinergic activity of the caudate nucleus mediates the performance of instrumental behaviors.

240.6 CENTRAL,BUT NOT PERIPHERAL,CHOLINERGIC INHIBITION PREVENTS HIPPOCAMPAL AND SEPTAL CONDITIONED UNIT RESPONSES AND RETARDS NICTITATING MEMBRANE CONDITIONING. S.D. Berry and A.T. Salvatierra*. Dept. of Psychology, Miami University, Oxford, OH 45056.

To clarify further the role of the septohippocampal system in learning, we recorded both EEG and multiple unit activity from the lateral septum and hippocampus after administration of an anticholinergic drug known to impair nictitating membrane (NM)conditioning.

Each of 16 New Zealand White rabbits was implanted with chronic recording electrodes in area CA1 of the dorsal hippocampus and in the dorsal lateral septal nucleus. Animals were given daily training sessions consisting of 13 blocks of 9 trials (8 paired;1 CS-alone). The CS was a 350 msec, 85 dB, 1KHz tone and the UCS was a 100 msec, 210 g/cm^2 corneal air puff occurring 250 msec after CS onset. Animals were trained to a criterion of 8 CR's in 9 trials or for a maximum of 4 sessions. Eight animals received scopolamine hydrobromide (HBR) and 8 received scopolamine methylbromide (MBR) as a peripherally-acting control. Drugs were given subcutaneously (1.5 mg/kg) 12 min before each session. Behavioral and Neural responses were recorded on magnetic tape for off-line analyses.

Baseline and postdrug EEG samples were analyzed with a zero crossing program and indicated that HBR produced significant shifts in EEG frequencies in the 1-12 Hz range in both structures, while MBR did not. Behaviorally, the HBR group took significantly longer (mean= 329 trials) than MBR to reach criterion (mean=120).

Analysis of unit activity consisted of passing filtered (500-5K Hz) records through a window discriminator and integrating the output in 10 msec segments, then averaging responses over 8 trials. While the MBR group developed the type of conditioned response characteristic of undrugged rabbits (Berger & Thompson, Brain Res., 1978, 145:323 and 156:293), the HBR group showed an almost complete suppression of learned unit responses in both hippocampus and lateral septum.

These findings corroborate relationships between hippocampal activity and learning rate in the rabbit NM paradigm and suggest that anticholinergic effects on learning may be mediated, in part, by a disruption of normal septohippocampal responses.

240.7 INCREASED GLUTAMATE RECEPTOR BINDING IN HIPPOCAMPUS FOLLOWING CLASSICAL CONDITIONING OF THE RABBIT EYELID RESPONSE.
R.F. Thompson, L.A. Mamounas, G. Lynch and M. Baudry. Dept. of Psychology, Stanford Univ., Stanford, CA 94305, and Dept. of Psychobiology, Univ. of Calif. Irvine, Irvine CA 92717.

During classical conditioning of the rabbit eyelid response, hippocampal pyramidal cells increase their rate of within-trial discharge. Long-term potentiation (LTP) is a candidate mechanism underlying this rapid, incremental and learning-dependent increase in neural activity. Similar cellular mechanisms may therefore mediate both LTP and the hippocampal neuronal changes associated with eyelid conditioning. The induction of LTP in hippocampal slices results in an increase in the number of glutamate binding sites in the potentiated region. The present study examines the kinetics of glutamate binding to hippocampal synaptic membranes following eyelid conditioning in the rabbit.

^{3}H-glutamate binding to hippocampal synaptic membranes was measured in three groups of rabbits: 1) a conditioning group that received paired presentations of the tone CS and corneal airpuff UCS; 2) a control group that received explicitly unpaired tone and airpuff presentations; and 3) a naive control group that received no handling and remained in the home cage until sacrifice. Paired animals were trained for three days -- a two hour training session per day. On the fourth day, they were given a thirty minute training session and were then returned to the home cage. One hour later, animals were decapitated and hippocampal synaptic membranes were prepared. Unpaired animals received identical amounts and sequences of unpaired sessions.

Animals receiving paired conditioning had significantly more glutamate binding sites (Bmax, 18.0 ± 1.8 pmol/mg protein) than either unpaired controls (12.6 ± 1.0) or naive controls (13.1 ± 1.3). There was a trend towards a decreased affinity (higher Kd) for the paired animals but this was not statistically reliable. The Hill coefficients for the three groups did not differ from unity. Several characteristics of ^{3}H-glutamate binding to rabbit hippocampal membranes and the regional distribution of binding sites within fields and layers of rabbit hippocampus indicate that, as in the rat, ^{3}H-glutamate binding is associated with a post-synaptic glutamate receptor.

Thus both repetitive electrical activation of hippocampal pathways which induces LTP and classical conditioning appear to produce increases in the number of glutamate receptors in hippocampus. This strengthens the argument that the neural changes in the hippocampus during eyelid conditioning are mediated by an LTP-like mechanism. 240.8 MICROINFUSION OF GABA ANTAGONISTS INTO THE CEREBELLAR DEEP NUCLEI SELECTIVELY ABOLISHES THE CLASSICALLY CONDITIONED EYELID RESPONSE IN THE RABBIT. L.A. Mamounas, J. Madden IV, J.D. Barchas and R.F. Thompson. Departments of Psychology and Psychiatry, Stanford University, Stanford CA 94305.

Discrete lesions of the dentate-interpositus region of the cerebellum have been shown to abolish selectively the well-conditioned, ipsilateral eyelid response in the rabbit (McCormick, et al, 1982). We are presently investigating the involvement of candidate cerebellar neurotransmitter systems in mediating this classically conditioned response. Several lines of evidence indicate that GABAergic processes are localized to these nuclear regions. Collectively, these observations provide an initial basis for examining the potential role of GABAergic processes in simple associative learning. We now report that microinfusion of GABA antagonists into the dentate-interpositus region of the cerebellum can produce complete, selective and reversible abolition of the well-conditioned eyelid response--with the unconditioned reflex response being unaffected by these manipulations.

These pharmacological effects behave in a dose-dependent fashion with 1.5 nmol (in 0.75 µL of vehicle) of either bicuculline methiodide or picrotoxin completely abolishing the ipsilateral conditioned eyelid response (CR) following drug administration. Lower doses produce a dose-dependent decrease in the CR peak amplitude. Typically this abolition dissipates over time--with CRs returning to predrug baseline levels by the end of the test session. This selective abolition by GABA antagonists can be produced regardless of the amount of prior training the animal has received. This effect appears highly selective based on its pharmacological specificity and anatomical localization of site of action. Several candidate agonists and antagonists thus far examined, including glycine and strychnine, produce no measurable effect on the conditioned behavior when administered in comparable molar doses. Histological verification of sites of infusion indicate that cannula tip placements are most effective in disrupting the CR if positioned immediate to the dentate-interpositus region. When training is shifted to the eye contralateral to the infusion cannula, bicuculline infusions (1.5 nmol/ 0.75 µL) are completely ineffective in disrupting the contralateral CR. This argues against the substance diffusing via the general circulation and producing its effect at distant sites.

Collectively these results suggest that GABAergic processes localized to the deep cerebellar nuclei may play a critical role in simple associative learning.
Supported by NIMH # 1 T32 MH 17047-01 to LAM; NIMH # MH 23861 to JM IV and JDB; NSF # BNS-81-17115, ONR # NOOO14-83-K-0238 to RFT.

240.9 MICROINFUSION OF PICROTOXIN INTO THE CAUDAL RED NUCLEUS SELECTIVELY ABOLISHES THE CLASSICALLY CONDITIONED NICTITATING MEMBRANE/EYELID RESPONSE IN THE RABBIT. J. Madden IV, D.A. Haley, J.D. Barchas and R.F. Thompson. Depts. of Psychology and Psychiatry, Stanford University, Stanford CA 94305.

A wealth of experimental evidence suggests that cellular processes within the dentate-interpositus region of the cerebellum play a critical role in the expression of at least some forms of simple associative learning, including the short-delay classically conditioned nictitating mebrane (NM)/eyelid reponse in the rabbit (McCormick, et. al., 1982, Mamounas, et. al., 1983). More recently, Haley, et. al. (1983) have observed that lesions of the contralateral red nucleus, a structure receiving major efferent projections from the dentate/interpositus region of the cerebellum, also abolish the conditioned contralateral NM/ eyelid response. These observations provide a basis for postulating that this stucture may also be an essential component of the conditioned response pathway. In an attempt to further examine this possibility, we have assessed the effects of pharmacological manipulations of this region on the expression of the conditioned response. We now report that microinfusion of 1.75 nmol of picrotoxin (in 0.75 uL of vehicle) into the caudal red nucleus selectively abolishes the conditioned NM/eyelid response--the unconditioned reflex response is essentially unaffected by this manipulation. Furthermore, this effect can be produced regardless of the amount of prior training the amimal has received. Collectively these results and those of Haley, et al (1983) suggest that the red nucleus is an essential component of the conditioned response pathway in this simple form of associative learning.

240.10 BEHAVIORAL MEASURES AFTER CENTRAL NORADRENERGIC DEPLETION WITH THE NEUROTOXIN, DSP-4: LACK OF IMPAIRMENT IN AVOIDANCE TASKS.
C. Bennett*, J.L. McGaugh, M. Arnold*, and K.C. Liang*. (Spon: G. Novack) Department of Psychobiology, University of California, Irvine, CA 92717

The behavioral effects of depletion of central norepinephrine (NE) by a neurotoxin specific for noradrenergic terminals, N-2-chloroethyl-N-ethyl-2-bromobenzalamine (DSP-4), were investigated by a variety of measures. In previous behavioral studies, lesions of the central NE nuclei or pathways have produced mixed results. In the present study we examined inhibitory avoidance retention, active avoidance acquisition and retention, activity, and shock sensitivity after central NE depletion with DSP-4.

Male Sprague-Dawley rats were injected with 50 mg/kg (ip) of DSP-4 synthesized by two of us (Arnold and Bennett), according to the method of Krueger and Cook (1975). This dose has been shown to deplete central and peripheral norepinephrine (NE) by 60-90%, depending upon the region. Behavioral measures were begun 14 days after the injection to allow regeneration of the peripheral sympathetic terminals. The rats were trained on a one trial step-through inhibitory avoidance task using a training footshock of either 0.75 mA, 1 s, or 1.0 mA, 2 s. Retention was tested 24 hours later. After two weeks, the rats were trained on an active avoidance task (0.64 mA, 30 s) to a criterion of three avoidances. Retention was measured by retraining the animals to the same criterion after 24 hours. Animals not reaching the criterion within 15 trials on the training day were not tested for retention.

For the inhibitory avoidance task, the two groups did not differ in their latencies to step through on the retention test. The DSP-4 treated rats, however, had significantly longer mean entrance latency on day-1 than the controls. In the active avoidance task, there was no significant difference between the two groups in the number of trials to criterion for acquiring the response, nor was there a significant difference in the retention scores. We also measured spontaneous activity by counting line crossings and rearings in an open field apparatus. There were no significant differences between the two groups, although the control group had higher mean values for both measures. Flinch-[illegible] lysis revealed that the two groups also had comparable thresholds for both flinch and jump, indicating that there is no difference in shock sensitivity.

In a variety of measures, therefore, DSP-4 treated animals appear remarkably similar to control animals. While acute pharmacological treatments affecting NE are known to influence behavioral measures of learning and memory, our findings suggest that functionally intact central NE systems are not essential for normal acquisition and retention of avoidance tasks.

240.11 YOHIMBINE'S ATTENUATION AND CLONIDINE'S FACILITATION OF SHORT-TERM HABITUATION OF THE ACOUSTIC STARTLE RESPONSE IN RATS. James V. Cassella and Robert N. Leaton. Dept. of Psychology, Dartmouth College, Hanover, NH 03755.

Previous research has shown that although many drugs modulate the amplitude of the acoustic startle response (ASR) in rats, only clonidine unambiguously alters short-term habituation of the response (Davis et al.,1977). Given clonidine's pharmacological specificity for NE alpha-2 receptors it was hypothesized that this class of NE receptors plays an important role in this habituation process. Accordingly, it was expected that the NE alpha-2 antagonist, yohimbine, would block clonidine's action on the ASR. Moreover, yohimbine itself was expected to attenuate short-term startle habituation. The present series of experiments explored the effect of yohimbine, as well as clonidine, on short-term habituation of the ASR.

In Experiment 1, yohimbine treatment (10, 15, 18 mg/kg, i.p.) significantly attenuated the short-term response decrement to 20 startle- eliciting tones (4-kHz, 118-dB, 100-ms duration, 20-s ISI). Contrary to previous observations, however, clonidine (.03 mg/kg) failed to accelerate the rate of habituation. The absence of a clonidine habituation effect might be attributed to a floor effect resulting from the significant depression of first-trial startle amplitudes in these animals.

In Experiment 2, first-trial startle amplitudes following clonidine treatment (.03 mg/kg) were comparable to control levels and, more importantly, habituation was accelerated. As predicted, pretreatment with yohimbine (1, 3, 10 mg/kg) significantly blocked clonidine's habituation effect.

Experiment 3 found that clonidine's facilitation and yohimbine's attenuation of ASR habituation were dependent upon the parameters of stimulation (white noise bursts), especially the combination of stimulus intensity and ISI. Clonidine's habituation effect was most consistently observed under conditions in which habituation in control animals was relatively weak, namely at a high stimulation intensity (110-dB) and/or long ISIs (60-s). Conversely, yohimbine's habituation effect was most consistently found when habituation in controls was relatively strong : at a low or moderate intensity of stimulation (90-100 dB) and/or short-to-moderate ISIs (10-30-s).

Given the antagonistic nature of clonidine and yohimbine on startle habituation and the opposing pharmacological actions of these drugs, the data suggest that NE alpha-2 receptors might play an important role in the mediation of short-term habituation of the ASR.

240.13 ENHANCING EFFECT OF EPINEPHRINE ON RETENTION OF AN INHIBITORY AVOIDANCE RESPONSE: LACK OF ATTENUATION BY DEXAMETHASONE. K. C. Liang*, C. Bennett*, J. L. McGaugh, D. A. Tam, Jr.*, and R. G. Juler*. Department of Psychobiology, University of California, Irvine, CA 92717.

Considerable evidence has shown that posttraining systemic injections of epinephrine or adrenocorticotropin (ACTH) enhance retention in various learning tasks. Recent studies indicate that epinephrine, given systemically, may act on the anterior pituitary and release ACTH. These findings suggest that epinephrine may enhance memory by way of releasing ACTH. According to this hypothesis, dexamethasone, which blocks the epinephrine-elicited ACTH release, should attenuate the enhancing effect of epinephrine on memory. The present study addressed this question.

Forty-nine male Sprague-Dawley rats received two subcutaneous injections (16 hrs apart) of dexamethasone (Dex, 2 mg/kg) or vehicle (Veh). Four hrs after the second injection, animals were trained on a one-trial step-through inhibitory avoidance task with a 600 µA, 0.5 sec footshock. Immediately after training, rats received an intraperitoneal injection of epinephrine (Epi, 0.1 mg/kg) or saline (Sal). Retention was tested 24 hrs later.

Retention performance is shown in the table. In the Veh pre-treated rats, posttraining Epi significantly enhanced retention ($U=39.5$, $p < 0.02$). The two groups of Dex pre-treated rats, when combined, had significantly longer retention latencies than the combined Veh pre-treated group ($U=172$, $p < 0.02$). The most critical finding is that in the animals pre-treated with Dex, posttraining Epi still caused a significant enhancing effect on retention ($U=24.5$, $p < 0.05$).

These results indicate that dexamethasone, which blocks the ACTH release elicited by epinephrine, failed to attenuate the retention-enhancing effect of epinephrine. These findings do not support the hypothesis that epinephrine enhances memory by way of releasing ACTH.

Pretraining treatment	Veh		Dex	
Posttraining treatment	Sal	Epi	Sal	Epi
Median retention latencies	193.9 (13)	548.1** (14)	370.3 (10)	600* (12)

** $p < 0.02$, * $p < 0.05$ different from the saline groups, two-tailed Mann-Whitney U-tests. ( ) = number of animals.

240.14 **TIME OF DAY IS IMPORTANT IN THE RETRIEVAL OF ENHANCED MEMORY FOR PASSIVE AVOIDANCE BEHAVIOR BY POST-TRAINING ETHANOL IN MICE.** **D.L. Colbern, and E.G. Zimmermann. Brain Research Institute and Department of Anatomy, UCLA School of Medicine, Los Angeles, CA 90024.**

Passive avoidance measured 24 h, 5 or 7 days later, is improved when mice are injected with ethanol immediately after footshock training in the afternoon (Alkana and Parker, Psychopharm., 66:117-119, 1979; Colbern, et al, Substance and Alcohol Actions/Misuse, 1:181-186, 1980). However, avoidance performance is not improved when mice are trained and injected with ethanol in the morning and tested 24 h later (Colbern, et al, Alcoholism: Clin. Exp. Res., 5:146, 1981).

In mice, the diurnal variation of ethanol-facilitated avoidance closely resembles the circadian pattern of corticosterone release during light hours. Endogenous levels of corticosterone are low in the morning and rise to a peak in the afternoon (Kakihana and Moore, Psychopharmacologia, 46:301-305, 1976), while the 3 g/kg dose of ethanol used in our studies produces maximal release of corticosterone (Kakihana, et al, Nature, 218:360-361, 1968). Glucocorticoid states after training and before testing may be an important condition for the retrieval of information regarding the training experience.

In a study designed to behaviorally determine if high afternoon levels of corticosterone might be necessary for the observation of enhanced avoidance, male Swiss-Webster mice were given passive avoidance training (0.1 mA) in the late afternoon and then immediately injected with ethanol (3.0 g/kg, 15 % v/v). Controls were given an equal volume of saline or a sham injection. Avoidance testing was conducted 24, 38, or 48 h later.

For all treatment groups, mice tested in the afternoon, 24 or 48 h after training, exhibited more avoidance behavior than did mice tested in the morning, 38 h later. However, mice injected with ethanol showed greater avoidance at these times than did mice given saline or sham injections. Thus, the similarity of endogenous states at times of training and testing was important in the retrieval of information for all mice. It appears that the effect of post-training ethanol on passive avoidance behavior is to potentiate normally occurring processes.

240.15 SUPPRESSION OF MEMORY EXPRESSION BY PUROMYCIN AND ANTAGONISM BY CLYCLOHEXIMIDE. R.A. Barraco, H. Normile*, G. Smoot*, H. Altman. Wayne State University, School of Medicine, Detroit, MI 48201.

Two types of interpretation have been enunciated to account for deficits during retention: either the memory no longer exists or the memory cannot be adequately retrieved. Impairment of retrieval processes by an amnestic agent can be substantiated when a given memory is recovered by amnesia-attenuation treatments. Although the memory-impairing effects of the majority of antibiotics are generally correlated with the temporal parameters of protein synthesis inhibition and the training-treatment interval, the situation for puromycin (PM) is very different. PM injections impair retention when they are made before or immediately after training or when they are delayed until 24 or more hrs after training. Further, although there is no evidence of memory restoration or amnesia attenuation for PM injections given immediately after training, the amnesia produced by delayed PM injections can be attenuated by a variety of manipulations (Barraco, R.A. and L.J. Stettner, Psychol. Bull. 83: 242, 1976).

Mice were trained in a lick-suppression task and given intracerebroventricular (ICVT) injections of PM 24 hrs training. PM produced a marked amnesia for the inhibitary avoidance response during retention testing 96 hrs later. Of all the antibiotics used in memory disruption experiments, only PM is effective as an amnestic agent when injections are delayed until 24 hrs after training. In another experiment, mice were trained in the same task and given concurrent ICVT injections of PM and cycloheximide (CXM). At the higher dose, CXM completely blocked the amnestic effects of PM. These results suggest that delayed PM injections block the retrieval or expression of memory. The fact that CXM does not attenuate the amnesia produced by immediate PM injections suggests the biochemical mechanisms for amnesia in each situation is not the same. Furthermore, since CXM blocks the formation of a fraction of puromycin peptides which has been isolated and shown to persist in the mouse brain for at least 96 hrs, the amnesia-attenuating effects of CXM strongly implicate the involvement of this persistent fraction of puromycin metabolites in blocking the expression of memory. We are now examining the bioactivity of these persistent puromycin metabolites using a number of in vitro and behavioral methods.

241.1 INDUCED REDUCTION IN FIBER NUMBER OF INDIRECT FLIGHT MUSCLES IN THE DROSOPHILA MUTANT SHIBIRE. W.J. Costello and L. Salkoff, Dept. Biomed. Sci./Col. Osteo. Med., Ohio Univ., Athens, OH 45701 and Biol. Dept., Yale Univ., New Haven, CT 06511.

The genetic approach to explain problems in development can be conducted with great success in studies utilizing the fruit fly Drosophila melanogaster. One mutant, shibire^{ts1}(shi) is temperature-sensitive, causing reversible paralysis of flies at temperatures above 28°C. As well, a variety of phenotypic responses to heat pulses are expressed at different developmental stages (Poodry et al(73)Dev. Biol. 32:373-386). Several morphological defects are seen in these heat-pulsed flies. Synapses contain few or no vesicles but do have numerous membrane-bound cisternae (Poodry & Edgar(79)J. Cell. Biol. 81:520-527). There are also cisterna-like structures seen in close association with the sarcolemma of the indirect flight muscles (Costello & Salkoff(82) Neurosci. Abstr. 8:494). Evidence suggests that shi may be causing an overall membrane defect affecting turnover and re-cycling.

We have found that the shi defect also prevents normal fiber formation of the dorsal longitudinal muscles (DLM) during pupal development. During normal development, adult myocytes in the early pupa ($\leq$10hrs) migrate to a set of larval muscles in the dorso-lateral region on either side. The myocytes organize themselves around the larval muscles and commence to fuse. Concurrently, the larval muscles undergo complete degeneration. The fused myocytes form into three units corresponding to the three larval muscles. Each unit then divides in half so that by 24 hrs of pupation there are six units formed. These six units are the precursors to the six DLMs of the adult.

In our experiments, shi flies were raised at 18°C. Pupae of various ages were heat-pulsed at 30°C for 2 hrs. Afterwards, the pupae were returned to 18°C for the duration of pupal development. The newly emerged adults were dissected at 18°C and prepared with cold fixative. We found that in adult flies which had been heat-pulsed between 0-17hrs of pupation the DLM fiber number was abnormal. The DLM, though present, consisted of only three units on either side. Serial sectioning confirmed that the units maintained autonomy throughout the thorax. Ultrastructurally, the three DLM units appeared normal: myofilaments were organized in normal fashion and sarcomeres were present.

The evidence suggests that the shi defect is preventing normal boundary formation in the development of DLM fibers.

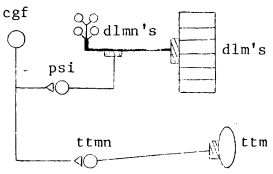
241.2 CHOLINE ACETYLTRANSFERASE MUTATIONS BLOCK ACTIVITY AT A CHEMICAL SYNAPSE IN DROSOPHILA MELANOGASTER. M. Gorczyca and J. Hall Dept. of Biology, Brandeis University, Waltham, MA 02254

Two temperature sensitive mutations of the choline acetyltransferase gene (Cha) have been used in the initial stage of identification of the neurotransmitter at a chemical synapse in the giant fiber motor circuit in Drosophila melanogaster.

These mutations, Cha^{ts1} and Cha^{ts2}, affect levels of choline acetyltransferase (CAT and acetylcholine (ACh). CAT activity declines to less than 2% after incubation at nonpermissive temperature for 3-4 days. Concomitantly, ACh levels are reduced to 25% wild-type (wt). This has been shown to severely affect courtship and locomotor activity as well as a transient spike in the electroretinogram.[1] Presumably, cholinergic neurons in the CNS are disturbed by the decrease in transmitter levels.

To circumvent the difficulties of recording directly from the CNS to assay neurophysiological abnormalities, a previously identified circuit in the fly was selected.[2] Access to both presynaptic and postsynaptic elements is possible. The giant fiber motor circuit mediates the animal's escape response which is channeled down two pathways: (1) cervical giant fiber (cgf) to peripherally synapsing interneuron (psi) to dorsal longitudinal muscle motorneurons (dlmn's) to the dorsal longitudinal muscles (dlm's) and (2) cgf to tergotrochanteral muscle motorneuron (ttmn) to the tergotrochanteral muscle (ttm).



Upon brain stimulation in wild-type flies, responses are evoked in the dlm's and the ttm. In both Cha mutants at restrictive temperature, the first pathway completely fails (no response) while the second pathway performs normally. The pathway from the dlmn's to the dlm's however, behaves as in wild-type flies. Hence, the psi is the aberrant component of the pathway. Since the synapse from the psi to the dlmn's is almost certainly chemical,[2] this suggests that acetylcholine is the neurotransmitter at that synapse.

A direct and positive correlation between diminution of CAT activity and the respose in the cgf-to-dlm pathway can be made using these mutations. It was found that CAT activity might be the limiting factor in the ability of these neurons to respond to high rates of stimulation.

241.3 BITHORAX COMPLEX MUTANTS TRANSFORM THE SEGMENT-SPECIFIC PATTERN OF 5-HT CONTAINING NEURONS IN DROSOPHILA. E. Martel*(SPON: K. Graubard). Dept. of Zoology, University of Washington, Seattle, WA 98195.

Certain aspects of a neuron's identity are a consequence of its segment of origin. In an effort to understand the genetic basis of this determination I have developed a segment-specific neuronal marker and used it to observe transformations of segmental identity in the central nervous systems of mutants of the Bithorax Complex. The fused segmental ganglia of adult Drosophila were stained using an antiserum produced against 5-Hydroxytryptamine (5-HT). Immunoreactive cell bodies were arranged in a segment-specific manner, with both the prothoracic and mesothoracic ganglia containing two pairs of cells and the metathoracic ganglia being devoid of staining. Immunoreactive cells are also seen in both larval and adult abdominal ganglia. The pattern of 5-HT staining in wild type flies is highly stereotyped.

Studies of the genetic basis of the determination of segmental identity in the epidermis of Drosophila have resulted in an understanding of the region of the genome known as the Bithorax Complex, which controls the identity of thoracic and abdominal segments. Loss of gene activity in this region is known to produce homeotic transformations, transforming the identity of epidermal cells to that of segments more anteriorly located. Application of antiserum to 5-HT on to the ventral nervous systems of Bithorax Complex mutants revealed apparently homeotic transformations of the pattern of staining similar to those transformations seen in the epidermis. In flies homozygous for the triple mutation abx bx^3 pbx, the metathoracic ganglia contained four immunoreactive cells arranged in the pattern seen in the mesothorax. Staining of double and single mutants reveals partial transformations. The pattern of 5-HT staining in all other segments is unchanged. This work indicates that the determination of segmental identity in the central nervous system is under the genetic control of the Bithorax Complex.

241.4 WIDESPREAD NEURONAL AND AXONAL DEGENERATION IN THE TORTURED, TOR, MUTANT MOUSE. C. F. Da Silva, J. C. COWEN* and R. L. Sidman. Depts. of Neuroscience, Children's Hospital and Neuropathology, Harvard Medical School, Boston, MA 02115.

An initial brief description (Sidman, in Kety et al. Genetics of Neurol. & Psychiat. Disorders, A.R.N.M.D., 60, 1983) of this new autosomal recessive mutation emphasized the grossly abnormal postures and adult-life progressive degeneration of cerebellar granule cell neurons. We now report widely distributed neuronal degeneration peaking at different times for different populations over a span of at least one year. At postnatal day 17 (P17), many dorsal root ganglion (DRG) neurons appear chromatolytic and others are abnormally small, though their peripheral and central axonal branches appear intact. At P27-50, Wallerian degeneration is widespread in motor and sensory peripheral nerves and roots, in all white matter funiculi at all levels of spinal cord, and in brainstem, but cerebellar white matter is only mildly affected and forebrain tracts appear normal. We recognized no distal-proximal gradients of degeneration along a given fiber system. Some medium- and large-sized neurons apparently had degenerated without residue in DRGs, ventral horns of spinal cord and in the cerebellar Purkinje layer and deep nuclei; these areas showed little further cell loss after the second month. By contrast, pyknotic and fragmented remnants of small cells were present in large numbers, peaking at about P30-50 in the caudate/putamen, P50 in nuc. accumbens septi and the polymorphic layer of the pyriform cortex, and later than P50 for periglomerular and granule cells of olfactory bulb and for cerebellar cortical granule cells. After the second month, Purkinje cells appeared to stabilize in number and increase in concentration as granule cells progressively disappeared and the cerebellum atrophied. Degenerating myelinated axons were first noted in both limbs of the anterior commissure and in the lateral olfactory tract at P50, and were more numerous at P79. A few degenerating fibers were observed in the optic nerve and chiasm at P223 and more were present at P373. The common feature among these neuronal populations that might suggest the mode of action of the tor genetic locus remains elusive: some affected neurons are large and others small, some central and others peripheral, some excitatory and others inhibitory; they share neither time of genesis nor time of degeneration.

241.5 THE ARCHITECTONIC AND HODOLOGIC ORGANIZATION OF THE REELER CEREBELLUM. A.Goffinet*, K.-F.So, V.S.Caviness Jr. Dept. Neurol.and Neuropathol., M.G.H. and E.K.Shriver Center, Boston, MA 02114.

The architectonic and hodological organization of the reeler cerebellum has been studied using cell and fiber stains, retrograde transport of HRP, anterograde autoradiographic labeling, and the Fink Heimer method. The reeler cerebellum is composed of six concentric zones: 1) a thin molecular layer,2) a sparsely populated Purkinje cell layer, 3) an irregular granular layer, also containing displaced Purkinje cells,4) a fiber layer, 5)a zone of heterotopic Purkinje cells, in which three masses (central, intermediate and lateral) are defined and 6)the roof nuclei. The Purkinje cell populations of the cortex and subcortex are continuous along two rostrocaudally aligned parasagittal planes. They serve to partition the hemicerebellum of the mutant into a midline and two more lateral rostrocaudally aligned compartments. Principal rhombencephalic afferent sources defined by intracerebellar HRP injection are, as in the normal animal, the inferior olivary nuclei, lateral reticular nuclei , trigeminal nuclei, cuneate nuclei, vestibular nuclei, locus coeruleus, raphe nuclei, pontine and reticulotegmentopontine nuclei. The inferior olive is less convoluted in reeler than in the normal animal (Goffinet,'83).Still the rostral to caudal axis of the cerebellar projection of the olivary complex is distributed continuously over the lateral to medial axis of the cerebellum as in the normal animal.The projection in reeler differs from that in the normal in that there is no apparent subdivision into sagittally aligned stripes in the mutant. Tracts carrying the mossy fiber projections are diminutive in reeler. Pontine afferents are distributed to the two lateral cerebellar compartments and terminate exclusively in the granule cell layer. Spinocerebellar afferents are limited to the medial compartment and terminate in the granule cell layer as well as among heterotopic Purkinje cell masses (Wilson et al.,'81). The pontine and spinal mossy fibers projections do overlap somewhat in the paramedian zone of Purkinje cells but principally they occupy differentially the paramedian and median cerebellar compartments, respectively. This study shows that the afferent connections of the reeler cerebellum are normally organized topologically but do include at least some classes of heterologous synapses. In addition, there is a correspondance between architectonic and hodologic compartments in the mutant, which is not found in the normal cerebellum.

241.6 SINGLE GENE INHERITANCE OF AN ABNORMALITY IN LAMINATION IN AREA CA3c OF THE HIPPOCAMPUS OF BALB/c MICE. R. S. Nowakowski. Dept. of Anatomy, Univ. Miss. Med. Ctr., Jackson, MS 39216.

In BALB/c mice the lamination of the pyramidal cell layer of area CA3c of the hippocampus is abnormal in that early-generated neurons are superficial and late-generated neurons are deep (Vaughn et al., '77, J. Comp. Neurol. 173: 41-52). This reversal from the normal pattern suggests that neuronal migration in BALB/c is perturbed and that late-generated pyramidal neurons fail to migrate past the previously generated ones. In addition, in BALB/c mice the mossy fibers which project from the granule cells of the dentate gyrus to area CA3c are distributed abnormally, forming an extensive intrapyramidal synaptic field in contrast to the normally occuring infrapyramidal synaptic field (Barber et al., '74, J. Comp. Neurol. 156: 417-434).

To determine the mode of inheritance of this strain difference, the distribution of mossy fibers was examined using the Timm's sulphide silver method in BALB/c x C57BL/6 F1 and F2 hybrids, in BALB/c and C57BL/6 mice which were fostered to females of the other strain before receiving their first meal, and in the CXB series of recombinant inbred strains (made using BALB/c and C57BL/6 as progenitor strains). The distribution of mossy fibers was classified as "BALB/c-like" if an intrapyramidal mossy fiber layer was present or as "B6-like" if an infrapyramidal mossy fiber layer was present.

In both male and female CB6F1 and B6CF1 hybrids the distribution of mossy fibers is BALB/c-like. In seven of nine F2 hybrids the distribution was BALB/c-like and in the remaining two B6-like. In the cross-fostered mice the pattern was always the same as normally raised mice of the same genotype. Of the recombinant inbred strains, five (CXBD, CXBG, CXBH, CXBI and CXBK) had BALB/c-like mossy fiber distributions and two (CXBE and CXBJ) had a B6-like distribution. These results are consistent with inheritance by means of a single autosomal gene. The degree of dominance of the gene and its linkage and the possible existence of modifying genes are under investigation.

The fact that, in a single subdivision of the CNS, a single gene affects both the position attained by migrating neurons and the establishment of connectivity of a population of axons indicates that the BALB/c mouse may be a useful tool for future studies of the cell biology of neuronal migration and neuronal specificity.

241.7 LACK OF FUNCTIONAL mRNA CODING FOR A MICROTUBULE-ASSOCIATED PROTEIN CORRELATES WITH POOR PERFORMANCE OF RATS IN A BEHAVIORAL PARADIGM. P. Strocchi, G.S. Zubenko* and J.M. Gilbert. Mailman Research Center, McLean Hospital, Belmont, MA 02178 and Harvard Medical School, Boston, MA 02115.

The cerebral cortical cells of Sprague-Dawley albino rats contain polysomal mRNA which directs the synthesis of one or both of two proteins, denoted A and B by Strocchi et al (1981), which co-purify with tubulin. The A and B proteins have apparent molecular weights of 54,000 daltons, but differ in their isoelectric points. The translation products synthesized from polysomal mRNA prepared from 153 individual cortices were subjected to two-dimensional polyacrylamide gel electrophoresis and fluorography. Three classes emerged with respect to these proteins: A, B, and AB. These qualitative differences in translation products reflect the presence of specific templates and not the inclusion of specific inhibitors of translation or contamination by an AB interconversion system since mixtures of polysomal mRNA that separately direct the synthesis of only one of these proteins direct the synthesis of both of these proteins in vitro. The similarity of these proteins along with the absence of rats whose cortices lack polysomal mRNA for both A and B (A^-B^-) are findings that are consistent with the hypothesis that the structural genes for these proteins are allelic.

As a serendipitous observation, we noticed that rats that performed poorly in a novel escape-avoidance paradigm tended to lack the functional RNA from cortical polysomes that encoded the A protein. Performance was measured by the length of time required for an animal to escape into the preferred dark compartment, a parameter called light-dark transition latency or LDTL (Jarvik and Kopp, 1967; Heinze, 1974; Strocchi et al, 1977). With a two-sample Kurskal-Wallis test, no significant difference ($p = 0.55$) could be demonstrated between the A and AB phenotypes. However, significant differences were observed between the A and B phenotypes ($p = 0.02$) and between the AB and B phenotypes ($p = 0.002$). The A and AB phenotypes are associated with a good performance and the B phenotype (A-deficient) with poor performance. This association does not result from a paradigm that induces a deficiency for protein A-encoding messenger RNA in the cortices of poor performers, for there is no increase in the relative frequency of animals bearing this phenotype in tested populations as compared to naive control populations. This deficiency may correspond to one of the genetic determinants previously demonstrated to affect this behavior in outbred strains of rats (Bignami, 1965; Broadhurst and Bignami, 1965; Wilcock and Fulker, 1973; Heinze, 1974; Wilcock et al, 1981; Hewitt et al, 1981). Supported by NIH grants MH36224, 5K02 70713 and The Marion Benton Trust.

241.8 IS THE β-NERVE GROWTH FACTOR GENE DEFECTIVE IN FAMILIAL DYSAUTONOMIA? X.O. Breakefield*[1], C.M. Castiglione*[1], L. Coussens*[2], F. Axelrod*[3] and A. Ullrich*[2] (SPON: D. Corey). [1]Dept. Human Genetics, Yale Univ. Sch. Med., New Haven CT 06510; [2]Genentech Inc., So. San Francisco CA 94080; [3]Dept. Pediatrics, N.Y. Univ. Med. Ctr., NYC 10016.

The availability of a cloned genomic probe for the human β-nerve growth factor (β-NGF) gene (Ullrich, Gray, Berman and Dull, in press) allows us to determine whether or not a mutation in this gene causes the inherited neurologic disease, familial dysautonomia. This disease is transmitted in an autosomal recessive manner and affects some 500 people world-wide, mostly of Ashkenazic Jewish descent. Symptoms include loss of sympathetic and sensory functions, e.g. poor control of digestion and blood pressure, insensitivity to pain and temperature, and lack of overflow tears and taste buds. Neuropathologic examination shows substantial loss of neurons in sympathetic, sensory and some parasympathetic ganglia even at early ages; the central nervous system is apparently unaffected (Pearson, Johnson and Brandeis, 1983, Devel. Biol. 96:32). Many of the pathologic features of this disease resemble those of rodents treated with antibodies to β-NGF in utero (Gorin and Johnson, 1980, Devel. Biol. 80:313) or post-natally (Aloe, Cozzari, Calissano and Levi-Montalcini, 1981, Nature 291: 413). Work by Ullrich and co-workers has shown that a single locus for β-NGF is present in the human haploid genome and that it codes for a protein with 90% homology to mouse β-NGF. We have used cloned fragments of this gene as probes to determine whether variations in DNA sequence occur in or near the β-NGF gene in families with dysautonomia. Variations in sequence are identified as differences in the length of DNA fragments that hybridize to these probes following digestion of genomic DNA with restriction endonucleases. Over 20 restriction endonucleases that cut the DNA at specific 4 and 6 base pair sequences have been tested. Two endonucleases have revealed variations in fragment length among individuals, and these variations are inherited as co-dominant alleles in families. These variations appear to be due to the presence or absence of specific endonuclease sites in non-coding regions of the β-NGF gene, and have no apparent relationship to the mutation causing the disease. These fragment length variations do serve, however, to mark both alleles of the β-NGF locus in some parents. Studies are underway to establish whether there is co-inheritance of specific β-NGF alleles from the parents and the disease state in six families. This analysis will exclude or implicate a lesion in the structural gene for β-NGF, including exon, intron and flanking sequences, as the cause of familial dysautonomia.

241.9 PNMT ACTIVITY IN THE RAT: CO-INHERITANCE OF ADRENOMEDULLARY AND REGIONAL BRAIN ENZYME? J.M. Stolk* R.B. Guchhait, G. Vantini*, B.D. Perry, D.C. U'Prichard and R.C. Elston* Maryland Psychiatric Research Center, Univ. of Maryland Sch. Med., Baltimore, MD 21228; Department of Pharmacology, Northwestern Medical School, Chicago, IL 60611; Department of Biometry, Louisiana State University Med. Sch., New Orleans, LA 70112.

PNMT, the enzyme that converts norepinephrine to epinephrine in adrenergic cells, is found in the adrenal medulla as well as in limited populations of neurons arising from the brain stem and distributing to spinal cord, medulla-pons, and hypothalamus. The adrenal enzyme is inherited as an autosomal co-dominant trait at a single locus in the mouse, presumably due to a regulatory gene (Ciaranello & Axelrod, JBC 248: 5616, 1973). We recently observed greater than 5-fold differences in adrenal PNMT activity within inbred rat strains; we employed the 2 strains having maximally different PNMT activity to assess inheritance, the type of gene or genes governing the adrenal enzyme, and possible co-inheritance of adrenal and brain PNMT activity. Inheritance was assessed in a F344 by Buf Mendelian cross. Enzyme activity in adult offspring yielded no evidence for sex linkage (in reciprocal cross hybrid males); inheritance is best accounted for by a single major autosomal gene superimposed upon a polygenic background. Detailed studies in the 2 parent strains strongly suggest that a structural gene is involved. The Buf enzyme is highly susceptible to thermal inactivation while the F344 enzyme is resistant; structural variants in the enzyme, perhaps, are associated with observed differences in affinity for the co-substrate, S-adenosyl-L-methionine (SAMe), although the strain with the more thermolabile enzyme has the higher affinity for SAMe (K_m= 3 μM in Buf, and 7 μM in F344). Analyses of medulla-pons and hypothalamus PNMT in F344, Buf and F_1 male offspring reflect directly the adrenal enzyme activity. Correlation coefficients of 0.786 and 0.920 are obtained for adrenal with medulla-pons or with hypothalamus, respectively. Initial evaluation of the F_2 generation similarly indicates a strong, positive correlation between adrenal and hypothalamus PNMT activity (R=0.874). These data are consistent with co-inheritance of adrenal and brain PNMT activity in the rat, and suggest that a single major structural gene is specifically involved. That the co-inheritance of adrenal and brain PNMT has functional implications is suggested by the inverse relationship between enzyme activity and α-adrenergic receptor density only in peripheral and central tissues with direct access to the PNMT product, epinephrine. (Supported by MH 32842, NS 15595, DA 02763, RSDA MH 00018 and NRSA MH 08834).

DEVELOPMENT OF INVERTEBRATES II

242.1 EVOLUTIONARY ORIGINS OF GIANT AXONS IN DROSOPHILA (DIPTERA). David G. King. Dept. of Anatomy and Dept. of Zoology, Southern Illinois University, Carbondale, IL 62901

Giant axons, like other highly differentiated neurons, pose several problems for neurobiologists: What is the adaptive value (if any) for such unique neuronal characteristics as great axonal diameter? What developmental mechanisms regulate specific features like axon size? How are the properties of specialized neurons encoded genetically? In evolutionary perspective, how can genetic variation in combination with natural selection mould development to yield individual adaptation in specific neuronal pathways? Comparative study of homologous neurons in related species may help elucidate such questions, by revealing both the ontogenetic constraints and the degrees of freedom available for evolutionary modification of specific neuronal form and function.

A pair of giant axons have long been known in Drosophila (Power '48, J.Comp.Neurol. 88:347). Recently similar axons have been reported in several other flies (King & Valentino in press, J.Comp.Neurol.; Strausfeld & Bassemir in press, J.Neurocytol.) These axons are well suited for phylogenetic investigation. Not only are they accessible to a variety of techniques, but they are found in a large and diverse group of animals that are already popular for developmental, genetic and evolutionary study. These giant axons appear to be adaptive; they provide increased speed and/or reliability for impulse conduction in a neural pathway which mediates a startle response. In the present study, giant axons were found in occasional nematocerans ("primitive" flies) and lower brachycerans, but these axons differ in course and position within the cervical connective from those previously reported in muscoid flies. Thus giant axons apparently do not form a primitive component of the dipteran system, but have evolved independently in different suborders. Giant axons similar to those in Drosophila were found only in the Cyclorrhapha (the most "advanced" of the three dipteran suborders) and in a brachyceran group closely related to the Cyclorrhapha. But giant axons are not present in all higher flies. The apparent homology among such axons when they do occur suggests that they have either evolved several times from homologous precursors or else been modified or lost from several taxa following their first appearance.

Whether giant axons can arise by evolutionary modification of the size of certain axons independently from others, or whether their exceptional size reflects one extreme of a size distribution whose evolutionary modification affects many other axons as well, remains to be determined. That many different neurons are characterized by specific axon size is clear (e.g., King & Tanouye in press, J.Exp.Biol.). To what extent such specificity is adaptive and/or subject to individual genetic modification is still unknown.

242.2 COMPUTER-AIDED MORPHOMETRY OF DEVELOPING AND MATURE ANTENNAL LOBES IN THE MOTH *MANDUCA SEXTA*. A.M. Schneiderman, J.G. Hildebrand and J.J. Jacobs*. Dept. of Biol. Sci., Columbia Univ., NY, NY 10027.

The antennal lobes (ALs) in the brain of *Manduca sexta* are sexually dimorphic. In addition to "ordinary" glomeruli, which are present in both male and female ALs, the male AL exclusively contains a large macroglomerular complex (MGC). The primary or only site for processing sensory information about female sex pheromone, the MGC contains dendritic arborizations of male-specific AL neurons [*Proc. Roy. Soc. Lond. B213*:249 (1981)] and arises during adult development only in ALs contacted by ingrowing male antennal sensory axons [*Nature 298*:844 (1982)]. As part of our studies of the functional organization and development of ALs and especially of their sexually dimorphic components, we are enumerating the glomeruli and neurons in male and female ALs and tracing the development of the MGC in normal male, and surgically produced gynandromorphic female, ALs [*Nature, Ibid.*].

We use the CARTOS system [*Annu. Rev. Biophys. Bioeng. 18*:323 (1979)] to visualize in 3-space the outlines and anatomical positions, volumes, and number of glomeruli and neuronal somata in ALs. Profiles are aligned and traced from serial sections stained by Bodian's silver-Protargol method, and with the aid of computer programs for quantitative manipulation of positional data, the number and volumes of glomeruli and the number of neuronal somata in each AL are estimated. Observations to date suggest that the number of "ordinary" glomeruli in male and female ALs may vary. Three normal female ALs exhibited 57, 57 and 61 glomeruli; 3 normal male ALs yielded 59, 61 and 61 (plus MGC); and 1 gynandromorphic female AL innervated by grafted male antennal afferents had 57 ordinary glomeruli plus an MGC. Such findings do not yet permit a decisive comparison between the populations of glomeruli in male and female ALs, but our evidence argues that the MGC arises independently of other glomeruli. We find that the nascent MGC can be identified, separate from the ordinary glomeruli, as early as day 5 of the 18-day course of adult development -- the second day (out of *ca.* 8) of ingrowth of antennal afferents and the stage at which glomeruli are first discernible in the AL neuropil [*Soc. Neurosci. Abstr. 7*:3 (1981)]. With the aid of the cell-counting program CELLS, we have also begun to count neuronal somata in normal and gynandromorphic male and female ALs. Our goal is to ascertain whether the number of AL neurons in males is greater than that in females as a preliminary test of the hypothesis that male antennal sensory axons "rescue" a population of AL neurons produced in both male and female ALs but destined ordinarily to die in normal females. Our findings from this effort will be reported.

242.3 SEXUALLY DIMORPHIC EXPRESSION OF POLYPEPTIDES IN ANTENNAL SENSORY NEURONS OF *MANDUCA SEXTA*. T.G. Kingan and J.G. Hildebrand. Dept. of Biol. Sci., Columbia Univ New York, NY 10027.

In the moth *Manduca sexta*, the neuropil of the male antennal lobes (ALs) contains a macroglomerular complex (MGC), which is not present in the female AL and receives primary-afferent inputs from the male-specific, pheromone-detecting neurons in the male antenna [Matsumoto and Hildebrand, *Proc. Roy. Soc. Lond. B213*:249 (1981)]. Experiments involving surgical production of chronically deantennated and gynandromorphic ALs have shown that the development of the MGC is controlled by the male sensory axons [Schneiderman, Matsumoto and Hildebrand, *Nature 298*:844 (1982)]. Because an MGC develops only in an AL directly contacted by ingrowing male antennal sensory axons, we hypothesize that the male fibers possess molecular "factor(s)" possibly polypeptides -- responsible for inducing or permitting the development of the MGC and associated male-specific AL neurons. We have begun to search for sexually dimorphic polypeptides (PPs) to be candidates for such a role.

To compare the patterns of PPs in the afferent axons, we label them *in vivo* with [^{35}S]methionine and subsequently analyze the labeled PPs by gel electrophoresis. We inject [^{35}S]met into the antennal flagellum 20 mm from its base to expose a population of sensory neurons to radiolabeled amino acid; extract the PP fraction from the intracranial segment of the antennal nerve (AN) and AL; separate the PPs by 2-dimensional gel electrophoresis; and visualize them by silver-staining and fluorography. Among the PPs we detect in extracts made 24 hr after injection is one with an apparent molecular weight of 24 kilodaltons (24KD-PP), which is greatly enriched in male ANs and ALs. This 24KD-PP is still detectable in AN extracts 3 days after injection of [^{35}S]met, when many more slowly transported PPs first appear in the intracranial AN and AL, and it appears to be produced or transported only between day 6 and at most day 16 of the 18-day period of adult development. Other experiments suggest that this 24KD-PP is not synthesized in the AL, optic lobes, or protocerebrum.

Although silver-staining alone does not reliably reveal the 24KD-PP, this procedure does demonstrate reproducible differences between the apparent levels of 4 51KD-PPs (with slightly different mobilities in the charge-dependent first dimension of the gels) in developing male and female ALs. In contrast to the 24KD-PP, the 51KD-PPs are not among the most rapidly transported PPs in the AN; they appear in the intracranial AN only about 3 days after *in vivo* labeling with [^{35}S]met. The sexual differences in the 51KD-PPs can be detected by silver-staining between days 6 and 14 of adult development. By day 18, however, the sexually dimorphic pattern of the 51KD-PPs has given way to a distribution resembling that in the developing male AN. (Supported by grants NSF BNS 80-13511 and NIH AI-17711 and an NINCDS Postdoctoral Fellowship to TGK).

242.4 POST-EMBRYONIC DEVELOPMENT OF GRASSHOPPER OVIPOSITORS AND THE OVIPOSITION MOTOR PROGRAM. Karen J. Thompson and Eric Schabtach.* Dept. of Biology, Univ. of Oregon, Eugene, OR 97403.

Mature female grasshoppers excavate chambers for the burial of egg-pods by rhythmical movements of specialized appendages (ovipositors) located on the abdomen tip. A central pattern generator (CPG) in the terminal abdominal ganglion drives these movements.

The periodic ovipositor muscle contractions are normally seen only in sexually mature females; however, the CPG underlying them can be activated as early as the fourth (penultimate) larval instar. Activation of the CPG is achieved by severing the rostral neural connections to the terminal abdominal ganglion. Neither in larval animals nor in immature adults does the recorded electromyographic pattern lead to mechanical activity in the muscles. Additionally, there appears to be suppression of the motor output in immature adults, since the electromyographic activity recorded from these animals is significantly reduced by comparison to both the mature and larval cases

Scanning electron microscopy was used to examine the structural development of the ovipositor. The ovipositor consists of paired appendages which are outgrowths of the posterior margins of the eighth and ninth segments. These appendages are present as rudimentary buds in the first larval instar. In successive instars they are enlarged, modified, and the sternal plate between them reduced such that they become two pairs of shovel-shaped structures aligned dorso-ventrally at the final moult to adulthood. Further development occurs in the immature adult. This includes substantial enlargement of ovipositor cuticle and muscle. The ovipositor is also heavily sclerotized during this time.

In conclusion, the structure of the ovipositor develops throughout larval and immature adult life. The functional state is achieved by the onset of sexual maturity. In contrast, the CPG for oviposition digging is fully functional in the larval stage, long before it is ever used by the animal.

242.5 THE EFFECTS OF HYPOINNERVATION UPON THE FREQUENCIES OF FLY PHOTORECEPTOR SYNAPSES. A.Fröhlich & I. A. Meinertzhagen, Life Sciences Centre, Dalhousie University, Halifax, N.S. Canada

In the first optic neuropile, or lamina ganglionaris, of the fly's visual system photoreceptor terminals form tetrad synapses with precisely controlled frequencies. The receptors are grouped into units (cartridges) such that normally six receptor terminals synapse upon two monopolar cells and upon α-processes of amacrine cells. Where dorsal and ventral halves of the lamina meet, at the so-called equator, a zone of naturally produced hyperinnervation occurs, cartridges having seven or eight presynaptic receptors instead of six. The number of postsynaptic cells remains constant. Previous observations (Nicol and Meinertzhagen, 1982) revealed that in the case of this hyperinnervation the synaptic frequency per cartridge does not stay constant, as it should if the number of synapses were controlled postsynaptically. Instead, the synaptic population per cartridge rises. Control of synapse frequency during hyperinnervation was therefore assumed to be largely presynaptic, with the postsynaptic cells accommodating to the increased synaptic load.

We have studied the reciprocal hypoinnervation normally occurring at the edge of the lamina at cartridges with two, three, four or five receptor terminals. Thus the range of observations is now extended from an innervation ratio of 8:6 (previously reported for the equator) to one of 2:6, at the edge of the lamina. Receptor terminals are smooth, cylindrical and orientated in parallel in the lamina. The number of their synapses and the perimeter of their transverse profiles are both readily sampled quantitatively in single-section EM.

As the number of receptor terminals per cartridge decreases, the number of synapses per terminal increases. This increase gets larger as the hypoinnervation becomes more severe. Thus there is a marked, though not complete, compensation for the decrease in the number of innervating receptor terminals. This suggests that in hypoinnervated cartridges the postsynaptic influence upon synaptic frequency is stronger than previously anticipated. The predominant influence upon synaptic frequency seems to shift with the innervation ratio, from largely presynaptic (in hyperinnervated cartridges) to largely postsynaptic (in hypoinnervated cartridges). The perimeters of receptor terminal profiles co-vary with the number of their synapses. Thus terminals of hypoinnervated cartridges are large and bear more synapses than their smaller counterparts in hyperinnervated cartridges. Consequently the mean presynaptic membrane perimeter per synaptic profile remains roughly constant despite variations in innervation ratio and subsequent changes in synaptic population size.

242.6 **DEVELOPMENT OF SENSORY HAIRS IN JUVENILES OF THE CHITON MOPALIA MUSCOSA.** **E.M. Leise* (SPON: B. Mulloney). Dept. of Zool., Univ. of Wash., Seattle, WA 98195**

The mantle epidermis surrounding the shell plates of Mopalia muscosa is covered by a cuticle and secretes tapered chitinous hairs and calcareous spicules. Hairs, up to 5 mm long and 400 μm wide, extend through and beyond the dorsal cuticle while spicules of various sizes lie within the dorsal, marginal and ventral cuticles. Stalked nodules, extensions of multicellular epidermal papillae, occur separately within the dorsal cuticle, within the dorsal hairs and at the bases of marginal and ventral spicules. Papillae that produce hairs were found to be innervated. Dendrites of putative sensory neurons occur in the stalked nodules; all nodules are proposed to be mechanosensory.

The integuments of larval, juvenile and adult M. muscosa are dissimilar. I examined the integuments of juveniles raised in the laboratory for one year to determine the sequence of events that occurs as the epidermis and particularly its sensory organs develop adult characteristics. At metamorphosis larvae secrete a cuticle over the dorsum, extrude small (3 μm by 9 μm) spicules into the cuticle and secrete the shell plates and small (2 μm wide and 15 μm long) chitinous hairs. Adult and juvenile spicules are discrete structures; the first juvenile spicules have no associated stalked nodules and are not innervated. Juvenile hairs become the tips of adult hairs. Each hair is initially secreted by one trichogenous cell. Within two days after metamorphosis the dendrite from a hair's first sensory cell protrudes into the adjacent trichogenous cell. This trichogenous cell will become part of the supporting sheath of a nodule. Each adult hair contains a row of mesial spicules and each spicule surmounts a stalked nodule. As a hair grows it develops more spicules and stalked nodules and hence, more sensory cells. Nodules in the hair develop sequentially and continue to elongate as the hair grows. Hairs do not develop all of their adult features until they are at least 300 μm long, at about one year of age in laboratory animals.

242.7 TRANSPLANTATION OF CRICKET SENSORY NEURONS TO ECTOPIC SITES REVEALS RULES FOR ASSEMBLING AFFERENT PROJECTIONS. S.E. Johnson* and R.K. Murphey (SPON: R. Oesterreich) Dept. of Biology, SUNY Albany, Albany, New York, 12222

Insect sensory systems are favorable for the study of the development of neural patterns because of the ease with which the sensory neurons can be manipulated, either surgically or genetically. We have discovered that in each segment an important step in the differentiation of sensory neurons commits these cells to arborize in one of two target areas. In the cercal system this step commits cells to arborize in one of two regions in the terminal abdominal ganglion. These two regions process information of different sensory modalities (Murphey, this vol.).

We have previously shown that when cerci were transplanted to the thorax, this dichotomy was retained: bristle hair sensory neurons arborized in a slab of neuropil on the ventral surface of the ganglion while filiform hairs arborized in an adjacent, more dorsal region. We have now looked at the normal projection pattern of leg bristle hair sensory neurons to the mesothoracic ganglion. Cobalt fills of single bristle afferents on the leg revealed that they arborize only in the most ventral neuropil area coextensive with the ventral association center (VAC). Thus bristles on the leg and on the cercus both choose to arborize in the same region of thoracic neuropil. Within the bristle hair target region we found that the morphology of single leg afferents reflects circumferential position of the receptors on the leg. Therefore the spatial organization of receptors on the limb is reflected in the CNS.

To further probe the rules for ordering sensory inputs to the CNS, we transplanted mesothoracic legs to the abdomen, forcing the leg sensory axons to regenerate into the terminal abdominal ganglion. The leg bristle hair neurons were able to discriminate between the two neuropil regions in the foreign ganglion: the bristle hair axons grow under the cercal glomerulus to arborize in the bristle-hair neuropil area. The leg afferents also maintain many aspects of their normal orderly projection pattern in this foreign ganglion.

In summary, sensory neurons in any region of the cricket body are of two types: a "bristle" type which is multiply innervated and arborizes in one area of neuropil. A second type includes all other receptors on or in the appendage which arborize just dorsal to the bristle hair area. A search of the literature reveals that this dichotomy appears to exist in other insects as well. This finding is important because it greatly simplifies the decisions a sensory neuron growth cone must make in order to find its synaptic partners. Supported by NIH Grant #NS 15571 to R.K.M.

DEVELOPMENT AND PLASTICITY: TROPHIC AGENTS II

243.1 BRAIN EXTRACT INCREASES LEVELS OF A_{12} ACETYLCHOLINESTERASE (AChE) IN CULTURES OF CHICK SKELETAL MUSCLE MAINTAINED IN HORSE SERUM-FREE MEDIUM. J.S. Addis* (SPON: N.L. Hayes). Dept of Anatomy, Univ. of Mississippi Med. Ctr., Jackson MS 39216.

It was recently reported that the appearance of the A_{12} form of AChE could be induced in cultures of chick skeletal muscle by removing horse serum (HS) from the medium (Bulger et al., Dev. Neurosci. 5:474, 1982). Since nerve extract has been observed to induce this form of AChE in chick skeletal muscle cultured in the presence of HS (Popiela et al., Soc. Neurosci. Abs. 8:195, 1982), it was of interest to determine what effect a nerve extract would have on the appearance of A_{12} AChE in muscle cultured in the absence of HS. Cultures, prepared by mechanical dissociation from the leg muscles of 11-day chick embryos, were maintained for 6 or 8 days in Dulbecco's MEM supplemented with 2% chick embryo extract/50 U ml^{-1} Penicillin/ 50 ug ml^{-1} Streptomycin/10% HS. Medium lacking HS then replaced the HS-containing medium for 4 or 2 days. Mouse brain extract (BE) was introduced into the HS-free medium at a concentration of 250 or 500 ug ml^{-1} after 8 days. At the same time, control cultures received medium to which bovine serum albumin had been added. After 10 days the cultures were extracted in 0.1 M sodium phosphate buffer, pH 7.0/0.15 M NaCl/0.25 mM EDTA/0.5% Triton X-100/0.1 mg ml^{-1} Bacitracin, and the molecular forms of AChE separated in 5-20% sucrose gradients.

In cultures maintained in HS-free medium for days 9-10, BE induced increases in both A_{12} activity (~3.5X) and in the ratio of A_{12} activity to total AChE activity (~2.3X). The latter value rose from ~3.1% in control cultures to ~7.3% in BE-treated cultures. Total AChE also increased in BE-treated cultures (~1.5X). In cultures maintained in HS-free medium for days 7-10, BE likewise induced increases in A_{12} activity (~2.3X) and in the ratio of A_{12} to total activity (~2X). Under these conditions, the ratio increased from ~7.5% to ~15%. Total activity in BE-treated cultures maintained from 7-10 days in HS-free medium was slightly less (~0.9X) than that in control cultures.

These results indicate that the addition of BE for a period as short as 2 days to muscle cultured in HS-free medium enhances both the absolute levels of A_{12} activity and the proportion of A_{12} to total AChE activity. The results moreover argue against the possibility that the induced appearance of A_{12} AChE by nerve extract in HS-containing medium is due to interaction between constituents of the extract and the serum.

(Supported by N.I.H. Biomedical Research Support Grant 5 S07 RR05386.)

243.2 TROPHIC INFLUENCE OF EPIDERMAL GROWTH FACTOR, FIBROBLASTIC GROWTH FACTOR AND INSULIN ON HUMAN MUSCLE DEVELOPMENT IN TISSUE CULTURE. G. Gallez-Hawkins* and V. Askanas. USC Neuromuscular Ct., Dept. of Neurology, Univ. So. Calif. Sch. of Med., Los Angeles, CA 90017.

Until now culturing of adult human muscle has required addition of both 10-15% fetal calf serum (FCS) and 2-5% chick embryo extract (CEE) to the medium in order to obtain satisfactory growth and maturation. Attempting to establish a more defined medium, which would eventually allow elimination of CEE and FCS and lead to better maturation of cultured adult human muscle, we introduced, per ml culture medium, 10 ng of epidermal growth factor (EGF), 50 ng fibroblast growth factor (FGF), and 10 ug insulin (I), separately and in combination with each other, with and without CEE and/or FCS. Cultures were established according to our standard conditions (Askanas, V. & Engel, W.K., Neurology 25:58, 1975), from 1 mm^3 explants or dissociated single cells. Living cultures were evaluated every day by phase-contrast inverted microscopy. Between 10-25 day of growth they were harvested for creatine kinase (CK) activity estimation. 11 experiments were established and 2-4 cultures in each experiment served for a given combination. Not all conditions were evaluated in each experiment. The mean and P values are each based on at least 8 experiments. a), b) and c) indicate three different culture conditions.

Morphology: a) omission of CEE resulted in much less myogenic appearance and greatly delayed myoblasts fusion. b) replacement of CEE with the triple combination of EGF, FGF and I resulted in decreased amount of fibroblasts, accelerated fusion, and the presence of well-developed, thick myotubes. c) in the regular condition (with CEE, but not I, EGF and FGF), fusion was 2-3 days later, cultures were more fibroblastic, and myotubes less mature than in (b). Biochemistry: Combined addition of I, EGF and FGF (condition b), resulted in 6.7 fold ($P < 0.005$) higher CK as compared to sister cultures with the addition of CEE but no factors (condition c), and 15.7 fold ($P < 0.001$) increase of CK as compared to sister cultures without CEE and no factors (condition a). There was 50% less CK activity in a) compared with c). Addition of I and FGF resulted in 2.8 fold, and I and EGF in 3.7 fold higher CK as compared to c, but statistical significance of these data are uncertain. Those double-factor additions, however, did give statistically significant increase of CK activity compared with condition a). Addition of I, EGF and FGF alone did not result in substantial increase of CK activity as compared to c). Total depletion of FCS resulted in no growth in spite of addition of I + EGF + FGF, but reduction of FCS to 2-5% was possible.

These studies: 1) provide a more defined (CEE free, FCS reduced) new medium for culturing of adult human muscle, 2) demonstrate synergistic positive influences of I, EGF and FGF on human muscle development and maturation in culture, and 3) provide a system in which selective lack of influence of those hormones individually on abnormal muscle might be demonstrable.

243.3 BENEFICIAL INFLUENCE OF INSULIN ON CHOLINERGIC PROPERTIES AND ENERGY METABOLISM OF RAT CULTURED VENTRAL SPINAL CORD NEURONS (CVSCNs) F. Moriwaka*, V. Askanas, W. K. Engel. USC Neuromuscular Ctr., Dept. of Neurology, Univ. So. Calif. Sch. of Med., Los Angeles, CA 90017.

We have previously demonstrated that activity of creatine kinase (CK) was high in rat CVSCNs, which contain lower motor neurons, and that the CK activity parallels the activity of cholineacetyltransferase (ChAT) in a given culture, as well as in the ventral part of spinal cord of fetal and adult rats in vivo (Schmidt-Achert, K.M., et al., Neurology 33:143, 1983). To the contrary, CK activity is practically undetectable in rat cultured schwann cells and very low in cultured skin fibroblasts. Therefore both ChAT and CK activities are measured in our laboratory when investigating the influence of various factors on CVSCNs. Cultures of the ventral part of spinal cord were established from 15-16 day old rat fetuses, according to the technique developed in this laboratory (Askanas, V. et al., Neurology 31, 1196, 1981). Cultures were established with 1 mm^3 explants; ventral regions of one entire spinal cord were placed in one 35 mm collagen-coated petri dish. 5 experiments were performed and in each experiment 4 culture dishes served for a given experimental condition. 10 ug and 25 ug of insulin (Sigma) were incorporated into culture medium from the time of initiation of the culture. During the first 5-8 days of growth, the culture medium consisted of Dubelcco's Modified Eagle's Medium (DMEM) with 400 mg% glucose and no glutamine, 10% fetal calf serum (FCS), and insulin. During this time non-neuronal cells were significantly reduced by an initial 3 days of antimitotic treatment. After antimitotic treatment was accomplished, FCS was eliminated from the medium. Then, control CVSCNs were cultured in DMEM alone, while experimental sister CVCSNs received DMEM plus various concentrations of insulin for 10-15 days. Elimination of FCS from the medium provided a suboptimal condition for control cultures and allowed more clear evaluation of insulin action on CVCSNs, since other hormonal influences were eliminated. ChAT, CK, acetylcholinesterase and total protein were measured. Treatment with insulin resulted morphologically (by phase-contrast examination) in better survival of neuronal cells and richer, more abundant neuronal processes. ChAT activity in insulin-treated cultures was increased 7.8 fold ($P = 0.02$) as compared to control cultures, and CK activity increased 4.7 fold ($P = 0.01$). Protein increased 2.3 fold ($P = 0.02$) and cholinesterase activity increased 2.2 fold ($P > 0.05$). Those results were not insulin dose related in the range studied. The results indicate a) definite beneficial influence of insulin on neuronal survival and on cholinergic and energy metabolism properties of rat CVSCNs, presumably reflecting properties mainly of lower motoneurons. The insulin effect on CVSCNs is probably trophic and receptor mediated. The observed increase of protein and cholinesterase with insulin treatment could be related to non-neuronal (as well as neuronal cells), on which the insulin might exert trophic and some mitogenic action in spite of antimitotic treatment.

243.4 TROPHIC EFFECTS OF MAMMALIAN NERVE EXTRACT IN VIVO ARE NOT DUE TO TRANSFERRIN. H.L. Davis and E.A. Heinicke*. Departments of Biochemistry and Anatomy, The University of Western Ontario, London, Canada, N6A 5C1.

Atrophy in a denervated muscle results from the disuse caused by paralysis of the muscle, and from the loss of special neurotrophic substances. Proteins extracted from rats' sciatic nerves have been shown to prevent the non-disuse atrophy of rats' extensor digitorum longus (EDL) muscles denervated for 7 days, when administered by daily intramuscular injections. Trophic influences of extracts of peripheral nerve have also been demonstrated on embryonic chick muscle in vitro. The trophic factor from chicken sciatic nerve has been purified and was found to be closely related in structure to transferrin (Markelonis et al., 1982:J. Neurochem. 39,315-320). The present investigation was undertaken to determine whether the trophic properties of mammalian peripheral nerve extract on denervated rats' muscles in vivo are due to the presence of serum transferrin in the extract.

Rats' EDL muscles denervated for 7 days and injected daily with one of several doses of iron-conjugated transferrin purified from rat serum exhibited a rate of atrophy equivalent to that in denervated muscles that either were not treated or were injected with buffered saline. Atrophy was assessed by measurement of wet weight and cross-sectional areas of muscle fibers in both denervated and normal contralateral EDL muscles. Data were expressed as percentages of normal control values.

Denervated EDL muscles injected with crude extract of rats' sciatic nerves had significantly smaller decreases in wet weight and areas of type IIB fibers (in sections stained for ATPase) than in untreated or saline injected controls. Transferrin was removed from the crude extract by immunoaffinity chromatography. The resin was produced by coupling Ig fraction of anti-rat transferrin to activated CH-Sepharose 4B. The specificity and capacity of the coupled ligand was tested by passing pure rat transferrin or rat serum through the column and subsequently examining eluted and desorbed fractions with polyacrylamide gel electrophoresis. Removal of transferrin from crude rat nerve extract did not diminish its ameliorative effects on denervated muscle.

Thus the trophic action of mammalian nerve extract on denervated rats' muscles in vivo is not due to the presence of serum transferrin in the extract.

Supported by the Muscular Dystrophy Association of Canada and the Medical Research Council of Canada.

243.5 PROTEINS FROM CONDITIONED MEDIA BIND TO NEURONS. Leonard M. Gralnik*, John N. Barrett, and David L. Wilson (SPON: Alan H. Lockwood). Department of Physiology and Biophysics, Univ. of Miami Sch. of Medicine, Miami, FL 33101

Skeletal muscle cells and lung fibroblast cells obtained from fetal rats and grown in tissue culture release a reproducible array of proteins into their media. Labeled, conditioned medium was prepared from muscle or lung cultures by replacing normal growth medium with serum-free medium containing ^{35}S-methionine. The medium was collected and analyzed by two-dimensional polyacrylamide gel electrophoresis (2-D PAGE). The labeled, released proteins are a small subset (less than 10%) of the total cellular proteins seen in homogenates analyzed by 2-D PAGE.

Unlabeled spinal cord cells from fetal rats were incubated with the labeled, conditioned medium from lung or muscle cultures. They were then washed extensively, and analyzed by 2-D PAGE to determine which proteins released by lung or muscle cells had bound to the spinal cord cells. A small number of proteins from medium conditioned by lung or muscle cultures (less than 10% of the proteins in the medium) bind to spinal cord cells (as well as to other CNS neurons).

Media conditioned by lung or muscle cells were chosen for this study because they are known to possess neurite-outgrowth promoting activity for spinal cord slices in vitro (Dribin and Barrett, Devel. Bio., 74:184, 1980). The binding experiments were carried out to search for the proteins eliciting the neurite outgrowth, since proteins that have trophic activity for spinal cord neurons should bind to the neurons. We acknowledge support from the National Parkinsons Foundation, from NSF grant BNS 81-17817, and from NIH grants NS 12207 and NIGMS 5T32GM07332.

243.6 THE NEURITE-PROMOTING EFFECT OF FIBROBLAST GROWTH FACTOR ON PC12 CELLS. Akifumi Togari,*Dole Baker,*Geneva Dickens*and Gordon Guroff. Section on Growth Factors, NICHD, NIH, Bethesda, MD 20205.

The PC12 clone of rat pheochromocytoma is the premiere model for the study of the actions of nerve growth factor. When these cells are treated with nanomolar quantities of the factor, they stop dividing, develop excitable membranes, grow neurites and will form synapses with appropriate muscle cells in culture. The wide-spread use of PC12 cells as a model has led to an interest in the various effectors acting on the cells. It has been shown that epidermal growth factor, TPA, and NECA, and cAMP derivatives have some effect on these cells. The actions of these other effectors are the same in some cases as those of nerve growth factor. However, none of these several other agents produces the single most characteristic action of nerve growth factor, namely, neurite outgrowth.

We report here that fibroblast growth factor, a partially purified material from either brain or pituitary, with mitogenic actions on a number of cell types, produces neurite outgrowth in PC12 cells comparable to that seen with nerve growth factor. These neurites are evident within 24 hours and continue to grow for at least 72 hours. The processes are long and thin, and appear to terminate in growth cones. Process formation is maximal at 50 ng of fibroblast growth factor per ml; brain and pituitary fibroblast growth factors appear to be equivalent. This action is preceded by an action on the marker enzyme, ornithine decarboxylase and, in both actions, fibroblast growth factor seems to be additive with nerve growth factor. The addition of equivalent amounts of platelet-derived growth factor or T-cell growth factor are without effect on either neurite outgrowth or ornithine decarboxylase activity.

The data suggest that the relevance of PC12 as a model system should be considered in the light of the many effectors which have been shown to act on these cells.

243.7 A NEW NEUROTROPHIC FACTOR ISOLATED FROM MAMMALIAN BRAIN: IN VITRO STUDIES ON FETAL RAT RETINA. J. E. TURNER, Y. A. BARDE AND H. THOENEN. Department of Anatomy, Bowman Gray School of Medicine, Wake Forest University, Winston-Salem, North Carolina, U.S.A. and Department of Neurochemistry, Max-Planck Institute for Psychiatry, F. R. Germany.

Tissue culture conditions have been defined where stimulation of neurite outgrowth from fetal rat retinal explants occurred only in the presence of a newly purified brain trophic factor (PF) or an intermediate active fraction (BE) from the brain extract purification procedure. Under these conditions, 20-day fetal retinal explants survive and continue to extend neurite for at least 3 weeks in the presence of BE. There was demonstrated in vitro an inverse relationship between increased developmental age and responsiveness to BE. There was also a significant relationship demonstrated between the increased length of time before BE was added to the culture medium and the inability of 20-day fetal explants to extend neurites onto the culture substrate. These results may imply that BE not only is required for stimulating neurite outgrowth from fetal rat retinal explants, but it may possess some survival value with respect to the neurite producing retinal neurons. This was indeed found to be the case when thick sections were evaluated by light microscopy for cell survival. After one week in culture, control explants showed extensive degeneration where BE treatment ensured cell survival and explant differentiation. Most importantly, we found that PF, like BE, was able to stimulate neurite outgrowth from fetal retinal explants. More specifically, a dose-response relationship was demonstrated in both the presence of increasing concentrations of either BE or PF with respect to the neurite growth index. The half-maximal response for BE was estimated to be between 5-10 µg/ml and for PF it was approximately 20 ng/ml. This makes a strong case for the presence of high affinity receptors on the neurite producing retinal cells. In addition, a dissociated fetal retinal in vitro system has been developed where cells survive in the presence of BE for periods of at least 2 weeks, but untreated controls do not survive beyond 2-3 days in culture. In conclusion, we have reported for the first time that a new brain derived trophic factor can stimulate neurite outgrowth and maintain cell survival from an appropriate target tissue. The fetal rat visual system represents an exciting new model for testing further the importance of PF in the CNS. We postulate that PF may be like NGF in the PNS with respect to its importance in the developing and regenerating mammalian CNS.

243.8 EFFECTS OF AN EARLY NERVE GROWTH FACTOR INJECTION ON ACTIVITY AND LEARNING OF A TWO-WAY ACTIVE AVOIDANCE TASK IN RATS WITH EARLY VENTROMEDIAL HYPOTHALAMIC OR SEPTAL DAMAGE. F. Eclancher*, J. J. Ramirez* and D. G. Stein. Brain Res. Lab., Dept. Psychology, Clark Univ.,Worcester, MA 01610.

Ventromedial hypothalamic (VMH) lesions or septal (S) lesions performed in 7-day old Wistar rats result in severe and persistent behavioral changes such as higher emotional reactivity and enhanced (S) or impaired (VMH) performance on a 2-way active avoidance (AA) task (Eclancher and Karli, 1982). The present study was undertaken to determine whether the same early lesions performed in Sprague-Dawley rats would result in similar behavioral changes. Moreover, since nerve growth factor (NGF) has been shown to ameliorate the behavioral effects of damage in certain subcortical areas (Hart et al., Brain Res. Bull., 3:245-250, 1978; Lewis et al., Brain Res., 176:297-310, 1979), we also wanted to determine whether NGF treatment immediately after VMH or S damage would alleviate the effects of the lesions. After being subjected to VMH or S lesions followed by NGF or saline injections directly into the damaged area, the rats were tested on an open field apparatus and a 2-way active avoidance (AA) chamber every 10 days from 20-90 days of age.

In confirmation of Eclancher and Karli's (1982) earlier work, lesions of the VMH resulted in hypoactivity in the open field test and in an impairment in the acquisition of the 2-way AA task. Septal lesions, in contrast, produced hyperactive behavior and facilitated the acquisition of the 2-way AA task. The NGF treatment had limited beneficial effects in both brain-damaged groups. The analysis of the number of crossings on the AA task, for example, indicated that the performance of the VMH-NGF and S-NGF groups approached control levels; more specifically, the VMH-NGF group made more frequent crossings between chambers whereas the S-NGF group made fewer crossings. In the open field activity test, the septal rats with the NGF treatment made significantly fewer line crossings than either the rats with saline treatment alone or the septal rats with saline treatment.

In general, it appears that early treatment with NGF may have long-lasting behavioral and limited ameliorative effects.

Supported by NIA Grant #5 R01 AG00295 and United States Army Research and Development Command Contract #DAMD-82-C-2205 to D. G. Stein, and grants from CNRS and NATO to F. Eclancher.

243.9 GM1 GANGLIOSIDE TREATMENT ENHANCES BEHAVIORAL RECOVERY FOLLOWING BILATERAL CAUDATE NUCLEUS DAMAGE. B. A. Sabel, M. D. Slavin* and D. G. Stein. Brain Res. Lab., Dept. Psychology, Clark Univ., Worcester, MA 01610.

Gangliosides, sialic acid containing glycolipids, are involved in neuronal development and repair. Toffano et al. (Brain Res., 261:163, 1983) found that rats treated with gangliosides showed less behavioral impairment following nigro-striatal hemitransection. An elevation of various enzymes in the striatum was taken to indicate that central sprouting may have mediated the behavioral recovery. In the present experiment, we investigated the effect of ganglioside injections on learning a cognitive task in rats with bilateral caudate lesions.

Male Sprague-Dawley rats (95 days old, 390-515 g) received sham operations (group C, n=8), or bilateral caudate lesions with IP injections of the monosialoganglioside GM1 dissolved in Ringer's solution (group LG, n=7), or Ringer's solution alone (group L, n=8). GM1 (30 mg/kg) was injected daily for 14 days, starting on the day of surgery. On the 10th postoperative day, animals were trained to run to their non-preferred side in a 2-choice learning maze for 10 trials daily. After they learned to avoid or escape footshock without error for two consecutive days (criterion), the rats had to run to the opposite side. In this manner, the animals underwent a series of spatial reversals for 30 days.

Both lesion groups (LG and L) were significantly impaired on this behavioral task compared to sham operates (C). However, rats with lesions and GM1-treatment performed significantly better on this task than animals with lesion alone (group L). Specifically, group LG had more days with 9/10 correct responses ($F=6.65$, $p<.023$), fewer escape failures per reversal ($F=5.33$, $p<.04$), and took fewer days to reach criterion after the first reversal ($F=9.8$, $p<.008$).

These results provide further support for the hypothesis that behavioral recovery from brain trauma can be enhanced by ganglioside treatment. To test whether GM1 treatment has long-lasting effects on recovery from brain trauma, the animals will be retested. A subsequent histological analysis will be done to explore physiological mechanisms that may underlie the behavioral recovery.

This research was made possible by the generous supply of GM1 from Fidia Laboratories, Abano Terme, Italy, and a contract from the United States Army Research and Development Command #DAMD-82-C-2205.

243.10 NERVE GROWTH FACTOR STIMULATES PHOSPHOLIPID METHYLATION IN TARGET GANGLIONIC NEURONS INDEPENDENTLY FROM THE CYCLIC AMP AND Na^+,K^+-PUMP RESPONSES. S. D. Skaper and S. Varon. Dept. Biol., Sch. of Med., Univ. of Calif. San Diego, La Jolla, CA 92093.

Our recent studies on the mechanism of action of Nerve Growth Factor (NGF) on its target ganglionic neurons have revealed that very dramatic changes are imposed within minutes after NGF administration. One response is an activation in the presence of NGF of the Na^+,K^+-pump in the neuronal membrane of sympathetic and sensory ganglionic cells. In another response, chick embryo dorsal root ganglia (DRG) display a rapid and transient rise in their cyclic AMP content when presented with NGF. It was subsequently shown that the cyclic AMP and ionic responses occur independently of each other in the chick DRG. The finding by Pfenninger and Johnson (1981) that NGF leads to a very early, though transient increase in phospholipid methylation in growing neurites from rat sympathetic neurons encouraged the speculation that such a cell function could be implicated in both short-latency responses. To test this idea, suspensions of neurons prepared from embryonic day 12 (E12) chick sympathetic ganglia (SG) were incubated with [methyl-^{3}H]methionine in the absence of NGF. Presentation of NGF for different periods of time resulted in an approximate 3-fold stimulation of radioactivity incorporated into total phospholipid, followed by a rapid decline thereafter. Both the magnitude and time of the response were dependent upon the NGF concentration used. Incubation of E12 SG neurons with transmethylase inhibitors failed to prevent reactivation of the Na^+,K^+-pump in response to NGF administration. E16 SG neurons and E15 DRG neurons, which do not depend upon exogenous NGF for control of their Na^+,K^+-pump still show a stimulation of phospholipid methylation when challenged with NGF. Blockage of the pump with ouabain also fails to prevent a methylation response. Thus, the pump and methylation responses to NGF occur independently of each other. NGF is also capable of eliciting a methylation response in intact E8 chick DRG, in addition to the transient rise in cyclic AMP content. For a given concentration of NGF, the peak of phospholipid methylation preceeds the peak of cyclic AMP. Methylation inhibitors prevent the methylation response, but not the cyclic AMP one. Dibutyryl cyclic AMP, which is able to cause a cyclic AMP elevation similar to NGF failed to produce any stimulation of phospholipid methylation. These data thus indicate a mutual independence among the short-latency responses. Identification remains to be made of a critical cell function which may lie between NGF-receptor binding and the separate branches defining each of the three short-latency events recognized thus far.

243.11 BIOASSAY AND RADIOIMMUNOASSAY OF NGF-LIKE ACTIVITY IN RAT PERIPHERAL NERVE. T. Ebendal* and P.M. Richardson (SPON: G.M. Bray). Dept. of Zoology, Uppsala Univ., Sweden and Div. of Neurosurgery, McGill Univ., Canada.

Three techniques were used to estimate the content of NGF-like activity in normal and injured rat sciatic nerves. Injured nerves were cut at several sites and left in the thigh for 1 - 7 days.

i) Whole sympathetic ganglia from chick embryos were cultured in collagen gels beside peripheral nerve fragments and neurite outgrowth assessed at 48 hours (Brain Res. 246:57, 1982). This method proved highly sensitive although difficult to quantify.

ii) Dissociated sensory neurons from chick embryos were exposed to serial dilutions of nerve homogenates and neurons with neurites were counted at 24 hours (Can. J. Physicl. Pharmacol. 60:707, 1982). The sensitivity of this bioassay was limited by toxic activity of concentrated extracts.

iii) Immunoactivity was measured by a two-site radioimmunoassay with affinity-purified antibodies to ß-NGF from the mouse submandibular gland (Proc. Nat. Acad. Sci. 75:4042, 1978).

In normal nerves, trace amounts of NGF-like activity were detected by the whole ganglionic assay but not by the other two methods. After injury, a transient rise in NGF-like activity maximal at 2 days, was demonstrable by all 3 techniques. By bioassay and radioimmunoassay, the peak concentration of NGF-like activity in injured nerves was approximately 3 fmoles/cm sciatic nerve. The levels of NGF-like activity in normal and injured peripheral nerves appear to be in a physiologically relevant range.

243.12 TROPHIC EFFECTS OF SKELETAL MUSCLE EXTRACTS ON NEURITE DEVELOPMENT IN PERIPHERAL GANGLIA. L. Hsu, D. Natyzak* and G.L. Trupin*, Depts. of Anatomy, New Jersey Sch. of Osteopathic Medicine and Rutgers Med. School, Piscataway, New Jersey, 08854.

Previously we have reported on the trophic effects of homogenized skeletal muscle extracts on the differentiation of spinal cord explants (Hsu, L. et al, J. Embry. Exp. Morph. 71, 1982). We now report that skeletal muscle extracts from embryonic chicks also enhances the differentiation of neurites from both dorsal root and sympathetic ganglia.

Within 2 days in vitro, ganglia grown in medium containing muscle extracts developed radial fibers extending over 800µm in length. Individual neurites or small fascicles accompanied by spindle shaped non-neuronal cells extended to form elaborate networks. In contrast, ganglia maintained in control medium with serum proteins only achieved limited neuritic and glial outgrowths. When muscle extracts were used to coat the substratum of either collagen or polyornithine, ganglia maintained on these surfaces in serum-less control medium showed significantly enhanced neuritic development. These studies indicate that the neurite-promoting component of the muscle extract may be mediating its trophic effect by interacting with the underlying substrate. Trophic activity appears to be specific to skeletal muscle since other tissue extracts such as brain were ineffective in enhancing neuritic development when used either as growth medium or as a substrate-conditioning agent. Pretreatment of the plastic dish surface with the cell-attachment factor, fibronectin, also did not promote neuritic outgrowth.

We have begun to characterize the trophic component of skeletal muscle extracts. Treatment with heat (60°C and 90°C), base (0.1N NaOH) or trypsin (0.5mg/ml) reduced the ability of muscle extracts to stimulate neurite outgrowth. Incubation with acid (0.1N HCl) or antisera to nerve growth factor, however, did not affect its trophic properties.

243.13 INJURY-INDUCED ASTROCYTE MITOGENIC AND TRANFORMATION FACTORS IN RAT BRAIN. M. Nieto-Sampedro, R.P. Saneto, J. de Vellis and C.W. Cotman, Dept. of Psychobiology, Univ. of Cal., Irvine, CA 92717 and Dept. of Anatomy and Psychiatry, School of Medicine, Univ. of Cal., Los Angeles, CA 90024.

We have previously shown that injury to rat brain elicits the appearance in both the tissue surrounding the wound and and in the wound cavity of substances capable of supporting the survival of dissociated neurons in culture (Nieto-Sampedro et al., 1982, Science: 217, 860).

CNS injury is well known to cause the proliferation of fibrous astrocytes in the tissue around the wound. Therefore, we initiated a study to demonstrate the appearance, following injury, of factors capable of stimulating astrocyte division and transformation in vitro. The main findings are as follows.

1. Low levels of mitogenic activity were present in normal rat brain. Following injury, this activity increased over time 3 to 10-fold. Maximum activity was reached 10 days post-lesion in the tissue surrounding the wound and about 15 days post-lesion in the gelfoam filling the wound cavity.
2. Factors capable of inducing the transformation of astrocytes from polygonal-flat morphology to fibrous-like morphology appeared in gelfoam extracts 15 days postlesion, but were not detectable at earlier times.
3. Temperature (50°C) or acid-pH treatments of the brain tissue extracts increased their mitogenic activity. These treatments also unmasked astrocyte transformation activity in the tissue at all times postlesion.
4. Both mitogenic and transformation factors were non-diffusable, and heat and trypsin sensitive, i.e. they had the properties of protein-like substances.

Brain tissue in the area of an injury releases substances that promote neuron survival. We show now that it also releases factors that cause astrocyte proliferation and transformation. The data suggest that the factors are present in the brain in an inhibited form and that injury perhaps releases them from inhibition and/or induces an increase in the synthesis of the active molecules. These factors are presumably responsible for the astrocyte reaction to injury (proliferation and transformation) typically observed in vivo.

243.14 CHARACTERIZATION OF INJURY-INDUCED NEURONOTROPHIC ACTIVITY IN NEONATE, MATURE AND AGED RAT BRAIN. D.L. Needels* S.R. Whittemore, M. Nieto-Sampedro and C.W. Cotman. Dept. of Psychobiology, Univ. of Calif., Irvine, CA 92717.

Previously, we have demonstrated that substances capable of supporting the survival of peripheral neurons in culture (neuronotrophic factors, NTFs) are present in low levels in the brain of both neonatal and adult rats, and are increased following injury (Nieto-Sampedro et al., Science 217:860).

A comparative study of the induction by injury of NTFs in neonatal, adult and aged rats has revealed the following:

1. Extracts of brain tissue from rats of all ages contained low levels of NTFs that increased following injury.
2. Rat brain NTFs supported the survival of avian ciliary ganglion (CG) neurons, but were 2-4 times more active on cultured neurons from embryonic rat corpus striatum, hippocampus and thalamus.
3. NTF activity, measured using striatal cultures, was about three times higher in normal brain of aged rats than that of young adult or neonatal animals.
4. Induction of NTF activity by injury was slower in aged brain than in young adult or neonate. For both peripheral and central neurons, maximum NTF activity in the brain tissue surrounding a wound was found 7 days post-lesion in neonates, 10 days post-lesion in young adults and 15 days post-lesion in aged animals.
5. These extracts also contain toxic activity for central neurons. Similar levels were found in rats from all ages, and did not appear to change following injury. CG neurons were unaffected by the toxic activity.

NTFs are probably involved in neuronal maintainance and injury repair. Neuronal death, ubiquitous in aged animals, is probably responsible for the increased basal NTF levels in aged brain. As the animal ages, the rate of induction of these factors diminishes, which may be involved in the decreased ability of aged neural tissue to recover from injury.

243.15 AN EFFECT OF NERVE GROWTH FACTOR ON THE PARASYMPATHETIC CILIARY GANGLION. F. Collins* (SPON: T. Parks) Dept. of Anatomy Univ. of Utah Sch. of Med., Salt Lake City, UT 84132

We have recently reported that mouse submaxillary nerve growth factor (NGF) at 0.1-10 ng/ml induces a two-fold increase in the rate of neurite elongation within 30 minutes of its addition to cultures of dissociated parasympathetic ciliary ganglion neurons from 8 day chicken embryos. NGF in these conditions has no effect on ciliary ganglion neuronal survival (Collins and Dawson, 1983, Proc.Natl.Acad.Sci.,U.S.A. 80:2091).

The concentration of NGF required to manifest this effect on neurite elongation is within the normal physiological range. We have now iodinated preparations of NGF which elicit this response and found that greater than 99% of the radioactivity detectable on polyacrylamide gels, run in reducing conditions, comigrates as a single band with unlabelled NGF. Greater than 85% of the radioactivity of such preparations can be precipitated using affinity-purified anti-NGF antibody. We are presently using radiolabelled NGF to determine whether ciliary ganglion neurons have binding sites for NGF which might mediate its growth promoting effects.

To answer the question whether the response of ciliary ganglion neurons to NGF is somehow a result of dissociation, we have determined the effects of NGF on undissociated ganglia As previously observed with dissociated cells, whole ciliary ganglia cultured in the presence of a substratum-conditioning factor which promotes neurite outgrowth also show a dramatic response to as little as 1 ng/ml NGF There is a highly significant increase in both the lengths and density of neurites in NGF-treated compared to control ciliary ganglia. As was previously known, NGF has analogous effects on embryonic sympathetic chain and dorsal root ganglia. However, we have observed that in identical conditions, explants of neural retina show no significant change in neuritic density or lengths upon addition of NGF. We are presently examining other neural explants to further determine the specificity of this unexpected effect of NGF.

243.16 CONCENTRATIONS OF α AND γ SUBUNITS OF 7S-NERVE GROWTH FACTOR IN MOUSE SUBMANDIBULAR GLANDS. N.J. Pantazis. Dept of Anatomy, Univ. of Iowa, Iowa City, IA 52242.

Two forms of Nerve Growth Factor (NGF) have been isolated from the mouse submandibular gland, 7S-NGF (Varon, S., Nomura, J. and Shooter, E.M. Biochemistry 6:2202, 1967) and NGF_1 (Young, M., Saide, J.D., Murphy, R.A. and Blanchard, M.H. Biochemistry 17:1490, 1978). Both forms of NGF appear to contain three subunits, called α, γ and β-NGF. The concentration of the β-NGF subunit is known to be approximately 10 times higher in the male gland compared to the female gland and this result was reconfirmed by radioimmunoassay specific for β-NGF. The apparent reason for this difference is that the granular tubule cell which is the site of synthesis of β-NGF in the gland is larger and more numerous in the male. In order to determine whether this same concentration difference was also present for the α and γ subunits, specific α and γ radioimmunoassays (RIAs) were used to determine the gland concentration of both these proteins. The concentration of α was 8-fold greater in the male gland while γ was 9-fold greater Since the male/female concentration ratios for β-NGF, α and γ are so similar, this would suggest that α and γ, like β-NGF, are produced in the granular tubule cells.

However, when β-NGF, α and γ concentrations were compared to each other within the male gland, a surprising result was evident. The ratio of β-NGF:α:γ in the male was 1:3:4 while in the female it was 1:4:5. For comparison, the stoichiometry of 7S-NGF (β-NGF:α:γ) is 1:2:2. This evidence suggests that the concentrations of α and γ are greater than is necessary to bind all of the β-NGF in the gland to form 7S-NGF. There appear to be considerable quantities of α and γ which are not bound to β-NGF and are apparently free in the gland. This is exactly the result seen on gel filtration chromatography (Sephadex G-100) of a male gland homogenate. The column elution position of the 7S-NGF complex with its three subunits was located using RIAs for α, γ and β-NGF. At a lower molecular weight of 25,000 both unattached α and γ were detected but not β-NGF. The advantages if any, of having excess concentrations of α and γ are not clear, but it may possibly be a mechanism of stabilizing the 7S-NGF molecule which is known to dissociate into its subunit components (Pantazis, N.J., Murphy, R.A., Saide, J.D , Blanchard, M H. and Young, M Biochemistry 16:1525, 1977). Finally, this data also indicates that if the synthesis and/or degradation of α, γ and β-NGF are coordinately controlled in the gland, it is done in a way which produces excess concentrations of α and γ

243.17 CHOLINERGIC HIPPOCAMPAL NEUROTROPHIC FACTOR:DEVELOPMENTAL CHANGES & RESPONSE TO INJURY. A.M. Heacock, A.R. Schonfeld & R. Katzman Dept. of Neurology, Albert Einstein College of Med.,Bronx, N Y.

While trophic substances required by cultured neuronal cells have been well-studied, their role in CNS development and response to injury has remained speculative. Chick embryo ciliary ganglion cells provide a sensitive bioassay which has revealed cholinergic neurotrophic factors(CNTFs)from many sources. Among these is chick heart conditioned medium(HCM) which we have found to also have effects in vivo on regeneration of the septohippocampal pathway (Schonfeld et al,Brain Res.229:541,1981). If septal neurons normally receive CNTFs from their target tissue, then the hippocampus could be a particularly appropriate source. Recently, (Crutcher & Collins(Sci.217:67,1982) reported that rat hippocampal extract enhanced the rate of neurite extension of chick ciliary ganglion cells. In this report, we describe survival-promoting activity present in rat hippocampus which is found at low levels at birth, reaches a maximum at one month postnatally and increases following injury.

A soluble fraction of adult rat hippocampus was diluted with culture medium, added to culture dishes containing dissociated ciliary ganglion cells and neuronal survival was assessed after 24-48 hr Maximal enhancement of survival was achieved with 30-40 ug hippocampal extract protein. Only sparse neurite outgrowth was observed even at the highest concentration tested(400ug/ml) In contrast, if the culture dishes were pre-coated with neurite-promoting factor from HCM, hippocampal extract supported extensive neurite outgrowth. The CNTF is heat and trypsin sensitive and is also present in cortex and cerebellum.

A possible correlation with developmental events was examined by determining trophic content of the hippocampus postnatally Activity is expressed in trophic units(TU) which is the amount supporting one-half maximal survival. During the first two weeks of life, there was no change in trophic activity from the level of 25 TU/mg protein at birth. By day 33, the adult level of 65 TU/mg protein had been reached. Such a time course, while not consistent with a neurotropic role for hippocampal CNTF in early development, may suggest a glial origin. Preliminary data indicate that there is no change in hippocampal CNTF with aging(1 and 2 yr)

The response of CNTF to injury was then determined. A small suction lesion of the anterior hippocampus produced a two-fold increase in trophic content in the tissue surrounding the wound and led to the accumulation of CNTF in the wound cavity fluid. A physiological relevance for this hippocampal CNTF measured in vitro is supported by the effects in vivo of a prior lesion of the hippocampus on CNS cholinergic regeneration (see Schonfeld et al, following abstract).

Supported by a Potamkin-Lerner Fellowship.

243.18 CHOLINERGIC HIPPOCAMPAL NEUROTROPHIC FACTOR: EFFECTS ON CNS REGENERATION IN VIVO. A.R. Schonfeld, A. Heacock and R. Katzman. Dept. of Neurol., Albert Einstein Col. of Med., Bronx, NY.

The hippocampus of adult rats contains at least one neurotrophic factor (NTF) capable of accelerating the growth of cholinergic parasympathetic neurons in vitro (Crutcher and Collins, Sci. 217: 67, 1982). Injury to the brain stimulates the accumulation of NTF(s) released from neural tissue and the trophic activity of these factors for cholinergic neurons in vitro increases within days following trauma (Nieto-Sampedro et. al., Sci. 217:860, 1982), In order to elucidate a role for NTFs in vivo, two experiments were undertaken to determine if (1) intracerebral administration of exogenous hippocampal NTF or (2) post-traumatic release of endogenous hippocampal NTF enhance the regeneration of injured, mature cholinergic axons in rat brain.

In the bioassay used for these studies, iris tissue implanted into the anterior hippocampus serve as targets for newly regenerating cholinergic septohippocampal fibers following transection (Svendgaard et. al., Brain Res. 102:1, 1976; Emson et. al., Brain Res. 135:87, 1977). Levels of choline acetyltransferase (CAT) within implants are used as an index of cholinergic regeneration (Emson et. al , 1977). In Exp. I, a cannula was stereotaxically placed in the medial septum at the same time that an iris was inserted unilaterally in the anterodorsal hippocampus of adult female Sprague-Dawley rats. Animals were administered 1 µl of either adult rat hippocampal extract (n=7) or control vehicle (n=8) daily. Eight days later, rats were killed by decapitation, the brains rapidly removed, irides dissected free from surrounding parenchyma, weighed, frozen and assayed for CAT according to Fonnum (J. Neurochem., 24:407, 1975). The results indicated no difference between treatments (CAT nmoles/mg/hr: $\bar{x}$ control = 4.84 $\pm$ 0.85; $\bar{x}$ hippocampal extract = 4.78 $\pm$ 0.74).

In Exp. II, 6 rats received a lesion produced by insertion of a fine glass rod in the anterodorsal hippocampus 1 week prior to iris implantation in the same location; 5 control animals were not lesioned prior to iris implantation. Eight days later, irides were removed and assayed for CAT. The results revealed a significant difference between groups for both CAT (CAT nmoles/mg/hr: $\bar{x}$ control = 2.01 $\pm$ 0.42; $\bar{x}$ lesion = 9.25 $\pm$ 1.16; t=5.43, df=9, $p<0.001$, t test) and protein (protein mg/10λ: $\bar{x}$ control = 0.0102 $\pm$ 0.0006; $\bar{x}$ lesion = 0.0163 $\pm$ 0.009; t=5.73, df=9, $p<0.001$, t test)

These observations and those of the preceding abstract (Heacock et al.) suggest that, under selective circumstances, NTFs contained in neural tissue are active in vivo. Differences in the results of Exps I and II may reflect injury-induced enhancement of trophic potency or differential sensitivity of cell soma and transected axonal endings to NTFs. (Supported in part by the Wood Kalb Foundation)

243.19 METHYLATION INHIBITORS BLOCK RESPONSES OF PC12 PHEOCHROMOCYTOMA CELLS TO NERVE GROWTH FACTOR (NGF), BUT NOT TO EPIDERMAL GROWTH FACTOR (EGF). P. J. Seeley*, A. Rukenstein*, J.L. Connolly*[a] and L. A. Greene* (SPON: A. Chalazonitis). Dept. of Pharmacology, NYU Sch. Med., New York, NY 10016 and [a]Dept. of Pathology, Harvard Med. Sch., Boston, MA 02115.

In an effort to uncover transductional steps in the mechanism of action of NGF, rat PC12 cells were assayed for responses to NGF and EGF in the presence and absence of varying concentrations of cellular transmethylation inhibitors. The agents used included 5'-deoxy-5'-methylthioadenosine (MTA), 5'-deoxy-5'-isobutylthioadenosine (SIBA), and 3-deazaadenosine (DAA) + homocysteinethiolactone (HCTL). HCTL potentiates the anti-methyl-transferase activity of DAA. Each inhibitor blocked rapid (i.e. occurring within 24 h), NGF-dependent neurite regeneration. HCTL alone was without effect but significantly potentiated the inhibitory action of DAA. Reversibility of the inhibitors was demonstrated by the reappearance of neurites following washout. Initiation of neurite outgrowth in response to NGF, which slowly occurs over several days, was also reversibly suppressed by MTA and SIBA. Moreover, reversible blockade occurred in the priming response, a transcription-dependent component of the NGF mechanism responsible for neurite outgrowth. Additional responses of the cells were examined that are promoted by both NGF and EGF. These included: 1) Rapid reorganization of surface architecture (i.e. loss of microvilli, transient ruffling) that is detectable within 30 sec of factor exposure. 2) Enhancement, within 15 min, of the phosphorylation of certain cell proteins, the most prominent of which is tyrosine hydroxylase. 3) Transcription-dependent induction of ornithine decarboxylase activity which is maximal by 4-6 hr of treatment. The inhibitors alone did not mimic these responses. In each case, the actions of NGF were suppressed by the inhibitors; in contrast, under the same conditions, each of the actions of EGF was either unaffected or significantly enhanced. The latter findings appear to discount the possibility that inhibition of responses to NGF was due to non-specific effects on cell function or to toxicity. HCTL alone was ineffective, but again potentiated the suppression of NGF responses by DAA. This is consistent with the possibility that the inhibition of NGF actions was due to blockade of transmethylation. One interpretation of these findings is that transmethylation (either ongoing or factor-stimulated) plays a necessary role in the action of NGF, but not of EGF. The observation that a variety of different responses to NGF were blocked, including those that are rapidly induced, suggests interference with one of the first steps in the mechanistic pathway of NGF. Supported by grant from the NIH (NS 16036 and AM 26920).

243.20 NERVE GROWTH FACTOR SYNTHESIZED BY MOUSE S-180 CELLS IN CULTURE. I. Kim* and N.J. Pantazis (SPON: J. Jew). Dept. of Anatomy, Univ. of Iowa, Iowa City, IA 52242.

Nerve Growth Factor (NGF) is synthesized by several different types of cells in culture. Do cells in culture produce NGF molecules similar to those seen in the mouse submandibular gland, the most potent source of NGF? Two forms of NGF have been isolated from the submandibular gland, 7S-NGF (Varon, S., Nomura, J. and Shooter, E.M., Biochemistry, 6: 2202, 1967) and NGF_1 (Young, M., Saide, J.D., Murphy, R.A. and Blanchard, M.H., Biochemistry, 17:1490, 1978). Both molecules apparently contain three subunits designated α, γ and β-NGF. Studies using specific radioimmunoassays (RIAs) for α, γ and β-NGF determined that neither α nor γ was present in medium conditioned by fibroblasts whereas β-NGF was readily detected (Pantazis, N.J., submitted to Biochemistry). Since two of the three subunits contained in 7S-NGF and NGF_1 were not present, this indicates that neither of these forms of NGF is produced by mouse fibroblasts.

A recent paper (Barklis, E. and Perez-Polo, J.R., J. Neurosci. Res., 6:21, 1981) suggested that mouse S-180 cells in culture produce a 7S-NGF molecule. Although the S-180 cell line is now called a sarcoma, it was originally characterized as an axillary carcinoma (Steward, H.L., Snell, K.C., Dunham, L.J. and Schlyen, S.M., Transplantable and Transmissible Tumors of Animals, p. 243, Armed Forces Inst. Pathol., Sec. 12, F40, Washington, D.C., 1956). S-180 cells were investigated to establish whether they are different from mouse fibroblasts and produce 7S-NGF. Radioimmunoassays of concentrated samples of S-180 cell conditioned medium detected little or no α or γ protein while β-NGF was present in significant quantitites (700-800 ng/ml). NGF bioassays indicated that the S-180 β-NGF was biologically active. The β-NGF produced by S-180 cells was examined on denaturing (5M guanidine hydrochloride) gel filtration columns and its molecular weight was identical to that of submandibular gland β-NGF. The S-180 β-NGF was further characterized on isoelectric focusing gels. The isoelectric point of the S-180 β-NGF was indistinguishable from that of submandibular gland β-NGF.

In conclusion, S-180 cells synthesize a β-NGF protein similar to that found in the mouse submandibular gland. However, radioimmunoassays were unable to detect α and γ. As in the case with the mouse fibroblasts, these results would suggest that neither 7S-NGF nor NGF_1 is produced by S-180 cells in culture.

243.21 MOTOR NEURON SURVIVAL AND NEURITE GROWTH: PROMOTION BY FACTORS FROM DIFFERENT CELL TYPES IN EMBRYONIC MUSCLE. V. Nurcombe*, S. Tout* and M.R. Bennett. Neurobiology Research Centre, University of Sydney, N.S.W. 2006, Australia.

Embryonic chick skeletal muscle releases both a motor neuron survival factor and a neurite expression factor in vitro (Nurcombe and Bennett, J. Comp. Neurol., in press 1983). The present experiments were designed to identify the cell type within skeletal muscle which is primarily responsible for these neurotrophic effects; the cell types studied were myoblasts, myotubes, fibroblasts, endothelial cells, undifferentiated mesenchyme and Schwann cells. Each cell type was prepared from skeletal muscle of the appropriate embryonic age (ranging from 4-10d of gestation) and grown to confluence in monolayer culture. Serum-free conditioned media (CM) obtained from these cultures were assayed for survival- and neurite-promoting properties against dissociated cultures of HRP-labelled motor neurons (MN; Bennett et al., Brain Res. 190; 1980). The MN were seeded onto polyornithine plates in CM diluted with standard medium containing 5% fetal calf serum (FCS). The proportion (%) of MN which survived and the proportion which expressed neurites were counted after 72h. Myotube CM was found to promote neuronal survival to levels over twice as high as the next most effective cell types, the muscle fibroblast and the myoblast. All CM were found to trigger neurite outgrowth; again, the greatest levels were triggered by the myotube CM.

Further experiments were performed to assess the effects of different cell types in embryonic muscle on neurite expression from organotypic explants of the lateral motor column. These explants were dissected from 8-9d embryos and tested against each of the CM; the CM was diluted with 0.5% FCS and the explants incubated for 5d. Myotube CM again enhanced neurite outgrowth to levels at least twice that of the next most effective cell type, the fibroblast.

These results support the hypothesis that in vivo myotubes release a neurite promotion factor which directs the advancing growth cone towards it (Bennett et al., J. Comp. Neurol., 215, 1983); they also support the possibility that myotubes provide a survival factor for the MN (Eagleson & Bennett, Neurosci. Lett., in press 1983).

243.22 SCHWANN CELL PROLIFERATION AND PROTEOLYSIS: REGULATION BY THE PLASMIN-GENERATING SYSTEM. N. Kalderon. The Rockefeller Univ., New York, 10021.

Schwann cells proliferate during development of the nervous system and in the adult nervous system upon regeneration as a result of nerve injury. This cell proliferation entails remodeling events in the tissue as the new neuronal-Schwann cell interactions are established. The role of the serum proteolytic system, plasminogen/plasminogen activator, in the regulation of nervous tissue remodeling processes in the proliferation of Schwann cells is being studied.

It is reported in this study that purified dividing Schwann cells in culture produce extracellular plasminogen activator, as measured by the biochemical fibrinolytic assay (details in Kalderon, 1979, PNAS, 76:5992). Purified Schwann cells in culture divide at a low rate. Recently a growth factor (GGF) from bovine pituitary was isolated which enhances Schwann cell proliferation (Brockes et al., 1980, J.B.C. 255:8274). However, fetal calf serum (FCS) is an essential component in the medium for its action (Raff, et al., 1978, Cell, 15:813). For our studies, purified Schwann cell cultures are obtained from the sciatic nerve of newborn mice (Brockes et al., 1979, Brain Res. 165:105), and are maintained in Dulbecco's minimal essential medium (DMEM) supplemented with 10% FCS and partially purified GGF from the bovine pituitary (Brockes et al., 1980). When the above medium is replaced with a chemically defined medium with or without the GGF, the Schwann cells proliferate at a minimal rate. The chemically defined medium is composed of DMEM supplemented with: 5 μg/ml bovine insulin, 5 μg/ml human transferrin, 20 nM progesterone, 100 μM putrescine dihydrochloride, 30 nM sodium selenite, 100 μg/ml bovine serum albumin. However, addition of plasminogen (0.05-1 μg/ml) with the GGF to the chemically defined medium was sufficient to stimulate Schwann cell division (3-4 times) to a rate similar to the one in the DMEM + 10% FCS (as measured by [^{3}H]thymidine uptake). The effect of plasminogen is partially blocked by the protease inhibitor trasylol; however, plasminogen without the GGF does not have any mitogenic effect.

It is concluded that the plasmin proteolytic activity (generated by the activation of plasminogen) is one of the serum components, required by the GGF to promote Schwann cell proliferation. However, it is not clear yet whether other serum components, e.g., protease inhibitors are also needed for the regulation of Schwann cell proliferation.

243.23 ASSOCIATION OF ^{125}I-NGF WITH PC12 PHEOCHROMOCYTOMA CELLS: EVIDENCE FOR INTERNALIZATION VIA HIGH-AFFINITY RECEPTORS ONLY AND FOR LONG-TERM REGULATION BY NGF OF BOTH HIGH- AND LOW-AFFINITY RECEPTORS. P. Bernd and L. A. Greene*. Dept. of Anatomy, Mt. Sinai Sch. of Med., New York, N.Y. 10029 and Dept. of Pharmacology, N.Y.U. Sch. of Med., New York, N.Y. 10016.

Association of ^{125}I-NGF with monolayer cultures of PC12 pheochromocytoma cells was studied under the same growth conditions (RPMI Medium + 15% serum) in which the cells exhibit numerous NGF responses (i.e. cessation of mitosis, neurite outgrowth, etc). Surface bound and internalized factor were distinguished from one another by differential release of the former at low pH, high salt (0.2M acetic acid, 0.5M NaCl). The validity of this approach was verified by EM radioautography and by the absence of non-acid-releasable binding when internalization was blocked at 4°C. ^{125}Binding to the surface was rapid; at 0.2 nM (5 ng/ml) of ^{125}I-NGF, binding to naive cells (NGF-untreated) reached a plateau within 2-5 min. Internalization, in contrast, as revealed by both EM radioautography and scintillation counting, did not start until approximately 2 min after exposure to NGF. Thereafter, internalization proceeded linearly for at least 1/2-1 hr. By the latter time approximately 75% of total bound NGF was within rather than on the surface of the cells. Binding vs. NGF concentration experiments and Scatchard analysis indicated 2 distinct classes of surface binding sites. For both naive cells and cells treated with NGF for at least a week (primed cells), about 7% of the sites had an apparent K_D of 0.3 nM; the remaining sites half-saturated at about 4 nM NGF. The number of each type of site was 3-fold higher/mg protein in the primed cells. For both naive and primed cultures, internalization appeared to be mediated by a single class of uptake sites which half-saturated at ~0.3 nM. Pulse-chase experiments indicated that NGF bound to the high affinity receptors is internalized with a half-time of 3-4 min. The maximal rate of uptake by primed cells (~200 fmol/hr/mg protein) was about twice that for naive cells. Light and EM radioautography indicated that the density of binding was substantially higher in primed cultures and that this increase took place over a time course of days to weeks. These findings suggest that NGF brings about long-term increases in its own receptors and are consistent with a model in which NGF binds to both high- and low-affinity surface receptors, but is internalized only via the high affinity sites. Supported by grants from the NIH (NS 16036), March of Dimes, and Pharmaceutical Manufacturers Association Foundation.

DEVELOPMENT AND PLASTICITY: TROPHIC INTERACTIONS II

244.1 MITOGENIC EFFECTS OF RETINAL EXTRACTS ON RADIAL GLIAL CELLS WITHIN ISOLATED TECTAL TISSUE IN VITRO. Deborah B. Henken and Myong G. Yoon. Department of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4J1.

Approximately five weeks following unilateral optic nerve crush (ONC) in adult goldfish, enhanced mitosis of radial glial cells was found in the contralateral (conditioned) tectum in comparison with the ipsilateral (normal) tectum (Stevenson, J.A., Br. Res., 153:345, 1978). At about this time, regenerating optic fibers begin to reinnervate their target tectal tissue. The present work aims to determine whether these two events are simply a temporal coincidence or whether the optic fibers exert mitogenic effects on the tectal radial glial cells. To test the latter possibility, we applied either extracts of regenerating retina or extracts of intact retina to normal tectal tissue. We then examined their differential effects on mitosis of radial glial cells.

Previous work in our laboratory has shown that isolated tectal tissue can incorporate exogenous tritiated thymidine into DNA and that this tissue remains viable for up to 125 hours in a biochemically defined culture. To assess whether a mitogenic factor is produced by the retina during tectal reinnervation, extracts were prepared from regenerating retina 35 days following ONC (experimental) and from intact retina (control). Particulate and soluble portions of the extracts were separated in both cases and introduced individually to culture dishes containing normal optic tectum. After 15 to 18 hours of incubation, tritiated thymidine was added to the culture in order to label proliferating cells. The tissue was processed for autoradiography.

Preliminary observations suggest that radial glial mitosis within a normal tectal slice is enhanced by extracts from regenerating retina as compared to normal retinal extracts.

244.2 RETINAL NEURITE OUTGROWTH STIMULATED BY EXTRACTS FROM ANOPHTHALMIC EMBRYOS. N.G. Carri and T. Ebendal*. Department of Zoology, Uppsala University, Box 561, S-751 22, Uppsala, Sweden.

An essential quality of the visual system is the precise arrangements of its axonal connections. Several mechanisms may be involved in creating these trajectories. An aspect currently studied is wheter trophic interactions(s) and trophic factor(s) may be attributed a role in the development of the visual system. In particular molecular factors regulating the growth of optic axons in culture interest us.

We have earlier shown a trophic effect by the normal optic lobe on the fibre growth from retinal neurons using a short-term bioassay (Soc. Neurosci. Abstr., Vol. 7, p 547, 1981). We now tested the effect of optic lobe missing its supply of retinal axons from anophthalmic chick embryos in the same bioassay. Chick retinal explants (white Leghorn) from 6-day-old embryos were cultured on collagen gels. Tissue extracts (1 gram of tissue in 5 ml of Eagle's Basal Medium, BME,) were dialysed and added to each dish (0.8 ml). They were incubated four days and maximum neurite lenghts were measured in an inverted microscope at 125 x magnification. The extracts (complete optic lobe from normal (OLN) and anophthalmic (OLA) chick embryos 18-day-old) were tested at a series of concentrations equivalent to 100-0.16 mg tissue per ml. Both extracts increased retinal response but the stimulation was about 40% better with OLA. The length of fibers as a function of the concentration of optic lobe extracts (OLN and OLA) were found to fit a sigmoid curve. The stimulative effect of OLA was also evident under serum free conditions.

The results show that extractable macromolecules from target areas stimulate the growth of retinal neurons and suggest that this effect may be greater in a target deficient in its innervation. The data suggest that the trophic interaction(s) during embryonic neural development could be regulated by feedback interactions.

244.3 RETROGRADE IMPULSE ACTIVITY IN REGENERATED NERVE FIBERS IN NEUROMA STUDIED IN VITRO. J. D. Kocsis and R. J. Preston*. Dept. of Neurology, Stanford University Medical School, and Veterans Administration Medical Center, Palo Alto, CA 94304.

Regenerating nerve fibers that are prevented from reaching their peripheral targets by nerve ligation can give rise to neuroma formation. It has been observed from extracellular unit studies in vivo that activation of a nerve trunk leading into a neuroma can lead to impulses that propagate centripetally. One suggested mechanism for this phenomenon is an "ephaptic" interaction resulting from close apposition of regenerating axon sprouts within the neuroma (Seltzer and Devor, Neurology 29, 1979). Another possibility is retrograde axonal sprouting of the regenerating fibers. In the present study we characterized retrograde impulse activity in an in vitro neuroma preparation, and then used a horseradish peroxidase (HRP) labelling technique to determine the extent of retrograde sprouting. Neuroma formation was induced by ligation of the sciatic nerves of Wistar rats 2 to 16 weeks before the nerves were removed, desheathed, and placed in an in vitro nerve recording chamber. The nerve trunk (1.0 to 1.5 cm) leading into the neuroma was split longitudinally. Stimulation or whole nerve recordings could be obtained from either branch. Stimulation of one branch leading into the neuroma gave rise to impulse activity not only within that branch, but also in a neighboring nonactivated branch. The two branches were connected only through the neuroma head. The response in the activated branch was a discrete short-latency negativity followed by temporally dispersed low amplitude negative components. Only low amplitude late activity was recorded from the nonstimulated branch, and it was abolished by an acute crush at the neuroma neck. From nerves where the interaction was demonstrated, one branch of two leading into the neuroma was dipped in HRP (3% in Kreb's solution) for 1 to 2 hours. The nerves were kept for 24 to 40 hrs at 5° C in Kreb's solution and then fixed in glutaraldehyde, transferred to PO_4 buffer, and processed for HRP histochemistry. HRP stained axons from the stained branch were seen entering and ramifying within the neuroma. When axons reached the distal end of the neuroma, they looped and coursed in a retrograde direction, but in most preparations did not enter the non-dipped branch although impulses were shown to propagate into this branch via the neuroma. However, in some preparations a few HRP stained axons were observed coursing in the non-dipped branch. These results demonstrate that while retrograde impulse activity can be recorded in the absence of morphological evidence for retrograde regeneration in neuroma, one cannot discount the possibility of some retrograde regeneration as contributing to the observed retrograde impulse activity. Supported by the National Multiple Sclerosis Society and the Veterans Administration.

244.4 ULTRASTRUCTURAL PROPERTIES OF CHEMICALLY FUSED PC12 CELLS: EFFECTS OF NERVE GROWTH FACTOR. K. Morrison-Graham and P.H. O'Lague. Dept. of Biol. and Jerry Lewis Neuromuscular Research Center, UCLA, Los Angeles, CA 90024.

Cells of the neuron-like clone PC12 fuse upon exposure to polyethylene glycol (PEG) to produce large multinucleate cells. These cells exhibit many properites of their unfused counterparts including the ability to extend neurite-like processes in response to Nerve Growth Factor (NGF; O'Lague and Huttner, PNAS, 77:1701, 1980). We have compared the ultrastructural properties of fused and unfused cells. Individual cells, previously identified as fused in the phase-contrast microscope, were shown to be fused at the ultrastructural level. All nuclei of fused cells were encased within one plasmalemma and their cytoplasmic constituents were qualitatively similar to those of unfused cells. In several cases evidence for fusion of nuclei was obtained, e.g., unusually large nuclei with more than 2 nucleoli. In fused cells mitochrondria and Golgi appeared normal, and chromaffin-like granules, a striking feature of unfused cells, were common. The chromaffin granules were similar to those of unfused cells in both size (40-170nm in diameter) and appearance.

The processes and growth cones exhibited by the fused cells in the presence of NGF were similar to those of the unfused cells (see also, Luckenbill-Edds et al., J. Neurocytol., 8:493, 1979) and to those of rat sympathetic neurons in vitro. Random cross-sections through fused and unfused cell processes revealed a wide range of process diameters (0.3-3.9μm). The cytoplasmic organization of these processes was similar although larger processes contained proportionally more microtubules and other organelles. The chromaffin granule diameters did not differ from those found in the cell bodies of non-NGF treated cells.

In cell bodies a qualitative increase in the number of rough endoplasmic reticulum (RER) cisternae was observed following a one week exposure to NGF (fused cells 10/14; unfused cells 13/25). In approximately 50% of the cells the cisternae were organized into roughly parallel stacks. These stacks were composed of 3-16 cisternae separated by ~0.1-0.2μm. Numerous free ribosomes were located in the cytoplasmic matrix between the cisternae. These orderly arrays resembled the Nissl substance of neurons. The time course was examined in unfused cells; 15% of the cells had an increase in the RER following a one day exposure to NGF while 86% of the cells showed an increase by 14 days. At this time 84% of the cells had RER organized into stacks.

In summary, these ultrastructural results provide further evidence for the usefulness of the fused PC12 cells as a neuronal model in studies of NGF action. (Supported by NIH grant NS-12901, MDA Center Grant, and a Giannini Foundation Fellowship to KM-G)

244.5 A COLLAGEN INDUCING FACTOR FROM EMBRYONIC BRAIN INDUCES PROLYL HYDROXYLASE ACTIVITY IN CULTURED MUSCLE CELLS. Z. Vogel, D. Duksin* and C. Kalcheim*(SPON: V. Teichberg). Depts. of Neurobiology and Biophysics, The Weizmann Institute of Science, Rehovot 76100, Israel.

Extracts from embryonic rat brain contain a factor which stimulates the production of collagen by cultured rat muscle cells. The newly formed collagen has a role in the aggregation of acetylcholine receptors on the surface of the cultured myotubes (Kalcheim et al., PNAS 79: 3077, 1982; J. Biol. Chem 257: 12722, 1982). Here we report that the collagen-inducing factor is found in extracts of embryonic rat and bovine brains as well as in embryonic spinal cord extracts. Some activity was also detected in embryonic kidney, but no activity was found in extracts of adult brain and placenta or in embryonic rat muscle, lung, liver and skin.

The collagen-inducing factor from embryonic brain was partially purified by membrane and gel filtration. The activity was eluted from Biogel P-10 or Sephadex G-25 columns (in 10mM HEPES, 150 mM NaCl, 5mM KCl, pH 7.4) as a single peak with an apparent molecular weight of around 700 daltons. The partially purified factor induced the production of collagenous proteins of types I, III, IV and V which were deposited on the surface of the treated myotubes in a distinct pericellular pattern.

The increased secretion of collagenous proteins is accompanied by a fifteen-fold increase in the hydroxyproline-to-proline ratio in secreted proteins (29% compared to 1.9% in controls) and a five-fold increase in the above ratio in cellular proteins (8.9% compared to 1.7% in controls). Moreover, a five- to fifty-fold increase in the activity of the enzyme prolyl hydroxylase was found in extracts derived from factor-treated cultures compared to controls. No stimulatory effect on prolyl hydroxylase activity was detected when the factor was exogenously added to cell homogenates. The procollagen mRNA level was not affected by treating the cultures with the factor. In addition, the level of activity of the muscle enzyme creatine phosphokinase was also unaffected.

On the basis of the above data we suggest that the effect of the neuronal factor which stimulates the production of collagen is achieved by inducing the synthesis or the activation of the enzyme prolyl hydroxylase in the cultured cells. (Supported by a grant from the Muscular Dystrophy Association).

244.6 INDUCTION OF SPINAL CORD ANDROGEN RECEPTORS BY MUSCLE FACTORS. C. L. Weill. Departments of Neurology and Anatomy, Louisiana State University Medical Center, New Orleans, LA 70112.

Motoneurons of the lateral motor column in the spinal cord of chick embryos have been shown to accumulate ^{3}H-dihydrotestosterone implicating the presence of androgen receptors (Exp. Brain Res. 44:243, 1981). Which cellular functions are regulated by these receptors is unknown. Studies were carried out to determine if these receptors are under trophic regulation by factors from skeletal muscle. Spinal cord cultures were prepared by plating dissociated 6-day old chick embryo spinal cord cells at a density of 3 x 10^6 cells/ml in collagen coated multiwell dishes. The number of nonneuronal cells in these cultures was minimized by plating in the presence of 10^{-5} M cytosine arabinoside for the first 48 hr. Muscle-conditioned medium (M-CM) was obtained from mature skeletal muscle cultures prepared from 12-day old chick embryo leg muscle myoblasts plated at a density of 4 x 10^6 cells/ml. Binding of the androgen, ^{3}H-methyltrienolone (^{3}H-R1881), was determined on intact cultures at 37° C using a monolayer assay procedure.

Specific ^{3}H-R1881 binding reached equilibrium in 2 hr and increased linearly with cell number over the range of 0.5 - 2.0 x 10^6 cells per determination. Specific binding was saturable and was inhibited by unlabeled R1881, testosterone and dihydrotestosterone, but not by dexamethasone and beta-estradiol. Specific binding to cytosols prepared from neuronal cultures was abolished by heating the cytosol at 100° C for 10 min or treating the cytosol with trypsin.

Spinal cord cultures maintained in MEM containing 10% horse serum and 5% chick embryo extract contain measurable levels of androgen receptor in the range of 117 +/- 10 fmole/mg protein (m +/- S.E., n=3). Dose response curves for M-CM indicated an optimum concentration of 40%. When treated with 40% M-CM for 4-6 days spinal cord cultures displayed a 2.00 +/- 0.36 fold (M +/- S.E., n=3) increase in specific ^{3}H-R1881 binding.

These data demonstrate that factors produced by skeletal muscle maintained in culture are able to cause an increase in the number of available androgen receptors in cultured spinal cord cells. This taken together with the accepted mechanism of action of steroid receptors suggests that target muscle may elicit its neurotrophic effects through steroid hormone mediated selective gene expression. (Supported by grants from the Amyotrophic Lateral Sclerosis Society of America and The Schlieder Foundation)

244.7 NUCLEAR ORGANIZATION AND CELL DEATH IN THE CHICK OCULMOTOR NUCLEUS FOLLOWING TARGET ALTERATION. D. B. Wayne* and M.B. Heaton. Dept. of Neuroscience, University of Florida College of Medicine, Gainesville, FL, 32610.

The oculomotor nucleus innervates four of the extraocular muscles. These muscles are derived entirely from mesoderm while the ciliary ganglion and connective tissue enveloping the muscle are neural crest derived. Within the nucleus, there is a segregation of motoneuron populations which innervate the different muscles (Heaton, M.B. and D.B. Wayne, J. Comp. Neurol., 217(3): in press, 1983). During normal development this segregation of motoneurons is produced by the migration of a subpopulation of cells and the separation into subnuclei. This is followed by a period of normally occurring cell death. The morphological arrangement of motoneurons in the absence of their normal target was examined during the period of developmental organization and following the period of cell death.

Following early removal of the paraxial mesoderm and neural crest the early developmental organization progressed as normal. In the twenty-one cases examined between 5-10 days of development both cell migration within the nucleus and the separation into distinct subnuclei occured. The configuration of the experimental nucleus mirrored that of the control nucleus despite a virtual elimination of the target muscle in some cases. Also, the nuclear organization did not seem to rest on the presence of neural crest derived tissue as indicated by the depletion of the ciliary ganglion. At the end of the period of normal cell death, day 16, virtually all the motoneurons deprived of their target have disappeared. Only a small population of cells remain along the midline on the experimental side. These are presumably the neurons which migrate across the midline during early development and provide innervation to the contralateral superior rectus muscle. It is the complete absence of cell groups and the location of the remaining cells which is of interest here rather than a quantification of the amount of cell death.

In a few cases the experimental manipulation caused the nerve to deviate from its normal course. In these cases the nerve crossed to innervate the muscle on the intact side. This yielded an effective reduction in the quantity of muscle available and altered any lateralized cues. As previously, the organizing events in the nucleus, migration and subnuclear separation, occurred as normal. The effect of this condition on the rate of cell death is currently under investigation.

244.8 GROWTH OF C-1300 NEUROBLASTOMA IN TISSUE CULTURE IS AUGMENTED IN THE PRESENCE OF SYMPATHETIC GANGLION EXPLANTS. E. Chelmicka-Schorr*, R.C. Yu, M.G. Sportiello* and B.G.W. Arnason. Brain Research Institute and Dept. of Neurology, Univ. of Chicago, Chicago, IL 60637.

We have shown previously that growth of C-1300 neuroblastoma (C-1300 NB) is significantly suppressed in mice sympathectomized or axotomized by pretreatment with 6-hydroxydopamine. When newborn mice were pretreated with nerve growth factor (NGF) to induce neuronal hypertrophy, neuronal maturation, and peripheral hyperinnervation of the sympathetic nervous system (SNS), the growth of neuroblastoma was augmented. These experiments suggest a modulatory role of the SNS on C-1300 NB growth (Chelmicka-Szorc, E., Canc Res ,36:382, 1976; Chelmicka-Schorr, E., Canc Res 38:1374, 1978). To explore this phenomenon, we cocultured sympathetic ganglia (SG) and C-1300 NB explants or S-20 NB cells. Superior cervical ganglia (SG) were taken from 1-day old rats and cultured in collagen-coated petri dishes. The culture medium was DMEM enriched with 10% FBS and NGF (84 ng/ml). Cultures were maintained at 37°C in humidified 5% CO_2 balanced with air. After 72 hours, 3-4 explants of C-1300 NB were added to petri dishes containing 2-4 well established SG that had extended multiple processes. Control cultures had either SG or C-1300 NB, both in the medium described above. The presence of SG in NB containing dishes significantly augmented growth of C-1300 NB cells as compared to C-1300 NB grown alone. The difference was easily noticeable 48 hours after coculturing and was striking 12 days later when proliferating C-1300 NB cells covered almost the entire petri dish. There was only sparse growth of cells from C-1300 NB explants grown without SG. Density of the C-1300 NB cells was significantly greater in the proximity to SG. A similar experiment was done with dispersed S-20 NB cells, a clonal line derived from C-1300 NB. An increased density of S-20 cells was again seen in proximity to SG. The growth of the SG themselves was not changed in the presence of C1300 NB or S-20 NB in the culture. We postulate that a trophic factor which increases the proliferation of NB cells is secreted by sympathetic ganglia. This finding would explain why growth of C-1300 NB in vivo is suppressed in mice with ablated SNS.

244.9 EVIDENCE FOR THE POSTINSERTIONAL STABILIZATION OF ACh RECEPTORS AT THE NEUROMUSCULAR JUNCTION. E. F. Stanley, and D. B. Drachman. Department of Neurology, Johns Hopkins Sch. of Med., Baltimore, MD 21205.

ACh receptors at innervated neuromuscular junctions are known to be very stable, with an average half-life of about 10 days in the mouse. However, denervated junctions have ACh receptors that are rapidly turned over, with a half-life of about 1 day (Levitt and Salpeter, Nature 291:239, 1981) similar to those that appear at extra-junctional regions of muscle fibers after denervation. We have recently reported that normal neuromuscular junctions have two populations of receptors: 1) a large sub-population (80%) of stable receptors, and 2) a small but significant sub-population (20%) that are rapidly turned over (RTOs)(Soc Neurosci Abstr 8:185, 1982). We have postulated that the RTOs are the precursors of the stable receptors, and that the stabilization process may depend on an influence from the motor nerve.

In the present study, we have tested this hypothesis in the mouse flexor digitorum brevis muscle by: 1) labeling junctional ACh receptors with ^{125}I-α-BuTx, 2) denervating by cutting the sciatic nerve, and 3) following the fate of the RTOs through a 6 day period when they were either degraded or converted to stable ACh receptors. Our hypothesis predicts that denervation would prevent the conversion of RTOs to stable receptors, and would result in a reduced number of stable AChRs in the denervated muscles as compared with the innervated muscles.

Details of the experimental procedures will be presented. The results show that there were more ACh receptors remaining in the innervated muscles than in the denervated muscles at the end of the 6 day period ($p < .001$). This was attributable to failure of conversion of the RTOs to stable receptors following denervation. Control experiments showed that this could not be accounted for by acceleration of degradation of the stable receptors.

Our results are consistent with the hypothesis that the RTOs are precursors for the stable receptors, and that an intact motor nerve supply is necessary for their conversion to stable receptors.

244.10 EXPERIMENTALLY LENGTHENED NERVES SHOW THAT NEUROTROPHIC MAINTENANCE DEPENDS UPON AXON LENGTH B. Oakley, E. Keppel and S. E. Hughes. Dept. of Zoology, Neuroscience Lab. Bldg. Univ. of Michigan, Ann Arbor, MI 48109.

The neurotrophic dependence of end organs can be demonstrated by nerve transection. Characteristically, longer nerve stumps prolong the survival of the end organ, such as the taste bud of the Mongolian gerbil (Meriones unguiculatus). Recently, we demonstrated a linear relationship between the length of the IXth nerve stump remaining attached to the gerbil's tongue and the time for taste response amplitudes to fall to 50% of their control magnitudes (Oakley et al., Brain Research 194:213-218, 1980). Perhaps axon stump length is responsible, but in such studies transections are necessarily made at different sites along the nerve trunk. Hence, differential effects might result from the changing axonal branching patterns or from greater disruption of the local blood supply when making nerve exposures nearer to the end organ. We lengthened the gerbil's IXth nerve by causing the axons to regenerate through a nerve splice (a segment of the superior laryngeal nerve). The experimentally lengthened nerves were about 50% longer that the control regenerated IXth nerves. In assessing nerve stump length dependency, both the control and experimental nerves were transected at the same location on the proximal portion of the IXth nerve. The peak magnitudes of the summated taste responses declined at a rate exactly predicted by the earlier nerve stump length dependency study with normal IXth nerves. These experimentally lengthened nerves reformed similar numbers of taste buds relative to control regenerated IXth nerves. We conclude that the trophic features of taste axons are indeed dependent upon axon length and not upon factors uncontrolled in designs which transect at different locations. Additionally, the extra burden of maintaining longer axons does not degrade the nerve's trophic performance in the maintenance of taste buds. Supported in part by NIH Grant NS-07072.

244.11 REGULATION OF CHEMOSENSITIVITY IN CULTURED CHICK CILIARY GANGLION NEURONS. Jeremy B. Tuttle, Physiology Section, Biological Sciences Group, The Univ. of Connecticut, Storrs, CT 06268.

Transmission through the intact ciliary ganglion operates via ganglionic nicotinic ACh receptors. Neurons from embryonic ganglia lose responsiveness to iontophoretically applied ACh during the initial week or so of cell culture. However, ganglionic neurons co-cultured with myotubes rapidly establish neuromuscular transmission and retain this chemosensitivity to ACh (Crean et al, 1982, J. Physiol. 33:87-108). Myotube membrane remnants, prepared by lysis of myotube cultures in water, also support the retention of neuronal ACh sensitivity (Tuttle, 1983, Science, in press). Neuronal responsiveness to other putative neurotransmitters was examined under conditions where nicotinic ACh sensitivity was either retained or had been lost.

Test compounds were dissolved in buffered saline (pH 7.4) and delivered onto cultured neurons by pressure ejection from 2-5 um pipets during intracellular recording. Thus, the extremes of pH and the restricted focal application of iontophoresis were avoided. ACh: (100 uM) Neurons insensitive to iontophoretically applied ACh often responded to ACh delivered by pressure-ejection with a slight very slow hyperpolarization. Current passage through the recording pipet suggested an increase in input resistance accompanied the response. Cells sensitive to iontophoretic ACh responded to pressure ejection with a large rapid depolarization and reduced input resistance. GABA: (1mM) (γ-Amino-n-butyric acid) All neurons tested responded to GABA, regardless of their sensitivity to ACh. If KCl filled the recording pipet, the response was a depolarization with a reversal potential of -30 to -45 mV, whereas the response was hyperpolarizing with a more negative reversal potential when K^+-acetate was used. In either case, input resistance fell during the response. L-Glutamic acid: (1mM) No responses were recorded to glutamate. Leucine Enkephalin: (100 uM) Slow 2-5 mV hyperpolarization resulted from ejection of Leu-enkephalin, accompanied by an increase in resistance on both neurons that had lost nicotinic ACh responses and those that retained sensitivity.

These results suggest the loss of active receptors of a single type (nicotinic ganglionic) is not accompanied by a general loss of responsiveness to other compounds. However, because the loss of nicotinic sensitivity to ACh is rapid in this culture system, longer-term studies are required before the totally independent regulation of transmitter sensitivities can be demonstrated.

244.12 KINETIC CHARACTERISTICS AND MOLECULAR WEIGHT OF ISOLATED NERVE GROWTH FACTOR RECEPTORS. R. W. Stach and J. R. Perez-Polo. Dept. of Human Biol. Chem. & Genet. and The Marine Biomed. Inst., The University of Texas Medical Branch, Galveston, TX 77550.

The nerve growth factor protein (NGF) acts as a classical neuronotrophic factor on vertebrate embryonic sensory neurons and sympathetic neurons at all stages of development. Even though the mechanism of action of NGF at the molecular level is not fully understood, it is known that responsive cells bind NGF at cell surface membrane receptors. There are two different receptors on sensory and sympathetic neurons as judged by kinetic and Rosenthal analyses. These two receptors have equilibrium dissociation constants of approximately 10^{-11} M for the high affinity receptor (type I) and approximately 10^{-9} M for the low affinity receptor (type II). Following isolation of the NGF receptor (NGFR) from embryonic sensory neurons, equilibrium binding studies demonstrated two different equilibrium dissociation constants. Those equilibrium dissociation constants were identical to those that have been determined on whole cells. Receptors from two other cell types (rat pheochromocytoma cells, PC12, and human neuroblastoma cells, LAN-1, which respond to NGF by extending neurites) were also isolated. Equilibrium binding data demonstrated two different equilibrium dissociation constants. These constants were not different from those obtained for the receptors isolated from embryonic sensory neurons. The molecular weights determined for the receptors isolated from embryonic sensory ganglionic cells and PC12 cells were similar. Each had receptor species with molecular weights in the 100,000 to 130,000 range and one or two species in the 200,000 range. It is interesting that both cells requiring NGF for survival, DRG, as well as cells that do not require NGF for survival, PC12 and LAN-1, display similar populations of NGF receptors as determined by kinetic and structural analyses. From kinetic analyses on isolated receptors from embryonic sensory neurons, association and dissociation rate constants were obtained. The association rate constant, determined at 23°, is approximately 1×10^7 M^{-1} sec^{-1} which is identical to that observed on whole cells. There are two different dissociation rates observed. A fast dissociation rate ($k = 3 \times 10^{-2}$ sec^{-1}) and a slow dissociation rate ($k = 2 \times 10^{-4}$ sec^{-1}). The pH binding profile for the two receptors is also different. For the type I receptor, binding displayed a bell shaped response as a function of pH with maximum binding at pH values 7.0-7.9. For the type II receptor, maximum binding was obtained at pH 3.5 and decreased to a constant level at higher pH values. Our evidence is consistent with the hypothesis that there are two different receptors for NGF on these different responsive cells.

244.13 ENZYME ACTIVITIES IN SINGLE FIBERS OF NEWLY FORMED MOTOR UNITS FOLLOWING NERVE CRUSH. W. R. Turk*, P. M. Nemeth, Dept. of Neurology, Washington Univ. Sch. Med., St. Louis, MO 63110

Muscle fibers within motor units have been shown to have quantitatively identical activities of selected energy-related enzymes (Nemeth et al., J. Physiol. 311, 1981), suggesting that metabolic characteristics of muscle are mediated by the specific neural input. Innervation of muscle fibers can be experimentally altered by lesions of the motor nerve. Collateral sprouting of regenerating motor axons results in a reorganization of the motor unit detected histochemically by the presence of fiber type grouping (Karpati & Engel, Neurol. 18, 1968). We have studied whether enzyme levels are quantitatively similar in fibers newly innervated by a common nerve.

The peroneal nerve of a rat was crushed, producing a motor deficit lasting 4 weeks, and the tibialis anterior muscle was removed five weeks after recovery. Myosin ATPase staining at pH 4.5 was used to demonstrate areas of fiber type grouping and to determine fiber types. Biochemical assays for lactate dehydrogenase (LDH) and adenylokinase (AK) were performed on individual fibers of newly formed motor units and on randomly selected fibers.

FIBER TYPE		n	LDH*		AK*	
I	Motor Unit A	14	29.06 ± 1.46	5.0%	46.75 ± 2.60	5.6%
	Motor Unit B	5	25.95 ± 1.52	5.9%	43.16 ± 0.99	2.3%
	Motor Unit C	6	24.48 ± 2.07	8.5%	30.04 ± 3.33	11.1%
	Random	4	31.69 ± 4.57	14.4%	41.20 ± 1.93	3.4%
	Total	29	27.94 ± 3.20	11.5%	41.83 ± 6.85	16.4%
IIa	Motor Unit	12	30.44 ± 1.74	5.7%	52.99 ± 4.21	7.9%
	Random	6	37.57 ± 4.80	12.8%	49.26 ± 4.48	9.1%
	Total	18	32.82 ± 4.55	13.8%	51.75 ± 4.54	8.8%
IIb	Motor Unit	9	61.11 ± 4.63	7.6%	85.58 ± 2.83	3.3%
	Random	12	64.79 ±11.86	18.3%	81.93 ±10.62	13.0%
	Total	21	63.21 ± 9.75	15.0%	82.91 ± 8.05	9.7%

*Enzyme activities are moles/kg dry wt/hr from duplicate samples expressed as mean ± S.D. and coefficient of variation for the fiber group (n=number of fibers).

The results shows that both enzymes are invariable within most of the new motor units, at the level of experimental error of the method (determined by multiple measures on the same fiber to be 5.8%). The coefficients of variations are significantly less within motor units than among fibers of the same histochemical type, either selected at random or belonging to other motor units. Thus, reinnervation following nerve crush produces new motor units composed of quantitatively similar muscle fibers for LDH and AK. This finding illustrates the marked influence of the motorneuron in directing metabolic plasticity of skeletal muscle fibers.

244.14 SURVIVAL NEURITOGENESIS AND CHOLINERGIC DEVELOPMENT OF ENRICHED CHICK MOTONEURONS GROWN ON HYDRATED COLLAGEN GELS. T.P. Flanigan*, J.G. Dickson* and F.S. Walsh*.(SPON: J. Kenimer). Institute of Neurology, Queen Square, London, U.K.

Considerable evidence has accumulated from in vivo and in vitro studies to suggest that the developmental and regenerative patterns of spinal motoneurons can be influenced by specific cellular and humoral interactions with target muscle fibers. Recently, Schnaar and Schaffner (J. Neurosci. 1, 204, 1981) described a motoneuron-enriched cell fraction (Fraction 1) prepared from 6-day chick embryo spinal cord whose survival in vitro was dependant upon co-culture with muscle cells or the supply of muscle-conditioned culture medium. We have further examined the cell type composition and skeletal muscle dependency of this motoneuron-enriched cell fraction in primary culture.

As previously described, the survival of Fraction 1 cells when cultured on polylysine- or collagen-coated substrata required the presence of myotube-conditioned medium in addition to standard medium supplements (10% horse serum, 10% fetal calf serum, 2% chick embryo extract). However, when seeded onto 3-dimensional hydrated collagen gels, a 75% survival of Fraction 1 cells and the formation of an extensive 3-dimensional neurite lattice was obtained after 7 days in vitro, even in the absence of myotube-conditioned medium. Cells present in these cultures were typically large with granular cytoplasm, distinct nuclei, and neurites extending up to several millimeters into and through the collagen network. Immunofluorescence staining analysis using monoclonal antibody specific for neurofilament protein showed that the cell type composition of cultures was stable up to 7 days in vitro with greater than 99% of cells supporting neurofilament-containing cellular processes. After 14 days in culture however, a number of colonies of proliferating non-neuronal cells were observed to occur at low frequency ($1:10^5$). In addition to cell survival, growth of Fraction 1 cells on the collagen gels resulted in a modest, 2.5-fold increase in the specific activity of choline acetyltransferase over 7 days in culture. This increase is comparable to that obtained during co-culture of Fraction 1 cells with chick myotubes.

The results indicate that the motoneuron enriched cell fraction does not require muscle-conditioned medium for cell survival and neurite outgrowth and, that if operating, any putative muscle-derived motoneuron survival factors must be present in adequate supply in 2% chick embryo extract. It remains however to be determined whether enhanced neurite outgrowth or quantitative changes in cholinergic properties will be produced in response to co-culture with muscle cells or exposure to muscle-conditioned medium.

244.15 A SENSITIVE PERIOD EXISTS FOR THE NEURAL INDUCTION OF CIRCUMVALLATE TASTE BUDS. M.A. Hosley and B. Oakley, Department of Zoology, Neuroscience Lab. Building, Ann Arbor, MI 48109.

The rat has a single midline circumvallate papilla which, at 90 days, contains 625±83 taste buds innervated by the IXth nerves. Removal of both IXth nerves results in the complete loss of taste buds. After unilateral avulsion of the IXth nerve 79% of the taste buds remain (496±54) because of bilateral overlap of the IXth nerves. In our experiments we investigated the role of the nerve supply upon the developmental formation of these taste buds. The right IXth nerve was removed at 3 days post-partum and circumvallate taste buds counted in operated and control rats at ages 5 to 90 days. By 90 days a stable value of 230±36 taste buds was present. These taste buds are widely distributed in the circumvallate papilla indicating that the intact IXth nerve had access to all areas of this gustatory epithelium. When both nerves were crushed at 3 days, 144±68 taste buds were formed by 90 days as a result of bilateral reinnervation. Alternatively, if at 3 days, the right IXth nerve was removed and the left IXth nerve was crushed, only 25±27 taste buds form by 90 days in response to the unilateral reinnervation. Over ages 0 to 30 days the greater the delay in unilateral removal of the IXth nerve, the greater the number of taste buds that eventually form e.g., 474±38 taste buds formed in animals operated on at 30 days and sacrificed at 90 days. We propose an early sensitive period extending to age 30 days in which nerve fibers and taste bud precursors must interact to ensure the formation of normal numbers of taste buds. Experiments with crushed nerves indicate that reinnervation after the critical period is ineffective from which we conclude that the effects, in these circumstances, of early denervation are irreversible.

244.16 TARGET INFLUENCES UPON TRANSMITTER SYNTHESIS IN CULTURED CHICK CILIARY GANGLION NEURONS. D. Bruce Gray and Jeremy B. Tuttle, Physiology Section, Biological Sciences Group, The University of Connecticut, Storrs, CT 06268

Primary cultures of chick ciliary ganglion neurons have been established as an in vitro model for studies of neuronal differentiation and its trophic regulation. Recent evidence from this lab has shown that co-culture of chick ciliary ganglion neurons with chick pectoral muscle increases acetylcholine (ACh) synthesis both at basal levels and after K^+-induced depolarization as compared to neurons cultured alone. Synthetic responsiveness to depolarization is a characteristic of mature ciliary neuromuscular junctions in vivo and may depend upon developmentally relevant target interaction.

Initially, the culture system was characterized metabolically by examining choline uptake, choline metabolism and ACh synthesis, measured by incorporation of ^{3}H-choline. Although large amounts of non-specific, Na^+-independent uptake of ^{3}H-choline occurred in cultures at low choline concentrations, Na^+-dependent ACh synthesis clearly predominated over Na^+-independent synthesis at choline concentrations of less than 10 uM with a Km at approximately 1 um and a Vmax at 2 fm ACh synthesized/hour/cell. Na^+-independent synthesis had a Km of >50 uM choline and a Vmax of >6 fm ACh syn/hour/cell. In our assay, synthesis and degradation appeared to reach equilibrium after 30 minutes in ^{3}H-choline, in both control and 0 Na^+ incubations.

Preliminary experiments show that co-culture of neurons upon a substrate of lysed myotube membranes mimic the ability of live myotubes to stimulate ACh synthesis following 10 min preincubation of cultures in high K^+ (55 mM). Lysed myotube membranes were prepared by incubation of 5-day cultures of 11 day chick pectoral muscle on collagen coated microwells, in distilled H_2O for 2 hours followed by 3 washes in normal growth medium. Neurons plated upon lysed myotube membranes increased ACh synthesis by 76% in response to high K^+ preincubation, as opposed to a <40% increase in cultures of neurons alone.

Live muscle in co-culture (Crean et al, 1982, J. Physiol. 33: 87-108) and the same lysed membrane preparation (Tuttle, 1983, Science, in press) also support neuronal chemosensitivity to ACh. Thus, these results implicate contact with target membranes as an important aspect of neuronal differentiation. Both the ability to rapidly replenish transmitter stores in response to demand and the responsiveness to transmitter of these cultured neurons are profoundly influenced by contact with target tissue membranes.

244.17 CONDITIONED MEDIA AND CYCLIC AMP INFLUENCE NEURONAL SURVIVAL DURING ELECTRICAL BLOCKADE. D.E. Brenneman, S. Fitzgerald, P.G. Nelson. (SPON: Elaine A. Neale) Lab. of Developmental Neurobiology, NICHD, NIH, Bethesda, Maryland 20205.

The relationship between electrical activity and the action of neuronal survival factors was investigated in dissociated spinal cord cultures. The possible role of cyclic nucleotides in determining neuronal survival during electrical blockade was also studied. Spinal cord-dorsal root ganglia (SC-DRG) cultures were prepared from 12-14 day old fetal mice.

Previous studies have shown that blockade of spontaneous action potentials with tetrodotoxin (TTX) produced a significant decrement in cholinergic development and neuronal survival. Vulnerability of spinal cord neurons to TTX treatment occurred during a limited period in development (days 7-21 in culture). We now report that conditioned media (CM) obtained before or after but not during the critical period produced a dose-dependent protection for neurons grown in the presence of TTX during the vulnerable period. This sparing effect of the CM was determined from neuronal cell counts, ^{125}I-tetanus toxin fixation, and choline acetyltransferase measurements. The protective action present in CM was shown to be TTX-sensitive; i.e., the presence of 10^{-7} M TTX during the collection period prevented the protective activity of the CM. This lack of protective action was not attributable to a loss of donnor neurons during the collection period. Cell counts revealed a 20-25% decrease in neurons when TTX was applied during days 10-15 in culture. Application of TTX plus CM from young cells produced a 25% increase in the number of neurons as compared to control cultures. CM alone produced no change in neuronal cell counts from that of controls. Thus, electrical blockade in the presence of CM from young cells produced an increase in neuron survival.

Supplementation of culture media with dibutyryl cyclic AMP and TTX produed a dose-dependent increase in ^{125}I-tetanus toxin fixation as compared to cells treated with TTX alone during the critical period. Similar effects were observed with 8-bromo cyclic AMP. Addition of 8-bromo cyclic GMP had no effect on the TTX-mediated decrease in ^{125}I-tetanus toxin. These studies suggest that increases in cyclic AMP may be involved in mediating the action of some survival factors during development.

These data indicate that neuronal survival factors are released during different periods in development. The release of some of these survival factors is dependent on electrical activity. The competition for or utilization of these factors may depend on the electrical state of target neurons. Cyclic AMP may also play a role in mediating the survival response. It is concluded that electrical activity has multiple roles in determining the survival of neurons during epigenetic development of the CNS.

244.18 DISSOCIATED NEURONS FROM ADULT RAT SUPERIOR CERVICAL GANGLION SHOW REDUCED NGF REQUIREMENTS IN CULTURE. M.I. Johnson, Dept. Anatomy & Neurobiol., Washington Univ. Sch. Med., St. Louis, MO.

The principal neurons from the superior cervical ganglion of adult rats were dissociated into culture using a previously described method (J. Neurophysiol. 42:1410, 1979). For experiments on acute survival the neurons were grown on supplemented medium containing human placental serum and embryo extract with or without NGF. After 10 to 14 days those cultures on medium without NGF were returned to NGF containing feed and one week later neuronal counts made. In 3 separate series neurons initially seeded in medium without added NGF showed greater than 80% survival compared to the neurons in fully supplemented feed. In contast neurons dissociated from perinatal rats and treated similarly showed only 0.9% survival. Established cultures of adult neurons were withdrawn from NGF and studied using neuronal counts and measurements of neuronal diameters. Neuronal counts decreased to approximately 50-60% of control cultures over 7-10 days of NGF deprivation; if NGF was added back neuronal counts returned almost to control levels. Neuronal diameter showed a rapid decrease to approximately 65% of control neurons but again increased to almost control values with the return of NGF in the medium. Sequential photographs of identified neurons in the living cultures showed morphological changes consistent with chromatolytic reaction upon NGF withdrawal and some neurons became unrecognizable by criteria established for the neuronal counts. It is concluded that SCG neurons from adult rats are less dependent on NGF for survival and maintenance than those from perinatal rats.

244.19 DEVELOPMENT OF OPIATE RECEPTORS ON RAT DORSAL ROOT GANGLIA IN TISSUE CULTURE: ROLE OF GLIAL CELLS. Samir F. Atweh and Riley Yu. Department of Neurology, University of Chicago, Chicago, IL 60637.

Opiate receptors are known to develop with time both in brains of fetal and new born rats (Coyle and Pert; Neuropharmacology 15: 555, 1976) and in Neuroblastoma x Glioma hybrid (NG) cells in tissue culture (Atweh; Soc. Neurosci. Abst. 7: 433, 1981). In the NG cells we previously demonstrated that a secreted factor, that is probably derived from glial cells, stimulates the formation and/or expression of opiate receptors (Atweh and Arnason; Soc. Neurosci. Abst. 8:187, 1982). In this study we show that opiate receptors develop on isolated rat dorsal root garglia (DRG) in vitro, and that non-neuronal supportive cells are important for the development of the receptors.

DRG's were carefully dissected from the cervical region of 17 day old embryos of Haltzman albino rats. One or two DRG's were explanted on a 22mm round coverglass coated with 50µl reconstituted rat-tail collagen and maintained in culture medium consisting of Eagle's minimal essential medium, human placental cord serum and chicken embryo extract. The medium was supplemented with glucose and glutamine and the cultures were maintained for 2-8weeks in a CO_2 incubator with 95% humidity. Some cultures were treated with 5-flourodeoxyuridine (10^{-5}M) for 48hrs. followed with cytosine arabinoside (10^{-5}M) for 48hrs. to control proliferating non-neuronal cells. This treatment was initiated one week after explantation and was repeated twice. At various intervals after explantation the attached DRG's were washed two times with physiological saline and incubated with ^{3}H-Etorphine (1nM,35Ci/mm) in 150mM-Tris buffer at room temperature. The slides were then washed twice in ice-cold buffer. The DRG's were then scraped off the slide, digested with tissue solubilizer and counted for radioactivity. Non-specific binding was determined in the presence of excess Naloxone (10^{-4}M) in the incubating buffer.

Specific etorphine binding (approximately 50% of total binding) occurred only on growing DRG's, and not on the collagen coating. Specific binding per mg DRG protein was negligible 2 days after explanation but gradually increased up to 4weeks in culture and was maintained up to 8weeks. The treated ganglia showed normal neuronal outgrowths, but they lacked supportive cells and there was no myelination. In these ganglia there was 84% and 79% reduction in etorphine binding at 4weeks and 8weeks, respectively, as compared to untreated ganglia. This system might be useful in studying some of the factors that regulate the expression of opiate receptors.

MORPHOGENESIS AND PATTERN FORMATION

245.1 EFFECTS OF NEURAL CREST DELETIONS ON THE SEGMENTAL PATTERN OF SKIN SENSORY INNERVATION IN EMBRYONIC CHICK HINDLIMB. S. A. Scott. Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY 11794.

Studies of normal development have shown that the segmental pattern of skin sensory innervation in the chick hindlimb is established in a precise, orderly manner (Honig, J. Physiol. 1982; Scott, J. Physiol. 1982), but have revealed little about the mechanisms that determine the axonal projection pathways and the location and size of dermatomes. To test whether competition among DRG axons plays a role in the development of skin innervation patterns, the DRGs that innervate skin on the anterior thigh and shank (T7-LS1) or on the distal shank and foot (LS4-6) were deleted by removing the parent neural crest region in St15-17 embryos, and the dermatomes and/or axonal projections of the remaining DRGs were mapped at St27-41.

In "mature" St37-41 embryos dermatomes of the remaining DRGs had expanded into denervated skin regions, partly but not completely replacing the lost innervation; the extent of the enlargement depended on the amount of skin denervated. Enlarged dermatomes were observed in embryos as young as St30, soon after skin innervation is established, indicating that axons ignored their usual dermatome borders, and grew without detectable delay into inappropriate, denervated skin regions.

Axonal projections were mapped physiologically in mature embryos, and with HRP injections in St27-30 embryos. In both groups the cutaneous nerves usually supplied by the deleted DRGs were missing, and axons from intact DRGs were seldom found in aberrant pathways. In the mature embryos, however, the distribution of DRG axons within their usual pathways was altered, projections from distant DRGs being larger than normal in the pathways near those of the deleted DRGs . These changes in axonal projections were apparently made at the expense of the intact DRGs' other projections, which occasionally were reduced in size or missing, as if all skin sensory axons shifted their projections into pathways near the deleted ones. Such altered projection patterns were seen in embryos as young as St27-30, before the bulk of cell death, and thus reflect a change in the initial outgrowth of axons. These changes in the relative distribution of axons may have been further enhanced in mature embryos by the selective rescue from cell death of neurons that innervated the denervated skin regions.

Together these results suggest that during normal development competition among ingrowing axons may be important in establishing both the borders between dermatomes, as well as the distribution of DRG axons among their projection pathways. (Supported by NIH grant NS16067 and an Alfred P. Sloan Foundation Fellowship).

245.2 DEVELOPMENT OF SUPRASPINAL INPUT INTO THE TAIL SPINAL CORD OF XENOPUS. R. H. Nordlander and T. J. Ryba*. Dept. Oral Biology, Case Western Reserve University, Cleveland, OH 44106

The earliest descending axons in the developing tail spinal cord of Xenopus are of local origin (Nordlander, R.H. Soc. Neurosci. Abst. 8: 635, 1982). The cell bodies belonging to these axons were identified using horseradish peroxidase (HRP) applied to the tail spinal cord near its tip. Following application to more rostral levels of the tail cord, HRP also appears in supraspinal neurons. It is these cells and the time course of the entry of their axons into the tail which will be described here.

Recrystalized HRP was applied to the spinal cords of Xenopus of stages 32-48 at the level of the 17th myotome. After 5 to 48 hr. of incubation, specimens were fixed, reacted according to the method of Hanker, et al. (Histochem. J., 9: 789, 1977), and processed for light microscopic viewing as wholemounts, vibratome sections or 5 µ plastic sections in transverse or horizontal planes.

Labeled axons appeared in two major fascicle groups extending from the application site to the brain. One, dorsolateral in the spinal cord, fans laterally upon entering the brain continuing rostrally as far as the cerebellum. It contains ascending processes of the Rohon-Beard cells of the spinal cord. The second group of labeled fascicles is located ventrolaterally in the spinal cord and continues ventrally in the brainstem. It is into these bundles that the earliest descending brain neurons feed their axons.

Early brain cells labeling under these conditions include reticular, raphe, and vestibular cells in the hindbrain and a cluster of mesencephalic neurons. Most prominent and earliest of the reticular neurons to appear are the paired Mauthner cells which first label at stage 37 and consistently thereafter. Other hindbrain reticular cells are added gradually over the period of this study. They are grouped in three clusters probably corresponding to the rostral, middle and caudal groups described in larval zebrafish (Kimmel, C.B., et al, J. Comp. Neurol., 205: 112, 1982) and the nuclei reticularis superior, medius, and inferior of older Xenopus tadpoles (ten Donkelaar, H.J. and R. de Boer-van Huizen, Anat. Embryol., 163: 461, 1982). In early Xenopus larvae the caudal (inferior) group is the most conspicuous. Medial to these cells and appearing at stage 40 are the raphe neurons. Vestibular cells (ventral nucleus of VIII) are arranged in a column along the dorsolateral fascicle of Rohon-Beard axons. The first of these to label, at stage 39, are those closest to the Mauthner cells. Labeled cells in the mesencephalon are located ventromedially near the junction of mid- and hindbrains and are considered to belong to the nucleus of the medial longitudinal fasciculus.

245.3 CHANGES IN CELL SHAPES DURING BENDING OF THE FUTURE BRAIN REGION OF THE AVIAN NEURAL PLATE. G.C. Schoenwolf and M.V. Franks*. Dept. of Anatomy, Univ. of Utah Sch. of Med., Salt Lake City, UT 84132.

It is widely believed that changes in cell shapes play an important role in the bending or folding of epithelial sheets. However, few studies have actually examined cell shapes in bending epithelial sheets. We have examined neuroepithelial cell shapes during bending of the neural plate at two craniocaudal levels of the future brain (mesencephalon and rhombencephalon) in stage 4-9 chick embryos. During elevation of the neural folds, bending of the neural plate is restricted to the midline, supranotochordal area of the neural plate. Likewise, bending is restricted to paired dorsolateral areas of the plate during convergence of the neural folds. In the future mesencephalon, the neural plate was subdivided into a supranotochordal area and paired lateral areas to examine cell shapes during elevation of the neural folds. In the future rhombencephalon, each lateral area of the plate was further subdivided into dorsolateral and intermediate areas to examine cell shapes during convergence of the neural folds (the dorsolateral area contains a well-defined locus of bending during convergence of the neural folds, whereas the intermediate area is located between the supranotochordal and the dorsolateral areas of bending). Neuroepithelial cells in all areas of the neural plate had four characteristic shapes: flask like (tapering apically), inverted flask like (tapering basally), sphere like (cells in the M phase of the mitotic cycle) and spindle like (tapering both apically and basally). The percentages of sphere-like and inverted flask-like cells remained statistically unchanged during bending of the neural plate. In contrast, the percentages of spindle-like and flask-like cells changed markedly in certain areas of the plate as follows. In the supranotochordal region of the future mesencephalon, spindle-like cells decreased sharply during elevation (from 69 to 28%), while flask-like cells increased (from 27 to 70%). Only slight changes occurred laterally (spindle-like cells decreased from 69 to 66%, while flask-like cells increased from 24 to 26%). In the dorsolateral region of the rhombencephalon, 57% of the neuroepithelial cells were flask like during convergence of the neural folds, while 39% of the cells were spindle like. In the intermediate area of the rhombencephalon, 34% of the cells were flask like and 61% were spindle like. These results demonstrate that many of the cells that are restricted to loci of bending during elevation and convergence of the neural folds become wedge shaped, whereas little change in cell shapes occurs in adjacent areas of the neuroepithelium. Whether these changes in cell shapes constitute a driving force for bending of the neural plate remains to be investigated. Supported by NIH grants nos. HD 15231 and NS 18112.

245.4 SOMA POSITION CORRELATES WITH TIME OF DEVELOPMENT IN TWO GROUPS OF IDENTIFIED NEURON TYPES OF THE LARVAL ZEBRAFISH (Brachydanio rerio). B. Mendelson* (SPON: D. P. Kimble). Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

Five types of identified reticulospinal neurons were studied in Brachydanio rerio in order to learn how particular morphological features may be correlated with time of development. These cells fall into two broad groups based on their morphology (Kimmel, C.B. et al., J. Comp. Neurol., 205:112, 1982). The first group includes the Mauthner neurons plus the MiD1 and MiD2 cell types. These neurons all have large somata located dorsally in the hindbrain reticular formation and axons which decussate to descend in the contralateral dorsal medial longitudinal fascicle (mlf). The second group includes the MiV1 and MiV2 cells. These hindbrain reticular neurons all have ventrally located somata and axons which descend in the ipsilateral ventral mlf. I proposed that the morphological differences observed between these two groups of cells are in part due to differences in the times of development of these identified neurons.

The time of origin of these neurons was determined by injecting ^{3}H-thymidine into the embryo. Neurons of the dorsal group were seen to change from 100% labeled to 0% labeled after injection between 7 and 12.5 hrs after fertilization. The ventral group of cells were always found to be labeled at the injection times so far tested (through 13 hrs post-fertilization). This shows that the birthday of the dorsal cells is earlier than that of the ventral cells.

The temporal order of axon outgrowth displayed by these cells was also studied, by finding the earliest developmental times that the neurons could be retrogradely filled with HRP from a lesion located about 200 μm caudal to their somata. The dorsal cells could be first labeled with HRP 20 hrs after fertilization while the ventral cells were first labeled 12 hrs later. If these different reticulospinal axons elongate at the same rate, then the dorsal cells initiate axon outgrowth before those of the ventral cells.

The differences in morphology displayed by the two groups of reticulospinal cells are correlated with differences in times of development of these neurons. Reticulospinal cells with dorsally located somata and axons which decussate leave the cell cycle and initiate axon outgrowth before reticulospinal neurons which display ventral somatic position and ipsilaterally projecting axons. The observed temporal order of developmental events may, in part, specify the somatic positions and modes of axonal projection. (Supported by NIH grant NS 17963 and #5 T32 GM07257-07.)

245.5 MORPHOLOGY AND DEVELOPMENT OF MOTONEURONS IN THE ZEBRAFISH SPINAL CORD. P.Z. Myers* (SPON: C. B. Kimmel). Inst. of Neuroscience, Univ. of Oregon, Eugene, OR 97403.

HRP injections into the axial muscles of the larval zebrafish have revealed two distinct classes of spinal motoneurons. The development of these two neuronal types, primary and secondary motoneurons, has been followed with both the light and electron microscope in order to explore the temporal relationships between their differentiation and the growth of the Mauthner axon into the spinal cord.

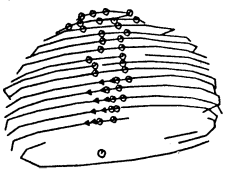
The primary motoneurons are large, distinctive cells situated laterally in the cord. They have thick, tapered ventral neurites which always pass medially and adjacent to the Mauthner axon, from which they receive a synapse before they exit the cord at the ventral root. Secondary motoneurons are much smaller cells which lie in a ventrolateral column. Their peripheral process always passes laterally and without any consistent association or apparent synapse with the Mauthner axon before entering the ventral root. I have hypothesized that the timing of development in the spinal cord may play a role in defining the primary motoneurons as the Mauthner axon's specific target.

Primary motoneurons in a given segment can be labelled from a peripheral lesion three hours before the Mauthner axon growth cone has reached that segment. I have not been able to label secondary motor neurons, however, until three or four hours after the Mauthner axon has grown by. New neurites appear to be added to the growing spinal cord laterally, and the relative positions of the axons of the primary and secondary motoneurons and the Mauthner axon also imply that they were added in the order primary motoneuron : Mauthner axon : secondary motoneuron.

These data indicate that there is a precise sequence of neurite growth in the spinal cord. I suggest that the Mauthner axon selects the primary motoneurons as its targets because they, specifically, have developed neurites which could serve as targets for synaptogenesis by the time they are contacted by the Mauthner growth cone. (Supported by NIH grant NS17963.)

245.6 COMPUTER AIDED RECONSTRUCTION USED TO VISUALIZE THE 3-D SHAPE OF CHIMERIC XENOPUS EYES. G.B. Stock*, K. Conway, and R.K. Hunt*. Jenkins Dept. Biophysics, The Johns Hopkins Univ., Balt. MD 21218.

When minute eyebud grafts are exchanged between normal and albino embryos, chimeric froglets with sectors of marked eye tissue develop. Analysis of the shapes of such regions provides detailed information about the growth of the eye and was accomplished both by photography of live, anesthetized froglets and by careful examination of histological sections of preserved eyetissue. Using a camera lucida attachment to a compound microscope, tracings were made from sections to obtain the contours of the pigment retinal epithelium (PRE), and also contours of selected extraocular landmarks, which were used to align and orient consecutively traced sections. Contours of marked PRE were also traced and identified. These contours were then converted to a sequence of representative cartesian coordinates using a digitizing tablet connected to an IBM 4341 via a CRT terminal. A Fortran program managed the data input so as to associate with each contour record an identifier of tissue type and a section number. This information, coupled with the section thickness and a magnification factor from the tracing optics, provides an accurate representation of the 3-D geometry of marked tissue in the eye and is readily manipulated during analysis. The data for each eye was stored on disk and archived on tape in a suitably labelled file. Eye features were visualized by interacting with a sophisticated Fortran program that created perspective images of the eye from any desired viewing angle. Additional manipulation was possible by viewing particular tissue types, changing the scale, creating stereo viewing pairs, and controlling the display of hidden lines. Displays could be routed to a variety of output devices, including the CRT, Tektronics CRT, Calcomp plotter, or a daisy wheel printer. The Fortran programs are easy to use and are available on request. The plotted images employed a variety of graphic symbols to highlight pigmented and non-pigmented regions of tissue. To ensure that no gross distortion had occurred as a result of the analytical procedures employed, a number of these images were compared to corresponding photos taken prior to fixation. This 3-D reconstruction technique is quite flexible yet inexpensive, is clearly useful in analyzing anatomical features, and is currently being applied to other systems, such as peptidergic neurons in the hypothalamus, and regions of cell death and damage in lesioned spinal cords. Also, once an eye is digitized, further numerical analysis of its geometry is feasible. We thank NIH (GM-07231, NS-14807), NSF (PCM 77-26987), and the Dean's computing fund at Johns Hopkins.



245.7 CLONAL GROWTH PATTERNS IN GENETICALLY CHIMERIC EYES OF XENOPUS. J.S. Cohen* and R.K. Hunt* (SPON: W.M. Cowan) Biophysics Dept., Johns Hopkins Univ., Baltimore, MD 21218, and The Salk Institute, P.O. Box 85800, San Diego, CA 92138.

The frog eye is an attractive model system for studies of clonal growth in organogenesis. A germinal ring, interposed between the retinal epithelia and iris, adds annuli of new cells to the margin of the pigment epithelium (PRE) and neural retina, such that the oldest cells lie at the back of the eye and the youngest at the front. Moreover, a ventral-to-dorsal gradient in cell accretion rates is demonstrable by ^{3}H-thymidine autoradiography, from metamorphic climax (Jacobson, Brain Res. 103:541, 1976). When small wedges of eye rudiment are surgically introduced from wild-type (or l-nu or 4n) pigmented donor embryos into albino (albP/albP) host anlagen (at stages 30-34), the marked wedge: (i) heals to form a sector of marked cells in the PRE, neural retina and iris of the early larval eye; (ii) the sector elongates radially during larval growth, by the addition of marked cells to its distal end, and (iii) can be analyzed for variations in sector shape, fine cell patterns at graft/host sector boundaries, and fluctuations in growth over later larval stages (Conway et al., 1980, Curr. Tops. Develop. Biol. 15:217). We have serially photographed the developing black/white sector pattern in 60 chimeric larvae, bearing wedge-grafts at dorsal or at the abutting posterior and anterior regions of the anlage - examining the relative decline in cell accretion rates at the dorsum of the metamorphosing eye. Sector patterns were stable during metamorphosis, save for new tissue added to the distal end of the sector, indicating that PRE cells do not move with respect to one another. New growth declined dorsally; marked dorsal sectors often tapered into single cell files; abutting posterior and anterior stem cells and iris veered dorsally, and began to make 'replacement' cell files for the attenuating dorsal files, which maintain continuity of the PRE cell sheet. Serial photography of elongating cell files permitted direct quantitation of mitotic rate and cell death. Mitotic rates varied up to 5-fold between individual cell files in a single eye, and significant variations occasionally occurred within a single growing file over time. Cell deaths were very rare but were easily visualized, and black cell debris was cleared gradually over several days. Although separate lineages for iris, PRE and neural retina are founded in the early larva (Conway et al., op cit.), the replacement cell files in dorsal PRE at metamorphosis arose in association with thin, radial iris fibers. These iris fibers may undergo metaplastic transformation from iris into PRE (Eguchi, 1975, Ciba Symp. 40, 241) or provide 'guidewires' for covert PRE stem cells, and are under study in TEM. Their role may also be more general: split sectors in anterior PRE also showed cell files associated with iris fibers; 4n/albino chimerae showed cell files in neural retina, strikingly similar in form to those in PRE, and continuous with the inner amelanotic layer of the iris.

Supported by NIH Grant GM-07231 and NSF PCM79-03827.

245.8 PARSIMONIOUS REPRESENTATION OF INFORMATION IN LAYERED NEURAL SYSTEMS. R. B. Glassman. Dept. of Psychology, Lake Forest College, Lake Forest, IL 60045.

Modelers must think not only about hypothetical neural networks that can do the behavioral job but about ones that can plausibly be thought to have evolved by small steps, each adaptive, but each random with respect to the cumulative outcome (Darwin, 1859). A corollary of this basic rule is that organisms likely have evolved fairly parsimonious, "cost-efficient" neural facilities for storing information.

Although the ideas of stages of information processing and layered or hierarchial structures have been considered extensively in the literatures of cognitive psychology and artificial intelligence, to my knowledge the point has not yet been made that a certain form of such structuring fits the above corollary. While the connections between levels of a functionally layered neural structure provide instances of organized products of evolution, this form of organization permits an "inexpensive," low degree of ordered complexity within levels. Indeed, the basic task of organizing inputs and outputs in a layered system can be accomplished by subsystems, within each of which the rule of association is simply synaptic spatial summation. To see this, consider a neural model of the cat's ability to orient its face toward a tactile stimulus at any point on the body.

As previously argued, somesthetic spatial orientation might rest equally well on a nonlayered neural foundation of all possible connections between all discriminable areas on the skin (say there are s) and all muscle groups (say there are r), for a total number sr of spatially summating connections. However, a single interposed associative layer, having three subsystems representing the vertical, horizontal, and anterior-posterior dimensions, could accomplish the same task with only 3s+3r spatially summating connections (1982 Abstract 272.13; Physiological Psychology, 1983).

It remains to note that this model is potentially a general one that may be used to describe any three successive layers of input-association-output in a multilevel system. One proviso is that a multitude of input-output relations must lend themselves to categorization according to a relatively few "dimensions," in such a way that each input-output relation is determined by a unique distribution of excitations of the subsystems in the associative layer.

Fine tuning of such systems, which would take the form of adjusting excitatory strengths of the various connections, must take place during ontogeny. Such fine adjustment of "biases" in earlier-developing subsystems must be a prerequisite for the organization of later-developing associative layers (Glassman & Wimsatt in Almli & Finger, Eds., The behavioral biology of early brain damage, in preparation, Academic Press).

245.9 INTRACEREBRAL GRAFTS OF DISSOCIATED CEREBELLAR TISSUE FORM TRILAMINAR CORTICAL STRUCTURES. R.H. Schmidt and R.K. Bhatnagar. Dept. Pharmacolgy, University of Iowa, Iowa City, IA 52242.

A new approach to intracerebral neuron transplantation has recently been described which is based on the stereotaxic injection of fluid suspensions of embryonic donor neurons (Schmidt et al. Brain Res. 218: 347). Because this technique involves the total trypsin dissociation of donor tissues, it was of interest to a) relate the survival of specific neuron types in the grafts to the variable of donor age, and b) study the architecture of the resultant grafts. Cerebellar tissue grafts were ideally suited for such a study.

Suspension grafts were prepared from donor rats ranging in age from embryonic day (ED) 15 to postnatal day 5, and injected into the forebrain of adult hosts. At survival times up to 7 months host brains were processed for cresyl violet and silver fiber staining. Purkinje cells (PC) were clearly discernable in grafts from ED 15-18 (14-30 mm CRL) donors and granule cells (GC) in grafts from all donor ages. Based on the normal proliferative periods for these neuron types it appears that PC do not survive the dissociation if taken more than 48 hours postmitotically. On the other hand the results with GCs show that neuroblasts do survive the dissociation and can proliferate within the adult host for a period of time.

Grafts from ED 16 donors injected into the parenchyma of the cerebral cortex did not develop any architectural organization. However, if the grafts were deposited onto a surface structure, such as the ventricular surface of the hippocampus, the grafted neurons organized into aggregates containing distinctly trilaminar architecture typical of the cerebellar cortex. PCs generally became aligned into monolayers between a cell-sparse molecular layer on the outer surface of the graft and an inner zone of densely aggregated GCs. Typically the width of the molecular layer was equivalent to the width of the GC layer, and in some grafts these zones exceeded 60 μ in thickness. Fiber staining showed that every PC was heavily invested with a basket-cell-like axonal plexus typical of the normal cerebellum. Details of the dendritic and fiber architecture in the molecular layer were not revealed. At survival times of 14-20 days post-transplantation the architecture was typical of the developing postnatal cerebellum with an apparent external granule cell layer, thin molecular and internal GC layers, small PC diameters and a sparse basket cell plexus. The architecture suggests that development within these grafts recapitulates the normal ontogeny of the postnatal cerebellum, with GCs migrating from an external proliferative zone into the internal granular layer. These grafts thus represent a novel model system with which to define the mechanisms of these developmental events. (GM-22365)

245.10 MORPHOLOGY OF SUBSTANTIA NIGRA NEURONS TRANSPLANTED INTO THE LATERAL VENTRICLE OF THE RAT: A GOLGI STUDY. B. Hoffer*, S. Wood*, W. Freed, R. Wyatt and G. Rose*. VMAC, Denver, CO and NIMH, St. Elizabeth's Hospital, Washington, D.C.

Transplantation of fetal substantia nigra into either the lateral ventricle adjacent to, or in a cavity created in the cortex overlying, a dopamine-denervated caudate will reduce or eliminate behavioral deficits caused by the denervation. As an initial step toward determining how this process occurs, we chose to examine the morphology of the transplanted neurons. The anlage of the substantia nigra was obtained from fetal donors, suspended in 10 μl of artificial CSF, and immediately injected into the lateral ventricle of adult (90-150 day old) host rats. Four months prior to transplantation half of the host animals had received a unilateral 6-OHDA lesion of the substantia nigra. Five months after transplantation all animals were sacrificed and the brains processed using the Golgi-Cox method of Van der Loos. Both neuronal and non-neuronal cells were impregnated in the transplants. The neurons could be roughly divided into three groups, based upon cell body size. Small cells (diameter <20μ) had mostly rounded somata, thin dendrites, usually with varicosities and lacking spines, and a generally stellate appearance. Medium cells (diameter 20-36μ) had somata that were either round or ovoid, although occasionally pyramidal or fusiform cell bodies were observed. These cells tended to have a bipolar orientation, with long dendrites having few branches. These dendrites were either spiny or varicose; only rarely were varicosities with spines observed. Large cells (diameter >40μ) had ovoid, fusiform or pyramidal somata, and thick dendrites lacking varicosities or spines except at their extremities. Small cells comprised approximately 11% of the neurons seen, medium cells 72% and large cells 17%. The three cell groups observed have good correspondence to those described for the in situ substantia nigra. However, in other respects the substantia nigra transplants differed from their in situ counterparts. No regional organization was apparent in the transplants; neither was any obvious dendritic orientation observed. In addition, dendritic varicosities were very often seen, perhaps indicating incomplete maturation of the transplanted neurons. Placement of the transplant adjacent to a dopamine-denervated caudate nucleus did not seem to promote either dendritic differentiation or outgrowth. In summary, neurons in transplants of fetal substantia nigra placed in the lateral ventricle of adult rats grow and differentiate into cells morphologically similar to their in situ counterparts. This process apparently does not require the presence of normal afferents to the structure.

245.11 A QUALITATIVE AND QUANTITATIVE STUDY OF MYELINATED AXONS AND GLIAL CELLS IN THE DEVELOPING MOUSE SPINAL CORD. J.C.Zagoren*, H.Nagara* and K.Suzuki. Depts. of Neuroscience and Pathology, Albert Einstein College of Medicine, Bronx, N.Y.10461. Glial and myelin development has been analyzed in dorsal and ventral tracts of mouse spinal cord during the first month of post-natal life. C57Bl mice at 1,3,5,6,7,8,9,13,16,18,24,and 30 days of age were prepared for microscopy by fixation, either immersion or perfusion, in 2.5% glutaraldehyde. Cross sections of cervical (C1-3 and C6-8), thoracic (T4-6) and lumbar (L2-3) cord were obtained from 45 animals. Glial cells were identified by comparing light microscope (LM) and electron microscope (EM) images in successive serial sections. Discrimination between glial cells was difficult, since cells with features of oligodendrocytes sometimes contained filaments typical of astrocytes upon EM examination. Total glial cells were counted at each timepoint and spinal level and found to increase as a function of tract, level and time. A three way analysis of variance was performed to ascertain the degree of significance in the numbers of glial cells and myelinated axons in a rostral to caudal direction, in a dorsal to ventral direction and a difference in numbers with age. The results showed no rostral to caudal difference in either the ventral or dorsal tracts but did show a change with age and an interaction between the dorsal and ventral tracts with days in the cervical, thoracic and lumbar tracts. Numbers of glial cells increased prior to myelinogenesis and decreased following myelin completion. Formation of myelin lamellae was first observed in the lumbar ventral tract at day 1. By day 3, only the lumbar dorsal area remained unmyelinated. At day 5 there was a 65-fold mean increase in myelinated axons and by day 9 mature nodes of Ranvier were seen. In summary, these data show that post-natal changes in glial number and pattern of myelination vary in individual tracts and levels of the spinal cord. The conventional idea that myelination proceeds evenly from caudal to rostral regions therefore may require further qualification.

245.12 A NEUROANATOMICAL CORRELATE OF SCHIZOPHRENIA. J.A. Kovelman and A.B. Scheibel, M.D. Dept. of Anatomy, UCLA Sch. of Med., Los Angeles, CA 90024.

We report a structural anomaly of hippocampal pyramidal cell alignment in the left hippocampi of ten chronic schizophrenics compared with eight age-matched, non-psychotic controls. Under blind conditions, three stations along Ammon's Horn were studied; the interfaces between CA1 and prosubiculum, CA1 and CA2, and CA2 and CA3. These positions were examined at three longitudinal loci: anterior, middle and posterior hippocampus. In order to quantify the cytoarchitectonic disorganization which was found, the angles of orientation of 120 pyramidal cells in each block of Nissl-stained tissue were measured against an ideal axis of reference drawn perpendicular to the ventricular surface at that point. Abnormally positioned pyramidal cells were observed in chronic schizophrenics with some rotated as much as 90° from the expected alignment, whereas neurons from controls showed significantly smaller amounts of deviation. Our results, limited so far to the left hemisphere, indicate that the chronic schizophrenic hippocampus has a significantly greater degree of pyramidal cell disorientation than controls at all three CA interfaces when the longitudinal axis is ignored. The effects of cell disarray are more striking in middle hippocampus and when values from anterior-middle hippocampal tissue are combined. No significant difference was found for any CA locus in posterior hippocampus. Note that abnormal electrical activity previously reported from deep temporal lobe stations in schizophrenic patients is found only in anterior and middle positions.

Studies of normal hippocampal development as well as those of several genetic mutants support our assumption that such cell disarray may occur during prenatal development when neuroblasts migrate and align themselves in primordial hippocampus. The findings of enhanced cell disarray in middle and anterior-mid hippocampus, but not posterior hippocampus are consistent with the concept that different parts of the hippocampus subserve different functions. Since deviations of smaller degree are also found in some non-psychotic patients, the study suggests a histopathological continuum related to behavior and character structure, from the borderline individual to the intractable, long-term psychotic.

245.13 CENTRAL TRIGEMINAL REPRESENTATIONS IN GUINEA PIGS DEPRIVED OF NERVE GROWTH FACTOR (NGF) IN UTERO. L. Sikich*, T.A. Woolsey & E.M. Johnson. Depts. of Anatomy & Neurobiology, & Pharmacology and McDonnell Center for Studies of Higher Brain Function, Washington Univ. Sch. Med., St. Louis, MO 63110.

In some rodents, somatotopically organized patterns corresponding precisely to the arrangement of the vibrissae are found at each level of the central trigeminal projections. In mice, the size of these representations is proportional to the peripheral innervation density (Lee & Woolsey, 1975). If groups of vibrissae are completely denervated during a defined critical period, their corresponding central representations are severely attenuated. We have studied animals in which all vibrissae were largely deafferented before birth.

Guinea pigs were exposed to maternal antibodies to NGF during the latter part of gestation. Newborn animals having high titers of the antibody were completely unresponsive to noxious stimuli. In affected animals, the infraorbital nerve was markedly smaller than that of normal animals and there were less than 20% the normal number of trigeminal ganglion neurons. Serial 50-µm sections tangential to the SmI cortex and transverse to the brainstem were stained for the mitochondrial enzyme, succinic dehydrogenase, in order to demonstrate the central vibrissae projection patterns. The representations in the spinal trigeminal nucleus and in the cortex were drawn using a camera lucida. Cross-sectional areas of the spinal trigeminal and cortical drawings of severely affected animals and normal animals were measured with an electronic tablet. The volume of the spinal trigeminal representation was calculated also. In spite of severe deficits in sensory function and neuron number, there were no significant differences in the sizes of the representations of the entire vibrissal field or individual vibrissal rows in either the spinal trigeminal nucleus or the cortex of severely affected animals as compared to normals. We conclude that in the guinea pig the total number of peripheral nerve fibers in prenatal life does not determine either the pattern or the size of the central representation of the vibrissae. (Supported by NIH grant NS 17763 and NS 18071, and the McKnight Foundation.)

245.15 **PRENATAL DEVELOPMENT OF THE NUCLEUS BASALIS /MEYNERT/ AND RELATED FIBER SYSTEMS IN MAN,** **I. Kostović, Section of Neuroanatomy, Department of Anatomy, Faculty of Medicine, University of Zagreb, 41001 Zagreb, Yugoslavia.**

Recent studies /Mesulam et al., JCN,214:170,1983/ suggest that large acetycholinesterase /AChE/ reactive neurons in the nucleus basalis /NB/ provide the single major source of cholinergic innervation for the cerebral cortex in the monkey. Evidence indicates a comparable cholinergic innervation of the human cortex: cell death which occurs in the NB in Alzheimer's disease results in a loss of cortical cholinergic markers. In order to provide new parameters for cholinergic innervation of the human fetal telencephalon we have analyzed the prenatal development of the histochemical reactivity in the NB. Brains from fetuses and premature infants ranging between 8 to 30 weeks of gestation /w./ were frozen cut and processed by thiocholine method for demonstration of AChE activity. The first sign of the histochemical differentiation of the basal telencephalon is the appearance of dark, AChE reactive "spot" situated between the anlage of the lenticular nucleus and the basal surface in a 9 weeks old fetus. The first AChE reactive bundle connects this area /nucleus basalis area-NBA/ with strongly reactive fiber system situated along the dorsal side of the optic tract. During the next stage /10,5 w./ there is significant increase in the size and reactivity of the NBA. At this stage we have seen AChE reactive bundle approaching /but not penetrating/ neocortical anlage through the external capsule. The supraoptic fiber system can be traced to the pregeniculate area and tegmentum. At 15 w. first AChE reactive perikarya appear and NBA become seggregated into several strongly reactive territories corresponding in position to the cell aggregations seen in Nissl preparations. At this stage NBA fibers from external capsule radiation enter "white" matter of the developing neocortex. In the next stage /18-22 w./ external capsule radiation penetrates transient subplate layer of the frontal, temporal and occipital lobe. In addition, strongly reactive fibers can be traced from NB to the subcortical structures: amygdaloid, caudate and mediodorsal thalamic nucleus. Between 22-28 w. there is significant increase in the number of large, strongly reactive neuronal perikarya in all divisions of NB: rostral, intermediate and caudal. In conclusion, NB develops earliest AChE activity in the telencephalon and sends fibers to the cortical anlage by the end of second trimester of gestation. These findings suggest that NB may be involved in early innervation of the cerebral cortex and developmental interaction with other growing afferents. **Supported by U.S.-Yugosl. Joint B. /I.K./**

245.16 IMMUNOCYTOCHEMICAL LOCALIZATION OF TUBULIN AND THE HIGH MOLECULAR WEIGHT MICROTUBULE-ASSOCIATED PROTEINS MAP1 AND MAP2 IN HIPPOCAMPAL NEURONS WHICH DEVELOP IN CULTURE. A. Caceres*, G. Banker, L. Binder*, and O. Steward. Department of Anatomy, Albany Medical College, Albany, New York 12208 and Departments of Neurosurgery and Biology, University of Virginia, Charlottesville, Virginia 22908.

Immunocytochemistry with monoclonal antibodies was used to study the distribution and development of β-tubulin, MAP1, and MAP2 in hippocampal cell cultures prepared from the brains of fetal rats. The binding specificity of each of the antibodies was determined by ELISA assays and cross reactivity to other proteins was assessed by staining immunoblots of extracts of whole hippocampus. In all cases the antibodies reacted only with their corresponding antigens.

After 2 weeks in culture, hippocampal neurons have elaborate processes which can be identified morphologically as dendrites and axons. Immunoreactivity for β-tubulin and MAP1 was found on both types of processes, as well as in the neuronal cell soma and in glial cells. In contrast MAP2 was only found in neurons, and within these cells was preferentially localized in dendritic processes. This pattern of labeling was the same for uninnervated, completely isolated cells in low density cultures as for cells in dense cultures, which receive heavy synaptic input. Hence this aspect of the molecular differentiation of the dendritic cytoskeleton occurs independently of innervation and despite the disruption of the normal temporal and spatial pattern of outgrowth which occurs in culture. It is likely that the three proteins analyzed in the present study are largely polymerized within the cytoskeletal network, since identical staining patterns were seen in Triton X-100 extracted cells (cytoskeletal preparations).

All three proteins were already present in cells at the time of plating. During the initial period of neuritic outgrowth (24-48 hrs after plating) all of the processes that emerged from the cells were equally immunoreactive for β-tubulin, MAP1, and MAP2. A gradual decrease in the immunostaining for MAP2 in the axonal processes was increasingly evident between 2 and 4 days after plating. By 7 days MAP2 staining had essentially disappeared from the axons, but remained present in the cell body and dendrites.

These results demonstrate that neurons in culture are capable of restricting MAP2 to dendrites, as they do in vivo. However, because MAP2 is initially present in both axons and dendrites, it seems unlikely that this protein plays a specific role in the early stages of dendritic development.

245.17 IMMUNOHISTOCHEMICAL LOCALIZATION OF TUBULIN AND THE HIGH MOLECULAR WEIGHT MICROTUBULE-ASSOCIATED PROTEINS (MAP1 & MAP2) IN THE DEVELOPING CEREBELLUM OF THE RAT. A.Frankfurter,A.Caceres, L.I.Binder* and L.I.Rebhun*. Depts. of Neurological Surgery and Biology, University of Virginia, Charlottesville, VA 22908

We have demonstrated that the electrophoretic migration pattern of the high molecular weight brain microtubule-associated protein, MAP2,changes during development(Binder et.al.,this meeting).In the cerebellum,this change is apparent at approximately 18 days postnatally.Based on this observation,and a recent report suggesting a developmental role for the differential localization of the high molecular weight microtubule-associated proteins (HMW MAPs) and tubulin in dendritic differentiation,we have used monoclonal antibodies specific for MAP2, MAP1,the other HMW MAP,and beta-tubulin as probes to compare the distribution of these proteins during cerebellar development and adulthood.At all ages studied,5,10,15,20 and 30 days,tubulin and MAP1 immunoreactivities are associated with neuronal cell bodies,dendrites and axons, as well as with glia.In contrast,MAP2 staining is always markedly more intense in dendrites than in axons,and does not appear to be associated with glia.Moreover,at equal antibody concentrations, MAP2 staining is qualitatively more intense in axons of developing cerebellum.At all ages examined,the three antigens are colocalized within the Purkinje cell dendrite.The present study, thus,suggests that the major differences in distribution of these three cytoskeletal proteins are: 1)the apparent absence of MAP2 in glia,2)the qualitatively more intense staining of dendrites with MAP2 when compared to axons,and 3)the qualitatively more intense staining of axons with MAP2 during early development.The disparity between the results of the present study and those reported by others appears to be due to technical considerations. Immunoreactivity of tubulin,MAP1,and MAP2 is differentially affected by both fixation conditions and washing schedules employed prior to and during the peroxidase-anti-peroxidase procedure.

In the present study,we have demonstrated that tubulin and the HMW MAPs are colocalized at all stages of dendritic development. The electrophoretic pattern change found for MAP2 at 18 days, therefore,cannot be the result of an abrupt appearance and colocalization of de novo tubulin with HMW MAPs. Any hypothesis regarding the role of the HMW MAPs in dendritic differentiation must account for their colocalization with tubulin.The developmental significance of MAP2 heterogeneity remains to be determined.

245.18 ELECTROPHORETIC HETEROGENEITY OF MAP2 DURING DEVELOPMENT IN THE RAT CENTRAL NERVOUS SYSTEM. L. I. Binder*, A. Frankfurter, A. Caceras, M. R. Payne* and L. I. Rebhun* (SPON: J. Greenlee). Depts. of Biology and Neurosurgery, Univ. of Virginia, Charlottesville, Va. 22901, and Dept. of Anatomy, New York Medical College, Valhalla, N. Y. 10595.

MAP2 is a high molecular weight (ca. 300,000 M.W.) microtubule-associated protein, largely neuronal in distribution, which co-purifies with brain tubulin in vitro and binds helically along the length of the microtubule in the process. Using high resolution polyacrylamide gels, MAP2 isolated from adult brains is electrophoretically heterogeneous consisting of 2 closely migrating polypeptides: a slower migrating species, MAP2a and a faster migrating species, MAP2b. Both of these polypeptides bind to microtubules and behave in solution as monomers. Three monoclonal antibodies directed against different epitopes on MAP2 have been isolated and characterized. All of these react with both MAP2a & MAP2b.

During development of the cerebellum and cerebral cortex, the electrophoretic pattern of MAP2 changes. At 10 days after birth, nitrocellulose blots of SDS extracts from either whole cerebral cortices or cerebella display only 1 MAP2 band when probed with any of the MAP2 monoclonal antibodies. Moreover, taxol stabilized microtubules made from these areas of the brain at this time also show only 1 MAP2 band copurifying with tubulin. Coelectrophoresis experiments indicate that the MAP2 species present in the 10 day animal is MAP2b. MAP2a, the slower migrating form appears at day 18 in both cerebral cortex and the cerebellum.

In addition to these experiments, SDS extracts of spinal cords were also assayed for their MAP2 complement. Adult spinal cords contain 3 immunoreactive species of MAP2: MAP2a, MAP2b and MAP2c, a minor polypeptide species which migrates somewhat slower than MAP2a on SDS-polyacrylamide gels. At 10 days after birth, the spinal cord, unlike the cerebral cortex or the cerebellum already contains its adult configuration of MAP2a, b & c. This demonstrates that the change in MAP2 occurs differentially in distinct regions of the central nervous system. Finer characterization of regional MAP2 heterogeneity is currently under study. Also, experiments are currently underway to determine the cause of this developmental alteration and to ascertain its effects on the interaction of MAP2 with microtubules.

Supported by NIH grant NS 17588 to A.F. and also by a grant from the Jeffress Memorial Trust to L.I.R.

245.19 MONOCLONAL ANTIBODIES THAT RECOGNIZE GRANULE CELLS OF RAT DENTATE GYRUS. Joseph R. Moskal*, (Spon.: A. Bruner). Lab. Cell Biology, NIMH, Bethesda, MD 20205.

Monoclonal antibodies were generated against dentate gyri from the left hemispheres of 5 day old rat brains. Hybridomas were made by the fusion of spleen cells with NS-1 myeloma cells. The identification of antibodies that bind to the hippocampus was performed with unfixed, fresh-frozen, coronal sections of rat brain using immunofluorescent methodology. Hybridomas secreting antibodies of interest were further subcloned twice at limiting dilution to insure monoclonality. In this way 11 monoclonal antibodies were generated that gave two types of staining patterns. Antibodies of type 1 bound distinctly to 5 day old rat dentate granule cells showing cell body (intracellular punctate) and plasma membrane fluorescence. No staining of neuronal processes was observed and granule-like cells outside the hippocampus also were distinguishable. The dentate granule cell layer also was stained in adult rats. This included both granule cell bodies, as above, and their processes. Moreover extrahippocampal cell staining was markedly reduced. Both 5 day old and adult rat cerebellar staining was similar to that observed above.Type 2 antibodies gave a diffuse, nonspecific binding pattern to 5 day old rat hippocampus but appeared to bind to extracellular material located specifically among dentate granule cells in the adult. Again, cerebellar binding of these antibodies was similar to that described above. It was also possible, by radioimmunoassay, to detect specific antibody binding to washed crude membrane pellets prepared from adult dentate gyrus. Thus monoclonal antibodies have been generated that bind to dentate gyrus granule cells of the rat hippocampus. The binding patterns of these antibodies change during development,probably reflecting changes in the organization of the dentate gyrus. These results further suggest that the antibodies identify antigens on the cell surface.

245.20 SCANNING ELECTRON MICROSCOPIC (SEM) INVESTIGATION OF THE ORIGIN OF SUPRAEPENDYMAL NEURONS (SEN). J. D. Decker*, D. E. Scott. (SPON: J. Dexter). Department of Anatomy, University of Missouri-Columbia, School of Medicine, Columbia, Mo. 65212.

Supraependymal cell populations of the vertebrate cerebral ventricular system consist of at least two cell types. One cell type has been identified as a phagocytic cell, (e.g., the Kolmar cells) which presumably are of mesodermal origin and gain entrance into the cerebral ventricular system via the vasculature of the brain. A second cell type has been identified by SEM and transmission electron microscopy as a supraependymal neuron. This latter type of cell appears on the ventricular ependymal surface, concentrated in the regions of the circumventricular organs. The origin of the SEN cell line has not yet been determined.

Recently, in our laboratories SEM studies of the early development of the chick embryo provide evidence that the SEN have their origin from the cephalic transitory neural crest, (NC) and enter the ventricular system prior to the closure of the anterior neuropore. Age related differentiation of neurons at various stages of early embryonic development have been demonstrated. As NC cells migrate over the intraventricular ependymal wall of the forming third (thalamic) ventricle the transition from bipolar migrating cells to multipolar SEN has been recorded.

The discovery of a medial migration of NC cells over the ependymal surface of the embryonic chick cerebral ventricular system provides an excellent model for the analysis of the morphogenesis of NC cells and the correlates of putative neuroendocrine functions suggested for SEN.

245.PO TRACING THE INTRANEURAL TOPOGRAPHY OF THE MEDIAN NERVE THROUGH A COMPUTERIZED MOVIE. Julia K. Terzis, M.D., Ph.D. and Bradford L. Felker*. Microsurgical Research Center, Eastern Virginia Medical School, P. O. Box 1980, Norfolk, Va. 23501.

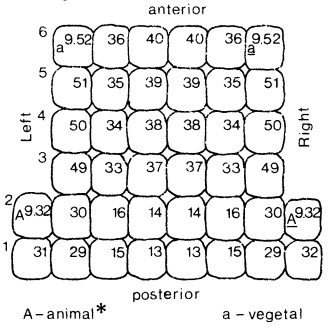
The intraneural topography of the median nerve was studied by examining one thousand five hundred (1,500) serial sections from a fresh cadaver median nerve. Each section was cut at sixty micron thickness. Sections were examined sequentially at 200 micron intervals from the middle arm level to the fingertips. The nerve was frozen and sections were cut using a freezing microtome (American Optical Histostat Microtome). Each section was projected to a semitransparent board and tracings were made. The exact perimeter of the outer epineurial sheath of the nerve trunk was recorded along with the constituent fascicular bundles by tracing their perineurial sheath. The intraneural fascicular organization was thus depicted at each level and the anatomical positions and exit points of the sensory and motor components accurately recorded. Each tracing was then encoded into a Crommemco System Three microcomputer using a Talos Digitizing Tablet computer. Each section was then serially recalled, displayed on a graphics screen and filmed using time lapse photography. The resulting movie illustrates for the first time the complex arrangements of the intraneural bundles in their journey to the periphery. The digitally computerized film traces motor and sensory fascicles in their natural anatomical positions as they maneuver their way within the epineurial sheath, split, rejoin, migrate and branch upon their exit from the main trunk for their respective muscles and cutaneous receptive fields.

It is hoped that data such as this study provides will greatly increase our understanding of the sensory-motor distribution and the intraneural organization of peripheral nerve trunks which is vital for functional restoration procedures following peripheral nerve injury and repair.

CELL LINEAGE AND DIFFERENTIATION I

246.1 CELL MAPS AND LINEAGE IN THE DEVELOPING NERVOUS SYSTEM OF THE ASCIDIAN TADPOLE LARVA. D. Nicol and I. A. Meinertzhagen. Dept. of Biology, Dalhousie Univ., Halifax, N.S., Canada B3H 4J1.

Larvae of tunicates (Urochordata: Ascidiacea) have a dorsal tubular nervous system widely touted as a signal feature of the group's chordate ancestry. In particular, the tunicate neural tube arises during development in the familiar vertebrate pattern, as an ectodermal neural plate which rolls up longitudinally. In other ways the embryo falls outside chordate orthodoxy. Its mode of development is mosaic and its cleavage apparently eutelic, yielding constant numbers of cells (i.e. neurones), properties more in common with various invertebrate groups. We have examined the early development of the embryo of Ciona intestinalis, from SEM and serial-section reconstructions of staged embryos, to investigate the morphology and lineage of the neurones of the larval nervous system, in an attempt to define some of the factors which generate the fundamental architectural features of the vertebrate nervous system.



The lineage of the embryo in Ciona is known from Conklin (1905) up until the 218-cell stage. At this time (7 hr. at 20°C) the neural plate contains 40 cells. These are arrayed in four rows of six and two rows of eight cells, as shown. Rows 1 and 2 divide first followed by rows 3-6, which divide in a medial to lateral and posterior to anterior sequence. By the time (9 hr., 20°C) row 3 has divided, taking the number of neural plate cells to 62, rows 1 and 2 have already commenced neurulation. At the end of neurulation (12 hr., 20°C), some of the daughters of rows 1 and 2 have divided again, taking the total number of row 1 and 2-progeny to about 56. These cells contribute the ependymal lining of the neural tube which comes to lie in the tail of the mature larva. The ependymal cells are arranged so that four comprise the neural tube cross-section, two laterally and one each dorsally and ventrally. At this stage there are 48 anterior cells constituting the brain region. These are the daughter cells of rows 3-6 and they go through at least one further division to complete their lineage.

Supported by grant A-0065 from NSERC.

*lineage nomenclature after Conklin (1905).

246.2 DEVELOPMENT OF PHOTORECEPTORS IN ZEBRAFISH. L. W. Nawrocki. Institute of Molecular Biology, Univ. of Oregon, Eugene, Oregon 97403.

Cone photoreceptor cells form a regular mosaic in the retina of the zebrafish, Brachydanio rerio (as previously observed for many other teleosts). The mosaic consists of alternating columns arranged along the dorso-ventral axis. One column is made of alternating single cones with absorption maxima at 415nm and 480 nm. The other column (two cells wide) is made of alternating rows of pairs of double cones with absorption maxima at 480nm and 550nm. (Absorption maxima of adult and young cells were measured in collaboration with M. Kaplan, R. Bremiller, and G. Streisinger.) Rod outer segments (503nm abs. max.) are located sclerally above the cones. The development of these receptors was investigated by light microscopy and their birthdates were established by tritiated thymidine labelling.

All cells in the presumptive neural retina are fusiform and histologically homogenous from day 0.5 (after fertilization) until day 2.4. Mitotic division giving rise to the neurons of the central retina occur at the ventricular surface. At day 2.4, the outer nuclear layer is formed, and all the cone cells in the central retina have completed their last mitotic division. These immature cones maintain a single layer of nuclei. Outer segments and synaptic terminals appear at day 3.0 in the central retina; on day 4, the nuclei of these cones have formed two layer in the outer nuclear layer, and on day 5, the first short single cones have moved to their mature position with their outer segments and their ellipsoids separated by the external limiting membrane. All three cone visual pigments have been identified in day 7 photoreceptor outer segments by microspectrophotometry. On day 9, the regular adult mosaic is present in cross section.

The first outer segments seen in the entire retina are those of precocious rods located close to the ventral retinal margin. Their nuclei lie close to the outer plexiform layer, and their outer segments are of mature diameter. Rod visual pigment has been measured with microspectrophotometry as early as day 6. On day 8, rods are found close to both the ventral and the dorsal margin. By day 12, rod outer segments are present in the central retina, but these rods had later birthdays than the cones in the same region.

The initial development of the zebrafish retina is thus quite different in the central than the marginal area. Central cones appear and develop into their mature forms prior to the appearance of rods (as has been established by T. Branchek). In contrast, at the ventral margin rods appear precociously, and exhibit mature outer segments, considerably before the appearance of cones.

246.3 SIMULTANEOUS EXPRESSION OF NEURONAL AND GLIAL PROPERTIES BY CHICK SENSORY AND AUTONOMIC GANGLION CELLS DURING DEVELOPMENT, H. Rohrer and I. Sommer* (SPON: Y.-A. Barde). Max-Planck-Institute for Psychiatry, D-8033 Martinsried, FRG and *Institute for Neurobiology, University of Heidelberg, D-6900 Heidelberg, FRG.

There is evidence to indicate that cells in cholinergic ciliary and sensory ganglia are able to acquire characteristics of adrenergic neurons when transplanted into trunk neural axis of stage 14 chick embryos. Recently it has been demonstrated that the adrenergic neurons do not originate from neurons but from non-neuronal cells present in the ganglion at the time of implantation (Ayer-Le Lievre and Le Douarin, Devel. Biol. 94: 291-310 1982). In the present study we have examined whether the non-neuronal cells of sensory or autonomic ganglia already express properties of adrenergic neurons before transplantation. Non-neuronal cells from dissociated chick dorsal root (DRG), sympathetic (SY) or ciliary (CIL) ganglia, grown in cell culture for 1 day, exhibit high affinity uptake for norepinephrine (NE) and/or specific receptors for nerve growth factor (NGF). Cells with NE uptake or NGF receptors were identified by autoradiographic methods, and such cells reacted with neither tetanus toxin nor with antibodies to neurofilament proteins or fibronectin. They were, however, positive for 04 antigen, which is recognized by a monoclonal antibody. This antigen is present on Schwann cells and oligodendrocytes (Schachner et al., Devel. Biol. 83: 328-338 1981).

At all ages studied between embryonic day six (E6) and embryonic day sixteen (E16), 70 to 80% of the non-neuronal cells were positive for 04 antigen in all ganglia analysed. 04 negative non-neuronal cells could be identified as fibroblast-like cells by staining with antibodies to fibronectin. The proportion of 04 positive cells with NGF receptors and NE uptake decreased during development. The percentage of 04 positive cells which have NGF receptors decreased from about 95% at E6 to between 10% (E16 SY) and 35% (E14 CIL and E16 DRG). The proportion of 04 positive cells with NE uptake decreased from 30 - 50% at E6 to between 3% (E16 SY and E16 DRG) and 15% (E14 CIL). We suggest that those cells exhibiting biochemical properties of both differentiated glial cells and neurons are precursor cells which have the potential to develop into either glial cells or neurons.

246.4 ENTERIC NEUROGENESIS BY NEURAL CREST-DERIVED BRANCHIAL ARCH MESENCHYMAL CELLS OF BIRDS. G. Ciment and J.A. Weston*. Dept. Biology University of Oregon, Eugene, OR 97403.

In earlier work (Devel.Biol.93:355,1982), we reported the establishment of a hybridoma cell line secreting a monoclonal antibody (E/C8) which recognizes an avian-specific epitope found in some cultured neural crest cells, both central and peripheral neurons in vivo, and in a limited number of non-neuronal tissues, including mesenchymal cells of the posterior (3rd and 4th) branchial arches. These latter tissues are transient embryonic structures which serve as the lateral and ventral walls of the primitive pharynx of vertebrates and are contiguous at the caudal end with the newly developing gut.

We report here that the antigen(s) recognized by the E/C8-monoclonal antibody in mesenchymal cells of the branchial arches and in peripheral neurons are the same. Moreover, the E/C8-positive mesenchymal cells of the arches can develop into morphologically-recognizable neurons either spontaneously in culture, or in tissue cocultures with aneural portions of the gut (where these branchial arch cells form apparently normal enteric ganglia). In contrast, these cells do not develop into melanocytes--another derivative of the neural crest--under several permissive conditions.

These data indicate that the mesenchymal cells of the posterior branchial arches are a population of partially-restricted neural crest-derived cells and may serve as precursors for neurons of the enteric nervous system.

Supported by NIH grant DE-04316 and NSF grant PCM-8218899.

246.5 MONOCLONAL ANTIBODIES AGAINST THE CHICK EMBRYO SPINAL CORD. H. Tanaka* and K. Obata Dept. of Pharmacology, Gunma Univ. Sch. of Med., Maebashi 371 Japan.

Molecular differences among neuronal cell surfaces will develop in the early stages of the embryo and play a role in cell-cell interactions leading formation of neuronal network. These differences will give specific identification markers of cell types in vivo and in vitro. Investigation on such molecules becomes possible with the development of the monoclonal antibody technique.

Mice were immunized by injecting crude membrane preparations of 6- and 13-day-old chick embryo spinal cords. Standard technique was used for fusion with X63-Ag8-653 cells. Hybridoma lines were screened by indirect immunofluorescence on 5 um thick paraffin sections of the chick embryo trunk. Chick embryos had been fixed and dehydrated in acetone at -80°C.

Of 700 cell lines screened, approximately 55% gave positive staining on spinal cord. Of these, 42% stained only the neuronal tissues, 13% stained neuronal and several non-neuronal tissues, and 45% stained all cells nonspecifically. Twenty independent lines were established. We described here 4 examples studied in detail. Since some staining pattern differed among trunk levels reflecting rostrocaudal gradient in the developmental stages, thoracic level was mainly investigated.

Antibody CESC 1 stained nerve fibers of spinal cord and dorsal root ganglion (DRG) cells. The staining appeared first on spinal cord cells at external mantle layer at stages 20-22 (Hamburger and Hamilton) and then DRG cells. In the later stages in spinal cord, the staining on somatic and visceral motoneurons was remarkable. Antibody CESC 2 stained dorsal funiculus but not cells in spinal cord. Outside the spinal cord, the staining was restricted on the surfaces of DRG and sympathetic ganglion cells and their fibers. However, the staining was not observed on neural crest and appeared after differentiation of ganglion cells at stages 24-25. Antibody CESC 3 stained the cell surfaces of both spinal cord and notochord from stage 16. Weak staining was also observed on mesonephros and somite and later on muscle cell surface. Staining on notochord disappeared at later stages. Antibody CESC 4 first stained notochord from stages 24-25 and then the spinal cord.

Monoclonal antibodies against embryonic nerve tissue, thus, revealed neuronal heterogeneity and development of antigenic determinants and their coexistence in such embryonic tissues as notochord and mesonephros.

246.6 NEURONAL AND GLIAL DIFFERENTIATION IN THE CERVICAL SYMPATHETIC GANGLIA OF THE RAT. K. Droms* and N. Sueoka* (SPON: B. L. McNaughton). Dept. of MCD Biol., University of Colorado, Boulder, CO 80309.

The neural crest origin of the neurons and glia of the sympathetic ganglia has been well documented. However, the developmental stage at which crest cells become committed to the neuronal and glial lineages has not been established. We have been examining this commitment by correlating the appearance of biochemical markers with morphological differentiation of neuronal and glial cells in the cervical sympathetic ganglia of the rat. Neuronal and glial cells first become morphologically distinguishable at embryonic day 14 (E14; EO = conception, E22 = birth). The S100 antigen, however, is not expressed in glial cells in the ganglia until after birth. The uptake of ^{3}H-GABA by glial cells is expressed much earlier in development (E15). At this stage only morphologically distinguishable glial cells take up GABA although many morphologically indistinguishable cells persist within the ganglion. Therefore, our observation is that morphology is the earliest detectable marker of glial differentiation so far found in this system.

We have also been studying the development of sympathetic ganglia in tissue culture. When E13 ganglia are cultured in our standard medium (DME, 12.5% horse serum, 2.5% fetal calf serum) supplemented with NGF no morphological differentiation of neuronal or glial cells can be detected. However, E14 ganglia plated in the same condition do exhibit neuronal differentiation, as evidenced by the extension of long cellular processes from the tissue explant. Hematoxylin and eosin stained sections of E14 ganglia after four days in culture display distinct morphological differentiation of neuronal and glial cells. Neuronal differentiation in E13 ganglia, as indicated by the extension of long processes from the tissue explant, does occur if the ganglia are cultured in medium without fetal calf serum (FCS). Sections of these cultured ganglia do exhibit two distinct cellular morphologies; one "neuronal-like" and one "glial-like," but the morphological differentiation of these cells is not as distinct as in ganglia cultured from later developmental stages. Ganglia from E14 and later developmental stages cultured in standard medium are indistinguishable from ganglia cultured in medium without FCS.

We are currently investigating the several possible interpretations of these phenomena. One exciting possibility is that E13 represents the stage at which commitment to the neuronal and glial lineages is in progress. We will test this idea by studying the relative dynamics of the neuronal and glial population in vivo and in vitro and by attempting to affect the choice of lineage by cultured ganglionic precursor cells.

246.7 DISTRIBUTION OF GLIAL CELL PROCESSES IN RETINA TRANSPLANTED TO THE RAT BRAIN. S. C. McLoon and H. J. Karten. Dept. of Anatomy, Medical University of South Carolina, Charleston, SC 29425 and Dept. of Neurobiology and Behavior, SUNY, Stony Brook, NY 11790.

Previous studies have shown that fetal rat retina will survive and continue to differentiate when transplanted adjacent to the superior colliculus of newborn hosts. The neuronal elements of these retinal transplants appear identical to their counterparts in normal retina for all characteristics studied so far. In the present study we have used immunohistochemical techniques to characterize the glial elements in the retinal transplants and compared these to the glial elements of retina in situ. The Müller cell processes of normal retina run from outer to inner limiting membrane as can be demonstrated by the Müller cell specific antibody G3 (developed by C. Barnstable), while an antibody to glial fibrillary acidic protein (GFA) only stains processes in the optic fiber layer. The GFA positive cells appear to be astrocytes that migrate into the retina along the optic nerve during the first post-natal week. At birth the GFA reactivity was confined to the optic nerve head and optic fiber layer immediately surrounding the nerve. During the next five days, the GFA reactivity expanded out from the optic nerve concentrically. By injecting colchicine into the eye or by injuring the retina, Müller cells develop a GFA antigenicity. In the retinal transplants, however, the staining pattern of both antibodies was the same. Glial fibers which appeared to be both GFA and G3 positive ran from the outer limiting membrane at the center of the photoreceptor rosettes through the ganglion cell layer. It is not clear at this point if the glial cells in the retinal transplants are astrocytes which migrated in from the host brain and which underwent a gene modification in the retinal environment to express Muller cell specific antigenicity or are Müller cells expressing an injury-like reactivity to the GFA antibody. It is interesting that in the disturbed environment of the transplants the glial processes were still capable of orienting radially through all the cell layers.

246.8 TEMPORAL SEQUENCE OF GRANULE CELL MIGRATION IN VITRO. E. Trenkner and N. Segil*. Dept. of Pharmacology, New York Univ. Medical Center, New York, NY 10016.

Questions of intrinsic vs. extrinsic control of cellular behavior have been central to the analysis of neuronal development. The reaggregating cerebellar culture system of Trenkner and Sidman (1) has been useful as an in vitro model for the study of granule cell migration during cerebellar development. In the present study we have confirmed the identity of granule cells in these cultures and described the temporal sequence of granule cell development and migration.

At postnatal day 3 (P3), the majority of cells dividing in the cerebellum are external granule cells, a subpopulation of which are destined to begin migrating within 24 hrs. (2). Therefore, we injected ^{3}H-thymidine into P3 animals and at various times thereafter prepared cerebellar cultures in order to determine whether this labeled, migrating population of cells appeared as migrating cells in cultures. 3 days after culture of P4 animals (injected 24 hrs earlier) 30%-40% of the migrating cells were labeled. This % was much lower in cultures prepared 96 hrs (P7) after ^{3}H-thymidine injection, indicating that there might be predetermined length of time during which these cells can migrate. To test this hypothesis, P3 cerebellar cells were labeled and then cultured for various times up to 7 days. The largest % of labeled cells on cables was found after 3 days in vitro. Subsequently, the % of labeled cells on cables declined to near 0, most probably as a result of migration into reaggregrates (1). Unlabeled cells continued to migrate on cables indicating that the cultures were still capable of supporting migration.

Reaggregates were studied in 1 sections prepared for autoradiography. Increased numbers of labled cells appeared in reaggregates with increased time in culture. This increase correlated with the increase in number of labeled cells in the internal granule cell layer in vivo. Also, the number of labeled cells observed in reaggregates was dependent on length of time after final mitosis. Cultures from animals labeled at P3 and cultured at P4 contained considerably fewer labeled cells in reaggregates than those cultured at P7.

This study confirms the electon microscopic evidence that the cells migrating on cables are granule cells and suggests that there may be a predetermined length of time for granule cells to migrate.

246.9 VENTRAL NEURAL TUBE AND NOTOCHORD OF RAT EMBRYOS CONTAIN AROMATIC L-AMINO ACID DECARBOXYLASE. G. Teitelman, C.B. Jaeger, V.R. Albert, T.H. Joh and D.J. Reis. Laboratory of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

In vertebrate embryos, the catecholamine (CA) neurons of brain and periphery arise from undifferentiated precursors in the ventral neural tube and neural crest to migrate to their final location where they first express tyrosine hydroxylase (TH). We sought to determine by immunocytochemistry and autoradiography whether the next enzyme of the CA pathway, Aromatic L-Amino Acid Decarboxylase (AADC) is expressed by CA precursors before or, as TH, after reaching their final site and by combining immunocytochemistry and radioautography of tritiated thymidine (^{3}H-thy) whether AADC is present in proliferating cells.

Rat embryos and adult tissue were fixed in 4% paraformaldehyde, sectioned and stained for AADC according to the PAP technique. For simultaneous radioautographic demonstration of labeling of AADC by ^{3}H-thy, pregnant rats were injected at the 14th day of development (E 14) with 5 uCi/g of the isotope and killed two hours later. After processing the embryonic tissue for immunocytochemical localization of AADC, the sections were coated with Kodak NTS$_2$ emulsion, exposed to two weeks in the dark, developed, fixed and mounted.

AADC was first observed on E 12 in all cells of the notochord along its entire length and in neuroepithelial cells of the ventral neural tube from the mesencephalic to the lumbar region. At E 14 the cells of the sacral basal plate of the neural tube also contained AADC. At this stage, some cells of the notochord and neural tube containing AADC were also labeled with tritiated thymidine. At E 16 the cells of the notochord lacked AADC immunoreactivity and at E 21 the enzyme was no longer detected in the ventricular layer of the developing brain. At this stage and in the adult stage, however, a few cells containing AADC were found scattered in the spinal cord. AADC was not detected in migrating neural crest cells.

This study indicates that in rat embryo: (1) AADC is expressed by cells of the ventral neural tube and notochord from E 12 until late gestation; (2) the onset of expression of AADC occurs prior to the last cell division; and, (3) at least in brain, the precursors of CA neurons express AADC while still in their site of origin, and TH after arriving at their final location.

246.10 GLUCOCORTICOID-INDUCED DELAY OF THE RESPONSE OF CULTURED ADRENAL CHROMAFFIN CELLS TO NERVE GROWTH FACTOR. L.E. Lillien and P. Claude. Wisconsin Regional Primate Research Center and Neurosciences Training Program, Univ. of Wisconsin-Madison, WI 53706.

Adrenal chromaffin cells from young rats form neurites and exhibit ultrastructural features that are characteristic of neurons when they are grown in vitro in the presence of Nerve Growth Factor (NGF) (Unsicker et al., 1978; Doupe, 1982). Glucocorticoid hormones have been reported to inhibit this response to NGF (Unsicker, 1978). We have followed the effects of dexamethasone (dex) on the NGF-induced changes in chromaffin cells over several weeks and find that dex appears to delay rather than completely inhibit the NGF response. Chromaffin cells grown in the absence of NGF (control cultures) are small (10-15 um in diameter), flat and polygonal and very few have neurites. No large, round cell bodies typical of neurons are present in control cultures. In the presence of NGF (100 ng/ml 7S NGF), the proportion of neurite-bearing chromaffin cells increases from approximately 15% after 1 week, to 40% at 2 weeks, to over 70% by 4 weeks in culture; the proportion of large spherical neuron-like cells (20-30 um in diameter) increases from 0% at 1 week and 1-2% at 2 weeks to approximately 80% by 4 weeks. In the presence of NGF plus 10^{-5}M dex (Decadron, Merck), the proportion of neurite-bearing cells at 1,2 and 4 weeks is approximately 3%, 10% and 20-50%, respectively; large spherical cells are not apparent at 1 or 2 weeks, and constitute 10% of the chromaffin cells present at 4 weeks. If chromaffin cells are grown for 1 week in the presence of dex alone, followed by the removal of dex and addition of NGF (100 ng/ml), the initiation of neuritic outgrowth is apparent about 4 days after the switch; when sister cultures are grown for 1 week under control conditions (no NGF or dex) then switched to NGF, process outgrowth is apparent by 2 days after the switch. These results also suggest a delaying effect of dexamethasone on the neuritic response of chromaffin cells to NGF. Possible mechanisms for this delay, specifically, a direct effect of dex on the binding or processing of NGF by chromaffin cells will be investigated, as well as a possible mitogenic effect of dex on adrenal chromaffin cells. Preliminary evidence from cultures labeled in vitro with tritiated thymidine suggests that while chromaffin cells divide in vitro under all conditions, the proportion of labeled cells in cultures grown in NGF plus dex is greater than in cultures grown in NGF alone.

Supported by NIH grant RR00167 to the Primate Research Center and by a Research Grant from the Muscular Dystrophy Assoc.)

247.1 CHANGES IN NEURONAL NUMBER IN THE DEVELOPING HAMSTER VISUAL SYSTEM FOLLOWING MANIPULATIONS OF TARGET AVAILABILITY. John Kirn*, Judy I. Raabe* and Barbara L. Finlay. Dept. of Psychology, Cornell University, Ithaca, N.Y. 14853.

The control of cell number through naturally occurring cell death in complex, interconnected systems is as yet poorly understood. Here two manipulations in the visual system designed to remove one retinal target and observe changes in both retina and other targets are examined, with regard to the relative contributions of afference and efference in the control of cell number.

In prior research designed to test the effect of increased afference (Wikler and Finlay, 1982) no change in cell death in residual tectum was observed following caudal unilateral tectal lesions in neonatal hamsters (48%-79% reduction in surface area). Our experiment examined cell loss in the retinal ganglion cell layer of these animals. Cell counts in the ganglion cell layer in horizontal sections through the retina were made on postnatal days 4-8, the period of maximal cell death in hamster visual system. The number of degenerating cells, recognized by their pyknotic appearance in light microscopy, were expressed as a fraction of normal cells. No difference in cell degeneration rates between eyes contralateral and ipsilateral to the lesion were observed. However, cell loss in peripheral retina of both eyes was higher than in normal hamsters on postnatal days 6-8. The caudal tectum does not receive bilateral projections in the adult. However, caudal unilateral tectal lesions performed neonatally apparently produce a bilateral reduction in retinal target availability.

Visual cortex removal in neonatal hamsters results in degeneration of the dorsal lateral geniculate nucleus and a potential excess of retinal innervation to other retinal targets such as the superficial layers of the superior colliculus. This manipulation also denervates posterior thalamic nuclei where visual cortex and superior colliculus both project, potentially increasing thalamic targets for superior colliculus efferents. The right visual cortex was removed on the day of birth in hamsters. The geniculate was reduced to 63% of its normal surface area by postnatal day 4 with progressively more degeneration seen on later days. Assessments of cell degeneration rates were made in superficial and intermediate layers of the superior colliculus on postnatal days 4-8. Rates of cell loss in superficial layers contralateral and ipsilateral to the cortical lesion were identical, suggesting no effect of potential excess afference ipsilateral to cortical removal on cell survival. In the intermediate and deep layers however, 6 out of 8 animals showed decreased cell loss ipsilateral to cortical removal, suggesting that the target area was increased for intermediate layer efferents.

These results suggest that target availability and not afferent supply is the primary factor controlling cell number in complex interconnecting neuronal populations.

247.2 EFFECT OF ISCHEMIA-LIKE CONDITIONS ON NEURONAL SURVIVAL IN CELL CULTURE W.J.Goldberg*, R.M. Kadingo*, and J.N. Barrett. Dept. of Physiology and Biophysics, University of Miami Sch. of Med., Miami, FL 33101

One of the major problems in the study of ischemia in vivo is the inability to dissociate the direct effects of oxygen and glucose deprivation on neurons from the secondary effects which result from vascular changes. We present here an in vitro system for assessing the ability of neurons to withstand and recover from the combined deprivation of oxygen and glucose. Dissociated cultures of basal ganglia cells (striatum and substantia nigra) from 14-16 day gestation rat embryos were maintained in nutrient medium supplimented with a survival factor isolated from horse serum (Kaufman and Barrett, Science in press). When cultures were deprived of both glucose and oxygen in the medium (PO_2 below detectable level using Pt electrode) for a period of three hours more than 90% of the neurons became swollen and had irregular nuclei. Within 24 hours the cells were replaced by debris. The sensitivity of neurons to this ischemic insult was found to be highly dependent upon the age of the culture. Cultures less than three weeks old were much less sensitive and at less than two weeks of age were not significantly damaged by this three hour deprivation of glucose and oxygen. We find that the combined deprivation of glucose and oxygen was much more damaging to neurons in culture than was anoxia alone since oxygen deprivation for three hours produced little or no damage. It has recently been reported that 14 hours of exposure to anoxic conditions does result in the death of neurons in culture (Rothman, Science, 220:536).

Both young and old neuronal cultures were not affected by many of the microenvironmental alterations which occur during ischemia in vivo. High ammonia (up to 5 mM), high lactic acid (up to 20 mM) and low pH (to 6.5) did not severely damage the cells provided that glucose and oxygen were present.

247.3 REGULATION OF NEURON NUMBERS IN XENOPUS: EFFECTS OF HORMONAL MANIPULATION ALTERING SIZE AT METAMORPHOSIS. D. G. SPERRY* and P. GROBSTEIN (SPON: J. Siegel). Sch. of Life and Health Sci., Univ. of Delaware, Newark, DE 19711 and Com. on Neurobio., Univ. of Chicago, Chicago, IL 60637.

The developmental mechanisms that operate to ensure a functional relationship between nervous system organization and body size are subjects of continuing interest. In frogs, the numbers of neurons with peripheral processes may be determined by signals relating peripheral size to the amount of naturally occurring neuronal death during metamorphosis. Neither the exact timing of such hypothetical signals nor the particular aspects of peripheral size they might relate are known.

To provide new information on neuron number regulation we studied frogs where metamorphosis was delayed and peripheral size at its completion was greatly increased by interfering with the hormonal balance necessary for metamorphosis at the normal rate. X. laevis tadpoles living in rearing medium containing the anti-thyroid agent propylthiouracil cease development at a late larval, hindlimb bud stage prior to the onset of motoneuron death. Animals remain viable, continue growing, and, when returned to standard rearing medium, complete normal metamorphosis but at an increased size.

Counts of lumbar lateral motor column motoneurons were made on four normal postmetamorphic frogs and four experimental post-metamorphic frogs. The experimental frogs completed metamorphosis six months later than their untreated siblings and had bodies of normal proportions but four to five times larger. Despite these size differences, motoneuron numbers were the same in both groups. We also counted muscle fibers in two hindlimb muscles. Surprisingly, muscle fiber numbers were not greater but actually diminished in the experimental animals. Our results indicate that the hypothetical signal regulating motoneuron numbers is not related to gross peripheral size during late metamorphic stages. The results leave open the possibility that the signal is related to muscle fiber number, although we did not observe a decrease in motoneuron number proportional to the decrease in muscle fiber number in the experimental animals.

Counts of dorsal root ganglia cells are in progress. Preliminary findings suggest an increase in neuron number in the thoracic ganglia porportional to the increase in body surface area of the experimental animals but no increase in those ganglia associated with the hindlimb. A difference between sensory and motor systems and between thoracic and lumbar body regions would be of interest in further analyses of possible peripheral regulation of neuron numbers.

247.4 DECREASED MOTOR NEURON SURVIVAL IN THE DEVELOPING MUSCULAR DYSTROPHIC CHICK. P.A. Stewart and M.P. Rathbone. Department of Anatomy, University of Toronto, Toronto, Ontario, and Department or Clinical Neurological Sciences, University of Western Ontario, London, Ontario CANADA.

Inherited muscular dystrophy in the chicken is characterised by a variety of muscular and neural abnormalities. In view of the early expression of dystrophy in the muscles one might predict a deficit in the motor neuron population. However, studies on the New Hampshire strain of dystrophic birds maintained in Davis, CA, have shown that the population of the lateral motor column (LMC) is normal. Since the expression of the dystrophic gene in birds is modofied by background genes, we questioned whether dystrophic chicks that have been outbred to White Leghorn, and maintained in Storrs, CT, might have abnormalities in their motor neuron pools.

We estimated total numbers of motor neurons in the brachial LMC in normal and dystrophic chicks at 6, 11 and 17 days of development and at 3 days post-hatching. Since motor neuron populations vary among White Leghorn sub-strains, we examined both of the dystrophic lines maintained at Storrs and, as controls, used the inbred normal birds supplied by the same facility and also locally obtained White Leghorns. We found that the motor neuron population was the same in all 4 lines at 6 days in ovo but by 11 days in ovo and thereafter both dystrophic lines contained about 80% of the normal number. Both normal lines had approximately the same population.

To determine whether the expression of dystrophy in the target muscles might affect the survival of motor neurons we transplanted the presumptive brachial region of the spinal cord between normal and dystrophic embryos at 2 days in ovo and evaluated the LMC population at 17 days in ovo in the resulting chimeras. We found that both normal and dystrophic spinal cords transplanted into dystrophic hosts had significantly fewer motor neurons than normal and dystrophic spinal cords transplanted into normal hosts. In fact, dystrophic cords transplanted into normal hosts had slightly more neurons than in unoperated dystrophic birds. Therefore we suggest that an interaction with normal muscle fibers was able to rescue a percentage of dystrophic motor neurons that would have died in their native environment.

We conclude that in the Storrs strain of dystrophic birds the observed deficit in the brachial LMC is secondary to some influence of the dystrophic target muscles.

247.6 TARGET TISSUE- AND SUBSTRATUM-DEPENDENT SURVIVAL OF LATERAL MOTOR COLUMN NEURONS IN LONG-TERM SPINAL CORD EXPLANT CULTURES.
E.D. Pollack, V.L. Liebig* and W.L. Muhlach* (SPON: K.R. Swiatek). Inst. Study of Develop. Disabil. and Dept. Biol. Sci., University of Illinois at Chicago, Chicago, IL 60608.

Both target tissue and the attachment substratum are critical for the in vitro survival of lateral motor column (LMC) neurons of tadpole spinal cord explants grown in defined medium (Pollack, Neurosci Abstr.,'82). We previously demonstrated that the number of neurons in the LMC after 21 days of culture was optimal in the presence of mesenchymal limb bud tissue and polylysine substratum. Longer term cultures have now been analyzed in order to assess the specific organotypic organization of cord explants with respect to potential maturational changes in the LMC resulting from continual peripheral target influences. Lumbosacral spinal cord and mesenchymal limb tissue were derived from young (stage V) Rana pipiens tadpoles and explanted on either collagen or poly-DL-lysine substrata.

Cord explants grown on collagen without target tissue could not be maintained beyond 4-5 weeks. By this time they exhibited no neuritic outgrowth and a generally disorganized cytoarchitecture lacking clearly delineated LMCs. The presence of limb bud tissue promoted explant survival with enhanced neuritic outgrowth for periods that can exceed two months. An organized LMC persisted with neurons that are apparently more mature than that seen after only 3 weeks of culture. Cords grown on polylysine without target tissue also survived for prolonged periods with typically well-formed LMCs. However, the LMC had a reduced neuronal population and contained larger numbers of necrotic cells than when target was present with cord explants on polylysine.

Of developmental significance is the finding that cord cultures with target tissue generally had an LMC present or prominent on one side only. This is further reflected in the fact that long-term cultures showed degeneration of what earlier had been healthy neurites in areas not spatially related to the target tissue. This more specific effect of the target was not seen in shorter term cultures. Group comparisons suggest that the target tissue offers a survival effect beyond an apparent stabilizing influence imparted by the polylysine substratum. Several cord explants were cultured with limb conditioned medium for 4 weeks during which time they extended target-dependent neurites and exhibited viable LMCs on both sides of the cord.

The results thus far indicate that the normal mesenchymal limb target for LMC neurons promotes selective long-term survival of those neurons in vitro while the nature of the substratum may provide a more generalized cellular stability that contributes to overall survival. (Supported in part by NIH grant NS 13814).

247.7 THE EARLY POSTNATAL RESTRICTION OF THE IPSILATERAL RETINOCOLLICULAR PROJECTION IS DUE TO CELL DEATH RATHER THAN COLLATERAL ELIMINATION.
Dennis D.M. O'Leary, James W. Fawcett,* and W.M. Cowan, The Salk Institute, P.O. Box 85800, San Diego, CA 92138.

Early in the postnatal life of rodents that have been studied there is a substantial ipsilateral retinocollicular projection. In newborn albino rats this projection extends throughout the colliculus, and arises from ganglion cells that are scattered throughout the ipsilateral retina. After the first few days postnatally this early extensive projection becomes progressively restricted, and by postnatal day 10 it is largely limited, as it is in adult rats, to the rostromedial part of the colliculus (Land and Lund, Science, 205:698, 1979).

To determine whether this restriction is due to collateral elimination or to the death of the ganglion cells from which the extensive projection arises we have used the retrogradely transported fluorescent tracers Fast Blue (FB) and Diaminido Yellow-dihydrochloride (DY), which label the cytoplasm and nucleus respectively, as long-term neuronal markers. Retinal whole mount preparations were made from albino rats in which three 0.1 µl injections of 2% FB were placed into the colliculus of one side and of 2% DY into the colliculus of the opposite side, on the day of birth. After survival times of 48 to 68 hrs a significant number of ganglion cells labeled from the ipsilateral colliculus was seen within all four retinal quadrants, with a markedly higher density in the lower temporal periphery. Only a very small proportion of the ipsilaterally projecting cells was doubly labeled.

A second series of animals injected in the same way was allowed to survive until postnatal day 12. In these cases the ganglion cells that were labeled from the ipsilateral colliculus were confined almost entirely to the lower temporal periphery as they were in the retinae of adult albino rats ipsilateral to a collicular injection made with either dye. In these cases very few doubly labeled cells were observed.

Our findings indicate that the ipsilateral retinocollicular projection is not formed by collaterals of axons that are directed to the contralateral colliculus. The postnatal restriction of the ipsilateral projection is due rather to the death of the ganglion cells that initially project to regions outside the rostromedial part of the ipsilateral colliculus, and not to collateral elimination.

247.8 A ROLE FOR ELECTRICAL ACTIVITY IN THE RESTRICTION OF THE IPSILATERAL RETINOCOLLICULAR PROJECTION.
James W. Fawcett,* Dennis D.M. O'Leary, and W.M. Cowan, The Salk Institute, P.O. Box 85800, San Diego, CA 92138 (SPON: Francis Crick).

In adult rats the ipsilateral retinocollicular projection arises from a restricted population of ganglion cells in the lower temporal retina and is limited in its distribution to the rostromedial part of the superior colliculus. However, early in postnatal life it extends across the entire colliculus and arises from ganglion cells that are scattered across much of the retina. Removal of one eye shortly after birth prevents the restriction of the ipsilateral projection from the remaining eye (Land and Lund, Science, 205:698, 1979), which suggests that there is normally competition between the fibers from the two eyes.

We have confirmed (using the anterograde transport of WGA-HRP and TMB histochemistry) that early in postnatal life the ipsilateral retinocollicular projection in normal albino rats covers the entire colliculus, and that by postnatal day 12 (P-12) the projection is largely confined to its rostromedial part. In a second group of animals, enucleated on P-2, the remaining eye was injected with WGA-HRP; here labeled fibers were found to cover the entire colliculus on P-12.

In a third group of animals we injected 0.03 µl of 0.1% tetrodotoxin (TTX) into one or both eyes on every other day, from P-2 to P-10, in order to abolish optic fiber electrical activity. On P-11 WGA-HRP was injected into one eye, and the animals were killed on P-12. In animals with monocular TTX injections, in which the other eye was filled with WGA-HRP, the ipsilateral projection from this eye was found to persist over the entire colliculus, and was similar to that seen in neonatally enucleated animals. If the TTX injected eye was filled with WGA-HRP the ipsilateral projection was either completely absent or was restricted to the extreme rostromedial part of the colliculus. When both eyes were injected with TTX and either eye filled with WGA-HRP, the ipsilateral projection was distributed over the entire colliculus. In control animals in which the TTX treated eye was retrogradely labeled with WGA-HRP injected into the contralateral colliculus, we have been able to confirm that TTX treatment does not increase normal ganglion cell death; in these cases ganglion cell density was the same as in normal retinae.

Our findings indicate that the competition between optic fibers which normally leads to the preferential elimination of ganglion cells projecting to the ipsilateral colliculus is mediated by electrical activity in the competing fibers.

247.9 SUPEROXIDE DISMUTASE-POLYETHYLENE GLYCOL (PEG-SOD) AS A FREE RADICAL SCAVENGER IN GERBIL CEREBRAL ISCHEMIA AND REFLOW.
†Joe S. Beckman* and §Charles J. Hannan, Jr.,(SPON: J.J. Bucccafusco), †Botany Dept., Duke University, Durham, NC 27706, and §Clinical Investigation Dept., DD Eisenhower Army Medical Center, Ft Gordon, GA 30905.

Preliminary findings, employing a 40 minute bilateral occlusion in gerbils, indicates a beneficial effect from a superoxide dismutase-polyethylene glycol preparation administered before occlusion. Superoxide dismutase (SOD) is a naturally occuring, ubiquitously distributed enzyme which plays a role in the protection of cells from oxygen toxicity. Free radicals of oxygen may be produced upon the reperfusion of ischemic tissue. SOD has been modified by bonding it to polyethylene glycol in order to increase its half life in plasma. The PEG-SOD prepared had an activity of about 2100 units/ml (assayed by inhibition of xanthine oxidase reduction of cytochrome c according to McCord and Fridovich, JBC 244: 6049, 1969). PEG-SOD (10 ul/gm or 20,000 units/Kg) was administered intraperitoneally to 20 animals and an equal volume of saline to a group of 13 control animals, 3 hours before occlusion. Mortality figures indicated a beneficial effect of PEG-SOD ($P = 0.0778$ by Chi Square). A clearance curve for PEG-SOD indicated plasma SOD activity to be considerably elevated at least 48 hours after injection.

These preliminary results are encouraging for a role of oxygen free radical damage during post ischemic reflow. Further studies to determine the exact time course for the protective effect as well as the role of vitamin E are now being conducted.

247.10 POSTNATAL DEVELOPMENT OF NEURONS IN THE OPTIC RADIATIONS OF THE CAT. D. M. Murakami*, G. J. Condo, and P. D. Wilson. (SPON: M. A. Baker) Dept. of Psychology, University of California, Riverside, CA 92521.

A population of neurons which may be transient during development was observed within the optic radiations of cats 1-6 weeks of age. These neurons could not be ascribed to the perigeniculate nucleus (PGN) or reticular nucleus of the thalamus (RNT). Corresponding regions in the adult cat did not reveal the same frequency and density of neurons as the younger kittens. In order to investigate the development and origin of these cells, intraocular injections of HRP were made in cats newborn to 52 weeks of age. Coronal sections through the dLGN were reacted with TMB and counterstained with thionin. No direct retinal projection to the PGN or RNT was observed at any developmental period. At birth through 4 weeks of age there is a high density of cells within the optic radiations between the PGN and RNT. The apparent number and density of these cells decreases after 4 weeks of age until 8 weeks when it becomes adultlike in density and frequency. Cells measured in the optic radiations reach a maximum diameter ($\bar{x}$=20.5μm) at 4-6 weeks of age and are circular in shape. By 8 weeks of age the cells are fusiform and smaller in diameter ($\bar{x}$=18.022μm). Morphological analyses of these cells in Golgi-Cox material indicates that they are clearly distinct from PGN neurons in that the optic radiation cells have a larger soma diameter, and 4-8 primary dendrites giving rise to a complex and relatively compact (200-249μm, $\bar{x}$=213μm) dendritic arbor, which is oriented perpendicular to the dLGN laminae.

Transsynaptic transport of WGA-HRP from intraocular injections were used to demonstrate projections of dLGN relay cells to the PGN and RNT. In adult cats HRP label was confined to regions near the somas and proximal dendrites of PGN cells, and was patchy to RNT neurons. No distinct label could be found in the region between the RNT and PGN. Cats 6 weeks of age and younger revealed broad and dense HRP label in the RNT. However, very little label could be found with the cells between the PGN and RNT typical of cats this young.

In conclusion, there is a distinct population of large round neurons between the PGN and RNT that do not receive visual input in young kittens. During the period of greatest maturation of the dLGN (4-8 weeks) a high proportion of these cells seem to disappear or migrate out of the region.

247.11 NEURAL TISSUE TRANSPLANTS RESCUE RUBROSPINAL NEURONS AFTER NEONATAL SPINAL CORD LESIONS. B.S. Bregman, Dept. Anatomy, Univ. Maryland, School of Medicine, Baltimore, MD 21201.

Spinal cord lesions sustained neonatally frequently result in massive retrograde loss of axotomized immature neurons. We have shown that implants of embryonic spinal cord survive, grow and differentiate when transplanted to the lesioned spinal cord in newborn animals (Bregman & Reier, SN Abstr, 1982). The current study was designed to determine whether red nucleus (RN) neurons which usually die after neonatal axotomy can survive in the presence of a graft of immature spinal cord. Spinal cord hemisections were made at T6 in 16 newborn rats, eight of which were recipients of fetal (E12-E14) spinal cord transplants. The other animals received no implant. At 30d to 1 year experimental animals and control (unoperated) littermates were sacrificed and the tissue blocks containing the RN were frozen and sectioned serially. A 1 in 5 series of 40um sections was collected in consecutive order and stained with cresyl violet. The volume of the RN and the number of neurons present were determined using a Zeiss MOP-30. In an additional series of animals, HRP-WGA was injected bilaterally into the lumbar spinal cord, caudal to the lesion or lesion and implant.

In implant recipients, labeled neurons were present in both RN, whereas, in hemisected animals without implants, only the RN ipsilateral to the lesion contained labeled neurons. The distribution of cells in the RN projecting to the intact spinal cord was identical with that in normal animals. The RN projecting to the side with implant contained labeled neurons in a more diffuse pattern, including some cells located in the dorsomedial portion of the nucleus. Cell counts indicate that neonatal spinal cord lesions result in the loss of approximately 45% of the neurons in the RN. ANOVA and Duncan's multiple range tests (α=0.05) indicate that there are significantly fewer neurons in the RN of animals with neonatal lesion alone ($\bar{x}$=2920.0) than in those with lesion and implant ($\bar{x}$=4790.6) or in control animals ($\bar{x}$=4444.3). Cell numbers in the control animals and those with implants were equivalent. The volume of the nucleus was decreased by 25% in animals with lesion alone but not in those with implants.

These results indicate that implants of fetal spinal cord can rescue immature axotomized RN neurons. At least some of these rescued neurons project caudal to the implant, as indicated by the retrograde HRP labeling. It is not clear whether these rescued neurons represent regenerating neurons, neurons sprouting rostral to the lesion, or later developing RST cells which are able to survive in the presence of the implant. The implant may provide a trophic influence necessary for cell survival that is absent after lesion alone.

247.12 AN EXAMINATION OF POSTNATAL NEURON DEATH IN THE LOCUS COERULEUS OF RATS. R. E. Ruth and S. K. Goldsmith. Inst. Study Dev. Disabil., Univ. Il. at Chicago, Chicago, IL 60608.

Naturally occurring neuronal death is one of the major steps in neurogenesis. In peripheral noradrenergic cells evidence indicates that cell death results from competition for a limited supply of nerve growth factor which, when retrogradely transported from the target to ganglion cells, promotes survival. The occurrence of cell death in central mammalian adrenergic neurons is less well documented. The rat locus coeruleus (lc) affords an opportunity to examine this phenomenon. The lc is relatively prominent at birth and all of its neurons are presumably norepinephrine-containing. Moreover these neurons cease proliferation and migration early in gestation. Therefore any decrease in cell number after birth would reflect the existence and magnitude of cell death.

Anesthetized rat pups were perfused with aldehydes on postnatal (P) days 1, 3, 6, 9, 12, 24, 40 or 120 days. Rate, volume and pressure of perfusate delivery varied as a predetermined function of age. Brains were embedded in paraffin, cut at 6um in sagittal or coronal planes and stained with thionin. Nucleolar counts were obtained from a 1-in-3 (P1,P3), 1-in-4 (P6—P12) or 1-in-5 (>P12) series through lc. Results presented here are derived from preliminary counts of P1 (n=5), P12 (n=3) and P40/P120 (n=2) brains. Each pup represented a separate litter; no correction factor was applied to the counts.

Light-microscopic features of the developing and adult lc were quite similar to previous descriptions (Sievers et al., 1981; Swanson, 1976). Particularly relevant for interpretting nucleolar counts, the size of lc neurons was smallest at P1 and largest at P12. By P40 neuronal size decreased slightly from the P12 maximum. Basophilia was also strongest at P12. Neuronal counts were actually lower and more variable at P1 (1724 195) than at P12 (1922 51) or P40/P120 (1840 28). Variations in neuronal counts across age were thus small and correlated with age-related variations in cell size, suggesting that thinner sections at P1 and P40 would yield higher estimates of cell number. In any event there is little evidence thus far to suggest that natural cell death occurs to any great extent in the postnatal rat lc. More firm conclusions await examination of the remaining tissue.

247.13 EFFECTS OF UNDERNUTRITION ON THE NUCLEUS RAPHE DORSALIS AND NUCLEUS LOCUS COERULEUS: A GOLGI MORPHOMETRIC STUDY IN RATS OF THREE AGE GROUPS. S. Diaz-Cintra, L. Cintra, T. Kemper* and P.J. Morgane. Worcester Foundation for Experimental Biology, Shrewsbury, MA 01545 and Instituto de Investigaciones Biomedicas. UNAM, Dpto. de Fisiology, C.P. 04510 Mexico, D.F.

Using morphometric analysis on cells of the nucleus raphe dorsalis and nucleus locus coeruleus in control and undernourished animals at 30, 90 and 220 days, we found in both nuclei similar types of cells: fusiform, multipolar and ovoid (Brain Res. 207:1-16, 1981; Brain Res. 247:17-28, 1982). In control animals all three cell types showed synchronous age-related changes in spine densities that in the two nuclei were out-of-phase with each other (Develop. Brain Res. 4: 487-490, 1982). In the nucleus raphe dorsalis protein deprived rats failed to show a period of proliferation and elimination of dendritic spines seen in controls resulting in a spine deficit at 90 days of age (Brain Res. 221: 243-255, 1981). In contrast, in the 8% casein diet rats the three cell types in the nucleus locus coeruleus more closely followed age-related decreases and increases in spine density seen in the controls. When the age-related changes in the nucleus locus coeruleus and nucleus raphe dorsalis in the protein deprived rats are plotted together it can be seen that the direction of the age-related changes are similar in the two nuclei. Thus, the out-of-phase relationship seen in the controls in these two nuclei fails to occur in 8% casein diet rats. Whether this is due to a failure of the reciprocal inhibition between these two nuclei or from some other mechanism cannot be answered at this time. It does suggest, however, a closer synchrony of the synaptic relationships between these two nuclei in the protein undernourished rat. Whatever the mechanism, it is clear that the relationship between these two nuclei appears to be fundamentally different in the 8% casein diet rats as compared to controls. Studies are in progress to determine how the altered interrelationships between these two biogenic amine nuclei may affect function in forebrain areas to which these nuclei project. (Supported by NIH Grant HD-06364).

247.14 CELL COUNTS IN THE INFERIOR OLIVARY NUCLEUS AND SYNAPSE ELIMINATION IN THE DEVELOPING OLIVO-CEREBELLAR SYSTEM OF RODENTS.
J. Mariani, N. Delhaye-Bouchaud, B. Geoffroy and H. Shojaeian, Dept of Molecular Biology, Pasteur Institute and Lab. Neurophysiologie Ontogénétique, Univ. P. et M. Curie, Paris, France.

In the developing rodent cerebellum, the multiple innervation of Purkinje cells (PCs) by climbing fibers (CFs) is maximal on postnatal (p.n.) day 5 and decreases thereafter until the adult mono-innervation is attained around p.n. day 15. Is this regression related to the withdrawal of redundant CF collaterals or to neuronal death in the inferior olivary nucleus (I.O.N.), which is the unique source of CFs in rodents ?

To answer this question, cells in the different I.O.N. subnuclei were counted in serial frontal sections of the medulla oblongata in developing rats from birth to adulthood. Appropriate corrections for double counting were applied. The total number of cells per-olive decreased from about 27,000 on day zero to about 21,000 on p.n. day 5. An apparent increase in the cell number occured subsequently and values in the adult were grossly similar to those found on day zero. The fraction of total cells represented by each different subnucleus remained approximately constant throughout this evolution. If no correction was applied the same biphasic evolution was observed. A similar postnatal increase in cell counts was observed in mice for the I.O.N. (Caddy and Biscoe Phil. Roy. Soc. Lond. 1979, 287, 167-201) and the PCs (Diglio and Herrup, Neurosc. Abs. 636, 1982). No conclusive explanation is yet available for this apparent increase since it is generally admitted that the last division of precursors of IO neurons occurs prenatally (Altman and Bayer, J. Comp. Neur. 179, 49-76, 1978).

Additional data were obtained by counting the IO population in adult mutant mice (weaver and staggerer) in which the multiple innervation of PCs is maintained. No significant difference was noted compared to control littermates of the same age.

In conclusion, this study reveals that cell loss occurs in the I.O.N. of the rat after birth. Nevertheless, it takes place before the peak of multiple innervation is attained and affects only 20% of total cells. Taken to-gether with the data obtained in adult mutant mice this suggests that neuronal cell death does not play a major role if any during elimination of redundant synapses between climbing fibers and Purkinje cells.

247.15 GOLDFISH STROBOSCOPIC ILLUMINATION: REGENERATION IN A FLASH FAILS TO SHARPEN THE RETINOTECTAL MAP.
J.T. Schmidt and L.E. Eisele*, Dept. Biol. Sci., SUNY Albany, Albany, NY 12222.

Using intraocular injections of tetrodotoxin (TTX) to block spike activity, we previously showed that the regenerating retinotectal map goes through an activity-dependent sharpening process during the time of initial synaptogenesis (20-34 days postcrush). Without activity the map was normally organized but the multiunit receptive fields at each point were grossly enlarged (25 to 40 degrees versus 11 normally). Single unit receptive field sizes were not enlarged. By 35 days the maps formed were relatively stable; that is, normal maps stay normal in spite of blockade of activity, and abnormal maps stay abnormal in spite of release from blockade for months. Therefore we have termed the 20-35 day period a sensitive period. Our working hypothesis is that neighboring ganglion cells, which are known to fire in a statistically correlated fashion, might use this relative synchrony of activity to eliminate inappropriate branches of an initially diffuse arbor and concentrate in one area. Within this area, their EPSP's would summate, perhaps leading to a strengthening of those synapses. If such a model is correct, then sharpening could also be blocked 1) if activity were allowed but all ganglion cells were made to fire synchronously (strobe light) or 2) if activity were allowed presynaptically but postsynaptic transmission were blocked by alpha-Bungarotoxin, which binds to nicotinic cholinergic receptors on tectal cells.

In the strobe rearing experiment, fish were placed in a white featureless environment inside a light tight box, strobed at 1/sec from day 20 onwards, and recorded at 35 to 90 days. All maps showed the same gross enlargement of the multiunit receptive fields as seen in the TTX fish, averaging 36 degrees vs 28 for TTX. Thus errors in targeting of the regenerating arbors were not eliminated when all ganglion cells fired in synchrony. This implies that the TTX results were not due to deleterious effects on ganglion cells, but to the elimination of cues in the spatiotemporal pattern of their activity.

In the alpha-Bungarotoxin experiments, an osmotic minipump was attached to the fish's head and a canula delivered 2-3 microliters of micromolar toxin per day from day 20 to 39 after nerve crush. Again the multiunit receptive fields were greatly enlarged, averaging 30 degrees vs 28 for TTX. Controls infused with Ringers were normal. We conclude that the elimination of misdirected branches of the initially diffuse arbors procedes via a mechanism whereby neighboring ganglion cells firing in relative synchrony stabilize each other's synaptic connections through summation of their postsynaptic potentials. 247.16 SYNAPTIC PROPERTIES OF MOTOR UNITS IN THE FROG CUTANEOUS PECTORIS MUSCLE.
L.O. Trussell* (SPON: A.D. Grinnell). Dept. of Biology, UCLA, Los Angeles, CA 90024.

The size, distribution, and synaptic physiology of motor units have been examined in frog cutaneous pectoris (c.p.) muscles. Unlike the frog sartorius (Grinnell & Trussell, 1983, J. Physiol., in press), very small motor units with high tetanus-to-twitch tension ratios were rare, consistent with the c.p. synapses' generally higher quantal content and suprathreshold operation (Grinnell & Herrera, 1980, J. Physiol., 307: 301-317). Nevertheless, motor unit tetanic tensions varied over a 30-fold range. Mapping of the distribution of synapses within motor units electrophysiologically and by HRP uptake revealed that single axons could innervate fibers throughout the entire muscle, showing little tendency towards a geographic localization of their innervation field.

EPPs from identified motor units in curarized muscles were examined to see if motor unit size and synaptic strength are directly related, as they are in the sartorius. Mean EPP size within motor units decreased with motor unit size, showing a 6-fold change over the range of units examined. Examination of the range of muscle fiber input resistances between units showed that small units were associated, in general, with smaller fibers. Thus, the differences observed in mean EPP amplitude with motor unit size must reflect even larger differences in quantal release.

While the mean EPP and fiber sizes of motor units varied with motor unit size, in many cases a marked variability was observed in the EPP, input resistance, and diameter of singly innervated fibers within the same unit. This variability in EPP size did not parallel fiber size differences. Thus, both transmitter release and the extent of growth of fibers may be regulated by more than just the identity and behavior of the innervating axon alone. Among the synapses formed by a given motor axon, the weakest inputs were generally members of a polyneuronally innervated junction. For smaller units, such complex junctions often appeared on the largest fibers in the motor unit, suggesting the overlap of small and large units, and the larger units' dominance in determining fiber properties.

These data suggest that, in the adult frog, motor neurons appear to differ in the mean level of transmitter release of their synapses, perhaps reflecting intrinsic differences in their ability to support synapses. Variation within a motor unit may be the result of competitive influences during and following the period of synapse elimination.

248.1 ULTRASTRUCTURAL LOCALIZATION OF SEROTONIN IN THE HIPPOCAMPAL FORMATION FOLLOWING RAPHE IMPLANTS IN NEONATAL RATS. V.R. Holets and C.W. Cotman. Department of Psychobiology, University of California, Irvine, CA 92717.

Fetal raphe (serotoninergic) neurons implanted into neonatal rats will reinnervate the developing hippocampus and dentate gyrus. However, the serotonin (5-HT) fibers do not form a laminated pattern as in normal animals, but hyperinnervate the entire hippocampal formation. The 5-HT immunoreactivity in the hippocampal formation appears as long, varicose fibers with enlargements that can be seen at the light microscopic level. Using the peroxidase, antiperoxidase (PAP) method we have identified 5-HT immunoreactivity at the ultrastructural level in the hippocampus and dentate gyrus in normal rats and raphe implant rats.

The entorhinal cortex was ablated and the fimbria cut in 3 day old neonate rats. The raphe nuclear area from rats of embryonic age 16-19 days was implanted into the entorhinal cortex site. Normal adult rats (60 days old) and rats which received lesions and implants (6 days post-implant) were perfused intravascularly with buffered 4% paraformaldehyde-0.2% glutaraldehyde. Vibratome sections (100 μm) were cut and processed for immunohistochemistry using the PAP procedure by Sternberger. Rabbit, anti-5-HT antiserum (supplied by Dr. Robert Elde, Univ. of Minnesota) was used at a dilution of 1/1000. The sections were then osmicated, dehydrated and embedded in Spurr's resin. Specificity of staining was determined using antiserum pretreated with 5-HT. The absorption controls indicated that the immunoreactivity observed was specific for 5-HT.

At the electron microscopic level, the morphology of the 5-HT varicosities was similar throughout the hippocampal formation in normal rats (ranging from 0.5-3 μm). In rats with raphe implants, the 5-HT immunoreactive varicosities were more frequent and large (0.6-5 μm) varicosities were observed. The 5-HT immunoreactive varicosities in the hilus and infragranular zone of the dentate gyrus of both normal and raphe implant animals measured 0.6-2.0 μm, and contained round clear vesicles (40-50 nm) and dense core vesicles. The 5-HT immunoreactivity appeared to be mainly associated with vesicles in the varicosities. Although the 5-HT immunoreactive varicosities were found to be distributed throughout the neuropil of the hippocampal formation in raphe implant rats and throughout certain areas of the normal rat (ie, hilus and molecular layer), they were infrequently observed to form synatic contacts with neuronal structures.

248.2 PLASTICITY OF NORADRENERGIC INNERVATION OF THE SUPRAOPTIC NUCLEUS FOLLOWING LESIONING. B.J. Davis, C.D. Sladek and J.R. Sladek, Jr. Department of Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, N.Y. 14642.

Vasopressin (VP)- and oxytocin (OX)-containing magnocellular neurons of the supraoptic nucleus (SON) are densely innervated by noradrenergic (NE) fibers that originate primarily in the A1 catecholamine cell group. NE input reaches the SON via the medial forebrain bundle (MFB) and the supraoptic decussations (SOD).

During the course of an ongoing investigation of plasticity of functional interactions of NE fibers and their VP target neurons, we found that bilateral lesions of the MFB and SOD, resulting in complete denervation of NE input to the SON, led to adipsia that was followed by death within 7-10 days. In contrast, partial denervation of NE input to the SON led to slight initial deficits of water intake that eventually recovered to normal levels. The purpose of the present investigation was to provide a morphological correlate of this apparent functional plasticity by evaluating regenerative responses of NE fibers in the SON following partial denervation.

Adult male rats were given unilateral intracerebral injections of 6-hydroxydopamine (6 ug in 1.5 ul ascorbic acid vehicle) into the MFB immediately caudal to the SON. Animals were killed after 4, 7, 10, 14, 21 or 35 days and brains were processed for formaldehyde-induced fluorescence. The pattern of NE varicosities in the SON on the lesioned side was compared with that of the intact side and with the SON of unoperated controls.

Four days following lesioning, fibers of the MFB appeared swollen, tortuous and brightly fluorescent, thus exhibiting morphology which is typical of damaged catecholamine axons. There was a marked reduction of NE varicosities in the SON ipsilateral to the lesion. Denervation of magnocellular perikarya was most pronounced in the lateral portion of the SON. The NE innervation pattern in the SON contralateral to the lesion appeared qualitatively similar to that of unoperated controls. At 7 and 10 days fine, delicate processes appeared to emanate from swollen profiles in the MFB. Varicose fibers also were seen crossing the lesion site, but they could not be traced into the SON. Swollen, brightly fluorescent varicosities were observed adjacent to magnocellular neurons within the SON. These reactive fibers, which appeared to be confined to the lateral portion of the SON, were increased in number at 14 and 21 days. By 35 days post-lesion the ipsilateral SON exhibited a striking increase in the number of varicosities with respect to the intact SON. These results suggest that partial denervation of NE afferent fibers to the SON led to an apparent hyperinnervation of their magnocellular target neurons. Moreover, they provide a morphologic basis for recovery from functional deficits following partial denervation of NE input to the SON.

248.3 **EFFECTS OF BLOCKING GABA ON HIPPOCAMPAL CA1 INHIBITION & PLASTICITY.** **C.Hendricks & T.J.Teyler. Neurobiology Dept., NE Ohio Coll Med, Rootstown, OH, 44272.**

GABA applied to CA1 cell soma appears related to basket cell recurrent inhibition, while dendritic GABA responses are quite different and may result from a feed-forward inhibitory mechanism (Alger & Nicoll, 1982; Andersen, etal, 1980). The present group of experiments: (1) characterized the effects of blocking GABA on different CA1 inhibitory responses and (2) determined what effects this disinhibition has on hippocampal plasticity.

The GABA blocking agent bicuculline (BIC) was applied to pyramidal cell soma or the mid-radiatum region of hippocampal slices via iontophoresis or pressure ejection. Using the paired-pulse method, inhibitory responses of the second pulse were titrated away with BIC. After titration was complete, tetanic stimulation (100Hz, 1sec) was given to the radiatum.

Inhibition was characterized by pairing stimuli from several different inputs (SC=Schaffer collaterals, OR=oriens, ANTI=alveus-antidromic). BIC ejected at pyramidal cell soma caused a strong disinhibition of what appeared to be recurrent inhibitory fibers. The second pulse of all pairings tested (SC-SC, OR-SC, OR-OR & ANTI-SC) lost inhibitory responses and single population spikes became multiple spikes, although they did not become larger in amplitude. Tetanus after this treatment sometimes resulted in potentiation of the stimulated fibers, but many times resulted in seizure activity with resulting postictal depression.

Application of BIC to the SC synaptic region caused strikingly different results. Inhibition of the SC-SC could be titrated out, while OR-SC and ANTI-SC inhibition was left intact. This indicated that BIC was localized to SC synapses, since the above cell soma response was not observed. Tetanic stimulation given to the SC in this condition not only potentiated the SC responses but also potentiated OR responses. LTP was pronounced and lasted over 1 hour in most cases observed, EPSP thresholds were unchanged. The results indicated local circuit interactions are more complex than present models of hippocampal function. These results also suggest that local inhibitory neurons probably play some role in modulating hippocampal plasticity, although they may not be responsible for LTP. (Supported by NSF)

248.4 CROSS-SPECIES SEPTAL TRANSPLANTS: CHOLINERGIC ENHANCEMENT OF T-MAZE PERFORMANCE. R.P. Bodony*, J.K. Daniloff, W.C. Low, and J. Wells (SPON: J. Held), Departments of Anatomy and Neurobiology, and Physiology and Biophysics, University of Vermont, Burlington, VT 05405

Both cholinergic graft and cell suspension transplants from small rat embryos restored T-maze behavior in rats subjected to bilateral fornix transection. Behavioral recovery correlated significantly with the extent of the transplant growth into the deafferented hippocampus (Dunnett, et al., Brain Res., 251: 335, 1982). Dopaminergic cross-species grafts induced a compensation to a turning response generated by a nigrostriatal lesion (Björklund, et al., Nature, 298: 652, 1982). Previously, we characterized the growth of fibers from cholinergic cell suspensions transplanted across species (Daniloff, et al., Anat. Rec., 205: 43A, 1983). The present experiment explores the ability of of xenogenic cell suspension transplants from the embryonic septum to restore T-maze behavior.

Three groups of Sprague-Dawley rats received bilateral operations: a sham group, a group with a fornix-fimbria lesion, and a lesioned group which received bilateral cell suspension transplants from C-57 Bl/6J mouse embryos. Beginning one month after surgery, animals were conditioned daily for a food pellet reward on an elevated T-maze for 3 weeks. After the conditioning period, performance testing was conducted daily for 9 weeks. For each trial, the animal was forced to choose one arm of the T-maze for its reward on the first run; immediately it was allowed a free choice on the second run. The correct response on the second run was to select the alternate arm for its reward. The number of times, in six daily trials, the animal alternated correctly on the second run was recorded. The animals were sacrificed and brain tissue was stained for acetylcholinesterase (AChE).

Sham animals stabilized at nearly 100% correct responses after 3 weeks. In contrast, animals with complete lesions showed little improvement above the initial 50% correct responses even after 9 weeks of testing. The transplant group steadily increased their performance after 3 weeks and performed at near normal levels (90% correct) after 9 weeks. These data are very similar to those reported for homogenic transplants (Dunnett, et al., 1982).

The relationship between AChE fibrous ingrowth and behavior will be discussed. The present results indicated that xenogenic septal cell suspension transplants can (1) restore part of the complex behaviors altered through hippocampal denervation and (2) in a manner similar to homogenic transplants.

248.5 ULTRASTRUCTURAL X-RAY MICROANALYSIS OF HIPPOCAMPAL ACETYLCHOLINESTERASE ACTIVITY DERIVED FROM SEPTAL TRANSPLANTS. W.C. Low[*1], P.R. Lewis[*1], S.T. Bunch[*2], A. Björklund[*4], U. Stenevi[*4], S.B. Dunnett[*3], and S.D. Iversen[*3]. [1]Dept. of Physiology and Biophysics, Univ. of Vermont, Burlington, VT, [2]Physiological Laboratory and [3]Experimental Psychology Laboratory, Univ. of Cambridge, U.K., and [4]Dept. of Histology, Univ. of Lund, Sweden.

Recent experiments have demonstrated that transplanted embryonic septal neurons are capable of reinnervating the hippocampal formation of adult rats. Transplant-derived acetylcholinesterase (AChE) activity was examined within ultrastructural compartments of the hippocampal formation using methods of electronmicroscopy in conjunction with electron probe X-ray microanalysis. Tissue taken from the septal-diagonal band region of fetal rat pups 15-17 days of gestation were graffed into a cavity overlying the anterior thalamus and rostral to the hippocampal formation. The cavity for implantation was created by unilateral aspiration of the fornix-fimbria which also eliminated the intrinsic cholinergic septal projection to the hippocampus. The contralateral septal projection to the hippocampal formation served as the control. Reinnervation of the hippocampal formation by transplant-dervied fibers was examined with AChE histochemistry. The pattern of staining in tissue reinnervated by the transplant was similar to the contralateral control tissue as seen at the level of the light microscope. The intensity of staining, however, was markedly reduced. At the ultrastructural level clusters of AChE reaction products (copper and sulfur) were observed in regions of the hippocampal formation which correlated with the staining seen at the light microscope level. There appeared to be fewer clusters in these regions in transplant-derived preparations, however, in comparison to contralateral controls. Electron probe X-ray microanalysis of these compartments revealed that the number of copper and sulfur X-rays emitted were similar for transplant-derived and control tissue. These results suggest that the enzymatic activity of AChE derived from septal transplants is the same as that in the contralateral control tissue, and that the reduction in transplant-derived AChE staining as seen at the level of the light microscope is most likely due to a decrease in the number of AChE containing fibers and/or a decrease in the compartments of AChE contained within each fiber.

248.6 THE ABILITY OF DAY 18 FETAL STRIATAL IMPLANTS TO REVERSE THE LONG TERM LOCOMOTOR ABNORMALITIES IN THE KAINIC ACID RAT MODEL OF HUNTINGTON'S DISEASE.
A.W. Deckel*, R.G. Robinson and P.R. Sanberg (SPON: D. Newman).

Kainic acid (KA) lesions of the striatum have been shown to produce biochemical, neuropathological, and behavioral deficits in rats similar to those seen in humans with Huntington's Disease. Recently, transplantation of fetal striatal tissue has been shown to survive in KA lesion rat striatal tissue. This experiment assessed the ability of these transplants to mediate behavior within the host brain of rats with previous KA lesions and reverse the long term locomotor deficits.

Twenty-one adult female Sprague-Dawley rats were assigned to one of three groups (7 per group), including lesion only (LO), lesion and transplant (LT), and control (CO) groups. Rats in the LO and LT groups received bilateral KA injections (0.8ug/0.4ul per side) in the anterior medial striatum. Seven days later, the LT rats received bilateral implants of day 18 fetal rat striatum directly into the KA lesion host striatum. The LO rats underwent the same surgical procedure as transplanted animals, but did not receive fetal striatal implants. The CO group received sham lesions and sham transplant surgical procedures. Twelve weeks later all animals were placed individually in computerized Animal Activity Monitors (Omnitech Electronics) and tested over 12 ten minute periods. These monitors provided detailed infomation of the animal's pattern of locomotion using 21 different variables measuring activity in the horizontal and vertical planes. A repeated measures ANOVA was used to analyze the statistical significance of the data.

The results demonstrated that although there were no differences between groups during the first period, the LO rats were significantly more active over the remaining eleven test periods than controls on 9 measures of activity (eg. total distance, movement time, etc.). This pattern of activity suggested that there was a slower rate of habituation by the LO group compared to CO. The LT group showed rates of habituation similar to the CO group, and appeared recovered from the habituation deficit shown by the LO group.

These findings suggest that the fetal implants will mediate behavior within the host brain, and reverse the locomotor deficits exhibited by the LO group. This procedure may provide a treatment for the long term behavioral disorders found in this animal model of Huntington's Disease. Supported by the Research Scientist Development Award (RGR) MH00163, NS15178, NS18622, by the Pratt Family and Friends Huntington's Disease grant, and Tourette Syndrome Association.

248.7 INTRAHIPPOCAMPAL INJECTIONS OF CYCLOHEXAMIDE REVERSIBLY BLOCK LONG TERM POTENTIATION. O. Steward and S. Brassel. Depts. of Neurosurgery and Physiology, Univ. of Va. Sch. of Med. Charlottesville,VA 22908.

Recent studies have suggested a relationship between long-term potentiation (LTP) in the dentate gyrus and protein synthesis. Duffy et al. (Sci. 212, 1148-1151, 1981) report an increased release of newly synthesized protein by hippocampal slices after the induction of LTP. Fifkova et al. (J. Neurocytol. 11, 183-210) report that peripheral administration of anisomycin (a protein sythesis inhibitor) suppressed the changes in spine size which accompany LTP. To date, however, there have been no studies of whether protein synthesis inhibitors affect the increases in synaptic potency which represent LTP.

Animals were prepared for acute neurophysiological recording with stimulating electrodes positioned bilaterally in the entorhinal cortex, and recording electrodes positioned in the dentate gyrus. A 1µl Hamilton microsyringe filled with 10µg of cycloheximide in 1µl of saline was positioned within 1mm of one of the recording electrodes. The stimulus intensities were adjusted so as to obtain approximately equivalent responses on each side; potentiating stimulation which results in similar response amplitudes usually leads to similar levels of LTP. Baseline responses were recorded for 30 minutes; the cyclohexamide was injected over a 5 minute interval; and a 30 minute post-injection baseline was obtained. Potentiating stimulation was delivered to each pathway (ipsilateral and contralateral to the cyclohexamide treatment) 30 and 90 minutes post-injection.

LTP was consistently observed on the control side, but was reduced or eliminated in the cyclohexamide-treated dentate gyrus when the potentiating stimulation was delivered 30 minutes post-injection. In some animals with complete suppression of LTP, there was no change in the baseline responses prior to potentiation. In other animals, where the recording electrode and the syringe were quite close, the pre-potentiation baseline responses were altered, in that the amplitude of the population spike increased. By 90 minutes post-injection, LTP could be induced in the cyclohexamide treated dentate gyrus to a level comparable to the control side.

LTP seems to require ongoing protein synthesis in the dentate gyrus. We propose that the process requires proteins which are produced in the postsynaptic cell, perhaps protein produced by the polyribosomes which are selectively localized under spine bases (see Steward & Levy, J. Neurosci. 2, 284-291, 1982). It is possible that LTP induces the synthesis of some protein, or that protein which is crucial for LTP turns over rapidly, and must be continually replaced by protein synthesis.

248.8 THE PLASTICITY OF SPECIALIZED SYNAPSES AND DIRECT CELL-CELL APPOSITION IN RAT SUPRAOPTIC NUCLEUS. Charles D. Tweedle and Glenn I. Hatton, Dept. of Anatomy and Neuroscience Program, Michigan State University, East Lansing, MI 48824.

Water deprivation for short periods of time (4-24 h) and parturition have been shown to dramatically increase the amount of direct soma-somatic contact between magnocellular neurosecretory cells (MNC's) of the adult rat supraoptic nucleus (SON). This increased contact is apparently by means of the withdrawal of thin astrocytic glial processes from between the MNC somata. It has been shown that more chronic stimulation of the SON induced by suckling or drinking 2% saline for 10 days leads not only to an increase in soma-somatic apposition, but also to the appearance of specialized "double" synapses (with one pre-synaptic terminal ending on 2 adjacent MNC somata). Such double synapses are extremely rare in the SON of control animals (Neurosci. 1981, 6, 919-930; Brain Res. Bull. 1982, 8, 197-204; Neurosci. Abstr. 1982, 8, 745). An experiment was designed to assess whether these specialized synapses, once formed, would disappear when the SON neurons were no longer chronically activated.

Young adult (100 day old) male and female rats were maintained 10 days on 2% NaCl instead of drinking water. Other rats were likewise maintained on saline for 10 days and then allowed access to drinking water again for 5 or 14 days. Thin sections from the saline-treated and control rats were quantitatively examined at the ultrastructural level. 1.9% of SON cells were in direct contact in control animals and 28.9% in the 10 day saline-treated group. 1.2% of MNC's showed double synapses in the SON of the control animals compared to 20.4% in the 10 day saline-treated group. In the animals rehydrated for 5 days the amount of SON cell apposition was back to control levels, but the number of double synapses was still elevated. In the animals rehydrated for 14 days only 2.4% of the MNC cells were contacted by double synapses. There were no sex differences seen in the results from these experiments.

It thus appears that not only can chronic activation of MNC's induce the appearance of new synapses in the SON, but that, with time, these synapses can also be eliminated when the stimulation ceases. Our working hypothesis is that the changes in cell-cell apposition by glial movement may be integral to the changes in synapse number and that both the changes in cell apposition and synapses are physiologically meaningful adaptations of the SON. (Supported by NIH Grant NS 09140).

248.9 PLASTICITY IN SUPRAOPTIC NEURONS: DENDRITIC BUNDLES AND DOUBLE SYNAPSES VARY WITH HORMONE DEMAND. L. S. Perlmutter, C. D. Tweedle and G. I. Hatton. Dept of Psychology, Anatomy and Neuroscience Program, Michigan State University, E. Lansing, MI 48824.

Magnocellular neurosecretory cells (MNCs) of the supraoptic nucleus (SON), which produce and release oxytocin, display a burst of activity that is proportional to the amount of oxytocin released in lactating rats (J. Physiol., 1975, 250, 443-461). Increases in the amount of soma-somatic apposition in post-partum and lactating rats and the percentage of MNC somata in lactating rats with double synapses (i.e., one presynaptic terminal making contact with two postsynaptic neurons) have also been found (Brain Res. Bull., 1982, 8, 197-204). These morphological changes may be involved in synchronizing the burst activity of the MNCs. Dendritic bundles (i.e., several dendrites in direct apposition) have been reported in several locations within the CNS, and it has been postulated that these bundles may serve to influence rhythmic activity (Golgi Centennial Symposium, Raven Press, 1975, 347-354). We now report that the presence of dendritic bundles in the SON, as well as the number of double synapses onto these dendrites, vary with hormone demand.

Four young adult rats from each of the following experimental conditions were used: Virgin females, pre-partum (day 21 of gestation), post-partum (2-24 hrs after delivery; litter size 4-13 pups), and lactating (for 14 days with a minimum of 6 pups). Rats were perfused transcardially, the SONs removed and prepared for electron microscopy morphometric analysis.

There was a significant difference in the average number of dendrites per bundle across the four groups ($H = 10.47$, $p < .02$). Planned comparisons using the Mann-Whitney U test revealed that virgins had a significantly smaller average number of dendrites per bundle than the three other groups, as did pre-partum compared with post-partum ($p < .02$ for each comparison). Further, the ratio of double synapses onto these dendrites to the total number of dendrites varied with treatment group ($H = 9.15$, $p < .05$). Comparisons revealed a significant increase in double synapses in post-partum compared with virgins ($p < .02$) and with pre-partum rats ($p < .02$). The total number of synapses per dendritic profile did not vary across conditions.

Formation of dendritic bundles and the increased occurrence of double synapses may be additional mechanisms to synchronize neuronal activity. The greatest change was found in the post-partum rats, suggesting a role in the rapid rise of oxytocin release immediately preceding parturition. The less extreme changes observed in the lactating rats indicate that these adaptations are reversible. Hence, rapidly occurring plasticity has been confirmed at the dendrite as well as at the soma of supraoptic MNCs.

Supported by NIH Grant NS09140.

248.10 TIME COURSE OF SYNAPSE REPLACEMENT IN THE MOUSE HIPPOCAMPAL DENTATE GYRUS. K.J. Anderson,* S.W. Scheff and S.T. DeKosky. Depts. of Anatomy and Neurology, Univ. of Kentucky and V.A. Medical Center, Lexington, KY 40536.

Our laboratory has focused on fundamental morphological changes in the central nervous system following damage. Specifically we have monitored the loss and reacquisition of synapses in the rat hippocampal formation. A unilateral ablation of the entorhinal cortex results in a major deafferentation of the granule cell dendritic field in the hippocampal dentate gyrus. Residual afferents to the dentate molecular layer are responsible for the reinnervation of this area, and play a role in the return of synaptic density to pre-operative levels. In the adult rat, return of synaptic contacts and removal of degenerative debris follow a strict time course. In other species it is not clear whether replacement of lost synaptic contacts is restricted to similar temporal parameters and involves the same reactive afferents. We have chosen to examine the process of axon sprouting and reactive synaptic replacement in a commonly used strain of mouse, the C57 black.

Thirty-five adult mice were subjected to a unilateral removal of the entorhinal cortex and allowed to survive for 2, 4, 6, 10, 15, 30, or 60 days following surgery. The hippocampi from these mice were fixed and processed for either light or electron microscopy. Sections for light microscopic study were stained either with the Holmes fiber method to assess changes in the commissural-associational fiber plexus or for AChE histochemistry to examine alterations in the septohippocampal afferents. Tissue for electron microscopy was processed by standard techniques and ultrathin sections encompassing the dentate gyrus molecular layer were cut. Photomontages were constructed from these sections that extended from the dorsal layer of the granule cells to the hippocampal fissure. All recognizable synapses were classified as either intact or degenerating and expressed as the number of synapses per 100 um^2. At this time, our preliminary results show that an entorhinal lesion initially reduces the synaptic density of the outer molecular layer to 7% of control. By 15 days post-lesion, synaptic density reaches 30% of control while at 30 days post-lesion, the synaptic density is restored to 50% of control. The course of the sprouting response in mice will be related to changes known to occur in the adult rat.

(Supported by NIH grants NS16981, NS00444, and the V.A. Medical Research Service.)

248.11 SURVIVAL OF ADULT MOUSE RETINAL GANGLION CELLS FOLLOWING INTRACRANIAL OPTIC NERVE TRANSECTION. M.R. Moore[1], R. Madison[2], and R. L. Sidman[2]. Yale Med. Sch.[1], Departments of Neuroscience and Neuropathology, Childrens Hosp. and Harvard Medical School[2], Boston, MA. 02115

Several laboratories have recently demonstrated a population of optic nerve axons and cells in the retinal ganglion cell layer which survive intracranial transection in the rat or mouse (see also Madison et.al., this volume). The following study was undertaken to determine if specific manipulations to the transected adult mouse optic nerve would affect the number or size class of cells surviving in the retinal ganglion cell layer. We tested the effects of: 1) intraorbital or 2) intracrainial optic nerve transection, or 3) intracranial transection with grafting of a short segment of either autologous sciatic nerve, or 4) intracrainial transection and grafting of a heterologous segment of neonatal optic nerve.

At the end of a 7-9 month postoperative survival time, animals were anesthetized and perfused with 20 ml 0.9% saline followed by 100 ml 20% formalin/saline. Retinal wholemounts were prepared from both transected and non-transected sides. Data were collected from retinal wholemounts with a computer-controlled light microscope. Cell size and location were entered on-line from a digitizing tablet to a display terminal and then to a VAX-11/780 computer for further analysis. The wholemount was divided into inner, middle and outer zones. Zone boundaries were established as 1/3 and 2/3 the radial distance from the optic nerve head to the wholemount outer border. Each zone was then divided into equal grid squares that were tabulated randomly at a final magnification of 1600 X. Approximately 1-2% of the total area of each retina was quantified.

Contralateral control retinal cell densities were 10.98 ± 1.65 (inner), 10.16 ± 1.3 (middle), and 8.06 ± 0.20 (outer); expressed as $10^3/mm^2$ of retinal area, mean ± SEM. Intraorbital transection resulted in complete necrosis of the retina within 10 days. Nine months after intracranial transection alone there are; 4.23 ± 0.34 (inner), 4.48 ± 0.40 (middle), and 4.25 ± 0.54 (outer). Both autologous sciatic nerve (N=2) or heterologous neonatal optic nerve (N=2) grafts are equally successful in allowing more cells to survive at 7 months after surgery; 7.98 ± 0.40 (inner), 6.70 ± 0.27 (middle), and 5.11 ± 0.09 (outer); $p<.01$ compared to intracranial transection alone, each and every zone. Under these processing conditions, many of the cells that are >40 μs in the mouse retina are believed to be ganglion cells. With intracranial transection alone approximately 10% or 0.43 ± 0.08 of cells >40 μs survive, compared to 17% or 0.69 ± 0.02 with the grafts; $p<.01$. 248.12 B-ADRENERGIC RECEPTOR REGULATION OF LONG-TERM POTENTIATION IN THE HIPPOCAMPUS. William F. Hopkins* and Daniel Johnston. Neuroscience Program, Baylor College of Medicine, Houston, TX 77030.

We have previously demonstrated that bath-applied norepinephrine (NE,1-10 uM) reversibly prolongs the duration of long-term potentiation (LTP) of the population EPSP amplitude in the CA3 subfield of the rat hippocampal slice preparation (Hopkins and Johnston, Neurosci. Abs. 8: 740, 1982). The experiments described here suggest that NE need only be present in the bath during the high-frequency train used to induce LTP to exert this action, and that the effect is mediated by B-adrenergic receptors.

Rat hippocampal slices were maintained in vitro at 32° C using standard techniques. Field potentials were recorded from stratum lucidum and pyramidale of the CA3 subfield in response to stimulation of the mossy fibers. LTP was typically induced with 100 Hz, 2 sec trains of 0.05 msec constant-current pulses. The amplitude of the population EPSP, expressed as a percentage of the pre-tetanic response, was measured as a function of time following the high-frequency train. Some slices were capable of demonstrating several similar LTP episodes in which the population EPSP amplitude decayed to baseline levels within 80 minutes. The time at which the population EPSP decayed to its half-maximal amplitude with respect to baseline (half-decay time) was used to quantify LTP duration. Half-decay times greater than 15 minutes and leftward shifts in I/O curves at 15 minutes post-tetanus were taken as evidence of LTP.

When NE was present only during tetanic stimulation, the mean± s.e.m. half-decay time was 105.6±7.1 minutes. This is similar to the value obtained in previous experiments in which NE was present during both tetanic stimulation and the decay phase (105.8±10.7 minutes). Similar measures for the control and wash episodes were 30.9±7.8 and 25.7±0.7 minutes, respectively.

The B-adrenergic agonist isoproterenol (1 uM) mimics the effect of NE on LTP duration. The mean half-decay time for experiments in which isoproterenol was present only during high-frequency stimulation was 112.5±3.6 minutes. The control and wash mean half-decay times were 23.9±5.9 and 25.1±0.3 minutes, respectively. Propranolol (10-100 nM), a B-receptor antagonist, blocks the NE effect on LTP, and reversibly blocks LTP. In contrast, the α-receptor antagonist yohimbine (1 uM) did not affect the action of 10 uM NE on LTP duration.

The mossy fiber synapses are electrotonically close to the cell bodies of CA3 pyramidal neurons (Johnston and Brown, J. Neurophys. in press). It may therefore be possible to explore the cellular basis of these effects using other electrophysiological techniques. 248.PO **RAPID PROCESS FORMATION BY DISSOCIATED ADRENAL CHROMAFFIN CELLS IMPLANTED INTO THE RAT BRAIN.** U. Patel, W.J. Freed, R.J. Wyatt. Preclinical Neurosciences Section, Adult Psychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032

Mechanical dissociation of adrenal medullary tissue is a quick method for obtaining viable adrenal chromaffin cells for injection into discrete regions of rat brain (for method see Wells, M.R. and Patel, U., this volume). To study the properties of these cells after implantation, mechanically dissociated adult adrenal chromaffin cells were injected into the denervated striatum of rats with unilateral substantia nigra lesions. In some experiments, cells were incubated for one hour in 0.05 uCi/ml [^{3}H] Lysine for short term protein labeling before injection. Injected animals were processed for glyoxylic acid-induced catecholamine histofluorescence and autoradiography from one hour to 30 days after injection. Control animals were injected with heat-killed dissociated [^{3}H] Lysine labeled cells. After implantation some injected cells began to enlarge and form thin cytoplasmic processes within the first hour. Most of the injected cells had formed processes exceeding the diameter of the cell by four hours after injection. The formation of processes continued for the first 24 hours. After four days, implanted cells as identified by histofluorescence and autoradiography were found 2-5 mm away from the injection site. The cells appeared to have migrated primarily, but not exclusively, adjacent to blood vessels. The formation of processes by these cells was much more extensive than that which has been observed in adrenal medullary tissue implants into cerebral ventricles (Freed et al., Nature, 292:351, 1981). While the results indicate that some dissociated cells injected into the brain demonstrate different properties than whole tissue implants, the difference could be due to the more intimate contact between dissociated cell grafts and the host brain. The possibility of injecting dissociated cells with minimal damage to the host brain may increase the effects of these grafts and may facilitate transplantation of catecholaminergic tissue into higher vertebrate brains. Possible influences of such implants on the host brain are under study.

MUSCLE AFFERENTS

249.1 NON-SELECTIVE MOTOR INNERVATION OF BAG$_1$ INTRAFUSAL FIBERS IN CAT MUSCLE SPINDLES. J. Kucera, Dpt. of Neurology, Boston Univ. Sch. of Med., Boston, MA 02118

Studies of living cat muscle spindles and experiments using the glycogen-depletion technique have shown that dynamic γ or β motor axons supply nuclear bag$_1$ intrafusal muscle fibers and static axons supply nuclear bag$_2$ and chain fibers. However, it has been unclear whether some motor axons may co-innervate the bag$_1$ fiber together with other types of intrafusal fiber in the same spindle. To answer this question we have reconstructed the motor nerve supply to 10 whole and 6 half spindles from serial semithin (1 um thick) and periodic ultrathin transverse sections of tenuissimus muscles removed from anaesthetized cats (sodium pentobarbital 35 mg/kg) and stained with toluidine blue or uranyl acetate. The motor axons were traced from their origin in intramuscular nerve trunks to their intrafusal terminals.

Of the 28 poles of the bag$_1$ intrafusal fiber encountered, 23 received motor nerve supply and 5 did not. All the innervated bag$_1$ fiber poles received 1 to 3 (mean 1.4) selective motor axons that supplied this fiber type only. Four of the poles (17%) received, in addition, terminals from a non-selective motor axon that also innervated one, but not more, of the chain fibers in the spindle. No motor axon branched to supply both bag$_1$ and bag$_2$ fibers. The chain fibers co-innervated with bag$_1$ fibers tended to have a higher density of nuclei at the equator, a greater polar length and a less granular appearance when stained with toluidine blue than most other chain fibers. Terminals of the non-selective motor axons on the co-innervated bag$_1$ and chain fibers were morphologically and ultrastructurally dissimilar. It is suggested that instances of innervation of the (dynamic) bag$_1$ fiber in common with a (? static) chain fiber represent an integral and, presumably, functionally meaningful part of the motor pattern in some cat spindles.

249.2 RELATION OF SINGLE FIBER EPSP AMPLITUDE IN SPINAL MOTONEURONS TO LOCATION OF AFFERENT ENTRY. J.E. Zengel, G.W. Sypert and J.B. Munson. VA Med. Ctr. and Depts. of Neuroscience and Neurological Surgery, Univ. of Fla. Coll. of Med., Gainesville, FL, 32610.

Many factors may be involved in determining the amplitude of EPSPs in spinal motoneurons. One factor that may affect the amplitude of EPSPs generated by muscle spindle afferents is the location of the motoneuron relative to the spinal cord entry point of the afferent. The present study investigated the amplitude of EPSPs generated in motoneurons by single homonymous muscle spindle group II afferents as a function of the location of the motoneuron relative to the rostral-caudal entry location of the afferent.

Three to 4 mm of spinal cord in the region of the L7-S1 dorsal root junction were systematically explored at 100 µm intervals in the longitudinal direction to locate medial gastrocnemius (MG) motoneurons. The spike-triggered averaging technique was used to record single-fiber EPSPs generated in these motoneurons by single spindle group II afferents. EPSP amplitude (or failure) was related to the entry level of the triggering afferent, which was determined at the conclusion of the experiment.

We measured the amplitude of 81 single fiber EPSPs generated by 4 spindle group II afferents (104 afferent-motoneuron combinations). We found that afferents entered the spinal cord at locations which were rich in MG motoneurons as indicated by the ease of recording MG motoneurons at these locations. Afferent-to-motoneuron connectivity and single fiber EPSP amplitude were greatest in the region of afferent entry. On average, connectivity and amplitude declined progressively at more rostral locations, but each again increased in magnitude at least over the interval 1.0-1.5 mm rostral of the afferent entry location.

These data, along with consideration of other anatomical and electrophysiological data (Ref. 1,2), suggest that EPSP amplitude and connectivity are each greatest at locations where afferent collaterals enter the motoneuron nucleus. A second region of relatively powerful innervation (high EPSP amplitude and connectivity) appears to exist 1.0-1.5 mm rostral to afferent entry, where another collateral probably descends into the motoneuron nucleus (Ref. 2). Additional such regions probably exist further rostrally.

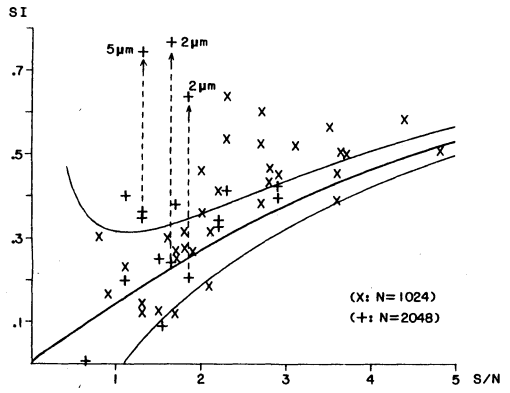
249.3 THE PRESENCE OF AFFERENT SYNCHRONY IN A PASSIVE MUSCLE AT FIXED LENGTH. T. M. Hamm, D. D. Roscoe, R. M. Reinking* and D. G. Stuart. Department of Physiology, University of Arizona Health Sciences Center, Tucson, AZ 85724.

We have previously reported the use of an index (SI) which tests for synchrony between neuronal spike trains by comparison of rectified and non-rectified averages, triggered by a reference train (Roscoe et al, Adv. Physiol. Sci. 1: 219-228, 1980; Reinking et al, Soc. Neurosci. Abstr. 7: 558, 1981). This index has now been modified to increase its sensitivity. Contrary to our previous findings, we now report the presence of afferent synchrony emanating from the passive, de-efferented cat medial gastrocnemius muscle when held at fixed length (see figure). This synchrony is subtle, as judged by comparison of SI values obtained at fixed muscle length and during small (2-5 μm) "quick" stretches. The significance of these results for interpretation of spike-triggered averages will be discussed.

Supported by USPHS grants NS 07888, NS 17887 and HL 07249.
Present address of D. D. Roscoe: Dept. of Surgical Research, St. Luke's Hospital, Cleveland, OH 44104.



SI values (based on averages of N = 1024 and 2048) plotted as a function of signal-to-noise ratio (S/N) of the reference-afferent spike in the neurogram. Solid lines show the expected value ± 2 S. D. (at N = 1024) for the condition of complete asynchrony. Dashed arrows show increase in SI with application of quick (5 ms duration) stretches of indicated amplitude.

249.4 SELECTIVE ACTIVATION OF SINGLE TYPE-IDENTIFIED MUSCLE RECEPTOR AXONS. C.-S. Yuan*, T. M. Hamm, R. M. Reinking* and D.G. Stuart. Department of Physiology, University of Arizona Health Sciences Center, Tucson, AZ 85724.

For the unambiguous study of Ib-motoneuronal connections, we have adapted the technique of Zealear and Crandall (J. Neurosci. Methods 5: 47-54, 1982) for stimulating single motor-unit axons to stimulating and recording from single Ib axons within a muscle nerve.

A stepping motor is used to advance a glass microelectrode into a fascicle from the cat medial gastrocnemius (MG) muscle within the sciatic nerve, which is mounted on a stable platform. Following penetration of an axon or its myelin sheath, the axon can be identified using conventional tests and its continuity with the spinal cord and the ability to activate the axon selectively verified by extracellular dorsal-root and muscle-nerve recordings, respectively (see figure).

This technique provides an alternative to the study of muscle receptor-motoneuronal connections using stimulation of single afferents in dorsal-root filaments (Honig et al, J. Neurophysiol. 49: 886-901, 1983) or a dorsal-root ganglion (Willis et al, Brain Res. 9: 152-155, 1968).

Supported by USPHS grants NS 17887, NS 07888 and HL 07249.

249.5 PATTERNS OF DISCHARGE OF PRIMARY AFFERENTS AFTER ADMINISTRATION OF 4-AMINOPYRIDINE IN THE CAT. R. Dubuc, J. Provencher* and S. Rossignol. Centre de recherche en sciences neurologiques, Département de physiologie, Université de Montréal, Montréal, Québec, Canada H3C 3J7.

Rhythmic bursts of activity (3-7Hz) are recorded from peripheral nerves following the injection of 4-aminopyridine (4-AP) in the decerebrate and paralyzed cat (Rossignol, S. et al., Soc. Neurosci. Abstr., 7, p. 863, 1981). Similar discharges are also recorded from the proximal stump of cut dorsal or ventral roots (Dubuc, R. et al., Soc. Neurosci. Abstr., 8, p. 957, 1982). Therefore it appears that the rhythmic discharges recorded from a mixed nerve in the periphery is a composite of both ventral root activity and antidromically conducted discharges in the primary afferents. In the present study primary afferent units were recorded in the dorsal roots.

Cats were decerebrated at the precollicular level, paralyzed and artificially ventilated. A spinal transection was effected at Th 13 and the lumbar enlargement was exposed. Glass-coated tungsten electrodes were utilized to record single units from the exposed dorsal roots. Cuff or Ag/AgCl hook electrodes were used to record and/or stimulate peripheral nerves which were cut distally to the electrodes. The conduction velocity of the units was determined from the latency of the stimulation-evoked discharge and the distance between the recording and stimulating sites measured post-mortem.

A total of 133 primary afferent units were recorded from eleven cats in which rhythmic discharges were observed from peripheral nerves after an i.v. injection of 10 mg/kg of 4-AP. 51% of the units discharged in bursts of spikes (200-400 Hz) which in some cases had the same rhythmicity as that observed in the peripheral nerves. Another 26% of primary afferents showed a tonic discharge pattern with a rigourously constant interspike interval. The rate of discharge of those cells ranged between 10 and 40 Hz. Finally, the remaining 23% of the cells were either silent or had an irregular single spike pattern of discharge. It was found that the conduction velocity of the great majority of bursting cells ranged between 40-80 $m \cdot s^{-1}$ while that for the majority of the tonic cells was between 80 and 120 $m \cdot s^{-1}$.

It is concluded that 4-AP may exert differential effects on primary afferents of different size. Experiments are underway to determine whether such differential effects are related to different types of primary afferents.

249.6 ANATOMICAL CORRELATES OF MOTOR UNIT/TENDON ORGAN (MU/TO) RESPONSE PATTERNS. J. M. Spielmann* and E. K. Stauffer. Department of Physiology, Sch. of Med., Univ. of Minnesota, Duluth, MN 55812.

An inherent characteristic of MU/TO physiology is that the Ib afferent responds to the intramuscular force coupled to the receptor's capsule rather than to the total force directed along the common tendon of the whole muscle. Analysis of MU/TO responsiveness is hampered, however, by the lack of data from the same preparation to make a direct comparison of physiology and anatomy. The present investigation was designed to examine the functional arrangement of single identified TOs, single identified MUs, and to relate this structure to the Ib afferent signal.

Soleus Ib afferents were isolated from subdivided ventral rootlets and their associated TOs were located on the posterior aponeurotic surface by finding the point of greatest Ib response to external pressure applied with a fine-tipped probe. Single MUs from subdivided ventral rootlets were studied if their contraction elicited a response from the TO. TO firing patterns were recorded during whole muscle and MU twitches. MUs were glycogen-depleted with intermittent trains (40 Hz) of short tetani (330 msec on, 670 msec off) for 1½-2 hr. after which the muscle was removed, trimmed, and frozen in isopentane (-160°C). Serial sections (10 μ) were stained separately: (1) with periodic acid Schiff to track the depleted MU fibers (DF); and (2) modified Gamori trichrome to examine the MU/TO anatomy.

All TOs that gave the typical accelerated discharge during the rising phase of whole muscle and/or MU twitch force profile had a DF attached specifically in series to the proximal tip (collar) of the end organ. In addition, TOs with an in series DF usually had a discharge pattern that extended throughout almost the entire duration of the MU twitch profile. Deviations from this common response could be explained in terms of an assumed unloading effect of nearby in parallel DFs from the same MU. In one case, a second DF attached onto the TO capsule near the equatorial region of the receptor. In this instance, the number of Ib afferent spikes was greatly reduced and the time of their occurrence was limited to the initial portion of the twitch force. We found no relationship between the TO discharge and the location of the inserting DF amongst the other circumjacent inserting fibers. There was, however, a direct relationship between the size of the TO's receptive field (i.e. total number of muscle fibers that inserted into the collar) and the magnitude of its Ib afferent discharge. These findings are consistent with and confirm earlier interpretations of MU/TO response patterns which rested solely on either physiological or anatomical data from complimentary but separate studies.

249.7 ULTRASTRUCTURAL LOCALIZATION OF CARBONIC ANHYDRASE ACTIVITY IN RAT SENSORY SPINAL NEURONS, AXONS, AND MUSCLE SPINDLE SENSORY AND MOTOR TERMINALS. D.A. Riley, S. Ellis*, and J.L.W. Bain*. Med. College Wis., Dept. of Anatomy, Milwaukee, WI 53226 and NASA Ames Research Center, Moffett Field, CA 94035.

Recently, we demonstrated histochemically that a subset of myelinated axons in rat peripheral nerves exhibited high levels of carbonic anhydrase activity (Riley et.al., 1982, J.H.C. 30:1275). The majority of the reactive axons were sensory. The present study examined the subcellular distribution of carbonic anhydrase activity in lumbar (L4,5) dorsal and ventral root axons, spinal ganglion cells, and the sensory and motor nerve endings of muscle spindles in extensor digitorum longus muscles. Male Sprague-Dawley rats (325-350 g) were perfused with 2.5% glutaraldehyde. Tissues were sectioned (20 μm) with a vibratome and incubated on gelatin-coated plastic slides in Hansson's medium. Following osmication at pH 6 in osmium-ferricyanide, sections were embedded in Epon. Specificity of staining was confirmed by inhibition with 10^{-5} M acetazolamide. In the spinal roots examined, nonmyelinated axons were always unstained. The axoplasm of highly reactive myelinated axons was densely stained throughout except for the cisternae of smooth endoplasmic reticulum. The staining in moderately reactive axons and in sensory neurons was predominantly localized in discrete patches on the cytoplasmic surface of the endoplasmic reticulum. In gamma motor terminals, similar patches of staining were present on synaptic vesicles and the endoplasmic reticulum. The cytoplasm of primary sensory terminals (Ia) was densely stained throughout. The intracrista spaces of mitochondria in reactive somata, axons and terminals were stained. The cytoplasmic distribution of carbonic anhydrase indicates that it is not secreted by neurons. The enzyme may regulate intracellular pH and CO_2 levels during impulse conduction. The preferential deposition on the endoplasmic reticulum indicates a functional association with this organelle. The present results identified a portion of the reactive sensory neurons as primary spindle afferents and demonstrated that some of the reactive axons in the ventral roots were gamma efferents. These findings are consistent with our hypothesis that carbonic anhydrase is highest in tonically-active cells. This work was supported by the Institutional Research Committee of the Medical College of Wisconsin and a NASA Ames University Consortium NCA-OR665-102.

249.8 MUSCLE SPINDLE DISCHARGE DURING SCRATCH REFLEX OF THE SPINALIZED TURTLE. Z. Hasan. Department of Physiology, University of Arizona, Tucson, AZ 85724.

In the study of muscle receptors and movement, the scratch reflex of spinalized vertebrates offers a potential simplification in that only one limb participates in the movement. The low-spinal turtle is of special advantage since in this animal the programs for scratching can be elicited readily, and also because sufficient information already exists regarding the muscular synergies and the kinematics.

Turtles (Pseudemys) were decerebrated under ether, ventilated artificially, and spinalized at the D2 level. Part of the carapace was removed, and the loss of the dorsal anchoring of the ilium was compensated. Unit afferent activity was recorded, using a monopolar electrode (75μm S.S.), from fine filaments, 1-2mm long, of the otherwise intact S1 dorsal root. Denervation of the shank and the foot left intact the contribution to the S1 root from knee flexor and/or hip retractor muscles with origins in the pelvic girdle.

Attention was focused on the Flexor Tibialis Internus (FTI) and Iliofibularis (IF) muscles. Electromyograms (EMGs) were recorded from these adjacent, two-joint muscles. Lack of cross-talk was confirmed since, in the A1 phase of the rostral scratch, IF was active while FTI was not, as has been reported. However, in the caudal scratch, the two muscles acted more synergistically, although IF activity always commenced before that of FTI. A length-gauge which relied on the resistance of saline in a Silastic tubing (0.9mm OD), was implanted in parallel with IF.

Spindle afferents were identified by the characteristic pause in discharge that occurred following an electrical stimulus to the muscle while the shank was held rigidly. During scratch-related muscle contraction, these afferents exhibited the full range of behavior from cessation of discharge to increase of the discharge rate during shortening. However, a particular afferent, if it increased its discharge rate during contraction of the receptor-bearing muscle, did so only after a particular level of EMG activity appeared to have been attained, and the increase was greater when the EMG was higher in amplitude. Thus, more vigorous cycles were associated with greater afferent discharge during active shortening. However, the peak rate of discharge was no higher than 40 imp/s.

These observations are consistent with spindle innervation by branches of skeletomotor axons in turtles. Mammalian spindle afferents, in contrast, have not been reported to exhibit silence at the onset of contraction in active movements. This difference may underlie the significance of the gamma system.

249.9 ORIGINS OF SENSORY FIBERS OF THE MASTICATORY AND EXTRAOCULAR MUSCLES IN THE RAT. H.Y. Bai* Z. Ye* and W.H.A. Yu (SPON: A.N. Bender). Department of Anatomy, Mount Sinai School of Medicine, New York, N.Y. 10029.

The localization of the somata and sensory neurons innervating muscles of mastications and the extrinsic eye muscles were investigated by means of retrograde transport of horseradish peroxidase (HRP) which was injected intramuscularly (5-10 ul of 10% solution) or applied directly to the proximal stump of the transected nerves supplying the corresponding muscles. The HRP tracing method revealed that the jaw-closing (temporalis, masseter, and medial and lateral pterygoid) muscles and the extraocular muscles received afferent fibers from neurons located in the semilunar ganglion (SG) and in the mesencephalic trigeminal nucleus (MTN). The jaw-opening (mylohyoid and anterior belly of digastric) muscles, on the other hand, did not receive afferents from the MTN. Projections to the masticatory and extraocular muscles from the SG and the MTN were unilateral except those to the muscles innervated by the oculomotor nerve, which received a bilateral innervation from the MTN. HRP labeled neurons in the MTN exended from the pons at the level of the nucleus of the abducens nerve to the midbrain rostral to the superior colliculus. There was a topographic organization in the MTN in that the neurons innervating jaw-closing muscles were represented caudally, while those supplying extraocular muscles occupied a more rostral level. Following each HRP administration a large proportion of the motoneurons was also labeled only in the appropriate motor nucleus, which served to indicate the reliability and precision of the delivery of the tracer. The abducens and trigeminal motoneurons were labeled unilaterally. The oculomotor and trochlear motoneurons were labeled bilaterally suggesting the presence of crossed and uncrossed fibers. In conclusion, the jaw-closing and extraocular muscles of the rat received afferent fibers from the semilunar ganglion and the mesencephalic trigeminal nucleus. The dual origins may represent functional segregation, each subserving different sensory modality.

250.1 SENSITIVITY OF NEURONS IN VESTIBULAR NUCLEUS TO ACTIVE AND PASSIVE HEAD MOVEMENTS IN ALERT RHESUS MONKEY. Sat Bir Khalsa*, D.W.F. Schwarz, R.D. Tomlinson*, & J.P. Landolt, Lab. of Otoneurology, Univ. of Toronto, Toronto, Ont., Canada, M5S 1A8.

Recent electrophysiological studies in the squirrel monkey (Goldberg, J.M. & Fernandez, C., 1980, J. Neurophysiol., 43: 986-1025) have indicated that the efferent vestibular system is capable of modifying primary afferent vestibular information. If the efferent vestibular system modifies the afferent signal in connection with a motor program for active head movements, then this should be apparent as a difference in neuronal firing characteristics recorded at the level of the vestibular nucleus. Rhesus monkeys were trained to fix a small target, which was used to evoke head movements. Crowns were implanted to allow for the mechanical fixing of the animal's head, for the recording of the EOG via silver wire electrodes, and for the recording of vestibular neurons in the vestibular nucleus through a recording chamber.

Tungsten micro-electrodes were used to isolate single units, and each unit was recorded under the following conditions: a) the animal's head fixed to a table oscillating in the horizontal plane with an earth fixed target, b) the animal's head fixed to the table oscillating in the horizontal plane with the target fixed on the table (a VOR cancellation task), c) the animal's head fixed to a stationary table with a moving target, d) the animal's head free to move in the horizontal plane within an angle of 90° left to right in order to pursue a moving target with both head and eye movements. Neuron spikes were transformed into digital pulses and collected into 5 ms bins and the head, eye and table movements were recorded.

The sensitivity of the units to horizontal vestibular stimulation in the above conditions was measured by calculating the peak velocities and corresponding spike rate of modulations. These values were assembled and a regression curve plotted to represent the characteristic sensitivity of each unit in the various conditions. Our preliminary data suggest that there is no difference between horizontal unit sensitivity in active head movements as compared with passive head movements under the conditions of this experiment. It is therefore unlikely that the efferent vestibular system contributes sensitivity changes due to head rotation motor programs, at least in the range of head velocities used.

Supported by MRC and DCIEM Research Contract 327-9016/8FU79-00252.

250.2 DIFFERENCES IN COMPENSATORY EYE MOVEMENTS DURING ACTIVE AND PASSIVE HEAD MOVEMENTS IN PRISM-ADAPTED CATS. R.M. Douglas & D. Guitton. AMRU and MNI, McGill Univ., Montreal, Canada H3G 1Y6

In the normal cat, gaze shifts are accomplished with a combined eye saccade and rapid head movement, while between saccades, a near constant gaze direction is maintained by the VOR. However, when the world is viewed through reversing prisms, this pattern is no longer appropriate. Ideally the saccade and head movement should go in opposite directions, but this was not seen in the present experiments. The most striking consequence of prolonged reversed vision was that the compensatory eye movement in the active state did not assume a uniformly low gain.

Three cats wore left-right reversing prisms for 2-12 weeks, during which time they were required to make orienting eye-head movements to obtain food, and to walk and jump around the laboratory. As expected from previous studies, the passive VOR gain, measured during 0.1-1.0 Hz sinusoidal rotation in the dark, dropped to about 0.1-0.3 during the first week and declined only slightly thereafter. In contrast, ocular gain was not consistently low when the adapted cats made voluntary active eye-head movements. Immediately after each saccade there was a brief period (<100 ms) during which the gain often reached surprisingly high values (0.8-0.9). For a wide range of head velocities and amplitudes, the mean gain from the end of the saccade to the end of the head movement was about 0.6. During passive rotation, there was no similar transient increase in gain after quick phases. This difference between active and passive gain measurements was not due to involvement of neck afferents, as the gain was always very low when the experimenter rapidly moved the cat's head while keeping the body stationary. These observations show that the pattern of vestibular activity was not critical, but rather suggest a role for the central motor program. This was corroborated by observations on eye-head movements evoked by electrical stimulation of the superior colliculus. During evoked eye-head movements the gain increased gradually from near 0.0 to 0.9, and this did not depend on when the evoked saccades occurred during the head movement. Thus the appearance of high gain after saccades during voluntary eye-head movements was not causal, but was more closely linked to the head movement component.

The utility of the brief high gain periods is suggested by the fact that in both the normal and adapted state, the combined movements began and finished with the eyes a few degrees from center. Without the high gain period the saccades, which even in the adapted cat always occurred with every head movement, would have left the eyes eccentric in the orbit and thus poorly positioned for the next movement.

250.3 PHYSIOLOGICAL CHARACTERIZATION OF NECK MUSCLES ACTION IN GAZE SHIFTS. A. Roucoux, M. Crommelinck::, A. Al-Ansari:: and C. Veraart::::. Lab. of Neurophysiology, Univ. of Louvain, Fac. of Med., B-1200 Brussels, Belgium.

Neck muscles play a major role in gaze displacement and stabilization. Their anatomical organization reflects, in its complexity, the numerous degrees of freedom of the head. In this study, we have reduced the number of these degrees of freedom to two on the basis of a number of observation demonstrating a close correlation between eye movement and neck muscle activity. More specifically, our starting point was our observation that, in the head fixed alert cat, a horizontal eye position signal is continuously sent to some of these muscles. The activity of a dozen of neck muscle pairs, most of them dorsal, has been recorded in alert cats, with head fixed or free, together with gaze horizontal and vertical position. Eye movements and, when pertinent, head movements, were recorded by the magnetic field technique. In a first series of experiments, with head fixed, the neck E.M.G. was correlated with both horizontal and vertical components of eye displacement. Most of the investigated muscles, to a variable extent, exhibited an increase of their discharge level when the eye was displaced towards the side of the muscle or upward. The muscles have been classified on anatomical grounds as horizontal or vertical movers of the head. Physiologically they can be distinguished by their "preferred direction" – i.e. the direction of the eye movement yielding the maximum discharge –. A muscle like the biventer cervicis, thought from the anatomy of its insertions to elevate the head, is also modulated by horizontal eye displacements. Its preferred direction, however, tends to be more vertical than that of the splenius, known as a horizontal mover. In some instances, motor units could be isolated. They had, in a given muscle, different thresholds and showed successive recruitement with increasing eye eccentricity. The same muscles were also recorded in the head free, body restrained, condition. As a whole, the different muscles acted according to their "preferred direction", as determined with head fixed. None of the muscles was exclusively horizontal or vertical.

The hypothesis is made that these muscles have a physiological pulling direction which is oblique and that pure horizontal or vertical gaze displacements, performed with the help of the head, require a tight and rather complex coordination of them. These results also raise the question of the mechanisms responsible for the distribution of gaze motor orders to sets of muscles having such different pulling planes as those moving the eye and the head.

250.4 LATERAL CUNEATE NUCLEUS: VESTIBULAR RESPONSES IN NECK AND SHOULDER AREAS BUT NOT DISTAL FORELIMB. David W. Jensen, Dept. Otorhinolaryngology and Program in Neuroscience, Baylor College of Medicine, Houston, Texas 77030.

The lateral cuneate nucleus (LCN) in the dorsolateral caudal medulla relays somatosensory input from ipsilateral C1 - T2 to the cerebellum. Vestibular nerve fibers also course through regions of the nucleus where unitary responses to electrical stimulation of the vestibular nerve are recordable (Jensen and Thompson, ARO Mid-Winter Meeting, 1980). The purpose of this study was to determine the location of the somatosensory receptive fields of these vestibular-responsive LCN regions. Guinea pigs were used, and were anesthetized with nembutal, fentanyl and droperidol. Electrical stimuli were delivered to the vestibular nerve in intensities relative to the threshold of the vestibular nuclear N1 potential while a glass micropipette was advanced through the ipsilateral LCN. Somatosensory stimuli were applied to the body surface with a blunt probe.

Vestibular-responsive units were largely confined to the rostral third and a ventral strip region of the mid rostrocaudal third of the nucleus. As seen with an extracellular microelectrode, these units showed slowly adapting responses to deep pressure applied to the ipsilateral neck or shoulder surfaces. Not all neck and shoulder units were vestibular-responsive, however. In addition, vestibular stimulation never activated a unit that had a receptive field on the distal aspect of the ipsilateral forelimb.

From these results it is speculated that postural control mechanisms may involve a selective vestibular sculpturing of somatosensory input that is most reflective of the body's center of gravity.

250.5 TWO-COMPONENT HUMAN OKAN. R.M. Jell, D.J. Ireland* and O. Proden*
Physiology and Otolaryngology, University of Manitoba, Winnipeg, Canada, R3E OW3.

The time course of optokinetic afternystagmus (OKAN) in animals and in humans has previously been characterized by a single time constant (one-component) decay after lights out, presumably related to some form of neuronal storage mechanism. Close examination of many OKAN records from normal humans leads us to conclude that this model is inadequate. Our results support a two-component model with terms representing an initial rapid decay followed by a slow decay.

OKAN was produced by full field stimulation in a rotating (40 deg/sec) vertical drum 80 cm in diameter in which the subject sat. Black vertical stripes (visual angle 2 deg) alternated with white bands (18 deg) on the inner surface of the drum. Chart records obtained by D.C. electrooculography were digitized by graphics tablet. Slow phase velocities after lights out were plotted against time and coefficients of the equation: SPV=A. exp (-Bt) + C.exp (-Dt) were computed by non-linear regression analysis.

In 21 subjects tested, the rapid decay was found to have a mean time constant of 0.93 secs (SD 0.83 secs) and initial value 39.0 deg/sec (SD 27.7 deg/sec) while the corresponding slow decay values were 51.4 secs (SD 55.2 secs) and 7.4 deg/sec (SD 3.7 deg/sec) respectively. The differences between rapid and slow decay parameters were significant at $p < 0.005$.

These data support the conclusion that OKAN decay is a two-component process, and that two different storage mechanisms are involved in normal human OKAN. Both storage mechanisms are presumably charged by the optokinetic stimulus during the lights-on period, but differing initial values obtained in the regression analysis suggest that the gains of the two discharge pathways are different. A suitable model would consist of two separate integrators, each with different forward and feedback gain factors, acting in parallel such that their outputs summated to generate a net eye drive signal to the motor nuclei of the extrinsic eye muscles.

250.6 SACCADE-LOCKED INITIAL STEP IN OKAN DECAY. D.J. Ireland*, R.M. Jell and O. Proden*. (SPON: K.W. Cheng). Physiology and Otolaryngology, University of Manitoba, Winnipeg, Canada. R3E OW3.

With appropriate stimulus conditions, optokinetic nystagmus is immediately followed in the dark by a time-dependent decay of slow phase velocity. This decay is called optokinetic after-nystagmus (OKAN). In normal animals and man, OKAN has been shown to be preceded by a step decrease in SPV to an initial value for the decay. The size of the step is dependent upon the velocity of the optokinetic stimulus. Our OKAN records reveal, in about 20% of cases, a step discontinuity in an early slow phase which is time-locked to the preceding saccade. This discontinuity usually occurs within one slow phase of the time of lights-out, and may occur whether lights-out occurs during a slow phase or during a saccade.

Analysis by graphics tablet and digital computer of 68 clearly visible discontinuities which we call "breaks", obtained in normal humans by full field stimulation, revealed that at the break the slow phase velocity (SPV) suddenly dropped by a mean of 48%. Pre- and post-break SPVs were of constant velocity, with a mean pre-break SPV of 42.3 deg/sec (SD 23.94) with stimulus velocity of 40 deg/sec. Mean time from the end of the previous saccade to the break was 0.248 sec (SD 0.116). These values were independent of the point in time at which lights-out occurred.

It would appear that the onset of the discharge process is time locked to the end of the prior saccade, following it with a delay of approximately 250 msec, and that at this point, the step decrease in velocity occurs before OKAN commences. In about 80% of records examined, no step could be seen by visual examination, suggesting that other unknown factors may cover up or prevent the occurrence of the discontinuity.

250.7 SIGNALS USED TO MAINTAIN SMOOTH PURSUIT EYE MOVEMENTS IN MONKEYS: EFFECTS OF SMALL RETINAL POSITION AND VELOCITY ERRORS. E. J. Morris* and S. G. Lisberger (SPON: M. I. Law). Dept. Physiol., Div. Neurobiol., UCSF, San Francisco, CA 94143

The aim of our study was to determine the signals used by the monkey pursuit system to maintain accurate tracking of smoothly moving visual targets, and particularly to study the role of small retinal position and velocity errors. Monkeys tracked a moving spot that appeared on a screen when they pressed a bar; after an unpredictable interval (500-2400 ms) the spot dimmed and monkeys were rewarded if they released the bar within 600 ms. Eye position was monitored by the magnetic search-coil technique.

Each experimental trial began with the monkey tracking a target moving horizontally at 15°/s. To allow precise control of visual inputs, we then opened the visual feedback loop by driving target position with a signal composed of the eye position monitor plus any desired error. When target position was stabilized on the fovea (imposing zero position and velocity errors), pursuit was maintained at the initial velocity. An objective technique was used to assess technical errors in opening the loop and to verify that those errors were too small to account for the maintenance of pursuit. Therefore visual errors are not necessary to maintain pursuit.

During maintained open-loop pursuit at 15°/s across a diffusely-illuminated background, imposition of small velocity or position errors caused large changes in smooth-pursuit eye velocity at latencies of 100 ms or less. For velocity errors up to 1.5°/s, eye acceleration increased monotonically up to 50°/s^2. For position errors up to 0.7°, accelerations increased up to 30°/s^2; for larger errors (up to 1.5°), the acceleration response saturated or decreased. If position and velocity errors were oppositely directed, they opposed one another in their effect on eye velocity. When the background was dark, the response to position errors was almost eliminated, but velocity errors were still effective, and eye velocity was still maintained in the absence of errors. For initiation of pursuit (eye starting from rest), small velocity errors caused accelerations similar to those produced during maintenance at 15°/s but position errors were much less effective: monkeys attempted to correct them using mainly saccades.

Our data demonstrate that at least three signals can be used to maintain accurate pursuit: 1) retinal velocity error, 2) retinal position error, and 3) a form of velocity storage (consistent with theories of positive feedback through the flocculus). The fact that position errors are utilized selectively during the maintenance of pursuit and in the presence of background illumination suggests that this error signal may come from a system that detects velocity contrast between target and background.

250.8 INTERMITTENT ILLUMINATION: A BETTER METHOD TO CHARACTERIZE HUMAN VELOCITY STORAGE DURING OPTOKINETIC STIMULATION? Stephen Liben* and Bernard Segal (SPON: A.Gonshor), Aviation Medical Research Unit Dept. Physiol., McGill Univ., Montreal, Quebec, Canada H3G 1Y6.

When man is suddenly exposed to constant velocity full-field optokinetic stimulation, slow-phase eye-velocity rapidly approaches stimulus velocity and rarely exhibits the gradual build-up (eg, (1)) seen in other species. Thus, in humans, it is not readily apparent that a hypothesized (1) slowly responding 'velocity storage' mechanism becomes gradually charged by such stimulation. However, subsequent to extinguishing all illumination, the presence of velocity storage is suggested by the persistence of a gradually declining component of optokinetic after-nystagmus (OKAN). Previously (1,2), the charging characteristics of velocity storage have been estimated from the relationship between the initial value of OKAN, and the duration of the preceding constant-velocity optokinetic stimulus (ie by many separate 'variable-duration illumination' experiments). We now suggest that these characteristics can be obtained using 'intermittently-illuminated' optokinetic stimuli, provided that darkness intervals are too brief to affect sluggishly responding velocity storage processes, yet are long enough to estimate the initial value of OKAN due to each darkness interval. The present study aims to compare the effectiveness of these two approaches. Methods: First, the variable-duration illumination experiments of Cohen et al (2) were essentially repeated. Next, intermittent illumination (light-on: 9.7s; light-off: 2s) was employed while subjects viewed a drum rotating with 0.01 Hz, 60°/s square wave angular velocity profiles for 3-6 min. Because the frequency of darkness intervals (0.085 Hz) was a non-integer multiple of the frequency of drum oscillation (0.01 Hz), darkness intervals occurred at different phases of drum rotation in successive cycles. Eye velocity at the end of all darkness intervals (initial OKAN estimates) was then suitably stimulus-locked averaged. Results: Modulation of velocity storage mechanisms obtained using intermittent-illumination was approximately exponential (time constant, T: 5-11s; saturation value, S: 9-17°/s), and agreed (generally T and S values were within +20% in the same subject) with that obtained by variable-duration illumination (T: 4-13s; S: 12-17°/s). Moreover, the intermittent-illumination results were usually obtained in 30-50% less time. Thus intermittent-illumination appears to be a better method for the characterization of velocity storage mechanisms because experiments are shorter and because systems analysis can be used more efficiently due to the potential to employ arbitrary stimulus velocity profiles.

250.9 RAPID EFFECTS OF VISION REVERSAL ON HEAD-EYE COORDINATION. G. Melvill Jones, D. Guitton, A. Berthoz*° and M. Volle*. Aviat.Med. Res. Unit, and Montreal Neurol. Inst., McGill Univ., Montreal, Canada, °Lab. Physiologie Neurosensorielle, CNRS, Paris, France.

A previous long term study demonstrated the development of a variety of interesting new strategies in head-eye coordination, after about 3-weeks of maintained optical reversal of vision. (Berthoz & Melvill Jones, Euro.Neurosci.Assn. Abstr. 1981). The present study on 2 human subjects investigated the early development of these changes during the first 6 hrs of the reversed vision experience. Horizontal head-eye coordination was tested by active head movements either in the light or dark. The task was to maintain fixation on the reversed (moving) image of a single earth-fixed target during a rapid voluntary change of head position. An electromagnetic brake could unexpectedly prevent an intended head movement.

Control tests consistently yielded VOR gains close to unity with no eye movement after sudden head brake. During the 1st hr. of reversed vision the induced eye movement was typically composed of 3 main sequential phases. 1) A short period of VOR whose gain was markedly reduced within the 1st few trials. 2) A 'catch-up' saccade in the direction of reversed image movement (i.e. same direction as that of the head) whose latency was compatible with visual triggering. 3) A smooth eye movement which could either resemble a further reduced 'VOR', or occur in the reversed direction, sometimes reaching velocities similar to that of the head, as is required for following the reversed target image. Tests in the 6th hr. yielded similar but more developed patterns of adapted response, including a decrease of saccade latency towards synchrony with head movement onset. Prevention of intended head movement was usually followed in both 1st and 6th hr test series by a particularly interesting new smooth eye movement in the appropriate (reversed) direction which, being synchronous with the intended head movement, suggests a newly established 'motor program'. Head rotation in the dark usually produced leading eye movements resembling slowed saccades. All measured effects became progressively more marked from 1st-6th hr. trials.

The reduction of initial VOR suggests either very early adaptive attenuation of gain, or an effect due to a new mental set, since it was manifest on initiation of head movement and hence could not be due to vision. The post saccadic smooth eye movement (see 3 above) could have comprised a combination of 'visuomotor' response (latency > 120 ms) and the 'motor program' mentioned above. Interestingly, the post saccadic movement sometimes seemed to merge with the preceding 'catch-up' saccade to produce a 'glissade' type of movement remniscent of adaptive readjustment of the neurological pulse-step ratio.

250.10 DOES PURSUIT CONTRIBUTE TO SUPPRESSION OF THE VOR? P. McKinley, B. Peterson, J. Goldberg Northwestern Univ. Med. School, Dept. Physiology and Rehab Med., Chicago IL 60611

By imagining a target rotating with them, human subjects (Ss) can suppress the vestibulo-ocular reflex (VOR) elicited by sinusoidal whole body rotation in the dark. This suppression (SUP) is thought to be mediated either by the smooth pursuit system (P) or by an independent predictive process (Robinson in Functional Basis of Ocular Motility Disorders. Lennerstrand et al 1982). In either case SUP should be less effective for pseudorandom rotations than for the predictable sinusoidal rotations used in the past.

As illustrated by the data below, we have examined the response of the SUP and P systems to an unpredictable stimulus (SSN) consisting of a sum of 5 sinusoids (0.2-1.9Hz) and found that while the P response gain is less than that obtained with (0.1-2.5Hz) sinusoids (SIN), the gain of SUP is unchanged. Eye movements were recorded by DC electrooculography, desaccaded and differentiated to obtain the velocity of smooth phase eye movements (VSE). The VSE obtained when Ss tracked a moving 1cm light spot at 1.5m distance was divided by spot velocity (85° /s) to obtain P gain. For SIN stimuli, this gain was 0.9-1.0 for frequencies up to 0.5Hz and then fell rapidly; for SSN, gain was low except at 0.2Hz. VSEs measured during 90°/s rotation in the dark with subjects instructed to relax (rVSE) or suppress (sVSE) were used to compute gain and phase of the SUP transfer function by performing the following operation vectorially:
SUP = (rVSE-sVSE)/rVSE. SUP gain was ~ 0.6 for SIN and SSN up to 1Hz, after which it declined for SIN.

These differences in gain behavior for SIN and SSN stimuli, which were observed in 4 normal Ss, indicate that pathways mediating SUP and P are not identical. The difference in phase behavior of the two processes shown at the lower right also supports this conclusion. The tendency of both SUP and P gains to fall off above 1Hz, especially for SIN stimuli which had higher accelerations, suggests however, that the two may share some common elements.

250.11 MECHANISMS UNDERLYING THE INTERACTION OF THE VESTIBULO-OCULAR REFLEX (VOR) AND SMOOTH PURSUIT (SP) IN MONKEY. S.G. Lisberger, Dept. Physiol., Div. Neurobiol., UCSF, San Francisco, CA 94143

Two models can account for the eye movements generated when eye and head movements are used to track a smoothly moving target: 1) a "linear addition" model, in which eye movements are produced by adding two velocity commands, one from the VOR and one from SP; 2) a "parametric control" model, in which tracking conditions momentarily alter transmission through VOR pathways.

We have discriminated between these models by a) placing the eye-head tracking system in modes that should bring out any parametric control, and b) using rapid steps of head or target velocity to make direct measures of the gain and latency of SP and the VOR in these different modes. Experiments consisted of a series of trials, each of which began with the monkey tracking a small target during passive head motion at 15°/s. Initial conditions were established by the mode of coordination between target and head. If the target moved with the head ("times zero" or x0-tracking), it was tracked by keeping the eyes fixed in the orbit; this could be done by momentarily reducing transmission through VOR pathways (parametric control) or by allowing the VOR to remain active and counterbalancing it with a command for SP (linear addition). If the target moved opposite to the head (x2-tracking), it was tracked by rotating the eyes at twice head velocity; this could be done by doubling transmission in VOR pathways, or by adding a command for SP to a normal VOR.

To measure the performance of the VOR, we have imposed step changes in head velocity at unexpected times, and averaged the eye velocity responses to at least 20 identical stimuli. The latency of the VOR was 14-15 ms and did not depend on initial tracking conditions. Superimposing the averaged responses from different initial conditions showed that the first 40 ms of the VOR was the same during both x0- and x2-tracking. However, differences became apparent 40-60 ms after the step of head velocity: the eye velocity of the VOR was up to 30% larger during x2- than during x0-tracking. These differences persisted if visual errors were eliminated by establishing open-loop tracking conditions for 200 ms before and after the change in head velocity. To measure the performance of SP, we have imposed step changes in target velocity. The latency of SP was 100-120 ms and did not depend on initial conditions; however, the open-loop gain of SP was up to 25% greater during x2- than during x0-tracking.

We conclude that the VOR is always active at a gain close to that measured during head motion in the dark and that combined eye-head tracking is effected largely by the addition of independent velocity commands from the VOR and SP. However, the gains of both commands are under some parametric control. (Supported by EY03878 (NIH) and by the McKnight and Sloan Foundations)

250.12 ATTENUATION OF THE OTOLITH-OCULAR TORSION REFLEX BY CHANGING ORIENTATION WITH RESPECT TO GRAVITY.
A. P. Arrott* and L. R. Young.
Man-Vehicle Laboratory, M.I.T., Cambridge, MA 02139.

Lateral tilt of the head in a gravitational field produces an ocular counterrolling response. Compensatory eye roll is in a direction to stabilize the visual field on the retina.

The indistinguishability of gravitational and inertial forces results in an ocular torsion response to lateral acceleration in a subject with his head upright. In this case, the gravitoinertial force (GIF) vector rather than the pure gravitational force vector is rotated with respect to the head. Furthermore, the centrifuge experiments of Woellner and Graybiel [J. Appl. Physiol., 14:833, 1959] suggest and the parabolic flight experiments of Arrott and Young [Soc. Neurosci. Abstr., 7:484, 1981] verify that a change in the lateral component of the GIF vector, rather than a rotation of the GIF vector, is a sufficient stimulus for ocular torsion.

This evidence supports the notion that retinal stabilization by ocular counterrolling is achieved by a simple reflex arc in which lateral GIF acting on the otoliths elicits ocular torsion. This is in contrast to a central integration view that sensory information from the otoliths for all of three dimensional space is integrated into an estimate of head orientation before such information is used to determine motor outflow. An experiment was devised to place the two notions in sharp contrast.

Using a linear acceleration cart, human subjects are accelerated laterally while lying supine. The lateral component of GIF sufficient for eliciting ocular torsion is present. However, the net rotation of the GIF vector is around the longitudinal axis of the subject and ocular torsion is an inappropriate compensatory response. In contrast, for lateral acceleration of the upright subject, even though the lateral component of GIF is identical, the rotation of the GIF is in the frontal plane, for which ocular torsion is appropriate. Therefore, in comparing the three cases of lateral acceleration: in upright, zero gravity, and supine conditions; we might expect ever decreasing support for ocular torsion from a central integration point of view. Measurements of the amplitude of ocular torsion in these conditions indicates that whereas the upright response is comparable to the analogous lateral head tilt, the supine response is reduced by a factor of three.

The results imply that a dominant simple reflex arc from lateral GIF to ocular torsion is capable of being attenuated but not eliminated by otolith information from other axes which deem the ocular torsion inappropriate for retinal stabilization.
(supported by NASA grants NAS9-15343 and NSG-2032).

250.13 DO THE EYES COUNTERROLL DURING BARBECUE ROTATION? Charles H. Markham and Shirley G. Diamond. Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

It has been known for 200 years that the eyes counterroll in response to roll about the naso-occipital axis. This reflex is called ocular counterrolling (OCR), and is now thought to be governed by the otolith organs in the inner ear, specifically the utricles responding in a reciprocal manner to the shear force exerted by gravity as they are tilted from the horizontal plane. When a subject is tilted to 90° in our laboratory's dynamic roll protocol, his eyes typically will counterroll about 6°. However, his head would be in the same final location if he had been turned on his side from a supine position. Does OCR occur during this maneuver? Might barbecue (BBQ) rotation, i.e. head and body longitudinal axis turning earth horizontal, be a means of inferring saccular function?

To examine these questions, 3 normal subjects and 4 patients with partial or complete unilateral vestibular nerve sections were tested in both roll and BBQ protocols. Roll consisted of tilting persons about their naso-occipital axes to 90° right ear down at a constant velocity of 3°/sec, held there for 30 sec, rolled to the opposite side to 90° left ear down, held 30 sec, and brought back through the upright position (Trial I). Without stopping the procedure was repeated (Trial II). BBQ rotation consisted of placing subjects in the supine position and turning them from nose up to 90° right ear down at a constant velocity of 3°/sec, holding them for 30 sec, returning them to nose up, held for 30 sec (Trial I), and repeating the procedure (Trial II). This was then performed for left ear down position. Acceleration and deceleration were calculated at 0.21°/sec², considered to be below the threshold of the semicircular canals. Photographs were taken of both eyes at each 10° of rotation. Measurements of OCR were made with a two-projector apparatus using a superimposition technique which is accurate to 0.25°.

Results showed that OCR does occur in BBQ rotation, and that the OCR in a subject's BBQ rotation closely resembles his OCR in roll, although usually somewhat attenuated in amplitude. Patients with unilateral vestibular nerve sections showed the same abnormalities in both modes, namely lack of consistency between trials, and disturbances in smoothness and symmetry. Tilted to the side of the lesion, OCR was normal; tilted to the intact side, OCR was disrupted. Patients who had sections of only the superior branch of the vestibular nerve showed the same OCR abnormalities as did patients with complete nerve sections. This would suggest that the utricle is responsible for OCR in BBQ rotation as well as in roll, since the preserved saccular function in patients with intact inferior branch was not sufficient for normal OCR.

250.14 ADAPTIVE PLASTICITY IN SHORT-LATENCY OCULAR FOLLOWING RESPONSES OF MONKEY. K. Kawano* and F. A. Miles. Lab. Sensorimotor Res., National Eye Institute, Bethesda, Md 20205.

The initial ocular following response to a sudden drifting movement of the visual scene is generated open-loop, and its magnitude is a function of the gain of the visual tracking system. If the gain were high, the eyes would tend to overshoot the moving scene, while a low gain would result in undershoot. To ascertain whether the gain is subject to adaptive regulation, we have examined the effects of repeated exposures to brief velocity-step movements of the scene that first initiate ocular following and then transiently induce retinal events resembling those expected during undershoot or overshoot.

Monkeys faced a screen subtending slightly less than 90° and their eye movements were recorded using the electromagnetic search coil technique. A random dot pattern was back-projected onto the screen via an x-y mirror galvanometer system under computer control. Initial tracking responses to movements of the scene were assessed using 100ms test ramps, randomizing time of onset, direction, and speed (10-100°/s). Without training or reinforcement, alert animals responded with unexpectedly short latencies of almost machine-like consistency. Latencies for 2 animals: means, 52ms & 53ms; ranges, 46-62ms & 45-63ms; average SD's for responses to given ramps, 4.7ms & 4.1ms.

During the velocity-step sequences used for adaptation, the scene was first drifted for 150ms in one of 4 directions at one of 7 speeds (10 to 100°/s); drift speed was then either stepped up to 100°/s (causing the eye to "undershoot" the moving scene) or, in other experiments, stepped down to 0°/s (causing "overshoot"), for a further 150ms. Each sequence was terminated by blanking the screen for 0.5s. (Initial velocities and inter-trial intervals varied randomly.) Over a 3-day period, clear adaptive changes were seen with both paradigms in both animals: After step-up experience, peak eye speeds elicited by 100ms test ramps increased on average by 74% & 92% (ranges: 41-91% & 4-224%), and after step-down they decreased on average by 49% & 61% (ranges: 42-63% & 56-65%). In the low-gain state, eye velocity response profiles began to deviate from controls at latencies of 60-70ms, while high-gain responses did not deviate significantly until 90ms or more after stimulus onset: The very earliest responses never altered and for at least the first 40ms responses were near maximal in the normal animal. Adaptation was also directionally selective: Responses in any one of the primary directions up, down, left or right, could be altered independently. Furthermore, if the velocity steps involved 90° changes in the direction of movement (speed constant), tracking responses to 100ms test ramps acquired corresponding orthogonal components. We conclude that ocular following response vectors are subject to extensive, visually-mediated adaptive regulation.

250.15 POST-SUPPRESSION VESTIBULO-OCULAR REFLEX (VOR) IN MAN: NON-PURSUIT VOR CANCELLATION? Bernard N. Segal. Aviation Medical Research Unit, Dept. Physiol., McGill Univ., Montreal, Canada H3G 1Y6.

When the head is turned while following an object that moves with the head, the normally compensatory action of the VOR is inappropriate and requires suppression. To clarify whether the pursuit system participates in such suppression, the present study examined VOR suppression during whole-body sinusoidal and triangular (0.01-0.17 Hz, 60°/s) oscillation about the vertical axis while subjects fixated on a stationary (re: head), intermittently-illuminated (light-on: 9 s; light-off: 2 s) point. The relative contribution of pursuit to VOR suppression was then estimated by comparing slow-phase eye velocity elicited when the fixation light was on (pursuit present) with eye velocity seen just after the light was extinguished (pursuit absent). To prevent the appearance in darkness of pursuit-afternystagmus (Vis. Res. 19: 1057, 1979), which normally could result from previous charging of velocity storage processes by efference copy, darkness intervals were chosen to be too brief for efference copy to activate sluggishly responding velocity storage processes. Furthermore, during target fixation, efference copy and full-field retinal slip, associated with residual eye movements, should all be too small for significant activation of velocity storage. METHODS: Because the frequency of darkness intervals was always a non-integer multiple of the frequency of body oscillation, darkness intervals appeared at different phases of successive cycles of body oscillation. Stimulus-locked averages of slow-phase eye velocity at the end-portions of all darkness intervals were suitably obtained, thereby providing an estimate of the 'post-suppression VOR'. To compare the post-suppression VOR with the normal VOR in maintained darkness, the fixation light was extinguished for about 1 min immediately following each 2-min test of intermittent VOR suppression. Six subjects were tested. RESULTS: When compared to the normal VOR in maintained darkness, the post-suppression VOR (1) was 25-45% smaller at all oscillation frequencies, and (2) exhibited larger phase shifts during lower frequency sinusoidal oscillation. When the fixation light was extinguished following intermittent suppression, the gain of the VOR required 6-30 s to build up to normal values (even in naive subjects). These latter values did not show any progressive adaptive attenuation over the course of experiments. These results suggest (1) that VOR suppression is achieved by BOTH pursuit and non-pursuit processes, and (2) that the non-pursuit processes, presently of unknown origin, are responsible for about 55-75% of this suppression. Finally, it is hypothesized that these non-pursuit processes might employ signals derived from the semicircular canals.

250.PO UNILATERAL CEREBRAL CORTICAL ABLATIONS IMPAIR VESTIBULO-OCULAR REFLEX (VOR) GAIN AND PLASTICITY IN THE CAT. J. L. Demer*, R. J. Tusa and S. J. Herdman. Wilmer Eye Inst., Johns Hopkins Hosp., and Univ. of Maryland, Baltimore, MD 21205.

Gain (slow-phase eye velocity/head velocity) of the VOR may be plastically modified by prolonged abnormal visual-vestibular experience, such as chronic wearing of magnifying spectacles or artificially induced motion of the visual field during head rotation. To study this plasticity, we measured VOR gain in 6 adult cats using the magnetic search coil in response to 30 and 60 deg/s head velocity steps and during sinusoidal head rotation in the dark at 0.05 or 0.25 Hz (± 30 deg/s). Animals were then exposed to 2-3 hrs of visual experience with a full-field optokinetic drum moving sinusoidally at the same velocity as the head but 180 deg out of phase. Following this, VOR gain was increased in all cats, typically by 0.15 to 0.40 for both left and right eye velocities. The optokinetic drum was then rotated in-phase with head velocity for an additional 2-3 hrs. Following this, VOR gain was decreased for both directions of eye velocity in all cats, by 0.15 to 0.80. These plastic gain changes are similar to those induced by magnifying or reversing spectacles.

Unilateral cortical lesions were made by subpial aspiration in anesthetized animals. Two cats underwent complete removal of visual cortex in the left hemisphere (VC); two underwent partial removal of the medial bank of the lateral suprasylvian sulcus (LS); one underwent removal of areas 17 & 18 on the left (17/18); and one underwent removal of areas 17 & 18 on the left plus corpus callosum section (17/18 + CC). VOR gain plasticity studies were repeated 2 or 3 times in each animal at 7 to 68 days post-operatively. Lesions were verified histologically.

VOR gain for eye velocities to the right was not significantly changed post-lesion, but was persistently decreased by 10-50% for eye velocities to the left (towards the lesion). The degree of reduction depended on the type (step or sine) and frequency of stimulus. Similarly, VOR gain plasticity for eye velocities to the right was unchanged post-lesion, but was persistently impaired for eye velocities to the left in the cats with VC and LS lesions. VOR gain and plasticity were unchanged in cats with 17/18 and 17/18 + CC lesions. Peak eye velocity in response to an optokinetic drum accelerating at 0.27 deg/sec² was persistently decreased to the left by about 50% in cats with VC, and 17/18 +CC lesions, and was transiently decreased by the same amount in cats with LS lesions.

These preliminary results indicate that cerebral cortical lesions can impair VOR gain and plasticity in a directionally-selective manner independent of effects on the optokinetic system.

251.1 HEAVY CELL LOSS IN DENTATE NUCLEUS OF THE MONKEY FOLLOWING NEONATAL ABLATION OF THE CEREBELLAR CORTEX. E. Meisami (SPON: G. Westheimer). Dept. of Physiol.-Anat., Univ. of Calif., Berkeley, California 94720

The dentate nucleus receives its most prominent input from the Purkinje cells of the neocerebellar cortex. Quantitative morphometric studies and cell counts were conducted in the left and right dentate nuclei of four adult Macaque monkeys that had been subjected to unilateral ablation of the cerebellar cortex during the early postnatal period. Examination of serial, celloidin embedded, Nissl stained, 25 u thick sections confirmed massive absence of the cortex of neocerebellar hemisphere on the operated side with no damage to the contralateral (control) side. Comparison of the dentate nucleus deprived of the cortical input with the contralateral dentate (unoperated control) revealed highly significant reductions not only in the total volume (40-80%), total number of large (20-40%) and small (40-55%) neurons, but also in the size of the remaining cells (5-20%). The loss in cell number was less marked when the lesion had spared the nucleus completely. The higher reductions in volume relative to cell number resulted in increased cell densities in the deafferented dentate. The remaining cells of the latter appeared normal, however, in other respects. These results indicate that in the postnatally developing monkey, the survival of a significant number of dentate neurons and the proper growth of others are critically dependent on some influence from the Purkinje cells of the neocerebellar cortex.

251.2 Climbing Fiber Projections from Physiologically Identified Areas of the Cat Dorsal Accessory Olive A. R. Gibson, J. C. Houk, and F. R. Robinson. Physiology Dept., Northwestern Univ. Med. Sch., Chicago, Ill. 60611.

The rostral dorsal accessory nucleus of the inferior olive (rDAO) contains a detailed map of the entire contralateral body surface (Gellman et al., J. Comp. Neurol., 215:228-243, 1983). Fibers from rDAO project to the anterior interpositus nucleus (NIA) of the cerebellum. Forelimb and hindlimb regions of NIA have been identified by tracing the interpositus connections to the magnocellular division of the red nucleus (RNm). We examined the projection from rDAO to the NIA to determine if the forelimb and hindlimb regions of rDAO project to the corresponding forelimb and hindlimb regions of NIA. We also studied the projection from rDAO to the cerebellar cortex to identify the regions that receive forelimb and hindlimb information from rDAO.

Small amounts (≈0.008 µl) of 1% wheatgerm agglutinin conjugated horseradish peroxidase (WGA-HRP) were pressure injected into physiologically identified forelimb and hindlimb areas of rDAO. We traced the anterogradely labeled fibers and terminals into the cerebellar nuclei and cortex. Injections into the forelimb region of rDAO labeled terminals only in the region of NIA that projects to the forelimb division of RNm. Injections into the hindlimb region of rDAO labeled terminals only in the area of NIA that projects to the hindlimb division of RNm.

Climbing fibers from the forelimb and hindlimb areas of rDAO terminate in largely nonoverlapping regions of the cerebellar cortex. Consistent with earlier studies, fibers from the forelimb area of rDAO terminate in parasaggital stripes in the posterior regions of the anterior lobe and in the rostral folia of the paramedian lobule. Fibers from hindlimb rDAO terminate in parasagittal stripes in more anterior regions of the anterior lobe and in the caudal folia of the paramedian lobule. Descriptions of cortico-nuclear projections suggest that the cortical areas receiving forelimb or hindlimb information from rDAO project to the corresponding fore- or hindlimb region of NIA.

The alignment of sensory input from rDAO with the motor output somatotopy in NIA suggests that the sensory information in rDAO influences movements of the body part from which the sensory information arises.

251.3 BASAL INTERSTITIAL NUCLEUS OF THE CEREBELLUM: A DEEP CEREBELLAR NUCLEUS RELATED TO THE FLOCCULUS. T.P. Langer* (SPON: C.R.S. Kaneko) Dept. of Physiology and Biophysics and Regional Primate Center, University of Washington, Seattle, WA 98195

In the course of studying the afferents and efferents of the flocculus in the rhesus monkey, it became apparent that a previously undescribed deep cerebellar nucleus exists that is reciprocally interconnected with the flocculus. In the monkey the flocculus is not connected with any of the major deep cerebellar nuclei, but there is an interstitial population of neurons in the white matter ventral to the deep cerebellar nuclei and extending into the peduncle of the flocculus that have reciprocal connections with the flocculus. This collection of neurons will be called the basal interstitial nucleus of the cerebellum.

Several lines of evidence indicate that the basal interstitial nucleus is a separate, distinct and complete nucleus. (1) Injection of HRP into the flocculus always labels a group of neurons immediately ventral to the deep cerebellar nuclei and extending posteromedially into the lateral margin of the nodulus and rostrolaterally around the caudal aspect of the y-group to infiltrate the peduncle of the flocculus. (2) In Nissl-stained material there is a readily seen nucleus, clearly distinct from the overlying cerebellar nuclei, with precisely the same distribution. The neurons in the basal interstitial nucleus of the cerebellum have a characteristic morphology. They are intermediate size chromatophilic multipolar neurons with a fusiform shape and rapidly tapering proximal dendrites. The cell nucleus is generally eccentrically placed in the cell body, against the cell membrane or in one pole of the cell. The Nissl substance is usually finely granular in the center of the cell body and forms dense clumps adjacent to the plasma membrane. (3) Anterograde label from injections of HRP or tritiated amino acids in the flocculus extends over the entire basal interstitial nucleus. In one brain with an HRP injection involving a part of the basal interstitial nucleus there was a patchy clustered distribution of labeled neurons extending throughout the flocculus and into the adjacent lateral parts of the simple lobules. The clusters tended to be confined to the medial half of many of the folia.

These observations suggest that a separate previously undescribed deep cerebellar nucleus exists in the monkey that interacts reciprocally with the flocculus and perhaps with parts of the simple lobules.

251.4 Distribution of Terminals in Cerebellar Cortex and Their Relative Absence in the Deep Cerebellar Nuclei from Three Major Sources of Mossy Fibers in Cat. R. Chen*, A.R. Gibson, J.C. Houk, and F.R. Robinson. Physiology Dept., Northwestern Univ. Med. Sch., Chicago, Ill. 60611.

Injections of WGA-HRP were made in the external cuneate nucleus, the lateral reticular nucleus, and the pontine nuclei of the cat. Sections were then reacted with a modified TMB procedure which allowed clear visualization of anterogradely labeled fibers and terminals. Cortical label was restricted to the granular layer and demonstrated mossy fiber glomeruli. The cortical distribution of labeling, in general, agreed well with previous investigations. Injection into the external cuneate nucleus labeled terminals in the medial and intermediate portions of both anterior and posterior lobe cortex. Injection into the lateral reticular nucleus labeled intermediate portions of anterior and posterior lobe cortex. The pontine nucleus injection labeled lateral and intermediate portions of the posterior lobe. The paramedian lobule is the only region of the cerebellum to receive input from all three mossy fiber sources.

The mossy fiber input to the cerebellar cortex is often considered to be diffuse but, in these experiments, it shows evidence of a high degree of specificity. The lateral reticular and external cuneate injections produced sharply delimited longitudinal borders between labeled and unlabeled regions. Following these injections the medial and intermediate portions of the anterior lobe contained several distinct longitudinal columns of labeled glomeruli.

It is generally assumed that cells which provide a mossy fiber input to cerebellar cortex also send an axon collateral to cells within the deep nuclei. Since the pontine nuclei, external cuneate, and lateral reticular injections each label a massive number of fibers leading to cerebellar cortex, it might be expected that a large projection to the deep nuclei would also be present. No such projection was found. Labeled fibers from the pontine injection passed laterally to the deep nuclei with no visible branching to them (Dietrichs et al., Br. Res., 259:127-131, 1983, report similar findings). Most of the labeled fibers from the external cuneate and lateral reticular injections coursed through the white matter surrounding the deep nuclei. Only in the case of the lateral reticular injection could terminals clearly be seen. They were lightly distributed within the interposed nuclei and clustered around the cell somas. The results indicate that the cerebellar cortex receives a heavy mossy fiber input that, for the most part, is not shared with the deep nuclei.

251.5 ANATOMIC CHARACTERISTICS OF PONTINE-PROJECTING NEURONS WITHIN THE DORSAL COLUMN NUCLEI OF THE CAT. J.G. May, III* and K.J. Berkley. Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306.

Recent anatomic studies have revealed efferent projections from the dorsal column nuclei (DCN) to the pontine grey in the rat (Kosinski et al., '82) and cat (Björkeland & Boivie, this vol.). The purpose of the present study was to characterize the cells of origin of this DCN-pontine projection anatomically.

Small injections of wheatgerm agglutinin:horseradish peroxidase conjugate or tritiated N-acetyl wheatgerm agglutinin were placed in the DCN-recipient regions of the pontine n. In all four cases, the majority of labeled neurons formed a band around the medial and ventral edges of the DCN complex. This band began by extending down the most medial aspect of the gracile n., bending laterally as it reached the basal region, and then continuing laterally through the basal portions of the cuneate n. A small number of labeled neurons were seen scattered within the dorsal portions and the rostral poles of DCN, as well as a few in the deep regions of the spinal trigeminal nucleus. Most of the labeled neurons were small and triangular, fusiform or multipolar in shape. Within the dorsal portions of DCN, only very few of the large, round "cluster" cells that are labeled after thalamic injections (Berkley, '75) were labeled by the pontine injections. Most labeled neurons in this region were large stellate or small fusiform cells.

The anatomic characteristics of DCN neurons projecting to the pons are different from those of neurons projecting to the thalamus, but similar to those of neurons projecting to the cerebellum, spinal cord, pretectum and tectum (Cheek et al., '75; Rinvik & Walberg, '75; Burton & Loewy, '77; Berkley et al., '80; Bull & Berkley, '82; Budell & Berkley, this vol.). Thus it appears that the pontine-projecting neurons may represent a distinct subset of a population of neurons that are located around the edges of and between the gracile and cuneate n. and that do not project to the thalamus.

A number of older as well as recent anatomic and electrophysiological studies indicate that the ventral portions of DCN receive considerable input from muscles and other deep structures. The present results thus suggest that information from these structures may be relayed to the cerebellum from a distinct population of DCN neurons by way of the pons. These projections along with the previously-reported projections from a similar group of DCN neurons directly to the cerebellum, pretectum, tectum and spinal cord (and perhaps other regions such as the red n., inferior olive and zona incerta) may form part of a complex efferent system from DCN that is functionally related to the fine control of proximal body, or head and neck movement.

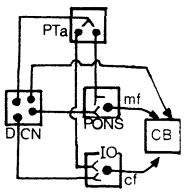
Supported in part by PHS grant RO1-NS-11892 from NINCDS.

251.6 INTRICATE RELATIONS BETWEEN THE DORSAL COLUMN NUCLEI, PRETECTUM, INFERIOR OLIVE, PONS AND CEREBELLUM IN THE CAT. M. S. Bull, J. G. May, III*, R. J. Budell* and K. J. Berkley. Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306.

In addition to their dense projections to the thalamus, the dorsal column nuclei (DCN) have a less well known set of projections to the cerebellum. These projections are not only direct, but also indirect, involving a climbing fiber route through specific portions of the inferior olive and a mossy fiber route through specific portions of the pons (Björkeland & Boivie this vol.; May & Berkley, this vol.).

Recent work has shown that neurons within another of DCN's targets, the anterior pretectal nucleus, project their axons to the DCN-recipient portions of the inferior olive (Mitchell et al., '81). The purpose of the present study was to determine whether the DCN-recipient portions of the pons likewise receive an input from the DCN-recipient portions of the pretectum.

After injecting wheatgerm agglutinin conjugated to horseradish peroxidase in the vicinity of the DCN-recipient portions of the pons and processing the tissue two days later with tetramethylbenzidine, retrogradely labeled neurons (but no anterogradely labeled terminals) were observed in the anterior pretectal n. (PTa). When injections of ^{3}H-leucine were placed in PTa, terminal labeling was seen in a region adjacent to and overlapping the DCN-recipient portions of the medial pontine n. In subsequent experiments, ^{3}H-leucine injections were placed into the PTa of cats that had also received DCN lesions. The autoradiographically-visualized pretectal terminations in the pons encompassed the region containing degenerating DCN terminations. These results indicated that, like DCN-recipient portions of inferior olive, DCN-recipient portions of the pons receive DCN-modulated input by way of the pretectum.



In conjunction with the results of studies in this and other laboratories demonstrating that the population of DCN neurons projecting to the pretectum, inferior olive, pons and cerebellum are distinctly different anatomically from those projecting to the thalamus (e.g. May & Berkley, this vol.), the present results suggest that the pretectally-influenced and DCN-modulated climbing fiber and mossy fiber routes to the cerebellum may be related to postural mechanisms or to the coordination of proximal body or head and neck movement.

Supported by PHS grant RO1-NS-11892 from NINCDS.

251.7 A DOUBLE LABEL RETROGRADE TRACING STUDY OF THE OLIVOCEREBELLAR PROJECTION TO THE PYRAMIS AND UVULA IN THE RAT, L. M. Eisenman and G. P. Goracci. Daniel Baugh Institute, Jefferson Medical College, Philadelphia, PA 19107

Recent electrophysiological (Faber & Murphy, 1969 and others) and anatomical (Brodal, et al., 1980) studies of the organization of the olivocerebellar projection in the cat suggests that climbing fiber collaterals innervate different parts of the same parasagittal zone and/or different parasagittal zones (Ekerot & Larson, 1982). This finding is not surprising when one considers the numerical mismatch between inferior olivary cells and Purkinje cells in this and other species (Escobar et al., 1968). In an attempt to determine whether climbing fiber collaterals innervate neighboring folia in the posterior lobe of the cerebellum in a different species, the rat, a double labeling experiment was undertaken. Based on previous HRP studies of the olivocerebellar projection to the uvula and pyramis in the rat, a zone within these folia which receives an input from subnucleus β of the caudal medial accessory olive (MAO) was chosen for further study. Separate microinjections of the fluorescent tracers nuclear yellow (NY) and fast blue (FB) were made in the medial zone of the uvula and the intermediate zone of the pyramis. As mentioned HRP studies had demonstrated that these two regions receive an olivary input from the caudomedial MAO and primarily subnucleus β. After a 24-hour survival time the rats were sacrificed and 30μ frozen sections were prepared for examination with a Zeiss epifluorescent microscope using a 48-77-02 filter system that provides an excitation wavelength of 365 mm.

In these experiments it was determined that most cells within nucleus β were labeled with either NY or FB. A third, smaller population of olivary cells in nucleus β contained both NY and FB. We could not detect any segregation of these three populations of cells within the caudomedial MAO. We conclude from these data that although these two cortical sites are not aligned with one another, they are part of the same parasagittal zone in that they get input from the same olivary region. Most of the olivary cells in the caudomedial MAO project to only one or the other of these cortical sites whereas a smaller population of olivary cells in this same area have climbing fiber collaterals which innervate both cortical regions. These three populations are not spatially segregated.

251.8 HYPOTHALAMO-CEREBELLAR PROJECTIONS IN THE SQUIRREL MONKEY (SAIMIRI SCIUREUS): AN HRP STUDY. D.E. Haines and E. Dietrichs*. Dept. of Anatomy, West Virginia Univ., Morgantown, W.Va. 26506, and Anatomical Institute, Univ. of Oslo, Oslo, Norway.

Although it has been suggested that the cerebellum may directly influence, or be influenced by, autonomic centers, the anatomy of these potential connections remains enigmatic. Recently Dietrichs (Science, 1983, in press) has described a direct connection from hypothalamus to cerebellar cortex in cat. The present study provides evidence of a hypothalamo-cerebellar projection in squirrel monkey.

Injections of horseradish peroxidase (Sigma, VI HRP in 35% solution; WGA-HRP in 2.5% solution) were made into the cortex of the paraflocculus and into dorsal paramedian, ansiform and dorsal culminate lobules using iontophoretic (HRP) and/or pressure (WGA-HRP) methods. Following survival times of 22-50 hours the animals were killed by transcardiac perfusion with an appropriate fixative followed by a wash solution. Hypothalamus, brainstem and cerebellum were cut in frozen section at 50μm and processed using tetramethylbenzidine as the chromogen. In no case did cortical injections involve the cerebellar nuclei.

In all experiments (save one dorsal culminate case) retrogradely labeled cells are present in caudal hypothalamus; the distribution is bilateral with a slight ipsilateral preponderance. Following the terminology of Emmers and Akert (1963) labeled cells are found primarily in posterior (APH) and lateral (ALH) hypothalamic areas, the supramammillary nucleus (SmH) and in the immediate area of the mammillothalamic tract. These latter cells may be displaced somata from SmH or ALH. Isolated, yet well labeled, cells are occasionally seen in the medial mammillary nucleus following injections of paraflocculus. No labeled cells are present in the adjacent subthalamic nucleus or substantia nigra; the occasionally labeled cells seen in the medial edge of the internal capsule are presumably displaced from ALH. In an effort to assess the possible reciprocity of this pathway pressure and iontophoretic injections were made into caudal hypothalamus. Following iontophoretic injections, largely restricted to ALH and APH, sparse numbers of HRP labeled cells are seen bilaterally in ventral areas of lateral and posterior interposed cerebellar nuclei. These results indicate a direct bilateral connection between caudal hypothalamus and the cerebellar cortex in this primate. Preliminary data from hypothalamic injections further suggests that some of the cerebellar nuclei project directly, and bilaterally, to caudal hypothalamus.

(Supported by NIH grant NS11327 from NINCDS (DEH)).

251.9 CEREBELLAR AFFERENTS IN THE MUTANT MOUSE WEAVER AS STUDIED BY RETROGRADE HRP INJECTIONS. D.E.Smith. Department of Anatomy, L.S.U. Medical School, New Orleans, LA 70112.

The disappearance of the granule cells in the neurological mutant mouse weaver leads to a cortical disarray in the cerebellum (Rakic, P., and R.L. Sidman, Proc. Nat. Acad. Sci. 70: 240, 1973) and retrograde changes within spinal cord nuclei that send afferents to the cerebellum (Smith, D.E., et al., Neuroscience Lett. 28: 175, 1982). In light of the retrograde changes seen in the spinal cord, studies were initiated to determine what, if any, alterations were present in other neuronal systems that project to the cerebellum.

In order to first establish whether or not there are any aberrant projections as a result of the loss of cerebellar granule cells, studies were begun to ascertain the location of neurons that project into the granule layer of the cerebellum in the mutant mouse weaver and compare these results with comparable injections into homozygous and heterozygous controls.

Breeding pairs of weaver mutants (B6CBA-A^{WJ}/A-wv) were obtained from The Jackson Laboratory and maintained in our vivarium. Offspring, ranging in age from 4 weeks to 4 months, received cerebellar injections of 0.2 µl of a 20% aqueous HRP solution at a depth of 600 microns. Following a 24 hour survival period, the animals were anesthetized and perfused with 1% paraformaldehyde - 1.25% glutaraldehyde solution in a 0.1 M phosphate buffer. The brain stem and cerebellum were subsequently removed, sectioned midsaggitally and processed for HRP enhancement according to the de Olmos technique (de Olmos, J.S., Exp. Brain Res. 29: 541, 1977).

Injections into lobules V and VI of the vermal region resulted in labeling of neurons within the following nuclei: lateral cuneate, hypoglossal, accessory olive, principal sensory, pontine, dorsal and ventral cochlear, and nucleus of the trapezoid body. Preliminary observations suggest that the major difference between the origin of cerebellar afferents in the mutants and the homozygous and heterozygous controls is one of the number of neurons that project to the cerebellum rather than the origin of the neuronal projections. These findings suggest the presence of an active neuron-target relationship in the postnatal development of those brain stem nuclei which have extensive cerebellar projections.

This work is supported by N.I.H. grant NS 13155.

251.10 ORIGIN OF THE CEREBELLAR TRANSCOMMISSURAL SYSTEM. A.Rosina* and L.Provini*(SPON: European Neuroscience Association), C.N.R. , Ist.Fisiol.Centri Nervosi,Via Mario Bianco 9,20131 Milano,Italy.

It was recently shown that neurons located in corresponding regions of the right and left pontine nuclei (PN) project by way of branched axons to common bilateral target areas of the cerebellum. Cerebellar midsagittal transection experiments,moreover, indicated that this axonal branching takes place within the cerebellum (Rosina et al.,Brain Res.195 ,461-466,1979).Thus this fiber system appears to be a transcommissural link between the two cerebellar hemispheres.

To further analyze the relative incidence and the origin of these fibers, we injected two spectrally different fluorescent tracers into the opposite cerebellar hemispheres of cats, one before and one after cerebellar midsagittal transection. In this way the first tracer retrogradely labels all the PN neurons projecting to one cerebellar hemisphere, while the second tracer selectively labels those PN neurons whose axons project directly, and not by crossing within the cerebellum,to the other hemisphere

The results of 5 such experiments showed that the neurons retrogradely labeled by the first tracer were located bilaterally within the caudal two-thirds of the PN . On the contrary, the neurons retrogradely labeled by the second tracer (injected after the cerebellar transection) were mainly localized contralaterally to the injected site, with the exception of labeled neurons in the dorsolateral nucleus.Within the areas in which the two labeled populations overlapped,double-labeled neurons were seen. The bilaterally projecting neurons were found throughout the caudal two-thirds of the PN, located in the peripeduncular , ventral , lateral and dorsolateral subdivisions, in which they could reach the incidence of 50%. Moreover the double-labeled neurons on the side ipsilateral to the first tracer injection (re-crossing neurons) greatly outnumbered the double-labeled neurons on the opposite side (crossing neurons) by an average of 9 to 1.

On the whole our data indicate that the bilaterally projecting transcommissural neurons represent 5-10% of the entire population of PN neurons projecting to the lateral hemisphere. The system is mainly composed of PN neurons whose axons re-cross the midline within the cerebellum after crossing within the brain-stem.

251.11 DEVELOPMENT OF CEREBELLOBULBAR CONNECTIONS IN THE POUCH YOUNG OPOSSUM. James C. Hazlett and Stuart D. Bagley* Department of Anatomy, Wayne State University, Detroit, MI 48201.

The present study is the third in a series of reports which emphasize significant details in the development of the long ascending somatosensory and sensorimotor pathways. Early stages in the development of cerebellar projections to the vestibular nuclei, inferior olivary complex and basilar pons were studied in litters of pouch young opossums 9, 12, 16, 20 and 26 days of age. Hemicerebellectomies performed in the 12 through 26 day old groups were followed by 18-24 hour survivals. The animals were sacrificed under hypothermic anesthesia with formol-saline and the brains were processed for degenerating developing axons with the Fink-Schneider '69 technique. In the youngest group (9 days old) tissue from cerebellar HRP injections was examined for the presence of cerebellofugal fibers. In these preparations a cerebellovestibular connection was identified as the result of the orthograde transport of the injected enzyme. This material was kindly provided by Dr. Georgia Bishop at The Ohio State University. Hemicerebellectomies performed at 12 days of age revealed a pattern of degenerating cerebellovestibular fibers which closely resembled the orthograde labeling described above. At later ages there was a steady increase in the density of cerebellar projections to the vestibular nuclei, especially to the lateral vestibular nuclei bilaterally. At 16 days of age a few degenerating cerebellar axons were observed in the contralateral descending limb of the brachium conjunctivum. These fibers approached the level of the inferior olivary nucleus (IO) but did not appear to penetrate its nuclear subdivisions. However, by 20 days of age a marked accumulation of degenerating cerebellar axons appeared within IO. In several locations within IO these fibers ramified in and around groups of neurons in a pattern similar to that exhibited by adult degenerating cerebelloolivary axons. At the same time argyrophilic granules were observed in the reticular formation overlying the basilar pontine gray. In litters 26 days old degenerating preterminals were present in the appropriate portions of IO and the basilar pontine nuclei. The adult-like distribution of cerebellar projections to these two sites was established somewhat later. Supported by National Science Foundation Grant BNS 80-22312.

251.12 THE POSTNATAL DEVELOPMENT OF THE RAT PONTOPARAFLOCCULAR PROJECTION. C. E. Adams*, G. A. Mihailoff, J. K. Chapin Dept. of Cell Biology, The Univ. Tx. Hlth. Sci. Ctr., Dallas, Tx. 75235.

The ontogeny of motor behavior may depend in part upon the time course of initiation and maturation of transmission within the cerebro-ponto-cerebellar system. Ongoing investigations in this laboratory are concerned with aspects of the anatomical and physiological maturation of one component of the cerebro - ponto - cerebellar system, the projection from the visual cortex via the pons to the cerebellar paraflocculus. The aim of this study was to determine the time course of the postnatal development of the pontoparafloccular projection in the rat. Our previous anatomical studies demonstrated that fibers of the developing rat visual corticopontine system initially formed terminal projection fields on postnatal day 3. The subsequent maturation of these corticopontine terminal fields was characterized by a two-stage process. During the first stage (postnatal days 3-13), the terminal field distribution pattern was more diffuse than that observed in the adult. A gradual focusing or constricting of the terminal field distribution was seen during the second stage (postnatal days 13-20) which resulted in the formation of the adult projection pattern.

Unilateral injections of 0.2-0.3 microliters of the fluorescent dye nuclear yellow (1 mg/ microliter) were made into the paraflocculus of the cerebellum. Following a survival time which ranged from 19-23 hours, the animal was anesthetized and the brain fixed by intravascular perfusion of 4% phosphate buffered paraformaldehyde. The brainstem and cerebellum were then sectioned on a freezing microtome and the basilar pontine nuclei examined. On postnatal day 4, a crescent-shaped pattern of cell labeling was observed bilaterally within medial and lateral regions of the rostral one-half of the pons, with a contralateral predominance. Slightly more caudally, neuronal labeling was found to decrease and then disappear sequentially within: 1) the medial and lateral ipsilateral pontine zones, 2) the medial contralateral pontine zone, and 3) the lateral contralateral pontine zone. This pontoparafloccular projection pattern, seen also on postnatal days 7 and 9, corresponds to the pattern previously described for the adult. These observations indicate that the projection pattern of pontoparafloccular fibers is established in a mature configuration quite early in the course of postnatal development. In contrast, the visual corticopontine projection does not exhibit an adult pattern until postnatal day 20. The maturation of pontine neuron morphology is not adult - like until 24 days of age while synaptogenesis whithin the pontine neuropil is not completed until postnatal day 16. Supported by BNS 80-04853 and NS 18041.

251.13 PROJECTIONS OF CEREBELLAR NUCLEI IN THE PIGEON. J.J.A. Arends*, R.M.L. Faull* and H. Philip Zeigler, Biopsychology Program, Hunter College, City University of New York, 10021 and Dept. of Anatomy Univ. of Aukland, New Zealand.

A combination of autoradiographic and histochemical tracing procedures have been used to define the terminations of projections from the cerebellar nuclei and to clarify the topographic organization of the nuclei. In initial experiments, pressure injections of tritiated amino acids and horseradish peroxidase were made into the nuclei under stereotaxic control to define efferent pathways and their areas of termination. Large injections of horseradish peroxidase were then placed into the hindbrain, midbrain and forebrain and the organization of cerebellar inputs to these regions was analysed. In the final experiments, iontophoretic injections of HRP/lectin into selected target areas were used to clarify topographic organization within the nuclei. Cerebellar projections to the following structures were defined: Hindbrain: vestibular complex, inferior olive, reticular formation (paramedian, medial, lateral), pre-and perihypoglossal regions and intertrigeminal area: Midbrain: central grey, n. Darkschewitsch, n. interstitialis (Cajal), n. ruber and prerubral field: Diencephalon: n. spiriformis medialis, Stratum cellulare externum, n. intercalatus, n. dorsointermedius posterior thalami. Cerebellar projections are similar in many respects to those described for mammals. However, thalamic projections were quite restricted,perhaps reflecting the absence in birds of a thalamo-cortical motor system.

Supported by Grant MH-00836 and by Research Scientist Award MH-00320 and by Grant BNS 79-14238.

251.14 THE ORGANIZATION OF THE IPSILATERAL CEREBELLO-RETICULAR PATHWAY IN RAT AND ITS DIVERGENT COLLATERALIZATION. M. Bentivoglio*, M. Molinari* (SPON: European Neuroscience Association). Inst. of Neurology, Catholic University, Rome, Italy.

Since Cajal's description of an ipsilateral cerebellar descending pathway not much attention has been devoted in the literature to the organization of this system. However, it has been reported in anterograde tracing studies (e.g. Faull, R.L.M., J. Comp. Neurol., 178: 519, 1978) that the ipsilaterally descending fibers of the brachium conjunctivum terminate in the lateral parvocellular reticular formation. The present study was aimed at the identification of the cells of origin of the ipsilateral cerebello reticular system in the rat. Several retrograde tracers (horseradish peroxidase and fluorescent dyes) were injected in different cases in the lateral part of the medullary reticular formation. The injections were made obliquely under direct vision from the dorsal medullary surface. In all cases labeled cells were found in the ipsilateral deep cerebellar nuclei. The labeled cells were located in the dorsolateral hump (Dlh), a subdivision of the rat's cerebellar nuclei located dorsal to the border between lateral and interpositus nuclei, as well as in the lateral part of the interpositus. A few labeled cells were also seen in the lateral nucleus. Further anterograde tracing experiments are at present in progress in order to confirm that cerebellofugal fibers descend ipsilaterally to the medulla oblongata from the Dlh and the lateral part of the interpositus.

Moreover, a search was made for identifying whether the descending ipsilateral cerebello-reticular fibers are represented by axon collaterals of the ascending contralateral cerebello--thalamic pathway, or they take origin from separate cells. The fluorescent retrograde double labeling technique was employed in this study. Different combinations of fluorescent tracers were used. One tracer was injected in the lateral medullar reticular formation and the other was injected contralaterally in the thalamus. In these cases a high percentage of deep cerebellar cells labeled from the ipsilateral medullary injections were double labeled from the thalamic injections. These findings indicate that in rat deep cerebellar cells give off divergent axon collaterals ascending to the contralateral thalamus and descending to the ipsilateral medulla oblongata.

251.15 REEVALUATION OF THE NUCLEOCORTICAL PROJECTION OF THE CEREBELLUM. J. Courville, A. Legendre* and F. Faraco-Cantin*, Centre de recherche en Sciences Neurologiques, Université de Montréal, C.P. 6208, Montréal, H3C 3T8.

A projection from the cerebellar nuclei to the cerebellar cortex has been described in several species with methods of axoplasmic transport of aminoacids and horseradish peroxidase. It was concluded that this system terminates in the granular layer as mossy fibers and presents a topographical organization which resembles that of the corticonuclear projection. Anterograde transport of L-leucine of low (60 Ci/mmol) and high (147 Ci/mmol) specific activity was used to study the projection in the cat. With survival periods of one or two days, small (0.2 ul) injections of leucine of low or high specific activity in various region of the interposed and dentate nuclei demonstrate fibers of passage ascending in the white matter. Their density is low except for those directed to the flocculus and paraflocculus which are slightly more abundant. In the granular layer of the flocculus, small alignments and accumulations of silver grains produce a picture which resembles the terminal distribution of primary vestibular afferents to that region. In all other regions of the cerebellar cortex, only rare deposits of coarse grain alignments similar to those of the white matter are seen. At 6 and 8 days, the number of linear deposits in the white matter and granular layer of the various regions is slightly increased. Occasionally, small clusters of silver grains are observed in the granular layer. They could represent glomeruli or cross sections of the coarse fiber segments. There is a striking discrepancy between the number of labelled fragments in the white matter and the number of terminal structures in the cortex. At survival periods from 3 hours to 24 hours, the picture is however very different. Several grain clusters having the size of glomeruli are encountered in the granular layer after 6 hours. At 18 hours, they have already disappeared. These results confirm the presence of a nucleocortical projection terminating as mossy fibers. In all the cases utilized and with all survival periods, dense projections to the contralateral inferior olive have been observed. It is concluded that the fast transported proteins which label terminal structures have a rapid turnover. Material transported by slower axonal flow is more stable but mostly demonstrates fibers of passage and preterminal segments.

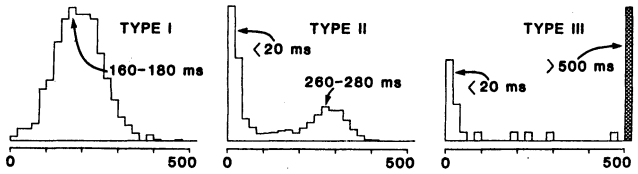
252.1 DISCHARGE PATTERNS OF PUTAMEN NEURONS IN THE ABSENCE OF MOVEMENT IN THE MONKEY. J. Rajkowski*, M. Kimura* and E. V. Evarts. Laboratory of Neurophysiology, NIMH, Bethesda, Maryland 20205.

During quiescent waking most putamen cells are silent but some have tonic discharge. This abstract reports that tonically active putamen cells may be divided into two classes on the basis of their discharge patterns and the next abstract reports that these two classes are related to behavior in ways that are subtle but potentially important.

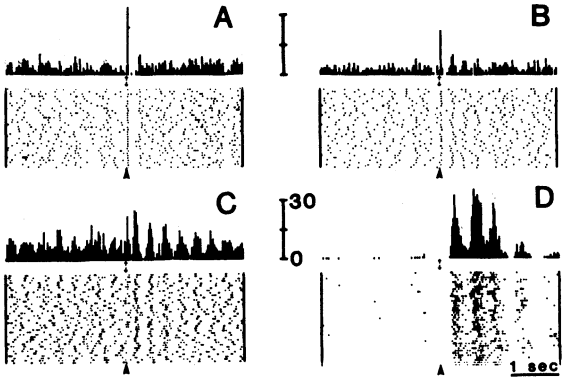
A microelectrode was advanced through the putamen during contralateral elbow flexion-extension movements that were periodically interrupted by the orofacial movements associated with consumption of a fruit juice reward. The 122 units upon which this report is based were initially picked up during limb and orofacial movements and then studied during a subsequent period of motor quiescence. 34 of these 122 neurons became virtually silent during absence of movement (average frequency less than 1 Hz). Such neurons (active with movement but otherwise silent) correspond to putamen neurons described by Crutcher and DeLong (1983). The activity of the 88 units that were not silent at rest fell into 3 categories, 2 of which had virtually continuous activity at between 3 and 7 Hz. In contrast, cells in the third category had relatively long periods of quiescence interrupted by occasional bursts. The first category of tonically discharging neurons (Type I) had a unimodal interspike interval distribution (IID) while the second category of tonic cells (Type II) exhibited a bimodal IID. Units that were for the most part silent but exhibited occasional bursts had IIDs with two modes, one of which was extremely short (corresponding to the intervals associated with the bursts) while the other was quite long, corresponding to the periods of silence. When units showing bursts and long periods of silence were carefully examined in relation to spontaneous movements occurring during periods that were otherwise quiescent, it was found that in fact their bursts were usually associated with slight spontaneous movements. IIDs for the 3 types are shown below with binwindths of 20 ms. There were no intervals greater than 500 msec for the Type I and Type II units, whereas the cross-hatched bar shows that pauses greater than 500 msec were common in Type III units.



252.2 EVENT-RELATED RESPONSES IN SPONTANEOUSLY ACTIVE PUTAMEN NEURONS. M. Kimura*, J. Rajkowski* and E. V. Evarts (SPON: J. C. Eberhart). Laboratory of Neurophysiology, NIMH, Bethesda, Maryland 20205

Tonically active putamen units were studied in 3 successive 40-trial blocks. SELF-PACED MOVEMENT (SPM): flexion-extension of elbow for juice reward followed by licking. FREE REWARD (FR): rewards delivered with arm position fixed; monkey promptly relaxed the arm with onset of FR. NO REWARD (NR): similar to FR except that the tube conveying the juice was occluded so the solenoid click was no longer followed by reward and licking extinguished after the first few solenoid clicks in the block of 40 NR clicks.

Tonically active units lacked intense discharge time-locked to movement, but type I tonic units often exhibited one or two impulses evoked at short-latency by the solenoid click preceding reward in SPM and FR, but not in NR, when click-triggered licks had extinguished. Type II units, (i.e., those with bimodal interspike interval distributions) rarely exhibited short-latency responses but did exhibit a synchronization of their tonic discharge following the solenoid click during SPM and FR. Synchronization also occurred in some type I units. Responses below are in SPM:



Solenoid click at arrow evoked short-latency responses in Type I unit in A, short-latency responses and synchronization in Type I unit in B, and synchronization alone in Type II unit in C. Movement-related activity time-locked to successive licks is shown in D for unit that was silent during arm movements at left of center and that then became intensely active as the monkey began to lick.

252.3 EFFECTS OF GLOBUS PALLIDUS LESIONS ON PAW REACHING BEHAVIOR IN RATS. U.E. Olazábal and J.S. Schneider. SUNY at Stony Brook, Stony Brook, N.Y. 11794 and Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

The globus pallidus (GP) has long been implicated in the control of arm movements. Findings from several studies suggest that the deficits in limb movements resulting from GP damage are not due to motor impairment, but are more complex in nature and involve sensorimotor processes. In an effort to understand the role of the GP in the forelimb reaching of rats, a fine-grained, high-speed film analysis of limb and postural movements was used.

Intact rats were trained to reach at various depths into a narrow tube with one forepaw to obtain food. A moveable piston positioned a food pellets 3mm to 23mm from the opening of the tube and thus determined the length of the paw reach. The wall of the experimental chamber to which the tube was attatched was opaque, hence eliminating the use of visual cues and making the response dependent on somatosensory and proprioceptive information. Body posture and limb movement were then photographed several times before and after lesioning. Paw reaching was rated for accuracy, duration, and posture. Normal rats easily reached and obtained pellets placed 10-20mm into the tube. Bilateral GP lesions caused obvious disruptions of this behavior. Typically, lesioned animals were inaccurate and unable to reach pellets placed within a few millimeters of the tube opening. Reach durations were also longer for the lesioned animals, particularly when the food pellets were positioned further from the tube opening. Also, the topography of the reaching movement in GP rats was characterized by a palm-sideways or palm-up posture, as opposed to the normal palm-down posture. This impairment contributed to the difficulties these lesioned animals had in grabbing and holding onto pellets. However, lesioned rats could pick up, manipulate, and eat pellets when they were visible and easily obtainable from a dish within the home cage. In addition, locomotion, grasping reflexes, and several other forelimb movements were not impaired by the GP lesions. Observations of gross postural changes showed that pre-lesion rats approached the tube staight on, tilted their heads sideways, and inserted their forelimb. After the GP lesions, various abnormalities in body position were noted-- a sideways approach to the tube accompanied by an exaggerated head tilt and body curvature.

These data indicate that disruptions of paw reaching behavior following GP damage are not simply due to a generalized forelimb motor deficit. Rather, basal ganglia damage interferes with the performance of organized limb movements whose succesful execution is dependent upon somesthetic and proprioceptive feedback. In addition, basal ganglia disruption of postural mechanisms contribute significantly to the observed forelimb movement deficits. (Supported by NINCDS Grant #16054).

252.4 DOPAMINE DEPLETION IN A NEOSTRIATAL SUBREGION DISRUPTS PERFORMANCE OF A SKILLED MOTOR TASK IN RATS. K. E. Sabol*, D. B. Neill*, S. A. Wages*, W. Church*, and J. B. Justice (SPON: K. Wallen). Depts. of Psychology and Chemistry, Emory University, Atlanta, GA 30322.

This experiment examined the role of specific subregions within the neostriatum in a skilled motor task requiring coordinated forelimb movements in the rat.

Food deprived rats were trained to reach with their preferred forelimb into a narrow slot to retrieve a 45 mg food pellet. Measures recorded were (a) successful attempts, (b) unsuccessful attempts, (c) individual reaches, and (d) the duration of each trial. Four trials/day were used; each trial included 10 pellets. After training, unilateral injections of 6-OHDA·HBr (8ug/2ul) were made into medial or lateral anterior neostriatum. Other rats received the ascorbic acid vehicle (0.1%) in either site. All injections were contralateral to the preferred paw. This surgery was performed using deep barbiturate anesthesia.

All rats were sacrificed approximately 6 wks. after surgery. DA depletion was determined by assaying (HPLC/EC) micropunches taken from medial and lateral neostriatum at different anterior-posterior levels.

Animals receiving lateral 6-OHDA injections showed a strong decrease in the number of successful attempts per total attempts (success ratio). This deficit was maintained for the 3 weeks of post surgical testing. Animals receiving medial 6-OHDA injections showed a smaller and transient decrease in the success ratio. Reach rate was impaired for both 6-OHDA groups but again the lateral deficit was stronger and longer lasting.

Qualitatively, the transient medial 6-OHDA induced deficit can be attributed to (a) rotational behavior or (b) a failure to initiate responding in a given trial. Rats with lateral 6-OHDA injections did not show consistent rotational behavior, and although they did show difficulty in initiating individual reaches, there was not an overall failure to respond. Their deficit seemed due to impaired coordination.

Dopamine assay data showed substantial DA depletion in the injected side with maximal depletion (15-20% of uninjected side) in the target striatal subregion. The deficit associated with the lateral 6-OHDA injected subjects appeared to be correlated with dopamine depletion in the lateral striatum at the level of the rostral pole of the globus pallidus.

These data support the hypothesis that skilled motor performance can be associated with a specific subregion of neostriatum.

252.5 SPEED IMPAIRMENT IN TRIGGERING AND EXECUTION OF LIMB MOVEMENT IN MONKEYS WITH LESION OF THE SUBSTANTIA NIGRA, F. Viallet*, D. Beaubaton, E. Trouche*, A. Nieoullon* and E. Legallet*. CNRS, INP, B.P. 71, 13277 Marseille Cedex 9, France.

Experiments were conducted on seven baboons with a view to establishing whether the substantia nigra (SN) is involved in the control of movement initiation and speed in monkeys. In a pointing task towards a fixed visual target, the latency, speed and accuracy of the baboons' pointing responses were determined from recordings of the reaction times, movement times and spatial errors. The results were then compared with the animals' performances after electrolytic or 6-OHDA SN lesions. The experimental conditions were varied with regard to either the spatial characteristics of the limb trajectories or the use of open or closed loop visual cues. Furthermore, the effects of electrolytic lesion, entailing destruction of the dopaminergic neurons, were compared with the specific effects of lesions produced with 6-OHDA.

After electrolytic SN lesions, the animals showed akinesia of the whole controlateral half of the body, with semi-flexion of the limbs for one to two weeks. They then took three months to recover their previous ability to perform the pointing task, initially showing increased latency and considerably decreased velocity in the contralateral limb, although the spatial accuracy was almost unaffected.

Animals with 6-OHDA lesions showed only mild contralateral akinesia which took less than 48 hours to recover. Nevertheless, they also exhibited a considerably decreased velocity in the contralateral limb whereas the accuracy and latency of the pointing response were not affected. Moreover, about 20 days after the 6-OHDA injection, an increase in movement latency was noted, which showed no tendency to recover.

When visual afferents were missing considerable impairment of movement occurred, and a comparison between visual open loop and closed loop performances revealed a significant interaction between the conditions of vision and SN lesion.

It thus emerges from these data that the SN is certainly involved in the control of movement initiation and speed. The results moreover clearly show that the role played by the dopaminergic system in the triggering of movement should not be overlooked. Lastly, as in human Parkinsonian subjects, visual information was used by these animals to compensate for motor deficits.

Investigations on the feedforward and feedback control of motor processes in primates should therefore take the probable involvement of the SN into account.

252.6 EFFECTS OF CHRONIC HALOPERIDOL ADMINISTRATION ON NEURONAL SENSITIVITY TO IONTOPHORESED GABA WITHIN RAT GLOBUS PALLIDUS, J. M. Frey, M. K. Ticku, and R. D. Huffman, Department of Pharmacology, Division of Neuropharmacology, The University of Texas Health Science Center at San Antonio, San Antonio, TX 78284.

Recent evidence suggests that chronically administered haloperidol results in an increase in GABA receptor binding sites in the substantia nigra (Gale, K., Nature 283:569,570,1980), possibly as a result of a decrease in the activity of the GABAergic strionigral system. The globus pallidus also receives a major GABAergic projection from the striatum; therefore, we decided to look at possible changes in GABA responsiveness of single pallidal neurons in rats that had been treated chronically with haloperidol. The effects of microiontophoretically applied GABA were assessed and compared on single pallidal neurons in control rats and in rats that had been fed haloperidol for 30 days (9.8±1.4 mg/kg) and then withdrawn from the haloperidol diet for 2 days. GABA binding in the substantia nigra is significantly elevated for at least 4 days after discontinuation of the chronic haloperidol feeding (Huffman, R.D. and Ticku, M.K.,Pharmac. Biochem. Behav. 18, 1983,In Press). Male Sprague-Dawley rats (250-300g) were anesthetized by the intraperitoneal injection of chloral hydrate (350 mg/kg) and a tracheotomy and jugular cannulation were performed. A left craniectomy was performed to expose the cortex overlying the globus pallidus. Extracellular single unit activity was monitored utilizing standard extracellular microelectrode recording techniques. GABA was applied by microiontophoresis from 5-barrel glass micropipettes with total tip diameters of 14-25µm. Drug concentrations utilized were as follows: GABA (5 and 10 mM in 0.2M NaCl, pH 3.8-4.0), dopamine (0.2M, pH 4.0), NaCl (3M for recording and 1M for current control). Electrodes were filled by centrifugation and utilized within a short time thereafter. In order to quantitate the sensitivity of GP neurons to iontophoresed GABA, EC_{50} values were estimated from dose-response curves compiled from the results of the systematic application of various ejection currents for two consecutive 20 sec recording periods. GABA produced profound inhibition of GP cell firing in both control and haloperidol-treated rats, but the haloperidol-treated group showed a statistically significant increase in GABA responsiveness with an average EC_{50} value 2.5 times less than controls (33.2±5.2 versus 84.4±12.2, df=34, $p<0.01$). Preliminary binding studies of GP tissue punched from 800µm frozen tissue sections revealed a 35% increase in the specific {H^3}-GABA binding within the treatment group when equilibrium GABA binding was measured using 4 nM{^{3}H}-GABA ($p<.07$). These data support the hypothesis that increases in {^{3}H}-GABA binding within the GP after chronic haloperidol treatment are accompanied by an increase in neuronal responsiveness to GABA.

252.7 EFFECTS OF PRENATAL HALOPERIDOL ON RECEPTORS IN THE DEVELOPING RAT STRIATUM: OPPOSITE CHANGES IN NALOXONE AND SPIPERONE BINDING. Sandra Moon Edley. Laboratory of Neurophysiology, National Institute of Mental Health, Bethesda, Maryland 20205.

A number of studies have shown decreased opiate binding to the the rat striatum after mechanical or chemical destruction of the nigrostriatal tract. Both of these approaches destroy not only a structural element of the striatum, namely, the nigral terminals, but also eliminate a chemical element, dopamine, and its regulatory effects. To further elucidate the interactions of the opiate and dopamine systems, dopamine receptors were blocked by haloperidol during an early dynamic period of striatal development.

Pregnant rats were anesthetized with ether on embryonic day 15 (E15), and 7-day osmotic minipumps filled with haloperidol (1 mg/day) or saline (0.9%) were implanted subcutaneously. Pups were decapitated on postnatal day 0 (P0) or 16 (P16). The frozen brains were cut in a cryostat. Some sections were processed immediately for dopamine fluorescence using a glyoxylic acid method. Others were incubated in either ^{3}H-naloxone, ^{3}H-spiperone or ^{3}H-muscimol to mark opiate, dopamine and GABA receptors, respectively, and apposed to ^{3}H-sensitive film. The film images were computer-analyzed to quantify ligand binding densities in the striatum.

Binding in tissue from animals treated with saline did not differ from untreated animals. At P0 the emerging heterogeneous pattern of naloxone-labeled opiate receptors is not altered by prenatal haloperidol. However, the density of opiate binding is reduced to about 70% of normal levels. This depressant effect of haloperidol was not general: in the same brains ^{3}H-spiperone binding, showing the normal modest high-lateral, low-medial gradient, was elevated by as much as 22%. The ^{3}H-muscimol distribution was patchy and unchanged.

By P16 naloxone-labeled receptors assumed the adult pattern of dense patches and subcallosal streak on a lightly labeled matrix. In the haloperidol-treated cases the adult pattern of naloxone labeling was acquired, but the density was slightly reduced. However, the partial recovery lagged in the patch (and streak) areas as compared to the non-patch zones. ^{3}H-spiperone, still showing a lateral-medial gradient, remained slightly elevated. The homogeneous muscimol binding was normal.

Dopamine, as demonstrated by fluorescence histochemistry, was present in the striatum, thereby discounting the possibility that nigral neurons were destroyed by the chronic haloperidol treatment. The finding of reduced naloxone binding after haloperidol treatment does not resolve whether a subset of opiate receptors is located on nigral endings, but it does suggest that striatal naloxone binding is modifiable through a mechanism involving dopamine receptor function.

252.8 OPPOSITE DIRECTIONS OF CIRCLING PRODUCED BY MEDIAL AND LATERAL SUBSTANTIA NIGRA LESIONS: ROLE OF MIDBRAIN. F.J. Vaccarino* and K.B.J. Franklin. (SPON: L.A. Switzman). Psychology Dept., McGill Univ., Montreal, Que., Canada H3A 1B1.

It is well known that unilateral stimulation or lesions of the nigrostriatal dopamine pathway cause animals to circle away from the more active nigrostriatal system. Thus, after unilateral substantia nigra (SN) lesions the indirect stimulant amphetamine causes rats to circle toward the lesioned side while apomorphine, acting on supersensitive DA receptors, produces circling contraversive to the lesioned side. Recently we have reported that when lesions or stimulation are restricted to the lateral portion of the SN rats circle towards the stimulated or more active side (Vaccarino and Franklin, Behav. Brain Res., 5:281, 1982; Vaccarino and Franklin, Pharmac. Biochem. Behav., 17:431, 1982). These findings indicate that the lateral portion of the SN acts in opposition to the more medial portion.

It has been shown that the main output pathway involved in nigrostriatal circling runs from the striatum to the pars reticulata of the SN and thence to the superior colliculus (SC) and midbrain reticular formation (MRF). To see if the same pathways were involved in the circling elicited from the lateral SN the present study examined the effects of lesions in the MRF and SC on circling following lesions of either medial or lateral SN. Consistent with earlier reports, Experiment 1 showed that unilateral SC lesions produced ipsiversive circling. Rats with combined medial SN and SC lesions (in the same hemisphere) showed no more ipsiversive circling than rats with SC lesions alone. In contrast to the non-additivity of the latter effects, the contraversive circling produced by lateral SN lesions was additive with the ipsiversive circling produced by SC lesions. Using the same design experiment 2 showed that neither the ipsiversive circling produced by medial SN lesions nor the contraversive circling produced by lateral SN lesions was additive with the ipsiversive circling produced by MRF lesions. Amphetamine dose-dependently increased circling in all rats without affecting direction.

Experiment 1 suggests that while the SC may be an output for medial SN derived circling it is not an output for the opposing lateral SN derived circling. Experiment 2 suggests that the MRF may be an output for both medial and lateral SN derived circling. This implies that medial and lateral nigrostriatal DA activity may modulate MRF activity in opposite directions.

(Supported by NSERC Grant A6303 and The Parkinson Foundation of Canada.)

252.9 CONDITIONED TURNING: EFFECTS OF UNILATERAL 6-OHDA LESIONS AND SIDE OF SPONTANEOUS TURNING PREFERENCE, S. B. Dunnett and A. Bjorklund. Department of Experimental Psychology, Cambridge, UK and Department of Histology, Lund, Sweden.

Unlesioned rats can be trained to rotate selectively in one direction and such turning is reported to be associated with changes in dopamine and DOPAC levels in the contralateral neostriatum (Yamamoto et al. Life Sci. 30:2155 1982).

Experiment 1. Fourteen rats under 23 hour water deprivation were trained to rotate in a hemispheric bowl in one direction for 0.1µl sugar water reinforcement, delivered to a nozzle in the wall of the bowl. After 9 days training, all rats received a unilateral lesion under barbiturate anaesthesia by injection of 8µg 6-OHDA in 4µl ascorbate-saline into the ascending dopamine mesotelencephalic bundle. The lesion was made on the same ("ipsilateral" group) or the opposite ("contralateral" group) side to the direction of initial training. Two weeks later, training continued over 4 days to turn in the same direction as previously. "Ipsilateral" rats continued to show high rates of selective turning in the reinforced direction whereas "contralateral" rats showed equal turning in both directions (group x direction, $F(1,12)=18.93$, $p<0.01$). The reinforced direction of turning was then reversed for a further 6 days "Ipsilateral" rats were unable to learn to rotate in the now reinforced direction contralateral to their lesion whereas the "contralateral" rats rapidly learned to turn selectively towards the now reinforced side (group x direction, $F(1,12)=5.10$, $p<0.05$).

Experiment II. Twenty-four unlesioned rats were tested for rotation under 5mg/kg amphetamine in automated rotometers. Three groups of 3 rats were selected which showed either >100 net right turns, >100 net left turns, or no turning bias over the 90 min test. These 9 rats were all trained to turn to the right for sugar-water reinforcement, initially under continuous reinforcement (each full turn to the right reinforced), then under fixed ratio 2, 3 and 4 schedules for 3 days each. All rats rapidly learned to turn selectively in the reinforced direction, and no differences were detectable between the 3 groups at any stage of testing.

Conclusions. Spontaneous side asymmetries in intact rats do not influence their ability to learn to turn selectively in one direction. 6-OHDA lesions producing >95% forebrain dopamine depletions abolish the rats' ability to learn to rotate selectively contralateral to the lesion. Neither motivation nor primary motor impairments can account for this pattern of results, which suggest rather that the lesion disrupted the ability to initiate contralateral turns.

252.10 BASAL GANGLIA MEDIATION OF CHEMICAL-INDUCED HYPERKINESIA IN RATS. J.S. Schneider, Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

Daily administration (7-10 days) of 3-3 iminodipropionitrile (IDPN) results in a complex hyperkinetic syndrome in rats, characterized by a spontaneous and permanent choreo-athetoid cervical dyskinesia and bursts of circling and locomotor activity. The cervical dyskinesia consists primarily of large amplitude vertical choreotic movements and to a lesser extent, lateral athetoid movements. While IDPN produced a motor disorder in all rats tested, there was much variability as to the severity of the disorder. While circling (both sides) and increased locomotor behavior were observed in some rats, others appeared somnolent and displayed low levels of locomotor behavior. Cervical dyskinesias were observed both when rats were moving and when they were stationary. In rats with prominent spontaneous head movements, stress greatly increased the frequency (and often the magnitude) of these movements. All rats had some degree of postural disorder consisting of body tilt to one side with forelimbs extended.

Five rats with severe spontaneous head movements were given bilateral globus pallidus lesions. These lesions were effective, in all cases, in permanently eliminating or greatly reducing the frequency and magnitude of both spontaneous and stress-induced head movements (mean post-lesion decrease in spontaneous movements of 95%).

Two rats with prominent spontaneous movements were given large bilateral ablations of sensory and motor cortices. These lesions had minimal effects on either the frequency or magnitude of head movements.

Another four rats with distinct head movements were given bilateral trigeminal ganglion lesions. Removal of most of the sensory inputs from the face was successful in reducing the frequency and magnitude of spontaneous head movements (mean 75% decrease) but had little or no effect on stress- or amphetamine induced head movements.

These results suggest that this chemically-induced motor disorder has a significant basal ganglíar component, since removal of basal ganglia outputs virtually eliminates the abnormal movements. It is suggested that descending influences from the pallidum are important for mediation of this disorder since sensori-motor cortex lesions are ineffective in attenuating the abnormal movements. Lastly, the reduction in spontaneous movements following loss of sensory inputs is consistent with the idea that the basal ganglia may play a significant role in the gating of sensory information to brainstem and cervical motor areas (Schneider et al., Exp. Neurology 77: 534-543 and Olazabal and Lidsky, Soc. Neurosci. Abst. 8: 960, 1982).

252.11 SIMULTANEOUS CATALEPSY AND APOMORPHINE-INDUCED STEREOTYPIC BEHAVIOR IN MICE. D.M. Yurek and P.K. Randall (Spon. S. Erlich) Dept. of Physiology & Biophysics, USC Sch. of Med., Andrus Gerontology Ctr., L.A., CA 90089.

The classical neuroleptics, haloperidol (HAL), chlorpromazine (CPZ) and spiperone (SPIP) effectively block apomorphine (APO)-induced stereotypic behavior in mice when injected intraventricularly at low doses producing little or no catalepsy. Domperidone (DOM) does not cross the blood-brain barrier and sulpiride (SULP) has limited access to the CNS. When administered intraventricularly both produce not only a highly cataleptic response but also a simultaneous augmentation rather than diminution of stereotypic behavior, especially gnawing.

Both C57BL/6J and BALB/cJ mice were surgically implanted with bilateral cannula allowing for direct injection of neuroleptics into the lateral ventricles. HAL (50 ug), CPZ (50 ug), SPIP (10 or 2 ug), DOM (50 ug), and SULP (2 or 0.5 ug) were injected intraventricularly (inj. vol. = 1.0 ul in each ventricle) followed 40 minutes later by a systemic injection of APO (2.0 mg/kg) to test for stereotypic behavior. Catalepsy tests were given 5 minutes prior to, and 10, 20, 45 and 75 minutes post APO. HAL, CPZ, and SPIP produced catalepsy at all times and blocked the expression of stereotypic behavior. High doses of SULP and DOM produced similar results. Low doses of SULP and DOM induced only a slight cataleptic response pre-APO. However, a few minutes after the APO injection we observed a coexisting state of catalepsy and stereotypic behavior in both strains. In addition, at high doses, SULP mice exhibited immediate stereotypic gnawing upon external sensory stimulation.

The behavior of the low dose SULP mice post-APO can be characterized as initially showing augmented stereotypic behavior over the controls and an unusual, persistent licking behavior that was not observed with any other treatments. During the early post-APO catalepsy tests both the low dose SULP and DOM mice maintained a rigid cataleptic posture while simultaneously gnawing and licking at the floor.

Our observations suggest that catalepsy and stereotypic behavior do not lie on opposite ends of a continuum. Rather, the specificity SULP and DOM have for D-2 receptors indicate that there possibly exists a subset of D-2 receptors that are not blocked by SULP or DOM and are specific for stereotypic behavior. Thus, both cataleptic and stereotypic behavior are elicited simultaneously. The augmented stereotypic behavior was marked with an unusual gnawing and licking behavior.

These results may be related to the clinical observations of coexistent tardive dyskinesia and drug-induced Parkinsonism in individual patients.

252.12 QUANTIFICATION OF BEHAVIORAL SUPERSENSITIVITY IN THE C57BL/6J MOUSE. R.J. Mandel* and P.K. Randall* (Spon. D.F.Lindsley)USC Sch. of Med, Depts. of Psych. and Physiology and Biophys. , and Andrus Gerontology Ctr. L.A., CA. 90089

Until recently, the rotational paradigm for measuring behavioral supersensitivity to DA agonists has not been entirely meaningful due to the lack of a relevant control group for comparison. Marshall and Ungerstedt (Eur. J. Pharm. 41:361-367,1977) first described the use of a lesion which completely blocked the behavioral output of one striatum. This enables one to obtain turning data which theoretically is caused by the behavioral outflow of one nonsupersensitive striatum in the rat. Their lesion is thought to be an interruption of the striatonigral projectons and is located in the ventral portion of the crus cerebri in rats. The present study has used this method to quantify the behavioral supersensitivity in the C57BL/6J mouse.

The lesion placement that was found to be most effective in the C57 corresponds closely to that found in the rat. A discrete electrolytic lesion of the ventral internal capsule (-1.6 AP, +2.0 Lat, -4.5 DV from bregma) produces reliable and marked ipsiversive turning to 2 mg/kg amphetamine. A repeated measures design was undertaken to determine the dose response curve for apomorphine. These same animals were then given 6-OHDA lesions in the opposite striatum and maintained for 21 days to allow supersensitivity to develop in the striatum with an intact output. These supersensitive mice were also treated in the repeated measures design to obtain another dose response curve for apomorphine for the supersensitive preparation.

The equation for the regression line for the pre-6-OHDA lesion dose response is $Y=42X+26$ with $r=.992$. The equation for the regression line for the post-6-OHDA lesion dose response is $Y=34X+149$ with $r=.985$. These data indicate nearly parallel dose response curves with a 32 fold increase in sensitivity.

The parallel dose response curves in a within animal design indicate a true shift of the dose response curve with no contamination with increased amplitude of response. This method is an important improvement in the rotational paradigm because it allows comparison of increases in sensitivity and not actual numbers of rotations. Therefore many organismic variables such as inherent differences in baseline activity levels or differential reactivity to drugs between different strains or ages of animals are controlled for and comparisons of disparate groups are meaningful. Taken together, these advantages make this technique a powerful tool for studying the parameters of behavioral supersensitivity in inbred mouse strains.

252.13 THE EFFECTS OF INTRASTRIATAL AND CORTICAL INJECTIONS OF SCOPOLAMINE ON POSTURAL DEVIATION AND REARING BEHAVIOR IN RATS. L.K.Chambers and C.Van Hartesveldt. Dept. of Psychology and the Center for Neurobiological Sciences, Univ. of Florida, Gainesville, FL 32611.

Intrastriatal injections of the anticholinergic drug scopolamine (SCOP) has been reported to elicit contralateral postural deviation and stereotyped rearing in separate experiments. We designed the present research to investigate the dose-response characteristics of both behaviors and to test the behavioral effects of the drug in the neocortex above the striatum.

Male Long-Evans hooded rats were implanted bilaterally with permanent guide cannulae (21 GA), so that the 27 GA injection cannulae were located in the anterior caudate-putamen (CPU) or rostral neocortex. Animals were unilaterally injected with either the vehicle (VEH) or one of three doses of (SCOP) 20, 30 or 40µg/.25µl buffer. After injection, animals were placed in a circular clear plexiglass chamber and monitored for postural deviation and number of rears. The cumulative scores for each 5-minute block of the 30 minute observation session were recorded. For statistical analysis, a dominant direction score for deviation was obtained by subtracting ipsilateral scores from the contralateral scores. The data were then analyzed with a factorial ANOVA for repeated measures, using the absolute difference scores between VEH and SCOP.

Animals with injections of SCOP into the anterior CPU showed consistent contralateral postural deviation with no clear dose related differences. Injections of SCOP into neocortex did not elicit contralateral postural deviation.

Unilateral CPU injections of SCOP produced significant increases of rearing which were dose related, but neocortical injections were also effective. There was a trend for neocortical injections to produce more rearing with a shorter latency of onset than CPU injections. Closer examination of exact neocortical injection sites, along the anterior-posterior dimension, indicated that the closer the site to the region dorsal to the CPU the shorter the latency to onset of rearing. These results suggest that while SCOP-induced contralateral deviation is localized in the CPU, SCOP-induced rearing may be localized in the neocortex.

252.14 PERCEPTUAL MOTOR DYSFUNCTION IN PARKINSON'S DISEASE IS RELATED TO A DISTURBANCE IN THE HIGHER-ORDER CONTROL OF MOVEMENT. Y. Stern*, R. Mayeux*, J. Rosen*, and L. J. Cote, Neurological Inst., Columbia Univ. College of Physicians & Surgeons, and City Univ. of the City of New York, New York 10032.

Perceptual motor dysfunction is the most common form of intellectual impairment in Parkinson's disease (PD). This behavior may be related to a disturbance in higher-order control of movement, particularly predictive or sequential movements. Fourteen parkinsonian patients without dementia or depression and 9 age-matched controls used a stylus to trace paths, including a horizontal line and a sawtooth pattern, presented on a vertical screen. After tracing each of these, subjects were presented with degraded paths: the line was degraded into two endpoints and the sawtooth path was degraded by eliminating a straight portion or one or two angles. Subjects filled in the missing portions. Previously we rated videotaped tracing performance (Stern et al. JNNP 1983;46:145-51), but in this study digitizing apparatus quantified tracing error (deviation from the path) and velocity during tracing. Subjects also completed a construction test and a measure of general intellectual function, and the severity of patients' parkinsonian symptoms was rated. Patients' tracing error was greater than controls' on all paths despite comparable tracing velocity in the two groups. All subjects performed more poorly as the paths were successively degraded, but patients' accuracy in tracing deteriorated more rapidly than controls'. Tracing error on the degraded paths correlated only with patients' performance on the construction task and was not related to the severity of their disease. Errors in the controls related only to general intellectual ability. This study suggests that the patients have a disturbance in the higher-order control of movement that is not related to the typical motor manifestations of PD and has a similar basis as poor performance on construction and other perceptual motor tasks. Both performance deficits represent an inability to formulate or act upon internal representations of space and are a consequence of basal ganglia degeneration.

252.15 BRAINSTEM DYSFUNCTION IN DYSTONIA MUSCULORUM DEFORMANS SUGGESTED BY POLYSOMNOGRAPHIC FINDINGS. W.R.Jankel, E.Niedermeyer*, M.Graf*, R.Allen*, and M.Kalsher*. Clin.Neurophysiol.Lab., Johns Hopkins Univ.Sch.of Med. and Hospital, Baltimore, MD 21205.

Dystonia musculorum deformans (DMD) is a progressive, heterogeneous disorder of unknown pathophysiology with three hereditary forms and appearing as a symptom in 20 other diseases. Intelligence is unaffected. Based on reports of relief from dystonia during sleep, the nocturnal EEG, EOG, and EMG were studied in nine patients with DMD and nine healthy controls.

Gold-plated silver cup electrodes were placed over frontal, central, and occipital regions in accord with the International 10-20 System. A standard bipolar montage was used for the recordings and EEG records were scored independently using the criteria of Rechtschaffen and Kales.

All of the dystonia patients were found to be poor sleepers. However, the sleep of patients in advanced stages of DMD revealed an EEG pattern which was characterized by pronounced, high amplitude (75-100µV) sleep spindles which were continuous for all of stage 2 and portions of stage 3 NREM sleep. Other sleep parameters including latency to sleep, per cent time in REM sleep, number of REM periods, and number of awakenings were progressively abnormal as the dystonia advanced.

Gibbs and Gibbs(1964) reported an exaggeration of normal sleep spindles which they called "extreme spindles" in young, cerebral palsied and mentally retarded children. These spindles were found most often in children less than 5 years of age and never in children older than 12. They suggested that the "extreme spindle" activity was associated with extrapyramidal dysfunction since cerebral palsy alone was insufficient to produce the spindles.

In normal healthy persons, sleep spindles become less frequent and diminish in amplitude with advancing age. The spindle activity of advanced DMD cases presents a stark contrast to this normal pattern. It differs from the "extreme spindle" pattern by a later age of onset (12-56yrs.of age), is not accompanied by retardation, and variations in spindle frequency within patients, is absent.

Successful treatments, in addition to relieving the clinical symptomatology, also normalize the sleep of these patients and reduce the amplitude of the sleep spindles. This may underscore the clinical significance of these sleep spindles as an index of the dystonia process, and further, suggest brainstem involvement in this disorder.

The elucidation of a sleep disorder which parallels advancing dystonia suggests that polysomnography may be an important adjunct to biochemical studies of dystonia and other presumed basal ganglia disorders.

253.1 DISTRIBUTION OF ACETYLCHOLINESTERASE IN THE MEDIAL AND VENTRAL PREFRONTAL CORTEX OF THE RHESUS MONKEY. H. Barbas, and D. N. Pandya. SAR, Boston Univ., and V.A. Med. Center, Bedford, MA.

Architectonic studies have shown that the prefrontal cortex contains two regions with a rudimentary laminar organization. One of these regions is situated on the medial surface of the frontal lobe at the rostral tip of the cingulate sulcus, and the other is located in the caudal orbitofrontal cortex. Each of these regions contains a bilaminar agranular cortex, (designated periallocortex), which is bounded by regions with an incipient isocortical type of laminar organization (called proisocortex). From each of these periallo-proisocortical (pAll-Pro) areas a stepwise laminar differentiation can be traced within the prefrontal cortex (Barbas and Pandya, 1982).

In addition to their distinct cytoarchitecture, as observed in Nissl stained sections, the frontal pAll-Pro areas can be distinguished from neighboring regions in material reacted for the visualization of acetylcholinesterase (AChE). Compared to dorsolateral frontal isocortices, the pAll-Pro areas contain heavier AChE activity, concentrated in distinct bands in layer I, and in the deep layers. Whether the heavy AChE activity observed in pAll-Pro areas is due predominantly to intrinsic AChE-positive neurons and their processes or to afferent projections, is not known. However, when AChE activity within fibers is suppressed by diisofluorophosphate pretreatment of the tissue, a similar number of AChE-positive neurons can be seen in layer VI in both pAll-Pro areas and dorsolateral isocortices. This suggests that the heavy AChE activity in the pAll-Pro areas in normal tissue is mainly due to AChE-containing afferent projections to the prefrontal cortex. This observation may be significant because AChE-rich pathways are potentially cholinergic and have been implicated in mnemonic processes.

In a previous study it was shown that the prefrontal pAll-Pro areas have widespread connections within the prefrontal cortex, compared to restricted intrinsic connections of prefrontal isocortices. This suggests that the prefrontal pAll-Pro areas may exert a broad influence on the prefrontal cortex.

On the basis of the above observations it is possible that disruption of putative cholinergic pathways in some of the degenerative neurologic disorders may partially deafferent the pAll-Pro areas, and may thus affect the normal functioning of the rest of the prefrontal cortex.

253.2 ALPHA AND BETA RECEPTOR MEDIATED EFFECTS ON PURKINJE CELL SPONTANEOUS ACTIVITY IN THE IN VITRO RAT CEREBELLAR SLICE, A. S. Basile and T. V. Dunwiddie. Dept. Pharmacology, Univ. Colo. Health Sciences Center, Denver, CO 80262.

Superfusion of Purkinje neurons in the in vitro rat cerebellar slice with norepinephrine caused dose-dependent increases and/or decreases in spontaneous Purkinje neuron firing rates. The excitation evoked by low concentrations of norepinephrine (0.5-10 uM) and by all concentrations tested of the beta receptor agonist isoproterenol (0.1-5 uM) were reduced by timolol, a beta receptor antagonist. Perfusion with higher concentrations of norepinephrine (25-100 uM) or with the alpha receptor agonist clonidine (0.5-50 uM) caused a depression of Purkinje neuron spontaneous activity. This inhibitory response was blocked by the alpha receptor antagonist phentolamine. The alpha-one selective agonist phenylephrine had no effect on spontaneous firing rates at concentrations up to 100 uM. All of these responses appeared to be due to a direct action on the Purkinje neurons, because neither the excitation nor the depression of Purkinje neuron activity caused by norepinephrine was substantially altered in a medium with reduced calcium and increased magnesium concentrations, which has been found to block synaptic transmission in vitro. The amplitude of excitatory responses appeared to be dependent upon the potassium concentration of the medium, such that the mean excitatory response elicited by 500 nM isoproterenol (218% above control at 5.2 mM K^+) was reduced to 3% at 3 mM K^+. Clonidine induced depressions were not significantly altered by the changes in the concentrations of potassium in the medium. However, it was not possible to determine if these were direct effects of potassium or due to changes in basal firing rates produced by changes in the potassium concentration of the medium. In summary, under these in vitro conditions, norepinephrine appears to increase the firing rate of Purkinje neurons via an interaction with beta adrenergic receptors, while norepinephrine induced depressions may be mediated by alpha adrenergic receptor interactions; both receptors appear to be located on the Purkinje neuron itself. Preliminary evidence suggests that potassium may be directly or indirectly involved in the excitatory responses elicited by norepinephrine.

253.3 THE EFFECT OF DESMETHYLIMIPRAMINE (DMI) AND RESERPINE ON PROTEINS FROM THE PARIETAL CORTEX AND THE HIPPOCAMPUS AS ASSESSED BY TWO-DIMENSIONAL GEL ELECTROPHORESIS (2DE). William E. Heydorn, G. Joseph Creed* and David M. Jacobowitz. Lab. of Clinical Science, NIMH, Bethesda, MD 20205.

Using 2DE, we have recently compiled an atlas of proteins from 25 discrete regions of the rat brain. Each protein was analyzed for molecular weight, isoelectric point (pI) and relative quantity, and assigned a permanent indexing number. Using this map, we now report on the effect of the tricyclic antidepressant DMI and the neurotransmitter depleting agent reserpine on proteins in the parietal cortex and hippocampus. In the first experiment, rats received either DMI 10 mg/kg IP twice daily for 3 weeks or a single 10 mg/kg dose of the antidepressant. Appropriate control groups received 0.9% NaCl. Rats were killed by decapitation 24 hours after their last dose, and tissue samples of parietal cortex and hippocampus were obtained by microdissection. Proteins were separated by 2DE, visualized using a silver stain, and quantitated by computerized scanning densitometry. Of the 125 proteins analyzed, repeated DMI administration produced a reduction in the concentration of two proteins in both the parietal cortex and the hippocampus. The first, identified on our maps as protein #10 (molecular weight 57,000 daltons, pI 6.2) was reduced by 65% ($p<0.005$) in the parietal cortex and 63% ($p<0.001$) in the hippocampus by chronic DMI administration, while the second, identified as protein #11 (molecular weight 57,000 daltons, pI 6.3) was reduced 41% ($p<0.005$) in the parietal cortex and 52% ($p<0.001$) in the hippocampus. In contrast, protein #41 (molecular weight 28,000 daltons, pI 5.9) was elevated by about 22% in both regions as a result of chronic DMI administration. In all three cases, acute drug admistration was without effect.

In a second experiment, rats were treated either acutely or repeatedly with reserpine. One group of rats received 2.5 mg/kg of reserpine once daily for 3 days and was killed on day 4. Another group of rats received a single 2.5 mg/kg dose of reserpine and was killed 30 minutes later. Control animals received 0.9% NaCl. In the hippocampus, protein #10 was increased 36% ($p<0.05$), protein #11 was increased 44% ($p<0.025$) and protein #41 was reduced 28% ($p<0.001$) in rats treated repeatedly with reserpine. In contrast, chronic reserpine administration had no effect on any of these three proteins in the parietal cortex. In all three cases, acute drug treatment was without effect. These results indicate that specific proteins within the rat brain can be altered by the chronic administration of agents affecting noradrenergic reactivity, and are of interest in view of the known effects of these drugs on neurotransmitter receptors. In addition, there appears to be some regional specificity as to the effect of these drugs among different neuroanatomical areas of the rat brain.

253.4 THE SUBSTRATE FOR SELF-STIMULATION OF THE PREFRONTAL CORTEX IN THE RAT: STRENGTH-DURATION CHARACTERISTICS. S. Schenk* and P. Milner*, Dept. Psychol., McGill University, Montreal, Quebec H3A 1B1, and P. Shizgal, Center for Studies in Behavioural Neurobiology, Concordia University, Montreal, Quebec, H3G 1M8.

The rewarding effects of stimulating the prefrontal cortex (PFC) and the lateral hypothalamus (LH) appear to be mediated by different populations of directly stimulated cells. In the present study we attempted to further differentiate these two populations by obtaining estimates of their strength-duration characteristics. These estimates may prove useful in distinguishing the neurons responsible for the rewarding effects from other neurons activated by the electrodes and hence, may expedite the identification of the reward-related cells by electrophysiological means.

Strength-duration functions were obtained from two PFC and two LH sites by determining pairs of currents and pulse durations that sufficed to maintain a half-maximal rate of lever pressing. The duration of the cathodal, constant current pulses ranged from 0.5 to 15.0 msec. Throughout the experiment train duration and pulse frequency were fixed at 0.5 sec and 25 Hz, respectively.

In order to standardize the results across placements, hyperbolae were fit to the strength-duration data, and the current (I) values were then divided by the rheobase (r). A three-way ANOVA (subject x duration x site), performed on the logarithms of these I/r values, yielded a significant interaction between pulse duration and site. This indicates that the strength-duration curves for the PFC and LH sites differ in shape. Indeed, the chronaxies of the PFC curves were 0.98 and 1.25 msec while the chronaxies of the LH curves were 1.59 and 1.90 msec.

Matthews (J.c.p.P., 1977, 91, 858-874.) has noted that the chronaxies of behaviorally derived strength-duration curves for the LH reward substrate are much longer than most electrophysiologically derived strength-duration curves for single central neurons. He proposed that the LH reward substrate must include some elements with unusually long chronaxies or neurons that fire repetitively in response to long stimulation pulses. It would appear that the contribution of such neurons is weighted more heavily in the LH reward substrate than in the PFC reward substrate.

253.5 AMPHETAMINE-INDUCED CHANGES IN SEROTONIN METABOLISM: OPPOSITE EFFECTS IN HIPPOCAMPUS AND STRIATUM. Craig D. Applegate* and Ronald Kuczenski. Department of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN 37232.

Results of previous investigations have suggested a contribution of central serotonin (5HT) systems to the alterations which occur in brain and behavioral functioning following the administration of low doses of d-amphetamine (AMPH). In the present study we have examined changes in 5HT metabolism in response to a low dose of AMPH as an initial attempt to characterize patterns of AMPH-induced changes in this measure in discrete regions of the forebrain and mesencephalon.

Male Sprague-Dawley rats were administered either saline or 0.6 mg/kg AMPH subcutaneously and sacrificed by decapitation 15, 30 or 45 minutes later. Brains were rapidly removed and dissected over ice after the method of Segal and Kuczenski (Brain Res. 68, 1974). Levels of 5HT and its metabolite 5-hydroxyindole acetic acid (5HIAA) were assessed in brain tissue samples from prefrontal cortex, nucleus accumbens, striatum, hippocampus and substantia nigra via high pressure liquid chromatography (electrochemical detection) using a modification of the methods of Magnusson et al. (J. Chromatog. 221, 1980).

AMPH administration resulted in a significant decrease in 5HIAA levels in the hippocampus and a significant increase in striatal 5HIAA levels. The decreases in hippocampal 5HIAA were maximal at 15 minutes (87% control), were partially recovered by 45 minutes (92% control) and occurred in the absence of changes in 5HT levels. Striatal increases in 5HIAA levels were maximal at 30 minutes (116% control), were partially recovered at 45 minutes (113% control) and were accompanied by significant increases in 5HT levels. Maximal increases in striatal 5HT (133% control) occurred at 30 minutes following AMPH administration and were completely recovered (105% control) by 45 minutes. Levels of 5HIAA in the accumbens were decreased and increased at early and late time points, respectively ($p = .08$), while cortical 5HIAA tended to increase with maximal effects observed at 30 minutes. 5HT levels were unchanged in either of these regions, and levels of 5HT and 5HIAA were unchanged in the substantia nigra.

Sources of 5HT for the hippocampus and the striatum are primarily from the median and dorsal raphe, respectively. Opposite changes in 5HIAA levels produced by AMPH in these regions may reflect differences in the source of 5HT innervation to these structures. Relative contributions of the dorsal and median raphe innervation to accumbens and cortex may be reflected in the patterns of AMPH-induced change observed in these areas as well. (Supported by NIDA grant DA02676 and training grant MH15452).

253.6 REGIONAL DISTRIBUTION OF RADIOLABELED ZINC AND INULIN AFTER INTRACEREBROVENTRICULAR INJECTION IN THE RAT. E.G. Drust*, N.F. Harris, and I.L. Crawford, Depts. Pharmacology and Neurology, Univ. Texas Hlth. Sci. Ctr. at Dallas and VA Epilepsy Ctr., Dallas, TX 75216.

Zinc is distributed unevenly in the CNS and little information is available on processes regulating its concentration in the brain. The present study was designed to determine the distribution and accumulation of radiolabeled zinc (65Zn) in rat brain after intraventricular injection relative to the distribution of 14C-inulin, a marker of extracellular space. Rats received a lateral ventricular injection of an equimolar solution of zinc and inulin containing 500nCi 65Zn (277mCi/mmol) and 80nCi 14C-inulin (11mCi/mmol) and were sacrificed 1 or 4 days later. Brains were removed and dissected; eight brain regions were sampled. Tissues were placed in a gamma counter to measure 65Zn content and then solubilized for scintillation counting. Corrections were made for the Compton electron effect and for tissue quench. A portion of the data is summarized below.

REGION	DAY 1		DAY 4	
	[Zn]	Zn/In	[Zn]	Zn/In
Hippocampus	12.89±2.95	3.63	8.58±1.03	3.70
Cortex	8.06±2.69	2.09	4.25±1.28	2.41
Striatum	2.40±0.66	2.64	1.35±0.27	3.38
Cerebellum	0.58±0.18	2.32	0.13±0.04	----
Pons-Medulla	0.32±0.16	1.88	0.12±0.03	----

[Zn] = nmol/g wet weight ± SEM, n=5

Zn/In = pmol Zn / pmol Inulin accumulated

Radiolabeled zinc distributed in the brain in a pattern similar to that of endogenous zinc. The hippocampus, which contains the highest concentration of endogenous zinc in the regions assayed, accumulated the greatest concentration of 65Zn. Ratios of zinc/inulin accumulated indicate that the distribution of centrally administered zinc is not simply attributed to diffusion from ventricular CSF into extracellular space. In addition, measurements at day 4 indicate that the half-life of zinc is not uniform but is dependent on the region examined. These results suggest that the uptake, storage or utilization of zinc in the brain is not identical in all brain areas. This finding may be indicative of different physiological functions of zinc in specific brain regions. Supported by a VA Merit Review Research Program and NIH NIGMS GM07062.

253.7 MONOAMINE METABOLISM IN MICE TREATED NEONATALLY WITH MONOSODIUM GLUTAMATE (MSG). R. Dawson and Z. Annau. Div. of Toxicology, The Johns Hopkins Univ., Baltimore, MD 21205.

Neonatal administration of MSG to rodents results in destruction of the arcuate nucleus of the hypothalamus, obesity and endocrine dysfunction. The morphological and behavioral consequences of neonatal MSG administration have been extensively studied in the mouse. Few studies have utilized the mouse in assessing the neurochemical effects of MSG-induced arcuate nucleus damage. The present studies were undertaken to determine the effects of MSG treatment on monamine metabolism in the mouse.

Male and female CF-1 mice were treated on postnatal day 4 with a single subcutaneous injection of MSG (4mg/g) or saline. Monoamine metabolism was assessed in adults by measuring monoamine and metabolite levels by high performance liquid chromatography coupled with electrochemical detection under normal conditions and after challenges with α-methyl-p-tyrosine(MPT,400mg/kg), pargyline(100mg/kg) and reserpine(2mg/kg).

MSG-treated mice were found to have significantly lower levels of hypothalamic dopamine (DA), however 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) levels were normal,suggesting increased DA catabolism. MPT administration resulted in a slightly accelerated decline in hypothalamic DA levels when compared to controls. Pargyline-induced DA accumulation and HVA decline were also increased in MSG-treated mice. Control mice exhibited a 23% decline in DA levels 1 hour after reserpine treatment while MSG-treated mice were unaffected. MSG treatment did not alter hypothalamic norepinephrine (NE) or serotonin metabolism. Brainstem NE decline after MPT administration was significantly attenuated in MSG-treated mice. Acute administration of MSG to adult mice resulted in significant increases in hypothalamic levels of DA, DOPAC and 3-methoxy-4-hydroxyphenylglycol 1 hour after injection.

Neonatal administration of MSG results in depletion of hypothalamic DA and increased DA metabolism which may represent a form of neurochemical compensation. Acute administration of MSG to adults does not result in permanent alterations in DA metabolism but does exhibit a powerful pharmacologic action. The alterations in brainstem NE after neonatal MSG treatment represent a potentially important neurochemical effect of MSG.

253.8 EFFECT OF BENZTROPINE ON DOPAMINE(DA) UPTAKE IN A9,A10 AND DA POOR REGIONS M. G. Hadfield and E. A. Nugent*. Neurochemistry Research Laboratory, Section on Neuropathology, Department of Pathology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA. 23298

Recently, we reported that cocaine and amphetamine inhibit the synaptosomal uptake of DA less well in A10 regions (prefrontal cortex and olfactory bulbs) than in A9 regions (caudate-putamen). This could be due to (i) differences in A9 and A10 uptake mechanisms and/or (ii) non-specific effects such as uptake into non-DA elements. Specific uptake differences in central DA systems would be important because it might then be possible to selectively manipulate them pharmacologically. If similar differences are present in humans, the potential would exist to fine-tune neuroleptic and anti-parkinson medication to produce maximal clinical effects while reducing unwanted side-effects. A difference in uptake would fit well with the findings of others that central DA systems differ in other respects, such as the number, affinity and distribution of receptors and autoreceptors.

In the present study, we used benztropine because it is a more selective blocker of DA uptake than cocaine or amphetamine. DMI was simultaneously added to prevent DA uptake into NE terminals. The brains of adult male ICR mice were rapidly dissected over ice to obtain the pre-frontal cortex, olfactory bulbs, caudate-putamens, occipital cortex and cerebellum. Synaptosomes were prepared and incubated with tritiated DA (0.2 uM), DMI 10^{-8}M and varying concentrations of benztropine (10^{-7}M--10^{-2}M) were carried out according to the methods of Hendley et al.

At a concentration of 10^{-4}M benztropine produced virtually complete inhibition of DA uptake in the caudate-putamen. In all other tissues, uptake inhibition was far from complete. In the A10 regions (prefrontal cortex and olfactory bulbs) it was respectively 58-63% and in dopamine poor regions (occipital cortex and cerebellum) it was respectively 40% and 24%. These regions could only be pushed to a maximum uptake inhibition for DA at 10^{-3}M, respectively 76%, 71%, 71% and 53%. At 10^{-2}M there was a paradoxical rebound, or lessening of uptake inhibition to 70%, 51%, 64% and 41% respectively. The IC_{50} values are 2.5×10^{-6} for striatum, 2.5×10^{-5} for prefrontal cortex, 2×10^{-5} for olfactory bulbs, 2.5×10^{-4} for occipital cortex and 7.5×10^{-4} for cerebellum.

The results demonstrate differences in DA uptake inhibition for benztropine in various brain regions. Some of this may be due to specific differences because the IC_{50} values are roughly an order of magnitude apart for A9 DA vs A10 DA vs DA poor terminal regions. Yet it is obvious that some non-specific DA uptake is taking place except in the striatum. This is best demonstrated in the DA poor regions.

253.PO MULTIPLE BINDING SITES OF TRICYCLIC ANTIDEPRESSANTS: REGIONAL DISTRIBUTION IN RAT BRAIN. Anat Biegon, Hoffmann-La Roche Inc. Nutley NJ 07110.

The binding of ^{3}H-amitriptyline (Ami) and ^{3}H-Nortriptyline (Nor) was characterized on brain sections and the regional distribution of the binding sites analyzed by quantitative autoradiography using tritium sensitive (^{3}H-Ultrofilm LKB) sheet film and computerized densitometry. The binding of both drugs shows saturation at 0°C in the nM range. Atropine and mepyramine, a cholinergic muscarinic and a histaminergic agent, respectively, displace ami binding in an additive manner. Together, they account for 50% of the displaceable binding of 4 nM ami. The distribution of ami binding in the brain does not resemble that of any particular drug or transmitter system. However, in the presence of 200 nM atropine + 200 nM mepyramine, the distribution of the residual sites is similiar to that of 5HT and imipramine binding, being highest in the raphe superficial layers of the superior colliculus, interpeduncular nucleus, substantia nigra and mamillary nucleus.

Nor binding is highest in those brain regions enriched in norepinephrine and in DMI binding sites - namely the locus coeruleus, anteroventral thalamus, ventral bed nucleus of the stria terminalis. However, there are moderately high concentrations in the caudate and substantia nigra, which contain neither NE nor DMI binding. Nor labeling of these areas is reduced following a lesion of presynaptic serotonergic terminals with 5,7 dihydroxytryptamine. Displacement studies show both drugs possess a low affinity binding component, which is displaceable by nor, ami and other tricyclics only in μM concentration. In conclusion, amitriptyline and nortriptyline bind with high affinity to a number of different presynaptic and postsynaptic sites, and they share a low affinity binding component similiar to the one described for DMI (Biegon and Samuel, Biochem.Pharmacol. 28:3361, 1979) and imipramine (O'Brien et al., Soc. Neurosci. Abst. 4:430, 1978).

PRESYNAPTIC MECHANISMS I

254.1 PROTEIN I PHOSPHORYLATION IN PC12 CELLS. W.P. Melega* and B.D. Howard. Dept. of Biological Chemistry, UCLA Med. School, Los Angeles, CA 90024.

PC12 is a clonal line of rat pheochromocytoma cells that store and secrete dopamine and acetylcholine by processes that appear to be normal with one interesting exception. Whereas the evoked secretion of many compounds from a variety of secretory cells and nerve terminals requires ATP, the secretion of dopamine and acetylcholine from PC12 cells is not dependent on ATP (Biochemistry 21; 4795, 1982). One postulated role for ATP in secretion is as a substrate for protein kinase; certain proteins are known to be phosphorylated in secretory systems that have been stimulated to secrete. Perhaps the best characterized of these proteins are M_r 86,000 and M_r 80,000 proteins called proteins Ia and Ib, respectively, and found in nerve terminals of mammalian brain and peripheral nervous systems. We have studied protein phosphorylation in PC12. Stimulation of PC12 cells with 56 mM K^+ or 1 mM carbachol (conditions that evoke transmitter release from PC12) induces the detectable phosphorylation of only one protein, a M_r 60,000 protein that likely is tyrosine hydroxylase. PC12 cells contain proteins equivelent to mammalian brain proteins Ia and Ib; antibody raised against bovine brain proteins Ia and Ib cross reacts with PC12 M_r 86,000 and M_r 80,000 proteins as determined by immunoblotting. Like mammalian brain, PC12 cells contain more protein Ib than Ia. However, unlike the situation in mammalian brain, the PC12 protein Ib did not exhibit detectable phosphorylation. Cells were grown for 21 h in medium containing $^{32}P_i$, and a cell lysate was immunoprecipitated with antiserum against bovine protein I and Pansorbin. The immunoprecipitate contained both proteins Ia and Ib, but only protein Ia was phosphorylated. An interesting possibility is that the lack of detectable phosphorylation of protein Ib is related to the fact that the release of dopamine and acetylcholine from PC12 cells is independent of ATP stores. It may be that some modification of protein Ib in PC12 not only prevents phosphorylation of the protein, but allows protein Ib to perform whatever function it might have in transmitter release, even in the absence of phosphorylation.

254.2 EXCITABILITY CHANGES IN DOPAMINE-CONTAINING TERMINALS IN THE STRIATUM INDUCED BY CORTICAL STIMULATION. L. Chavez* and M. Garcia-Munoz. Dept. Neurosciences, Research Center in Cellular Physiology, U.N.A.M., Mexico.

Since glutamate is the neurotransmitter contained in cortical afferents to the striatum, and it has been shown that it induces dopamine release, both in vivo and in vitro, we decided to study changes in excitability, by electrically stimulating the dopamine-containing terminals within the striatum. The amount of current necessary to produce an antidromic action pot ential was recorded. As a depolarizing agent, glutamate 200 ng/ 0.2 ul, was injected into the frontal cortex. After cortical excitation, a mean of 21 ± 2 % increase in threshold was observed. In the cases where it was possible to follow the cell for a long time, it was observed that the change initiated its return to basal levels at 25 min post-injection. It is tempting to postulate that the dopamine release observed after glutamic acid, in other experiments, is accompanied by a decrease in terminal excitability.

254.3 **DUAL EFFECT OF LEAD ON TRANSMITTER RELEASE AT THE FROG NEUROMUSCULAR JUNCTION.** L. Kolton*, M.E. Selzer, and Y. Yaari* (SPON: M.S. Kreider). Department of Physiology, Hebrew University-Hadassah Medical School, P.O. Box 1172, Jerusalem, Israel 91010 and the Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104

Lead causes a decrease in EPP at low quantal content without affecting the quantal voltage, suggesting a presynaptic effect of lead (Manalis and Cooper, Nature 243:354, 1973). Using intracellular recordings, we have noticed that the reduction in endplate potential (EPP) at low lead concentrations was time dependent and that the depression was followed by an increase in EPP amplitude. We have examined this dual effect in more detail by sampling the endplate currents (EPC) of multiple endplates simultaneously with a surface-electrode at normal calcium concentrations (1.8 mM), and curare to eliminate muscle contractions. Curves of extracellular EPP amplitude versus log (Pb) were linear from 0.25-2 uM, but deviated from linearity in some experiments at 3-5 uM. This deviation was found to be due to the above mentioned time and concentration dependent increase in transmitter release.

When lead was removed by a specific lead chelator (2,3-mesodimercaptosuccinic acid) following an observed non-linear behavior, the EPP was increased above control. Moreover, the EPP showed superimposed population spikes, indicating that some muscle fibers had reached action potential threshold.

We conclude that lead has a dual effect on presynaptic transmitter release: an initial rapidly reversed reduction, and a delayed and longer lasting increase in transmitter release. Since these two effects can occur simultaneously, they probably occur at different presynaptic sites.

254.4 FURTHER EVIDENCE FOR SEPARATE REGULATION OF MOTOR NERVE TERMINAL SIZE AND QUANTAL TRANSMITTER RELEASE AT MAMMALIAN NEUROMUSCULAR JUNCTIONS. D.S. Zahm* and Yong I. Kim. Department of Neurology and Clinical Neuroscience Research Center, University of Virginia School of Medicine, Charlottesville, VA 22908.

Numerous anatomical and physiological investigations have demonstrated a positive correlation between the diameter of a muscle fiber (MFD) and the quantum content (m) of the evoked transmitter release at low stimulation frequencies. Motor nerve terminal (MNT) size, expressed as the summed lengths of the branches of the terminal arborization, has also been thought to reflect m and therefore to be positively related to MFD. Grinnell and Herrera (J. Physiol. 307:301-317, 1980), however, demonstrated that two frog muscles with equal MNT sizes differed significantly in their respective m values, indicating that transmitter release/unit length of MNT is not necessarily uniform across different frog muscles. Differences in the ultrastructure and sprouting capacity of mammalian MNTs in muscles with different firing patterns or contraction properties have also been shown, but as yet MNT structure in mammals has not been investigated with respect to m.

We investigated MNT size, MFD, and m in several rat muscles. MNT sizes were measured on light micrographs (1000X) of zinc iodide- osmium tetroxide (ZIO) impregnated MNTs using the Zeiss Videoplan Image Analysis (ZVIA) measuring program. Diameters were estimated from micrographs of unsectioned, ZIO impregnated material and calculated as a function of the area of transversely sectioned, aldehyde-fixed, plastic embedded muscles using ZVIA. Quantum content was estimated by either the direct method using buffer containing 10 mM Mg^{++} or by the indirect method in curarized muscle. Conventional intracellular recording methods and a microcomputer system programmed for on-line aquisition and analysis of the junctional biopotentials and m were used.

MFDs from the flexor digitorum longus (FDL), soleus (SOL), sternocostalis, and focally innervated fibers of the superior oblique extraocular muscle (EOM) formed an ascending continuum with a range of about 10 to 75 μm. Quantum content measured both ways formed parallel ascending series of values. Mean MNT size for each muscle, however, appeared to be unrelated to any trend in m or MFD values. There was no significant difference in the mean size of EOM and FDL MNTs although m in FDL exceeded that in EOM by a factor of 2-2.5. SOL MNTs were the largest and most elaborate, but SOL m values did not exceed those of FDL. Within muscles, however, estimated MFD and MNT sizes were poorly but positively correlated. Several presynaptic factors, i.e., stimulation pattern and rate, transmitter storage and mobilization requirements, motor neuron size, or motor unit size may contribute to the regulation of MNT size. MFD and m alternatively may be co-regulated, possibly by predominantly postsynaptic factors.

254.5 PRESYNAPTIC CURRENTS IN NEWLY FORMED NEUROMUSCULAR JUNCTIONS IN THE MOUSE. D. Angaut-Petit* and A. Mallart. Lab. Neurobiologie Cellulaire, C.N.R.S., 91190 - Gif s/yvette, France,

Uneven ionic channel distribution has been shown to exist along branches of adult mouse motor endings : Na channels are exclusively located close to the myelin while K channels are located only at the remainder part of the terminal. Thus, presynaptic currents recorded at the proximal parts show two negative components which correspond respectively to inward active Na current and inward capacity current caused by ionic outward K current at the remainder of the terminal. Distal signals consist in two positive deflections which are mirror images of those from proximal parts (Brigant and Mallart, J. Physiol., 333 : 619, 1982). We performed an in vitro electrophysiological study of channel distribution on regenerating motor endings in triangularis sterni muscle 13-14 days after nerve crush. To this purpose presynaptic membrane currents elicited by nerve stimulation were recorded by focal electrodes positioned under precise visual control (X 500).Signals recorded in our experimental conditions differed from those of adult endplates by two features. First, initial negative and distal positive late waveform components which signal K current were missing in many endplates. Absence of K dependent waveform components does not necessarily indicate absence of K current but, rather an even K current density in both proximal and distal parts. This hypothesis was tested by TEA+3,4 DAP ionophoresis close to recording electrode which revealed inward capacity current promoted by K outflux at adjacent regions of the terminal. Second, the sharp negative deflexion which has been shown to correspond to active inward Na current by its sensitivity to ionophoretic TTX application, could be recorded from a considerably enlarged length of the terminals.

In conclusion, regenerating motor endings do not show the sharp Na-K channel separation typical of mature endings but rather channel overlap as described in regenerating myelinated axons (Ritchie, Proc. R. Soc. Lond. B, 215 : 273, 1982 ; Kocsis et al., Proc. R. Soc. Lond. B, 217 : 77, 1982). Supported by the INSERM grant n° 816003.

254.6 INTRACELLULAR RECORDING OF ACTION POTENTIALS FROM VERTEBRATE NERVE TERMINALS USING POTENTIOMETRIC OPTICAL PROBES. A.L. Obaid*, B.M. Salzberg, H. Gainer, and D.M. Senseman*. Department of Physiology and Pharmacology, School of Dental Med. and Institute of Neurological Sciences, University of Pennsylvania Philadelphia, PA. 19104 and Lab. of Neurochemistry and Neuroimmunology, National Institutes of Health, Bethesda, MD. 20205.

Progress in achieving a better understanding of the physiology of synaptic transmission in vertebrates has been slowed by our inability to measure rapid changes in the membrane potential of nerve terminals. The giant synapse of the squid has provided a successful invertebrate model for the study of the release of transmitter substances because both the postsynaptic and the presynaptic membranes are accessible for electrophysiological study and intervention, including voltage clamp. Much of our knowledge of vertebrate synaptic physiology derives from the study of the frog neuromuscular junction but here "the small size of the nerve terminal prevents a direct measurement of the presynaptic potential change" (Katz, 1969). Optical methods that employ potential sensitive molecular probes are shown here to monitor rapid changes in membrane potential from a population of nerve terminals in the posterior pituitary (neurohypophysis) of amphibia, and the effects on the shape of the nerve terminal spike of extracellular calcium and other agents known to affect transmitter release may be studied. Calcium antagonists such as cadmium and nickel are shown to block a component of the action potential that probably reflects a calcium mediated potassium conductance and Tetrodotoxin blocks an inward sodium current, revealing a small calcium component to the action potential upstroke. The ability to record membrane potential changes from secretory terminals should be a significant aid in the study of excitation-secretion coupling in vertebrates.

254.7 CHANGES IN THE DURATION OF SYNAPTIC CURRENT DURING DEPRESSION, FREQUENCY FACILITATION AND PTP AT SYNAPSES RC1-R15 OF APLYSIA CALIFORNICA. G. Grenon* and J.P. Tremblay. Dept. Anatomy, Laval Univ., Québec, Canada, G1K 7P4.

Cell R15 of Aplysia californica was voltage clamped at -100mV. Synapse RC1-R15, located between a fiber of the right connective and cell R15, was stimulated repetitively 100 times at 1.5 Hz and 40 times at 0.033Hz. This stimulation produces a characteristic sequence of changes in the amplitude of the synaptic current of successive responses due to synaptic depression, frequency facilitation and posttetanic potentiation (PTP). During the stimulation at 1.5Hz the latency of the synaptic current increases significantly but returns rapidly to its initial value when the rate of stimulation is reduced to 0.033Hz. This increased latency may be due to a reduced speed of propagation of the presynaptic action potential. The duration of the growth phase (beginning of synaptic current to its maximum) and of the decay phase (maximum synaptic current (MSC) to 50% of it) were also measured. There is a significant correlation between the depression ratio (i.e. MSC of 2nd response at 1.5HZ, over that of the 1st response) and the ratio of the growth phase duration of these responses for 40 trains of stimulations obtained in 11 preparations. However there is no significant correlation between the depression ratio and the ratio of the decay phase duration. The growth phase and the decay phase were significantly increased during facilitation and PTP by 1.0 to 3.0ms. A significant coefficient of correlation was also obtained between the facilitation ratio (i.e. MSC of the hundredth response at 1.5Hz over that of the 1st response at 1.5Hz) and the ratio of the growth phase duration of these responses. The facilitation ratio was also significantly correlated with the ratio of the decay phase duration. Similarly the PTP ratio (i.e. MSC during the 1st response after the train at 1.5Hz over that of the 1st response at 1.5Hz) was also significantly correlated with the ratio of the growth phase duration and with the ratio of the decay phase duration of these responses. These results indicate that the increased duration of the growth phase and of the decay phase of the synaptic current contribute to the facilitation and the PTP phenomena.

The increased duration of the growth phase and of the decay phase observed in these experiments is probably due to an increased duration of the neurotransmitter release. This may be due to a widening of the presynaptic spike such that each presynaptic bouton liberates the neurotransmitter during a longer period. These increased durations may also be due to an invasion of more branches of the terminal arborization such that although the release period is the same in each bouton, the total duration of the release period is increased due to the non synchronous invasion of all the participating boutons.

254.8 MINIMAL OR NO POSTSYNAPTIC CONDUCTANCE CHANGES IN MOTONEURONS DURING PRESYNAPTIC INHIBITION IN CHLORALOSE ANESTHETIZED CATS, D.A. McCrea*, P.L. Carlen. Playfair Neuroscience Unit, Toronto Western Hospital, and Addiction Research Foundation Clinical Institute, Depts. of Physiology and Medicine, University of Toronto, Ontario, Canada.

Eide et al, (Structure and Function of Inhibitory Neuronal Mechanisms, Pergamon Press, pp. 215-219, 1968) reported that conditioning stimuli which were effective in reducing the amplitude of the monosynaptic IaEPSP produced by stimulation of low threshold muscle afferents, did not produce a change in the membrane conductance of the motoneuron (MN) and thus provided evidence that the inhibition of the IaEPSP was presynaptic (PSI). Using the more sensitive techniques of signal averaging and the measurement of focal conductance changes by estimating the changes in membrane time constants with short current pulses, Carlen et al. (J. Physiol. 298: 539, 1980) were able to detect changes in MN conductance as well as small long-lasting IPSPs during presynaptic inhibition. These authors sugested that these changes were not insignificant and could be responsible for the small reduction in the amplitude of the IaEPSP produced by the PSI seen using barbiturate-anesthetized cats.

We have re-examined this question of postsynaptic phenomena accompanying and perhaps being responsible for PSI in cats anesthetized with alpha-chloralose. In this preparation we have seen as much as a 60% reduction in the size of the IaEPSP in medial and lateral gastrocnemious and hamstring MNs produced by preceding the test IaEPSP with a train of 5 stimuli (300 hz) to the nerve from the hamstring muscles at a condition-test interval of 50 to 70 ms. We have used both short (50-80 nA, .2ms) and long (2 nA, 30ms) hyperpolarizing pulses to measure the conductance changes produced by the conditioning stimuli and have found very minor or no conductance increase at a condition-test interval that produced a large reduction in the IaEPSP amplitude. In addition, we have examples in which there is no detectable IPSP (i.e. < .2mV) with a large reduction in the size of the IaEPSP. We conclude that in chloralose-anesthetized cats, while there may be small postsynaptic events occuring during PSI, they are of insufficient magnitude to account for such large reductions in the IaEPSP amplitude, as compared to barbiturate-anesthetized cats. In this case, the most likely location for the phenomenon causing PSI is indeed presynaptic. (Supported by MRC 6019).

254.9 STUDIES OF MINIATURE ENDPLATE CURRENTS SHOW THAT THE QUANTUM OF RELEASE IS COMPOSED OF SUBUNITS. C. Erxleben*, G. Carlson*, and M.E. Kriebel* (Spon: R. King) Dept. of Physiol., Upstate Medical Center, SUNY, Syracuse, NY 13210.

Miniature endplate potential (MEPP) amplitude histograms show integral peaks that are multiples of the first peak (s-MEPP class) and these peaks remain stationary over time (Kriebel, et al., 1976, J. Physiol. 262:553). Unitary evoked endplate potential (EPP) histograms match those of MEPPs showing that unitary EPPs and MEPPs have the same subunit (Kriebel, et al., 1982, 322:211). However, Magleby and Miller (1981, J. Physiol. 311:267) were not able to find stationary and integral peaks of miniature end plate potential amplitude distributions. We voltage clamped (-140 mV) mouse diaphragm junction with 2 electrodes. Flectrode (5 megohm, 8 M CsCl) sealing and low holding currents were achieved with a 25 mM Ca^{++} saline at 20°C or 30°C. With these conditions MEPc frequencies (20/sec) were appropriate to collect 8000 MEPcs from a single junction. The mean MEPc (3.5 nA) to noise (35 pA rms) ratio was 1%. Signals were stored on magnetic tape and MEPc amplitude, time-to-peak, rise time, net charge, falling phase and baseline noise were determined for each MEPc with a computer program. The falling phases of s-MEPcs and bell-MEPcs were single exponential curves. MEPc amplitude histograms showed integral peaks and peak stationarity. We found that a bin size 1/50th that of the mode MEPc and 1.5 x base line noise produced smooth peaks separated by 5 or more bins when the sample size was large enough to yield 50 MEPcs in each bin. Thus, random variations due to small sample size neither obscured integral peaks nor produced spurious peaks; and, 1200 MEPcs were adequate to define the central 3 or 4 peaks. The peak intervals with identical conditions were constant within and between preparations although the number of peaks varied (range of modes 8 to 12, adult). The post-synaptic effects of either different temperatures or eserine were found to change peak intervals but not the number of peaks. Eserine increased the peaks of the MEPP amplitudes by about 80%. Decreasing the temperature from 30°C to 20°C decreased the MEPcs by 30%. The integral peaks of MEPc amplitude histograms demonstrate a physiological subunit of the quantum of transmitter release. Because of the small variance of each peak and large vesicle volume variance (see Hanna and Kriebel, this volume), it appears improbable that the subunit represents the release of free ACh from a vesicle. The small variance of each peak, which is the result of pre- and post-synaptic variance, could be explainable with macromolecules that bind a constant number of ACh molecules so that the subunits correspond to the number of macromolecules involved in the release process.

254.10 DEPRESSION AND RECOVERY OF NEUROMUSCULAR TRANSMISSION DURING PROLONGED TETANIC STIMULATION. Toshio Narahashi and Mladen I. Glavinovic. Dept. of Pharmacol., Northwestern Univ. Med. Sch., Chicago, IL 60611, and Depts. of Anaesthesia and Physiol., McGill Univ., Montréal, Québec, H3G 1Y6, Canada.

It has generally been believed that synaptic depression as a result of prolonged presynaptic tetanic stimulation at high levels of transmitter release is due to insufficient replenishment of the store of transmitter immediately available for release (n). This was supported by statistical analysis, which showed that depression was associated with decrease in n and not in p (probability of release) which remained largely unchanged. One can directly estimate the changes in the depletion and replenishment of the immediately available store from the changes in the synaptic output.

End-plate potentials (EPPs) were recorded from the unparalyzed "cut" rat phrenic-diaphragm preparation. Short tetanic stimulation (50 Hz, 500 msec) were applied to the nerve at a frequency of 1 Hz. During the initial tetanic stimulation the amplitude of EPPs first increased and then decreased reaching an apparent steady-state level. Recovery of EPPs occurred during the following 500 msec rest period as indicated by the amplitude of the first EPP in the subsequent, second train of tetanic stimulations. During the second train, the EPP amplitude again decreased reaching a new apparent plateau level. This pattern of change in EPP amplitude remained throughout a series of tetanic stimulations. The amplitudes of both the first and the last (25th) EPPs during a series of short tetanic stimulations decreased as the stimulation proceeded. Surprisingly, the amplitude of the last EPPs decreased faster than that of the first. During a series of tetanic stimulations, there was an increase in the relative depression which is defined by the ratio of the difference between the first and last EPPs in a train to the first EPP. An increase was also observed for the relative recovery which is defined by the ratio of the difference between the first EPP in a train and the last EPP in a preceding train to the first EPP of the preceding train. A model suggested before by Glavinovic (J. Physiol. 290, 481, 1979) can be used to explain the observed phenomena. According to this model, two processes occur simultaneously during the tetanic stimulation. In addition to the depletion of the immediately available store as well as the store behind it, there is an increase in the capacity of the immediately available store to contain transmitter (presumably caused by entry of some substance such as calcium). As a result, the immediately available store is rapidly replenished during recovery, although the store behind it is still largely depleted. Supported by MRC and MDA of Canada to MIG and by NIH, NS14145, to TN.

254.11 SYNAPSIN I (PROTEIN I) BINDS SPECIFICALLY AND WITH HIGH AFFINITY TO HIGHLY PURIFIED SYNAPTIC VESICLES FROM RAT BRAIN.
W. Schiebler*, J. Rothlein, R. Jahn*, J. P. Doucet* and P. Greengard (SPON: C. Romano). Dept. Pharmacology, Yale Univ. Sch. Med., New Haven, CT 06510.

Synapsin I (Protein I) is a neuron-specific phosphoprotein present in most, and possibly in all, synaptic nerve endings, where it appears to be associated primarily with synaptic vesicles (De Camilli et al., J. Cell. Biol., 96, 1337 & 1355, 1983). It is a prominent substrate for cAMP-dependent and Ca^{2+}/calmodulin-dependent protein kinases (Huttner, DeGennaro and Greengard, J. Biol. Chem., 256, 1482, 1981). We have now investigated the interaction between homogeneous Synapsin I and purified synaptic vesicles in vitro.

Synapsin I was purified to homogeneity from rat brain synaptosomes by a novel procedure, including a salt-detergent extraction with 150 mM NaCl/1% CHAPS and purification through CM-cellulose- and hydroxylapatite-columns (Doucet, Schiebler and Greengard, manuscript in preparation). Synaptic vesicles were purified from rat brain synaptosomes using techniques of sucrose density gradient centrifugation and of chromatography on controlled pore glass beads (Huttner, Schiebler, Greengard and De Camilli, J. Cell Biol., 96, 1374, 1983). Binding experiments were performed by ultracentrifugation and/or centrifugation/gel filtration through Sephacryl S-300 columns. The amount of bound Synapsin I was determined by immunological methods.

For these binding studies, synaptic vesicles were depleted of endogenous Synapsin I by diluting and washing with 200 mM NaCl or 200 mM KCl. Binding of Synapsin I to Synapsin I-depleted synaptic vesicles demonstrated time-dependent, saturable binding, which was not seen in experiments using Synapsin I-containing vesicles or control membranes such as membranes derived from human red blood cells and rat brain nerve endings. Binding was found to be dependent on ionic strength. In 40 mM salt, the K_d for binding was 3 (±2) nM (measured by centrifugation/gel filtration and/or ultracentrifugation). At physiological ionic strength (equivalent to 150 mM NaCl), the K_d increased approximately threefold (measured by ultracentrifugation). The amount of Synapsin I bound to synaptic vesicles at saturating concentrations was comparable to the amount of endogenous Synapsin I found in non-depleted vesicles. We are currently investigating the regulation of the binding of Synapsin I to synaptic vesicles. These studies include examining the effect, on binding, of phosphorylation of Synapsin I at distinct sites by cAMP-dependent and Ca^{2+}/calmodulin-dependent protein kinases.

254.12 A PRESYNAPTICALLY TARGETED NEUROTOXIN THAT BLOCKS VARIOUS CHEMICAL SYNAPSES IN FROG.
Doju Yoshikami, Lynne M. Kerr and Keith S. Elmslie* (SPON: M. McPheeters). Dept. of Biology, University of Utah, Salt Lake City, Utah 84112.

We reported at these meetings last year that a small, basic neurotoxic peptide from the marine snail, Conus geographus, irreversibly inhibits synaptic transmission in skeletal muscles of frog by blocking transmitter release. This peptide, called ωCgTX, also irreversibly blocks the Ca^{++} component of the action potential in dorsal root ganglion (DRG) neurons from embryonic chick. We report here that ωCgTX irreversibly blocks synaptic transmission in the sympathetic ganglion and spinal cord of frog.

Sympathetic ganglion: Extracellular recordings from isolated preparations reveal that within minutes of the application of μM concentrations of ωCgTX, ganglionic transmission is totally and irreversibly blocked. Intracellular recording from principal neurons within the ganglion show that upon ωCgTX treatment, antidromic responses remain unaltered at a time when orthodromic responses are totally eliminated. This shows that ωCgTX blocks synaptic transmission without affecting the propagation of action potentials in the ganglion. Furthermore, during the course of toxin action when the block is incomplete, the quantal content of transmitter release is reduced. Thus, ωCgTX produces a state resembling that normally achieved by lowering $[Ca^{++}]_o$. In this regard, ωCgTX blocks ganglionic and neuromuscular synapses similarly, and it does so apparently by preventing Ca^{++} entry into the nerve terminal during the presynaptic action potential.

Spinal cord: Extracellular potentials from the ventral root of an isolated, hemisected lumbar spinal cord were monitored. The response produced by stimulation of the dorsal root consists of multiple components and reflects contributions from presynaptic action potentials as well as synaptic potentials. Addition of ωCgTX to the bathing medium exclusively blocked all synaptic components. In this respect, the effect of ωCgTX is the same as that produced by exposing the preparation to low $[Ca^{++}]$-high $[Mg^{++}]$. Unlike low $[Ca^{++}]$-high $[Mg^{++}]$ however, the synaptic block produced by ωCgTX was not reversible. It is also notable that the response to bath-applied quisqualate, an excitatory amino acid agonist, was not affected by ωCgTX treatment. This result is consistent with the hypothesis that ωCgTX does not act post-synaptically at CNS synapses, but rather its site of action is presynaptic -- just as it is for peripheral synapses.

We thank Dr. B. M. Olivera & W. R. Gray of our Department for supplying us with pure ωCgTX. This research was supported by PHS grants NS15543, NS00465 and an MDA Postdoctoral Fellowship to L. M. K.

254.13 SKATE ELECTRIC ORGANS GENERATE TWO CLASSES OF SPONTANEOUS MINIATURE ELECTROCYTE JUNCTION POTENTIALS.
C.E. Gross* and M.E. Kriebel* (Spon: J.B. Preston) Dept. Neurosurg. Un. Col., Denver, CO 80220 and Dept. Physiol., Upstate Medical Center, SUNY, Syracuse, NY 13210.

The frog neuromuscular junction generates two classes of miniature endplate potentials (MEPPs) and the ratio of small MEPPs (s-MEPPs) to bell-MEPPs (classical) can be changed with periods of elevated temperature, calcium or nerve stimulation (Kriebel and Gross, 1974, J. Gen. Physiol. 64:85, Kriebel, 1978, Brain Res. 148:381). Electric organs have been extensively used in acetylcholine and isolated synaptic vesicle studies; and, although spontaneous potentials have been reported they have not been studied in detail. Since electrocytes are embryologically like muscle and are richly innervated we report the amplitude distribution of spontaneous miniature electrocyte junction potentials (MEJPs). A two mm thick section of skate tail (R. binoculata) was pinned to a small bath containing elasmobranch saline (room temp). Microelectrodes (3 M KCl) were lowered perpendicularly to the surface of the electric organ and signals were recorded on magnetic tape and a chart recorder or from an oscilloscope with film. Because of the low electrocyte input resistance, MEJPs recorded from the interior were very small and usually skewed to the noise. However, with 50 K ohm microelectrodes (20 μV peak-to-peak noise) we found that MEJP amplitude histograms had a peak at 60 μV and showed a slight right-hand skew with MEJPs up to 1 mV. When recording microelectrodes were advanced against the innervated membrane from either outside or from inside the cell, we recorded identical focal potentials (only polarity reversed) with means of 3 to 5 mV. Most of these were generated at the electrode tip and their frequencies were increased with electrode pressure. Focally recorded MEJPs generated at the electrode tip are readily distinguishable from those generated at remote junctions which have slow time characteristics. At 10°C, mainly focal MEJPs with fast time characteristics were recorded. MEJP amplitude histograms of focally recorded MEJPs with fast rise times show two bell-shaped peaks. The small mode MEJP peak was about 1/20th the amplitude of the larger class of MEJPs (bell-MEJPs). These small mode MEJPs (s-MEJPs) were lost in the noise when the electrode tip was internal. The ratio of s-MEJPs to bell-MEJPs was variable since the bell-MEJP frequency was more dependent on the electrode pressure. Graphs of time-to-peak vs. amplitude show that both classes of MEJPs fall on the same line. We suggest that the s-MEJPs recorded from the electrocytes are similar to the s-MEPPs recorded from frog and mouse neuromuscular junctions.

254.14 Na-DEPENDENT NOREPINEPHRINE RELEASE FOLLOWS INHIBITION OF THE Na,K-ATPase IN SYMPATHETIC NEURONS.
Kathleen J. Sweadner. Neurosurgical Research, Mass. General Hospital, Boston MA 02114.

Ouabain, a specific inhibitor of the Na,K-ATPase, has been previously found to elicit release of transmitter by a Ca^{+2}-independent mechanism in a variety of systems. There are two different Na,K-ATPases in the nervous system which differ in their affinities for ouabain (Sweadner, 1979. J. Biol. Chem. 254:6060). Many, if not all, neurons of the CNS express a high affinity form, but sympathetic neurons express the same low affinity form that is found in the heart. Ouabain is best known for its ability to cause inotropy (increased contractility) in the heart. Other investigators have shown that the inotropic effect of ouabain occurs at concentrations well below those required to inhibit the Na,K-ATPase 50% in vitro; thus the increase in contractility precedes symptoms of toxicity. The mechanism may involve the indirect regulation of intracellular Ca^{+2} levels through an alteration of intracellular Na^+ levels. In search of an analogous effect on transmitter release, the ionic basis of the vesicular release of norepinephrine (NE) was studied in primary cultures of sympathetic neurons.

First, the Ca^{+2} and Na^+ dependence of classical stimulants was tested. When NE release was elicited by 54mM K^+ it was dependent on extracellular Ca^{+2}, and was not blocked by TTX or by reducing extracellular Na^+ to 14 mM (substituting choline). When NE release was elicited with the Ca^{+2} ionophore A23187 it was not dependent on extracellular Ca^{+2}, presumably because it penetrates the cell and releases Ca^{+2} from intracellular stores. Release elicited by A23187 was enhanced in 14mM Na^+, presumably because 14mM Na^+ reduces efflux of Ca^{+2} by Na:Ca exchange. Release was also elicited by veratridine and blocked by TTX, and this was independent of extracellular Ca^{+2}.

The Na,K-ATPase was inhibited by ouabain or by removing extracellular K^+ (substituting Na^+). In both cases, NE release was independent of Ca^{+2}. TTX, however, was able to delay release by hours, and 14mM Na^+ blocked the release entirely. The implication is that the effect of inhibition of the Na,K-ATPase on release is secondary to the entry of Na^+.

The concentration of ouabain and of extracellular K^+ required to elicit NE release was compared to the concentrations required to inhibit Na,K-ATPase activity. Little or no release was seen below a threshold of 70-80% inhibition. Release was followed by a marked morphological deterioration of axonal processes as well, indicating that it is part of a pathological process unlike inotropy. (Supported by NS 18233; Established Investigator of the American Heart Association)

254.15 THERMODYNAMIC ANALYSIS OF THE BINDING OF A CALCIUM ANTAGONIST TO SYNAPTOSOMAL MEMBRANES. G. A. Weiland and R. E. Oswald. Department of Pharmacology, Cornell University, Ithaca, NY 14853.

Radiolabeled calcium antagonists such as [^{3}H]nitrendipine have been utilized to identify putative calcium channels in membranes from a number of tissues. The binding of radiolabeled 1,4-dihydropyridines has yielded information regarding the interaction of calcium antagonists with their binding sites, including the dependence of binding on divalent cations. To study the mechanism of the binding reaction, the temperature dependence of the binding of [^{3}H]nitrendipine to brain membranes was examined and the thermodynamic properties characterized.

Synaptosomal membranes were prepared from rat brain using the Ficoll gradient flotation method. [^{3}H]Nitrendipine binding was determined in the presence of 1 mM calcium, using a rapid filtration assay. The radioligand bound specifically with high affinity (K_D = 0.61 nM) to a single class of sites on the membranes (B_{max} = 550 fmol/mg protein) and was displaced by nanomolar concentrations of unlabeled nitrendipine. Kinetic analysis of the association and dissociation rates was consistent with a simple bimolecular reaction (k_{-1}/k_1 = 0.88 nM).

The temperature dependence of the equilibrium constant and the association and dissociation rates for [^{3}H]nitrendipine binding were examined between 0°C and 25°C. Significant loss of binding was observed at 37°C, probably reflecting binding site lability at elevated temperatures. The binding was almost independent of temperature over this range, the equilibrium and kinetic constants increased only 2- to 3-fold with the increase in temperature. Thermodynamic analysis of binding at equilibrium demonstrated approximately equal changes in enthalpy and entropy ($\Delta H°$ = -5.0 kcal/mole, $\Delta S°$ = +24 e.u., $-T\Delta S°$ = -7.05 kcal/mole). Thus there is probably a significant contribution of hydrophobic bonding to the reaction, as has been observed for many binding reactions. The activation energies were 6.1 kcal/mole (ΔH^+ = 5.4 kcal/mole, ΔS^+ = -13 e.u.) for association and 10.6 kcal/mole (ΔH^+ = 10.0 kcal/mole, ΔS^+ = -39 e.u.) for dissociation. Thus the enthalpic and entropic contributions to the transition state barrier are approximately equal. These results will be discussed in terms of the molecular mechanism of nitrendipine binding to the putative calcium channel and of the effects of divalent cations on the calcium antagonist binding site.

254.16 **TEMPORAL CHARACTERISTICS OF POTASSIUM-STIMULATED ACETYLCHOLINE RELEASE AND INACTIVATION OF CALCIUM INFLUX IN RAT BRAIN SYNAPTOSOMES.** M.E. O'Leary* and J.B. Suszkiw. Dept. of Physiology, Univ. of Cincinnati, Coll. of Medicine, Cincinnati, OH 45267.

The time-course of Ca^{2+}-dependent [^{3}H] ACh release and inactivation of ^{45}Ca entry were examined in rat brain synaptosomes depolarized by 45mM $[K^+]_o$. Under the conditions where the intrasynaptosomal stores of releasable [^{3}H]ACh were neither exhausted nor replenished in the course of stimulation, the K^+-evoked release consisted of a major (40% of the releasable [^{3}H]ACh pool), rapidly terminating phase ($t_{\frac{1}{2}}$=17.8 sec), and subsequent, slow efflux which could be detected only during a prolonged, maintained depolarization. The time-course of inactivation of K^+-stimulated ^{45}Ca entry suggests the presence of fast-inactivating ($t_{\frac{1}{2}}$<5s), slow-inactivating ($t_{\frac{1}{2}}\sim$40 sec) and a noninactivating, or very slowly inactivating ($t_{\frac{1}{2}}$>300sec), components.

The present data do not permit unequivocal determination which component of Ca^{2+} -entry in synaptosomes is instrumental in the phasic release of [^{3}H] ACh. Nevertheless, since inactivation of that Ca^{++}-entry pathway with which transmitter release is associated should precede inactivation of transmitter release, it is probable that only the "fast" inactivating pathway is involved in the fast phase of transmitter release. The noninactivating Ca^{++}-entry may account for the slow phase of transmitter release. These results indicate that under conditions of maintained depolarization of synaptosomes by high $[K^+]_o$ the time-course and the amount of transmitter released may be a function of the kinetics of inactivation of the voltage-dependent Ca-channels. (Supported by NIH grant NS17442)

254.17 LOCALIZATION OF CALCIUM ENTRY IN THE AXONAL TERMINALS OF MEDIAL PHOTORECEPTORS OF THE GIANT BARNACLE DETECTED WITH ARSENAZO III. N. Stockbridge* and W.N. Ross. Department of Physiology, New York Medical College, Valhalla, NY 10595.

Previous studies have shown that there is a calcium current in the terminal region of the decrementally conducting medial photoreceptor axons of the giant barnacle, Balanus nubilus. But these studies had poor spatial resolution (Ross and Stuart (1978) J. Physiol. 274: 173-191; Edgington and Stuart (1979) J. Physiol. 294: 433-445). We have used the calcium indicator dye Arsenazo III to examine the spatial distribution of calcium influx in the photoreceptor. A study of calcium influx and removal may aid understanding of how transmitter release at this tonically active synapse differs from the phasic release seen, e.g. at the squid giant synapse.

The ocellus containing the medial photoreceptors and the supraesophageal ganglion to which they project were mounted in a chamber on the stage of a Zeiss compound microscope. Arsenazo III (75 mM) was iontophoresed into the 20 um diameter region of a photoreceptor axon and allowed to diffuse several hundred microns to much finer presynaptic terminals in each hemiganglion. The preparation was imaged upon a 100 element photodiode grid permitting spectrophotometric measurements with 25 um resolution. Later filling of the cell with Lucifer Yellow permitted close correlation of the anatomy with the spectrophotometry.

In response to a depolarization produced by brief light flashes or electrically via the microelectrode, an absorbance increase in each terminal was observed at 660 nm, a smaller absorbance decrease was observed at 532 nm, and no signals were apparent at either 577 or 750 nm, all of which is consistent with an increase in ionized calcium interacting with the dye. Absorbance changes were detectable even when the dye concentration in the terminals was too low to see. These changes were larger when calcium action potentials were induced by bathing the preparation in saline containing 50 mM TEA and could easily be observed without averaging.

Detectable absorbance changes were confined to the region of the terminal arborization, typically to within the final 100 um. Even within that distance, most of the signal was confined to the last 50 um. Within 50 um of this focus, the signals fell at least 25-fold. This was true even though any concentration gradient in Arsenazo III should have been in the opposite direction.

254.18 INTRACELLULAR RECORDINGS FROM SYNAPTIC TERMINALS DURING FACILITATION OF TRANSMITTER RELEASE. George D. Bittner and Douglas A. Baxter. Department of Zoology, University of Texas at Austin, Austin, TX 78712.

Crustacean neuromuscular junctions exhibit an impressive range of use-dependent changes in synaptic efficacy. During a brief, high-frequency train of action potentials (APs), the amplitude of the excitatory junctional potentials (EJPs) can increase as much as 600-fold. This phenomenon, called short-term facilitation (STF), decays with time course of about 700 msec. STF can be shown to result from a presynaptic increase in the mean quantal content. However, little is known about possible electrophysiological changes in the nerve terminals that may accompany these phenomena. We have therefore made intracellular presynaptic recordings from the terminals of the opener-excitor motor neuron of crayfish during and after tetanic stimulation of the axon.

Crayfish (P. simulans) opener muscle fibers are innervated by a single excitor axon. By removing the closer muscle it is possible to expose the synaptic terminals of the opener-excitor as it branches over the ventral surface of the opener muscle. Primary, secondary, or tertiary nerve branches can be suspended above the muscle surface and penetrated with 30-60 MΩ, 3 M KCl microelectrodes. These recording sites are within 100-300 µm of nerve-muscle contacts and are electrotonically close (about 0.5λ) to presynaptic release sites.

APs at the terminal are 96 ± 4 mV (mean ± SD; N = 15), overshoot the -75 ± 7 mV rest potential, and are followed by a depolarizing afterpotential (DAP) of 10 ± 2 mV. The DAP has a duration of 30-50 msec and the AP afterpotential reverses polarity at about -65 mV. During stimulus trains of 10 impulses at 100 Hz, the peak voltage of the second and successive APs are between 2-10 mV larger than the first AP (mean = 5.7 ± 4 mV). In contrast, the total foot-to-peak amplitudes of the second through the tenth APs are reduced by an average of 6 mV. The duration of the APs increase by 18% (0.40 to 0.47 msec). Although the amplitude of the EJPs grow throughout the entire stimulus train, progressive increases in the peak voltages and the duration of APs never continue for more than 4 impulses. Hence it is unlikely that changes in AP amplitude are responsible for STF.

During prolonged stimulation (2-8 sec), the nerve terminals become hyperpolarized. This post-tetanic hyperpolarization decays with a time constant of 18 sec. Its amplitude (400 µV to 10 mV) is related to the frequency and duration of stimulation. This potential change may be responsible for a component of post-tetantic facilitation having a time constant of 10-40 seconds.

254.19 EFFECTS OF Pb^{2+} and Cd^{2+} ON TRANSMITTER RELEASE AND Ca^{2+} FLUXES IN NERVE TERMINALS. J.B. Suszkiw, G.P. Cooper and M. Murawsky*. Dept. of Physiol. and Environ. Health, Univ. of Cincinnati, Coll. of Med., Cincinnati, OH 45267.

These experiments examined the effects of Pb^{2+} and Cd^{2+} on: (a) transmitter release,in electrophysiological studies of the frog neuromuscular junction and (b) ^{45}Ca movements, in biochemical studies of rat brain synaptosomes. Pb^{2+} reduces (K_D, 1 µM) evoked transmitter release (endplate potential; EPP) and stimulates spontaneous quantal release (MEPP). Similar concentrations of Cd^{2+} block the EPP (K_D, 2.6 µM) but have no effect on MEPP frequency. The effects of Pb^{2+} and Cd^{2+} on the EPP are additive; however, Cd^{2+} actually reduces the Pb^{2+}-induced increase in MEPP frequency. Both Pb^{2+} (K_D, 2 µM) and Cd^{2+} (K_D, 3.7 µM) competitively block the K^+-depolarization-stimulated influx of ^{45}Ca in synaptosomes. In the subcellular fractions of nerve endings the following effects are observed: (a) Pb^{2+} and Cd^{2+} competitively inhibit the ATP-dependent accumulation of ^{45}Ca in cholinergic synaptic vesicles (K_D=50 µM, both metals); (b)in hypo-osmotically disrupted, NaN_3 poisoned synaptosomes, Cd^{2+} inhibits (K_D, 50 µM) the ATP-dependent uptake of ^{45}Ca but the principal effect of Pb^{2+} is the enhanced passive binding of ^{45}Ca. This effect is interpreted to result from the increased Ca-^{45}Ca exchange in subsynaptosomal Ca-sequestering structures (endoplasmic reticulum and/or mitochondria) and indicates a disruption of the Ca-permeability barrier in these subsynaptosomal structures by Pb^{2+}. However, this effect is prevented by Cd^{2+}. These results suggest that the differential effects of Pb^{2+} and Cd^{2+} on MEPP frequency can be explained by the Pb^{2+} (but not Cd^{2+})-induced leakiness of intracellular membranes to Ca^{2+}. The relatively high concentrations of the metal ions necessary to block ATP-dependent Ca-sequestration systems explain why Cd^{2+} is ineffective in increasing MEPP frequency. The block of Pb^{2+}-induced increase in MEPP frequency by Cd^{2+} may be explained by either its competition with Pb^{2+} at the external Ca-channel and/or by its negating effects on Pb^{2+}-induced Ca^{2+}-leakiness at the intracellular sites. Supported by NIH grants NS 17968 and ES 00159.

254.20 CALCULATION OF K-TRAPPING IN THE PSEUDOPODIAL INDENTATIONS FORMED BY ABUTTED NERVE TERMINALS. E.B. Lankford* and A.F. Boyne, Department of Pharmacology and Experimental Therapeutics, University of Maryland School of Medicine, Baltimore, MD 21201.

It has been established that blind-ended pseudopodial indentations (PSI) form between abutted afferent nerve terminal swellings synapsing onto smooth dendrites in the globus pallidus and substantia nigra (Boyne and Tarrant J. Neurosci. 2, 463, 1982). The cavity is a diffusion trap because ions or solutes released non-synaptically during electrical activity of the parent nerve (e.g. action potential release of K^+) must diffuse along the extracellular space around the shaft of the pseudopodium before they reach the outlet to the three-dimensionally branching corridors of the general extracellular space. The highest concentrations of non-synaptically released substances will therefore develop at PSI tips. It has been suggested that overgrown PSI could predispose the substantia nigra to an irreversible loss of its inhibitory tone (Boyne and Phillips, Fed. Proc. 41, 2188, 1982). Hippocampal mossy fiber nerve terminals bear PSI; a possible role in the development of long term potentiation at this site is therefore also evident. We have sought a method of normalizing the varied geometries of individual PSI by calculating the expected K accumulations when firing at given frequencies. With reconstructions of real PSI, the complex geometries and complex boundary conditions make a closed form solution impossible. However, a finite difference equation is tractable using numerical techniques and computerized iterations. Three dimensional modelling of serial sections has been used to determine the overall shape of PSI. The K trapping can now be calculated by taking the dimensions from, and performing the calculations with, a number of segments which is equal to the number of cross sections prepared.

The results show that K accumulations which are known to modulate neuronal electrophysiological processes when applied in bulk solution (up to 10 mM; Sykova, J. exp. Biol. 95, 93: 1981) are attained at the tips of PSI of previously observed lengths (3 microns) over a firing frequency range of 50 to 200 Hz. This encourages the view that PSI, which are known to be plastic, could modulate nerve terminal electrophysiology by generating variable K 'hot spots' deep within the boutonal swellings. The conversion of complex geometry information to an applied K accumulation value shows that slight stimulation-induced changes in PSI size/shape would have more substantive effects on K trapping.

254.21 PRESYNAPTIC MODULATION OF ADRENERGIC NEUROTRANSMISSION IN THE RABBIT IRIS-CILIARY BODY. J.E. Jumblatt and L. O'Connor*. Dept. of Biochemistry and Pharmacology, Tufts Univ. School of Medicine, Boston, MA 02111.

Intraocular pressure in mammalian eyes is regulated by autonomic control of aqueous humor formation and outflow. Although adrenergic drugs are used routinely to treat glaucoma, the cellular mechanisms which underlie their effects on aqueous humor dynamics are complex and somewhat paradoxical. For example, α_1-, α_2- and ß-adrenergic agonists, as well as α- and ß-antagonists, have been reported to lower intraocular pressure in various species. This complexity has been attributed to the multiplicity of postsynaptic adrenergic receptor subtypes thought to exist in ocular blood vessels, ciliary epithelium, smooth muscle and aqueous outflow channels. The possible contribution of presynaptic receptors at autonomic nerve terminals has received little attention. To investigate presynaptic regulatory mechanisms in the rabbit eye, we have studied the effects of endogenous and exogenous mediators on field-stimulated release of ^3H-norepinephrine (^3H-NE) in the isolated, superfused iris-ciliary body.

Iris-ciliary bodies dissected from male albino rabbits were preloaded with ^3H-NE, mounted between two platinum ring electrodes in a temperature-controlled plexiglass chamber, and superfused at 37 °C with buffer containing 1µM cocaine to inhibit neuronal catecholamine reuptake and 3µM indomethacin to inhibit prostaglandin synthesis. Ca^{++}-dependent release of ^3H-NE into the superfusate was evoked by 30 sec trains of pulses at 12 V/cm (10 Hz, 3 msec duration). Test drugs were introduced 5 min before stimulation, and their effects on stimulated (i.e., total minus basal) release were compared to an initial drug-free stimulation of each iris.

Results: (1) α_2-adrenergic agonists strongly depress ^3H-NE release. This inhibition could be overcome by the selective α_2-antagonist yohimbine, which alone facilitated release. Thus α_2-receptor mediated autoinhibition operates in this system. (2) The muscarinic cholinergic agonists acetylcholine (+ eserine) and pilocarpine also inhibited ^3H-NE release. The antagonists atropine and scopolamine alone enhanced release, suggesting that ACh released from parasympathetic neurons may modulate release of ^3H-NE at adrenergic terminals. Stimulation-evoked release of acetylcholine was confirmed by preloading the iris with ^3H-choline and analysis of the release products. (3) No presynaptic effects were seen with ß-agonists, serotonin, morphine, enkephalins, dopamine, histamine, or adenosine at appropriate concentrations. (4) Forskolin, a potent activator of adenylate cyclase, caused a marked enhancement of ^3H-NE release. We are currently exploring the possibility that presynaptic, inhibitory α_2 and muscarinic receptors in the iris-ciliary body may mediate the inhibition of adenylate cyclase. 255.1 THE BLOOD-BRAIN BARRIER: CORRELATION BETWEEN MORPHOMETRY AND PERMEABILITY. B.L. Coomber* and P.A. Stewart. Dept. of Anatomy, University of Toronto. Toronto, Ontario CANADA M5S 1A8.

This study examines the correlation between the morphometry of brain capillaries and the regional permeability of the blood-brain barrier (b-bb). Although several morphological differences have been described between barrier and non-barrier capillaries, little quantitative data are available. It is not known, for example, whether increased vesicular formation in permeable areas of the b-bb accounts for their higher permeability, or whether an inter-endothelial route is also necessary. Morphometric parameters of capillaries from gray and white matter of both cerebrum and cerebellum in the mouse were evaluated and compared with those in a permeable area of the brain (area postrema) and with those in muscle. The tissues were fixed by perfusion and examined in the electron microscope. Photographed capillary profiles were measured using computer-assisted planimetry. Non-specific transport across barrier capillaries is restricted by continuous bands of tight junctions and by a low level of vesicular transport as judged by the small number of pinocytotic vesicles observed. We found that vesicle density is uniformly low in gray and white matter endothelia but is 3 times higher in area postrema and 6 times higher in muscle endothelia. Gaps between endothelial cells were never observed in gray and white matter and were only rarely seen in area postrema and muscle. We suggest therefore that the increased permeability of area postrema and muscle vessles is due to increased vesicular transport. Elevated mitochondrial density in barrier vessels is thought to provide energy necessary for maintaining ionic gradients across the barrier. We found an elevated mitochondrial density in cerebral white matter, but not in cerebral gray matter or in cerebellum. Since the b-bb develops later in the cerebellum than in the cerebrum, in the four week old mice the mitochondrial density in the white matter may not have reached adult values. Essential nutrients are transported across the b-bb by membrane-bound transport mechanisms and by diffusion across the endothelial cytoplasm. We hypothesized that the thickness of the endothelial wall may be a rate-limiting factor in this transport, and, therefore, that the walls of barrier capillaries might be thinner than those of non-barrier capillaries. We found that the mean thickness of the endothelial wall is, in fact 50% smaller in cerebral and cerebellar capillaries than in area postrema or muscle capillaries. We suggest that this quantitative approach is useful for evaluating the regional variation in the b-bb both in the developing brain and in the adult brain under normal and pathological conditions.

255.2 IS THE BLOOD-BRAIN BARRIER OF INSECTS JUST A SINGLE SEAL OF TIGHT JUNCTIONS, AS IN VERTEBRATES? Stephen R. Shaw, Psychology Dept., Dalhousie University, Halifax, N.S., Canada, B3H 4J1.

Experiments on the insect nerve cord have established that the CNS there is protected by a potent blood-brain barrier (BBB). For many years, the mechanism hypothesized to account for this has been essentially that recognized for the vertebrate CNS: occlusion by a restricted superficial seal of tight junctions connecting up non-neural cells, and confined to the CNS-blood interface (review: Lane, N.J., Int. Rev. Cytol. 73, 243, 1981).

The plausibility of this hypothesis has been tested ultrastructurally on the eyes of Orthoptera and Diptera using extracellular tracers, including lanthanum. The optic lobe contains a barrier that is continuous with the BBB of the nerve cord; the exterior location of the eye facilitates introduction of tracers at different points relative to the putative barrier. Tracer introduced first into the blood penetrates only the outer covering of the CNS, in agreement with earlier work. However, the perineurial cells (supposed site of the BBB in insects) fail to stop the tracer, which comes to rest on the glial layer immediately beneath them. Tracer introduced "behind" the barrier into the eye diffuses freely throughout the retina, despite a recent claim to the contrary. In vivo observations with dyes give a diffusion time of ~15 min per mm for first detection. Tracers also diffuse radially back towards the barrier, but stop abruptly just below the eye's basal lamina, at some distance from the site of arrest when applied to the blood, as found earlier (Shaw, S.R., Cell Tiss. Res. 188, 35, 1978). These results show that the BBB is not a simple, single structure. To test whether it might be a double system made up of two single, separated barriers, tracer has been introduced between the two limits described above. It fails to penetrate detectably beyond a zone of superficial damage, indicating that the barrier property is distributed throughout the tissue.

Several mechanisms cooperate to constitute the barrier. The superficial part is formed by an extreme physical narrowing of the diffusional entry route, by a monolayer of elongate glial cells. Examination of one of the sites of tracer arrest reveals particle rows present on axon membranes along the dominant diffusion route. These are not tight junctions, though they could be some new type of occlusive apposition. True tight junctions are present deep inside the barrier, however, in agreement with a recent report. Finally, both septate junctions and adsorption by the intercellular matrix may form part of the barrier defences. The insect BBB is therefore not present at a single site, does not involve perineurial cells, and appears to be unlike the barrier covering the vertebrate CNS.

255.3 A MATHEMATICAL MODEL FOR PREDICTING BRAIN CONCENTRATIONS OF THE LARGE NEUTRAL AMINO ACIDS IN HYPERAMMONEMIC RATS. J.H. James*, L.L. Edwards* and J.E. Fischer* (SPON: Alix Mathieu). Dept. of Surgery, Univ. Cincinnati Med. Ctr., Cincinnati, Ohio 45267.

When rats are infused with ammonium salts or are made hyperammonemic by construction of a portacaval anastomosis (PCA), the concentrations of many of the large neutral amino acids (LNAA), particularly phenylalanine, tyrosine and histidine, rise several-fold in the brain. Several reports have shown that the rise in concentration of these amino acids in the brain cannot be accounted for either by their absolute level in plasma or by the ratio in plasma of any one of these amino acids to the sum of its competitors for blood-brain transport. Therefore, some other factor, acting either at the blood-brain barrier or in the brain itself, may alter the transport of the LNAA into the brain. This factor may be related to glutamine, which is synthesized in brain from ammonia and glutamate.

Based on plasma and brain amino acid data from 188 rats which were either infused with ammonium salts and amino acids or underwent a PCA, we have developed a mathematical model which can predict with reasonable accuracy brain concentrations of most of the LNAA from the plasma concentrations of the LNAA and the brain glutamine concentration. The model was developed as follows: (1) The ratio of each LNAA (except tryptophan) to its apparent K_m of transport was calculated both in plasma and in brain, letting glutamine also serve as a competitor with a K_m of transport of 8.5 mM (determined by its ability to competitively inhibit the brain uptake of radiolabeled phenylalanine). (2) The relationship between the calculated ratio (AA/K_m^{app}) in plasma and the same ratio in brain was determined to fit well to a straight line, being near a slope of 1 for amino acids slowly metabolized by brain (phe, his, tyr, met) and around 0.5-0.6 for those which brain can metabolize (leu, ile, val). (3) The eight equations (one for each LNAA - thr, val, met, ile, leu, tyr, phe, his) expressing the relationships between plasma and brain competitor ratios for each amino acid were considered to form a set of eight simultaneous equations in eight unknowns and were rearranged to a form suitable for solution by computer.

Using the series of equations in the model, the brain levels of the LNAA were predicted for the original 188 rats using as input only the plasma LNAA and the brain glutamine level of each rat. The correlation coefficients between the observed and predicted levels were as follows: thr, r=.795; met, r=.838; ile, r=.897; leu, r=.887; val, r=.904; tyr, r=.958; phe, r=.964; his, r=.948. The accuracy of prediction suggests that the primary effect of brain glutamine on the brain levels of other LNAA is as a competitive inhibitor for their efflux from brain.

255.4 STRUCTURAL EVIDENCE FOR UNSTIRRED LAYERS IN THE CHOROID PLEXUS EPITHELIUM. P. A. Grady and O. R. Blaumanis*. Dept. of Neurology, Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Secretion of cerebrospinal fluid (CSF) by the choroid plexus is an active process in which the pumping of sodium is followed by passive movement of water along an osmotic gradient. A serious dilemma in modeling this system arises from the fact that (a) the sodium pumps are located in the apical membranes of the choroidal epithelial cells which face a large volume of moving fluid, and (b) CSF secretion occurs in the absence of bulk phase osmotic gradients. It has been postulated that local, standing gradients or unstirred layers constitute the osmotic compartment which is required to explain the coupling between sodium and water transport. We present evidence for the existence of the possible structural basis for the postulated sequestered spaces of unstirred layers.

Aldehyde fixed choroid plexus from rats, rabbits and cats was treated with ruthenium red in the presence of osmium. Transmission electron microscopy of the microvilli of choroid epithelial cells revealed dense cell coats on all villi and cilia of these cells. These coats are approximately 20-50 nm thick and appear to be continuous with the outer leaflet of the cell membrane. Neuraminidase, chondroitinase and hyaluronidase digestion diminish or eliminate the staining by ruthenium red, indicating that the coats are composed largely of glycoproteins and are therefore similar to other cell coats. Sections cut perpendicular to the axes of the microvilli showed that the coats of adjacent villi often overlap and are generally in close apposition. Preliminary calculations indicate that the geometry of the microvilli and their thick coats may account for the necessary sequestered space for local osmotic gradients. (Supported in part by PHS Grant #NS16332).

255.5 SIMULTANEOUS DETERMINATION OF REGIONAL BRAIN BLOOD FLOW AND WATER PERMEABILITY BY A DOUBLE-LABEL RADIOISOTOPIC METHOD: INFLUENCE OF STATUS EPILEPTICUS AND HEMISPHERAL NOREPINEPHRINE DEPLETION. M.D. Ginsberg, R.Busto*, S.I. Harik and E. Martinez*. Cerebral Vascular Disease Research Center, Univ. of Miami Sch. of Med., Miami, FL 33101.

We have used a double-label method in the rat to assess regional brain blood flow (rCBF) with (14)C-butanol (a highly extracted diffusible indicator), and permeability with (3)H-water. A mixture of the 2 tracers is infused intravenously over 30 sec, and multiple arterial samples are obtained. The brain is then frozen, and samples are punched from multiple regions of interest. Isotopic activities are computed by a dual-channel internal-standard method. The generalized operational equation derives from Kety: $dCi/dt = mf(Ca - Ci/\lambda)$ (Eq. 1) where Ci and Ca represent tissue and arterial tracer activity; f is rCBF (ml/gm/min), λ is the brain:brain partition coefficient, and m is a diffusion-dependent term for non-ideal tracers. As shown by Crone, $m = 1 - \exp(-PS/f)$. In the present study, a value of m=1 is assumed for the (nearly) ideal tracer butanol. "True" flow f is computed from Eq. 1; the extraction fraction (m) and permeability-times-surface-area product (PS) for water may then be computed.

In Wistar rats ventilated on 100% oxygen, status epilepticus was induced by the IV administration of bicuculline, and secondary hypertension was prevented. After 8 min of seizure activity (by EEG), a radioisotopic study was performed. In one group, norepinephrine (NE) depletion of one cerebral hemisphere had been induced 2 weeks earlier by a 6-hydroxydopamine lesion of the locus ceruleus (LC).

In normocapnic control rats ventilated on 100% oxygen, mean (butanol) flow values (rCBFb) in anterior and posterior neocortex were 2.78±0.78 (SD) ml/gm/min, and mean extraction fraction for water (Ew) was 0.77±0.12. In rats with seizures, rCBFb was 4.08 ±1.17 and 3.89±1.13 ml/gm/min ipsilateral and contralateral to the LC lesion, respectively; and Ew was 0.66±0.09 and 0.67±0.09. Thus, unilateral NE depletion failed to affect either rCBFb or Ew under conditions of intense cortical activation. The regression equations relating Ew to rCBFb in all structures of the 2 animal groups were:

100% O2 CONTROLS: $Ew = -0.056 \times rCBFb + 0.881$, $r = -0.81$

SEIZURE ANIMALS: $Ew = -0.112 \times rCBFb + 1.052$, $r = -0.76$

These 2 equations yield virtually identical values for Ew in their regions of overlapping validity (rCBF range 2-4 ml/gm/min). Thus, brief status epilepticus fails to alter brain water permeability. (Supported by USPHS Grant NS-05820-17.)

255.6 BRAIN ENDOTHELIAL CELL TUBULAR TRANSPORT STRUCTURES ARE NOT FIXATION ARTIFACTS. A.S. Lossinsky*, A.W. Vorbrodt* and H.M. Wisniewski* (SPON: J. Shek). NYS Institute for Basic Research in Developmental Disabilities, Staten Island, N.Y. 10314

Our previous studies of blood-brain barrier (BBB) transport across endothelial cells (ECs) from injured brain cortex showed elongated tubular profiles in addition to pinocytic vesicles. These tubules are thought to serve as conduits for the trans-EC passage of macromolecules because they were shown to transport horseradish peroxidase and ferritin. Further, it was shown that the limiting membranes of both tubules and vesicles showed activity of alkaline phosphatase, an enzyme bound to the plasmalemma of ECs of brain micro-blood vessels. It has also been proposed that the EC tubules (channels) manifest as the result of fusion between adjacent pinocytic vesicles due to improper stabilization by glutaraldehyde of the lipid portion of the plasma membrane. In the present study, we wanted to determine whether or not prefixation of EC plasma membranes with (1) buffered OsO_4 or (2) an osmium-glutaraldehyde coctail would prevent tubular formation. Mice or rats were divided into two groups. Some animals were subjected to crude leptomeningeal injury and perfused fixed initially with either buffered OsO_4, or OsO_4 coctail, followed by glutaraldehyde fixation. These animals were compared to those perfused with glutaraldehyde followed by OsO_4. Fine structural analysis of ECs from both prefixation groups using OsO_4 showed tubular structures similar to the group initially perfused fixed with glutaraldehyde indicating that EC tubules represent transport structures that form in vivo after BBB injury and are not artifacts of fixation.

255.7 A COMPARISON BETWEEN THE MICROVASCULAR RESPONSE OF PROXIMAL AND DISTAL CORD SEGMENTS AFTER TRANSECTION. L.J. Noble. Dept. of Anatomy, Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Spinal cords have been examined 10 min., 1 hr., 3 hrs., 1 day, and 3 days after transection at the T2 vertebral level in the rat. Ultrastructural changes in microvascular permeability proximal and distal to the transection were studied using horseradish peroxidase (HRP) as a vascular tracer. As previously reported (Exp. Neurol., 79:188-211, 1983) a statistically significant increase in pinocytotic activity of HRP was present in sites as remote as 18mm distal to the transection. This response was accompanied by the appearance of reaction product in the vascular basement membrane and cord interstitium from 1 hour through 12 hours post-transection. Similar studies proximal to the surgical site indicate that this impairment of the barrier to HRP persists beyond 12 hours and has been detected 10mm proximal to the transection at 3 days. Despite this evidence of enhanced vascular permeability at later periods the overall microvascular response to HRP appears reduced. Preliminary data demonstrates a characteristic pinocytotic uptake of HRP but often without concomitant leakage into the cord interstitium. Occasional instances of avid pinocytosis of the tracer at the luminal front coincide with intense reaction product in the lumen, suggesting a concentration dependent uptake mechanism. Although the tracer was commonly associated with endothelial vesicles, a majority of these structures remained unlabelled. HRP was also demonstrated in the basement membrane without apparent labelling in the interstitium. However, localization of reaction product in the interstitium may be difficult as it can freely diffuse from abluminal sites. The labelling of the basement membrane in the absence of leakage into the interstitium suggests that it may act as a temporary restraining site for HRP. This research was supported by the Univ. of Maryland Pangborn Fund, 1982-1983.

255.8 ASYMMETRICAL EFFECT OF UNILATERAL CORTICAL SUCTION LESIONS ON RAT CEREBRAL VASCULATURE, R.L. Margolis* and R.G. Robinson, (SPON: E.M. Gruenberg) Dept. of Psychiatry, Johns Hopkins U. Sch. of Med., Baltimore, MD 21205

We have previously demonstrated that a focal lesion of the right frontal cortex in rats produces marked hyperactivity and bilateral catecholamine depletions in the anterior and posterior cortices and in the locus coeruleus. Neither hyperactivity nor catecholamine depletion was produced by identical lesions of the left frontal cortex (Pearlson, G.D., and Robinson, R.G., Brain Res., 218:233, 1981).

To further explore this asymmetry, we examined the effect of focal cortical lesions on cerebral vasculature. Male Sprague-Dawley rats received suction lesions 1.5 mm in diameter in either the left or the right frontal cortex (9.5 mm anterior to ear bar zero). One, five, or fifteen days postoperatively, these rats and controls without lesions were anesthetized and injected intravenously with 15 uCi/Kg ^{14}C-inulin. Seven minutes after injection, when cerebral concentrations had reached a steady state, the rats were sacrificed. Anterior and posterior regions of right and left cortices were dissected using a brain slicing apparatus and assayed for ^{14}C-inulin and protein content.

Analysis of variance revealed a significantly higher anterior ipsilateral ($p < .05$) and posterior contralateral ($p < .003$) cortical inulin content in animals receiving right cortical lesions than in animals receiving left cortical lesions. Differences in inulin levels between the two groups on postoperative days five and fifteen contributed to this effect. The inulin levels of the other two cortical regions examined (posterior ipsilateral and anterior contralateral to the lesion site) were also elevated in rats receiving a right cortical lesion, though not to a statistically significant level.

The pattern of inulin accumulation following unilateral cortical lesions suggests that right and left frontal cortical lesions have different effects on cerebral vasculature. This asymmetry may be related to the depletion of cortical and midbrain catecholamines that is produced by right, but not left, frontal cortical lesions.

255.9 EFFECT OF INTRACAROTID HYPEROSMOLAR MANNITOL ON CEREBRAL CORTICAL ARTERIOLES - A MORPHOMETRIC STUDY. D. W. Beck*, M. N. Hart*, and K. E. Hansen*. (Sponsor: J. C. Godersky). Department of Pathology, The University of Iowa, Iowa City, Iowa 52240

Intracarotid hyperosmolar mannitol infusion has been used as a means to transiently open the blood-brain barrier to proteins and water soluble compounds. The infusion is associated with a transient increase in cerebral blood flow. This study addresses the mechanism of the increased blood flow.

Experiments were performed on 16 male rats weighing between 200 and 220 grams. The rats were anesthetized with pentobarbital and ventilated artificially. Arterial pCO_2, pH, and pO_2 were measured periodically during each experiment and arterial blood pressure was recorded continuously. In nine rats 1.6 M mannitol and 0.9% NaCl was infused into the internal carotid artery via the external carotid artery at a rate of .08 cc/second for 30 seconds. In seven rats 0.9% NaCl alone was infused. Immediately following the infusion the brains were frozen in situ with isopentane cooled in liquid nitrogen, and the wall to lumen (W/L) ratios of the cortical arterioles in the two hemispheres were compared.

Our results show that mannitol causes a decrease in the W/L ratio in all vessels tested compared to controls. For <50μ vessels, W/L was .275 (n = 158) vs. .303 (n = 215) in the opposite hemisphere ($P < .0001$). In >50μ vessels, W/L was .185 (n = 142) vs. .194 (n = 100) ($P > .05$). NaCl infusion alone caused no change in W/L ratio in any sized arterioles.

These results suggest that intracarotid hyperosmolar mannitol causes significant dilation in small cortical arterioles, which may contribute to the transient increase in cerebral blood flow and in addition may contribute to the mechanism for transient opening of the blood-brain barrier.

255.10 MODIFICATION OF BRAIN EXTRACELLULAR SPACE BY CO_2: NEURAL REGULATION. T. A. Kent*, G. Nagy*, A. Oke, S. Preskorn, R. N. Adams (SPON: M. K. Shellenberger). Depts. of Psychiatry and Pharmacology, Univ. of Kansas Medical Center, Kansas City, KS 66103 and Dept. of Chemistry, Univ. of Kansas, Lawrence, KS.

Several groups have reported that increasing cerebral blood flow (CBF) increases the brain capillary permeability and surface area product (PS) of a variety of compounds. The single pass PS to the diffusion-limited compound, water, increases with CO_2, a relationship which is altered by adrenergic manipulation (Preskorn, et al, Science, 1981). In this study, we examined whether this PS change reflects an alteration in the brain microenvironment. We measured the effect of CO_2 on brain extracellular space (ECS) by means of an ion selective electrode sensitive to alpha-naphthalene sulfonate (ANS). This compound has been used as a marker of ECS (Nicholson & Phillips, Neurosci. Abst, 1981). Rodents were anesthetized (chloral hydrate, 400 mg/kg i.p.), intubated, and passively ventilated with N_2 (55-70%), O_2 (30%), and CO_2 (0-15%). Two glass pipettes were implanted into the thalamus, and Na-ANS was introduced via a nanoliter pump through one pipette. The pipette used to measure ANS concentration changes was filled with a PVC-based ion exchanger mixture containing Aliquat (Aldrich)/Na-ANS as active material. CO_2 produced a dose dependent decrease in local concentration of ANS, indicating an increase in its volume of distribution, consistent with a 10-20% increase in ECS. This effect reversed when CO_2 was stopped. Moreover, lidocaine (2%, 5-8 ul) injected into the brainstem in the region of the locus coeruleus reversibly decreased the CO_2 effect by ca. 50%. These results suggest that CO_2 expands ECS, presumably by a transfer of water and/or other solutes from the intravascular space, although intracellular shifts cannot be ruled out. Moreover, a neural contribution to the effect, probably by the central adrenergic system, is suggested. These CO_2 effects differ from Cameron, et al, (Yale J. Biol. Med., 1969) who found no change in the volume of distribution of ^{14}C-sucrose in brain as measured by ventriculocisternal perfusion. Possible reasons for this difference, such as pH or blood flow artifacts, are being investigated. We are also currently examining the effects of amitriptyline--a tricyclic antidepressant and indirect adrenergic agonist, known to increase PS to water--on the CO_2-induced increase in ECS. This data may aid in development of strategies employing low doses of CO_2 and adrenergic agonists to increase the brain concentration of poorly diffusible chemotherapeutic agents.

255.11 INFLUENCE OF PENTYLENETETRAZOLE INDUCED SEIZURES ON 86-RUBIDIUM TRANSPORT IN CEREBRAL MICROVESSELS, K.M.A. Welch, J.A. Helpern and S.J. McGee*. Dept. of Neurology, Henry Ford Hospital, Detroit, MI 48202.

Techniques for the isolation of metabolically active cerebral microvessels (MV) are well established (Goldstein GW, et al, J Neurochem, 25:715, 1975). The isolated MV allows for the study of the blood brain barrier in vitro. Previous studies from this laboratory have shown that pentylenetetrazole (PTZ) induced seizures in gerbils increased 2-deoxyglucose uptake when compared to control (Nell JH, Welch KMA, Ann Neurol, 7:457, 1980). The presence of Na^+-K^+ ATPase dependent K^+ (as 86-Rubidium) uptake in isolated cerebral MV has previously been documented (Eisenberg HM and Suddith RL, Science, 206:1083, 1979; Chaplin ER, et al, Biochem Pharm, 30:241, 1981). We now demonstrate an effect of PTZ induced seizures on 86-Rubidium (86-Rb^+) uptake in isolated cerebral MV. Sprague-Dawley rats were injected with PTZ (IP, 150 mg/kg) and allowed to seize for 1 minute after onset of clonic seizures. Another group of animals were allowed to seize until death. MV were isolated from the cortical shells, which had been dissected free of white matter. Isolated MV were incubated in 1.0 ml of Hepes buffered Ringers (pH=7.4) containing 2.5 μCi/ml of 86-Rb^+ for 0,2,4,6 and 8 minutes. Uptake was stopped by the addition of 3 ml of ice cold buffer. The MV were then washed 3 times with 3 ml each of ice cold buffer. The radioactivity remaining in the MV was determined by liquid scintillation and the data normalized per mg protein. MV isolated from animals 1 minute after the onset of clonic seizures showed no increase in uptake of 86-Rb^+ when compared to control. In contrast, MV isolated from animals allowed to seize until death showed a significant ($p< 0.05$) increase in 86-Rb^+ uptake. This increase in uptake over control was not inhibited by the addition of oubain. We conclude that the increased uptake of 86-Rb^+ into isolated MV, after prolonged seizure, reflects a passive diffusion (leakage) of K^+ through an impaired blood brain barrier and not active transport.

255.12 ASYMMETRICAL EFFECT OF CEREBRAL INFARCTION ON DISTRIBUTION VOLUMES FOR C-14 INULIN IN THE RAT CORTEX. R.S. Black*, and R.G. Robinson (Spon: Scott Lukas) Dept. of Psychiatry and Behavioral Sciences, The Johns Hopkins University School of Medicine, Baltimore, MD 21205

We have previously described the asymmetrical effect of ischemic lesions of rat frontal cortex on behavior and brain catecholamines. Right middle cerebral artery ligation led to behavioral hyperactivity, and bilateral 20-40% depletions in cortical and midbrain norepinephrine with complete or partial return to control levels over a 40 day postoperative period. Left-sided lesions, however, produced no such changes (Robinson, Science, 205:707-710, 1979). To further investigate this asymmetry we have used intravenous infusion of radiolabeled inulin to quantitate the effects of these lesions on the cerebral vasculature.

The right or left middle cerebral artery of 300-350 g rats was visualized through a fronto-parietal craniotomy, ligated with an 8-0 silk suture and severed. The lesion produced involved only the cortex and resulted in no postoperative mortality or lasting neurologic deficits. C-14 radiolabeled inulin (New England Nuclear) was injected intravenously at 15 uCi/kg at 1, 5, and 15 days postoperatively. Seven minutes after injection rats were sacrificed and 3 mm wide anterior and posterior full thickness samples of cortex were dissected using a mechanical brain slicing apparatus. Brain slices were assayed for protein and C-14 inulin content.

In animals sacrificed one day after surgery both right and left anterior ipsilateral sample groups (those containing the lesion) had inulin counts higher than control (t-test,$p<.001$); at 5 days only the right anterior ipsilateral group remained elevated compared to control ($p<.001$); and at 15 days all sample groups were significantly below the control levels ($p<.05$). Analysis of variance revealed significantly higher inulin content ($p<.05$) in the anterior ipsilateral cortex of right sided animals compared to left. Individual means were significantly different on day 5 with right greater than left in anterior ipsilateral and contralateral groups ($p<.05$), with comparisons in the posterior cortex near significant ($p<.1$). By day 15, however, samples from left lesioned animals had consistently higher counts than right, though not significant. No right-left differences in lesion size or protein content (tissue quantity) were detected. Asymmetries in inulin space between right and left lesion animals paralleled asymmetries in cortical and midbrain catecholamine deficits seen in earlier experiments, suggesting a relationship between the biochemical and vascular consequences of ischemic injury in this model.

255.13 DIFFERENTIAL EFFECTS OF CARNITINE, OCTANOYLCARNITINE AND OCTANOIC ACID ON THE UPTAKE OF 5-HYDROXYINDOLEACETIC ACID BY RABBIT CHOROID PLEXUS. C.S. Kim* and C.R. Roe* (SPON: J.F. Howard). Dept. of Neurology and Biol. Sci. Res. Ctr., Univ. of North Carolina Sch. of Med., Chapel Hill, NC 27514 and Dept. of Pediatrics, Duke Univ. Med. Ctr., Durham, NC 27706.

The roles of carnitine in fatty acid metabolism include (1) facilitated transport of acyl compounds into mitochondria and (2) acylcarnitines are one of the primary forms transporting in plasma. The pathogenesis of brain encephalopathy involves the production of free fatty acids in the brain and these acids play an important role in mitochondrial damage and subsequent cerebral energy failure. Carnitine deficiency and increased fatty acids are common metabolic disorders in Reye's syndrome. The present *in vitro* study was undertaken to determine whether carnitine and acylcarnitine have any protective role on the transport of endogenous organic acid, 5-hydroxyindoleacetic acid (5-HIAA).

Choroid plexus (CP) was collected from the lateral and fourth ventricles (LVCP,FVCP) and incubated for either 10 min or 60 min in artificial CSF containing ^{14}C-HIAA. When the incubation medium contained either 0.1mM or 1.0mM octanoic acid, the uptake of ^{14}C-HIAA at 10 min was reduced in a dose related manner (37% and 53% in FVCP; 48% and 67% in LVCP, respectively). After 60 min incubation, T/M ratio of 4.1 ± 0.4 (S.E.) and 6.0 ± 0.6 were achieved in FVCP and LVCP in control media. The ratios were decreased to 2.5 ± 0.2 and 2.8 ± 0.2 in media containing 1.0mM octanoic acid (P<0.001). With the same levels of exposure to octanoylcarnitine, the uptake was inhibited only at higher concentration (1.0mM) by 36% and 43% in FVCP and LVCP, respectively, at 10 min incubation. The prolonged incubation for 60 min abolished the inhibitory effect of octanoylcarnitine on uptake completely. However, treatment with carnitine at the same concentration did not inhibit ^{14}C-HIAA uptake by either FVCP or LVCP. Carnitine actually appeared to stimulate the uptake at higher concentration (1.0mM) during both 10 min and 60 min incubation.

We have previously shown that the 5-HIAA transport mechanism shares the choroidal carrier for other organic acids. The present study demonstrates that carnitine and octanoylcarnitine in contrast to octanoic acid improve the uptake of 5-HIAA by choroid plexus through a mechanism known to be a major route for excretion from the brain *in vivo*. Carnitine may be a useful therapeutic adjunct for removal of toxic organic acids from the CNS in Reye's Syndrome.

255.14 EFFECT OF ACETAZOLAMIDE AND OUABAIN ON CEREBRAL ZINC METABOLISM IN RATS. E. J. Kasarskis and D. Walls*. Dept. Neurology, VA and Univ. Kentucky Med. Ctrs., Sanders-Brown Aging Ctr., Lexington, KY 40536.

Previous studies from this laboratory have demonstrated a slow rate of entry and turnover of zinc (Zn) in rat brain following pulse administration of ^{65}Zn (Soc Neurosci Abstr 7:87,1981). In contrast to neural tissue, the choroid plexus avidly accumulated ^{65}Zn suggesting that the choroid plexus may function in regulating cerebral Zn homeostasis. In order to test this hypothesis, ouabain and acetazolamide, drugs known to affect the secretory and absorptive function of the choroid plexus, were administered to determine if these drugs altered cerebral Zn metabolism.

Twenty adult male Sprague-Dawley rats received a single intraperitoneal dose of either ouabain (10 mg/Kg), acetazolamide (100 mg/Kg) or saline vehicle followed 15 min later by intravenous ^{65}Zn [25 μCi/Kg in 0.1 mL saline] under thiopental anesthesia. Rats were sacrificed after 6 hrs; samples of plasma, CSF, lateral ventricle choroid plexus, arachnoid, eye, and brain (subsequently dissected into 7 regions) were obtained for assay of ^{65}Zn content according to our previously-described methods (Soc Neurosci Abstr 7:87,1981). In addition, samples of liver, kidney, and muscle were taken in order to assess the effect of these drugs on systemic, extracerebral Zn metabolism.

Acetazolamide increased ^{65}Zn concentration 3-fold in CSF despite lowering plasma ^{65}Zn to 75% of control but did not affect the content of ^{65}Zn in the choroid plexus itself. The level of ^{65}Zn was elevated between 1.3 and 1.5-fold in all brain regions due to acetazolamide. In contrast, ouabain decreased ^{65}Zn concentration in brain regions to 90% of controls. Both drugs significantly decreased the Zn content of eye, arachnoid, and kidney but neither drug affected Zn metabolism in liver or muscle.

These data suggest that the carbonic anhydrase inhibitor, acetazolamide, can acutely alter Zn metabolism in rat brain causing significant elevations of newly administered ^{65}Zn. Although the mechanism underlying this effect is unknown, inhibition of choroidal secretion of CSF by acetazolamide and reduction of CSF turnover may retard intracranial elimination of Zn via CSF outflow pathways, causing a "backing up" of ^{65}Zn in extracellular fluid of brain. Alternatively, the choroid plexus could function by transporting Zn from CSF back into plasma as has been demonstrated for calcium (J Neurosci 2:1322,1982). Further studies are needed to evaluate these hypotheses. (Supported by VA Research Service and TIDA grant, NS 00768).

255.15 RADIATION INDUCED BBB BREAKDOWN IN RATS: THE THRESHOLD? M. P. Remler and W. Marcussen*, Dept. of Neurology, VAMC, Univ. of California, Davis, Martinez, CA, 94553

Ionizing radiation is known to lower the blood brain barrier (BBB) (Remler, M.P., Exp. Neurol. 73:310, 1981). The threshold of this effect for tissue has been confused by varying species, volumes of tissue radiated and techniques for monitoring the change in BBB function. The mechanism for the delayed BBB breakdown remains unclear. Using systemic convulsants, it is possible to detect very small BBB lesions (Remler, M.P., Acta neurol. scand. 65:51, 1982).

Bicuculline methiodide (Bm), the GABA blocking epileptogen, crosses the normal BBB of rats poorly (Pong, S.F. Brain Res. 42:486, 1972) and produces no consistent abnormality behaviorally or on EEG at 6.0 mg./kg. (n=10). The BBB opened in 0.25 cu. cm. of cortex by alpha particles. The 33 out of 33 rats radiated were clinically normal. When challenged with 6.0 mg./kg. Bm. 2 out of 11 showed some scattered sharp waves and 1, presumably with accidental cortical trauma, prominant spike activity. When 6,000r are given and then the Bm this results in an intense highly localized epileptiform discharge which begins about 20 minutes post injection and lasts 30 to 90 minutes in 18 out of 19 rats. This result is reproducible for the 1 week the BBB is open after irradiation. The radiation degredation of the BBB is detectable as low as 4,000r.

The probability of microfluctuations of background radiation reaching toxic levels to individual cells is discussed. The role of exposure of the brain to otherwise sequestered chemicals and the release of sequestered brain antigens into the circulation as mechanisms of delayed toxicity will be discussed.

255.16 VASOPRESSIN CROSSES THE BLOOD-CSF BARRIER IN BRATTLEBORO RATS. J.M. Lyness*, C.D. Sladek, and D.M. Gash (SPON: S.J. Wiegand). Departments of Anatomy and Neurology, University of Rochester, Rochester, NY 14642.

The permeability of the blood-cerebrospinal fluid (CSF) barrier to vasopressin was examined in the homozygous Brattleboro rat, which congenitally lacks vasopressin. The effects of chronic infusion were studied by the use of intraperitoneally implanted osmotic minipumps (Alza, Palo Alto, CA) set to deliver 1 μl/hr of physiological saline vehicle. Controls (n=10) received only saline; experimental animals received 0.1 μg/hr (n=5), 1.0 μg/hr (n=5), or 5.0 μg/hr (n=4) arginine vasopressin (AVP, Bachem, Torrance, CA). Three days after pump implantation the animals were anesthetized (Chloropent, .3 ml/kg b.w.); blood samples were obtained for serum AVP radioimmunoassay (RIA) by cardiac puncture, and blood-free CSF samples, obtained from the cisterna magna, were pooled for AVP RIA. Similar procedures were used on acutely infused animals, which were taken one hour after intraperitoneal injection of saline (n=6) or 0.1 μg (n=6) 1.0 μg (n=5), or 5.0 μg (n=6) AVP.

The results show that higher levels of AVP, chronically or acutely infused, do cross the blood-CSF barrier. In both chronic and acute cases, saline controls had very low serum levels of cross-reacting substance (measuring ≤ 1.0 pg/ml), and undetectable levels in the CSF (≤1.0 pg/ml). The 0.1 μg groups had average serum AVP levels of 12.8 pg/ml with chronic infusions and 6.8 pg/ml with acute infusions; CSF levels were 1.1 pg/ml and undetectable (≤1.0 pg/ml), respectively. The 1.0 μg chronic group had 68 pg/ml in the serum and 58 pg/ml in the CSF; the 1.0 μg acute group had a serum level of 70.5 pg/ml and a CSF level of 34 pg/ml. The 5.0 μg animals had extremely high serum AVP levels (≥ 160 pg/ml chronically and ≥ 400 pg/ml acutely) but only slightly higher CSF levels than the 1.0 μg groups (64 pg/ml and 81.4 pg/ml, respectively).

These results suggest that the AVP found in normal rat CSF is secreted into the CSF independently of systemic release, since at the 0.1 μg level, which produced serum AVP levels in the high physiological range, AVP did not cross the blood-CSF barrier in appreciable quantity. However, the permeability of the barrier at higher levels indicates that the behavioral effects of systemically injected AVP could be due to central effects of the peptide. Why AVP can cross the barrier at higher levels is unknown; the possibility that the peptide's hypertensive effects at high levels may disrupt the barrier and alter its permeability to AVP is currently being investigated.

Supported by grant No. NS15109 and AM19761.

255.17 Na/H EXCHANGE IN THE RAT CHOROID PLEXUS (CP). Vincent A. Murphy* and Conrad E. Johanson. Dept. of Pharmacology, Univ. of Utah, Salt Lake City, UT 84132.

The functional relationship between Na transport and the $pH/pCO_2/HCO_3$ system is a fundamental, but poorly understood problem in electrolyte physiology. Na/H exchange transport has been demonstrated in various systems: small intestine, kidney proximal tubule, gall bladder, gastric parietal cell, and skeletal muscle. Demonstration of H gradient-dependent Na uptake is one way to show the existence of this system in a tissue.

Male adult rats were used in all studies. Animals were nephrectomized under ether anesthesia prior to agent and isotope treatment. Either NaCl, $NaHCO_3$, NH_4Cl, or HCl 4.7 mmol/kg; acetazolamide 25 mg/kg; or vehicle was given IP to alter the transmembrane H gradient. One hour post nephrectomy the rats were anesthetized with ketamine 80 mg/kg IP and plasma, CSF, and lateral and fourth ventricle CP's were obtained as samples. Isotopes were administered as follows: i) ^{14}C-dimethadione and ^{3}H-raffinose, 0 min. post treatment; ii) ^{22}Na, 0, 12, 24, 36, 42, or 48 min. post treatment; and iii) ^{51}Cr-RBC, 50 min. post treatment. The dimethadione, raffinose, and RBC were used to determine CSF/CP cell pH, extracellular fluid volume, and residual erythrocyte volume respectively. Na and K were measured by first extracting with 0.02 N HNO_3/0.015 N Li, then using flame photometry. Isotopes were counted by either a Beckman Biogamma or LS 7500. Na uptake was determined by either taking the slope of the volume of distribution (V_d) vs. time (CSF) or by curve stripping using the stable Na V_d as steady state (SS), ln (SS - V_d) vs. time (CP).

A strong correlation between the basolateral H gradient (blood side) and Na uptake into the CP was found (r=0.99); the basolateral HCO_3 gradient also correlated but not as well (r=0.90). CSF uptake of Na also correlated with CP uptake indicating that a basolateral system is being affected. Other parameters such as plasma, CSF, and CP cell [Na], [K], [H], and [HCO_3] correlated less significantly ($r < 0.85$) with ^{22}Na uptake.

The results demonstrate that much of the Na uptake into the CP is due to Na/H exchange transport and possibly Na/HCO_3 cotransport. This permits a further understanding of the relationship between H/HCO_3 and Na uptake in the CSF/CP system. (Supported by NIH grant NS 13988.)

255.18 TRANSPORT KINETICS OF LARGE NEUTRAL AMINO ACIDS ACROSS THE BLOOD-BRAIN BARRIER. Y. Takasato*, Q.R. Smith and S.I. Rapoport. Lab. of Neurosciences, Gerontology Research Center, National Institute on Aging, Baltimore City Hospitals, Baltimore, MD 21224.

To characterize the transport kinetics of large neutral amino acids at the blood-brain barrier, we measured the concentration-dependent uptakes of tryptophan, leucine, isoleucine and cycloleucine, using an in vivo brain perfusion technique. In pentobarbital-anesthetized rats, the right pterygopalatine artery was ligated and the external carotid artery was catheterized. Just after ligation of the common carotid artery, the right cerebral hemisphere was perfused by retrograde infusion (0.083 ml/s) of a physiological saline (37° C, pH 7.4) into the external carotid artery. During perfusion, circulating blood contributed less than 3% to capillary fluid flow in the right cerebral hemisphere. The capillary fluid flow in the cerebral cortex, as determined by ^{57}Co-labeled microspheres, was $1.17 \pm 0.05 \times 10^{-1}$ s^{-1}. The perfusion fluid contained ^{3}H-inulin, ^{14}C-labeled amino acid and various concentrations of unlabeled amino acid (0-20 mM). After 5 to 60 s of perfusion, the rat was decapitated and samples from 6 brain regions and infusion fluid were analyzed for radiotracer content. The cerebrovascular permeability-area product (PA) was calculated from the brain parenchymal concentraction of tracer (C*br), perfusion fluid tracer concentration (C*pf), perfusion time (T) and brain capillary fluid flow (F); PA = -F.ln (1- C*br/F .C*pf.T). For each amino acid, Vmax and Km for the saturable component of uptake and Kd for nonsaturable uptake were determined from nonlinear regression analysis; PA = Vmax/(Km + Cpf) + Kd, where Cpf = amino acid concentration.

In the parietal cerebral cortex, PA for each amino acid decreased approximately 100 fold when Cpf was elevated from 0 to 20 mM. Calculated Vmax ranged from $0.93 \pm 0.07 \times 10^{-3}$ µmol/s/g for cycloleucine to $1.05 \pm 0.08 \times 10^{-3}$ for isoleucine. In contrast to this relative constancy of Vmax, Km (mM) was 0.010 ± 0.004 for tryptophan, 0.024 ± 0.006 for leucine, 0.057 ± 0.007 for isoleucine and 0.280 ± 0.040 for cycloleucine. A nonsaturable component of uptake (Kd) was not detected for isoleucine or cycloleucine, whereas, for both tryptophan and leucine, Kd was significantly greater than zero and approximated PA for passive diffusion, as predicted by the octanol/water partition coefficient. Lastly, significant regional differences in Vmax, Km and Kd were not observed among the 6 perfused brain regions. These data show that large neutral amino acids cross the blood-brain barrier predominantly by carrier-mediated transport, and that the carrier affinity for the amino acids is greater than previously thought.

255.19 BRAIN UPTAKE OF ERYTHROSIN B, A FOOD DYE, PREVENTED BY BINDING TO PLASMA PROTEIN IN RATS. H. Levitan, Q.R. Smith, Y. Takasato,* S.I. Rapoport, and Z. Ziylan*, Lab. of Neuroscience, GRC, National Institute on Aging, Baltimore, MD 21224.

Food colors have been held responsible for several behavioral disorders such as minimal brain dysfunction and hyperactivity. Some dyes affect neuronal function when directly applied. There is no information however on whether significant quantities of the food coloring dyes enter the brain after consumption or parenteral administration. To determine if a widely-used food dye, erythrosin B (FD&C Red No. 3), can cross the blood-brain barrier (BBB) and enter the brain, we administered ^{14}C-erythrosin B directly into the circulation of mature (3 month-old), male, Osborne-Mendel rats, and measured radioactivity in brain regions at several times thereafter. We found that ^{14}C-erythrosin B did not enter the brain from the blood, but penetrated the BBB when infused directly into the carotid circulation in the absence of blood protein. Under pentobarbital anesthesia, the right external carotid artery of a rat was cannulated distal to its junction with the common carotid, and the right common carotid artery was encircled with thread. The cannula was connected to a syringe containing ^{14}C-erythrosin B (0.1-0.2 µCi/ml, spec. act. 630 mCi/mmol) and ^{3}H-inulin (0.6-1.1 µCi/ml, spec. act. 1750 mCi/mmol) in an oxygenated and warmed bicarbonate Ringer's solution (4 experiments) or in heparinized rat whole blood (4 experiments). The common carotid artery was ligated, and Ringer's solution or whole blood was infused immediately into the external carotid artery. The animal was decapitated after 60 s and the brain dissected into six regions (frontal lobe, parietal lobe, occipital lobe, hippocampus, caudate nucleus, thalamus-hypothalamus). Net brain ^{14}C-radioactivity was corrected for residual intravascular tracer by subtracting the radioactivity attributable to inulin, which does not cross the blood-brain barrier. Significant parenchemal concentrations of ^{14}C-erythrosin B were detected in all brain regions when it was perfused with protein-free Ringers. The cerebrovascular permeability-surface area product (PA) ranged from $6\text{-}7 \times 10^{-4}$ s^{-1}, about 300x the PA of sucrose, as predicted from the octanol-water partition coefficient of the dye. Insignificant parenchymal radioactivity was detected in brains infused with dye in whole blood. From equilibrium dialysis, about 99.7% of the dye was shown to be bound to plasma protein. The results show that, although free erythrosin B can rapidly cross the BBB, signficant brain uptake of intravascular dye is prevented by its binding to plasma protein, and by blood-brain barrier iimpermeability to the dye-protein complex. Sensitivity to food dyes such as erythrosin B in some individuals may reflect altered plasma protein binding capacity, which can vary with disease and age.

259 SYMPOSIUM. POST-TRANSLATIONAL PROCESSING OF NEUROPEPTIDE PRECURSORS AND NEURONAL PROTEINS. H. Gainer, NICHD, NIH (Chairman); R. Hammerschlag, City of Hope, Nat'l Med. Center; Y. P. Loh, NICHD, NIH; L.D. Fricker, Johns Hopkins Univ.; C. Glembotski, Univ. of Penn.; N.A. Ingoglia, New Jersey College of Medicine.

It has become apparent in recent years that the phenotypic expression of a gene product in the nervous system and other tissues depends on more than transcriptional and translational processes. Many post-translational modifications of the newly synthesized protein may be necessary before these molecules become functionally active. In addition, such processing mechanisms can serve to activate or inactivate a peptide or protein either reversibly or irreversibly. Among these mechanisms are glycosylation, sulfation, phosphorylation, acetylation, amidation, aminoacylation, methylation, ADP-ribosylation, and limited proteolysis. Biologically active neuropeptides are subjected to many of these processes, and examples of these mechanisms will be described here for the ACTH-endorphin and enkephalin precursor proteins. The emergence of α-MSH and endorphin from the ACTH-endorphin precursor first requires the hydrolysis of specific peptide bonds in the precursor by limited proteolysis (at loci in the precursor which contain pairs of basic amino acids, eg. Lys-Arg). This is followed by further limited proteolysis (eg. carboxypeptidase-B-like enzyme action), and N-acetylation and amidation of the peptide products. All of these mechanisms are necessary to produce the appropriate peptide structure for biological activity (or inactivity, in the case of N-acetylated endorphin). The intracellular organization of post-translational processing is a highly relevant issue and will be discussed both for neuropeptide biosynthesis and fast axonally transported (i.e., neuronal membrane) proteins. The phenomenon of axonal transport in neurons provides an experimental window through which the subcellular localizations of some of these processes can be examined, and the mechanisms of glycosylation and sulfation will be addressed in this context. Although it is well known that axons and nerve terminals do not synthesize proteins de novo, recent evidence indicates an abundance of transfer-RNA in axoplasm. A potential post-translational processing role for this t-RNA, and a possible function for aminoacylation in growth and regeneration in axons will be discussed.

260 SYMPOSIUM. EFFERENT CONTROL OF THE ORGANS OF HEARING AND EQUILIBRIUM. S.M. Highstein, Albert Einstein College of Medicine (Chairman); J.M. Goldberg, University of Chicago; J.C. Adams, Medical University of South Carolina; J.J. Guinan, Massachusetts Eye and Ear Infirmary; J. Art*, University of Cambridge.

Using a multidisciplinary approach, the central nervous system control of the organs of hearing and equilibrium is being studied in squirrel monkeys, cats, turtles and fish. Efferent control of the lateral line organs is inhibitory and is thought to prevent self excitation of exteroceptors. In the cat, auditory efferents have been divided into "lateral" and "medial" groups of cells. Axons of lateral neurons are myelinated and project to the inner hair cell region bilaterally (mostly ipsi) and medial neurons (unmyelinated) project to the outer hair cell region bilaterally (mostly contra). The morphology suggests that most of the results from electrical stimulation of crossed and uncrossed olivo-cochlear fibers are due to stimulation of myelinated fibers from the medial subgroups and not to activation of unmyelinated fibers from lateral cells. Further, extensive double labeling experiments with retrograde tracers and cholinesterase staining demonstrate central collaterals of both the auditory and vestibular efferents. The auditory cells have terminal plexes restricted to the anterior ventral cochlear nucleus and to the dorsal pole of the dorsal cochlear nucleus. Vestibular efferents have central terminal plexes beneath the entire extent of the olivo-cochlear bundle from below the MLF to the facial nerve genu, in the interstitial nucleus of the VIIIth nerve and in the ventro-lateral vestibular nucleus. Intracellular records taken from turtle hair cells indicate that electrical stimulation of efferents generates hyperpolarizing synaptic potentials and a concomitant loss of tonal sensitivity and tuning. Ion substitution experiments suggest that the hyperpolarization is mediated mainly by an increase in the hair cell membrane permeability to potassium. Dr. D.O. Kim has been invited to discuss the biomechanical effects of efferent activation on the organ of Corti.

In squirrel monkeys, vestibular primary afferent activity is increased by electrical stimulation of the efferent vestibular system. Irregularly discharging afferents are 10-20X more sensitive than regularly discharging afferents. The efferent vestibular system may function to extend the dynamic range of the afferents. In toadfish, efferent vestibular neurons are separated into distinct subgroups on cytoarchitectural grounds. They have central axon collaterals in the MLF, and branch centrally to innervate more than one peripheral endorgan. Intracellular recording demonstrates certain patterns of electrical coupling among various subgroups. Efferent neurons increase their discharge frequency when the fish is roused to move. The speakers will attempt a unified hypothesis for the physiology of these efferent systems.

OPIATES III

261.1 OPIATE WITHDRAWAL BEHAVIOR AFTER PROLONGED FOCAL BRAIN STIMULATION IN THE RAT. B. E. Thorn-Gray and D. A. Williams*. Dept. of Psychology, The Ohio State University, Columbus, OH 43210.

Focal electrical stimulation of the periaqueductal gray (PAG) produces analgesia in rats. This analgesia is assumed to be partially mediated by the endogenous opiates since the phenomenon is attenuated by Naloxone. The analgesic effect of stimulation-produced analgesia (SPA) is behaviorally similar to the effects observed after morphine administration. If morphine is administered for a prolonged period of time, opiate withdrawal behaviors (indicative of opiate dependence) are observed after administration of Naloxone. This study investigates whether Naloxone-elicited opiate withdrawal behaviors result from prolonged SPA.

Twelve albino rats were surgically implanted with one bipolar stimulating electrode into the PAG. The tail-flick technique was used to assess analgesia. Withdrawal behavior was measured by injecting the rat with Naloxone (IP, 1 mg/kg), placing it in an observation box, and checking for the presence of opiate withdrawal behaviors as delineated in published opiate withdrawal scales.

Each rat, serving as its own control, was exposed to three conditions: Condition I (control) - No stimulation-Naloxone-Withdrawal Test, Condition II (control) - 2 hr. confinement in stimulation tubes (no stimulation)-Naloxone-Withdrawal Test, Condition III (SPA Trial) - Stimulation (10" of stimulation every 2' for 2 hr.)-Naloxone-Withdrawal Test. (Parameters: freq. 50 hz., intensity 20-100 μa, pulse duration 1 μsec.)

Compared to the control conditions, after two hours of SPA and Naloxone administration, rats exhibited a significantly greater frequency of opiate withdrawal behaviors ($Q = 6.17$, $p < .05$). Additionally, the mean number of withdrawal behavioral categories increased from $\bar{X} = 2.5$ for controls to $\bar{X} = 6.3$ following the SPA condition ($Q = 9.08$, $p < .05$).

The withdrawal behaviors following the SPA trial were behaviors usually associated with a low grade dependence on morphine. This finding suggests an association between prolonged SPA and low grade opiate dependence in rats.

261.2 THE NEUROCHEMICAL MECHANISM FOR STIMULATION-PRODUCED ANALGESIA: COMPARISON OF TESTS INVOLVING TONIC AND PHASIC PAIN. K.E. Plotkin* and B.E. Thorn-Gray (SPON: D. Meyer) Lab of Physiological and Comparative Psychology, Ohio State University, Columbus, OH 43210

The hypothesis that different types of pain may be mediated by separate neural subsystems has been extended by Ronald Melzack and others. Melzack suggests that pain measures such as the Tail-Flick Test primarily engage a group of fibers (lateral pain-signalling system) that are responsible for the communication of transient stimuli. Conversely, the Formalin Test involves the injury to tissue (via a .05 ml injection of 5% Formalin solution) on the dorsal surface of a rat's forepaw, imposing a constant, inescapable pain stimulus. A large component of the pain resulting from tissue damage may be tonic in nature, and transmitted by a more medial set of fibers. These neural subsystems may be modulated separately, and may serve discreet purposes in the integrative aspects of pain response. This experiment investigated the possibility that different neurotransmitters are involved in stimulation-produced analgesia as measured by the Tail-Flick and Formalin Tests.

Male albino rats were implanted with bipolar electrodes in the periaqueductal gray. During the procedure of each pain test, analgesia from focal brain stimulation (Parameters: freq. 50 hz., intensity 20-50 μa, pulse duration 1 μsec.) was challenged with either IP naloxone (3 mg/kg) or methysergide (1 mg/kg).

Using the Tail-Flick Test, both naloxone and methysergide reduced analgesia or eliminated it. Using the Formalin test naloxone failed to reverse stimulation-produced analgesia; mean pain ratings remained at analgesic values after the opiate antagonist was administered. However, methysergide reversed the analgesia significantly; mean pain ratings increased to 70% of baseline values after its administration. The data suggest that a non-opioid system is involved in the mediation of tonic pain.

261.3 ANALGESIC POTENTIATION AND THE DISTRIBUTION OF MORPHINE IN THE BRAIN IN THE PRESENCE OF TRIPLENNAMINE IN MICE. R. Bluhm*, M.A. Evans, and E.K. Zsigmond. Lab. of University of Illinois at Chicago, Chicago, IL 60612.

Interest in the interaction of opioids and histamine antagonists arose from the observation that abusers of pentazocine and triplennamine experience a heroin-like euphoria that neither drug alone produces. The present study was conducted to evaluate the analgesic properties of the combination of the histamine antagonist, triplennamine (TRP), and morphine (MS). Analgesia was assessed in male, Swiss Webster mice weighing 25-35 gm using the hot plate at 55°C and all drugs were administered intravenously. TRP had no analgesic effect. When a sub-optimal dose of MS (3.5 mg/kg) was combined with TRP in a dosage range of 2.5-5 mg/kg the latency in response to pain 10 minutes after drug administration was significantly increased relative to morphine alone. Values for the three treatment groups were 1.79±0.36sec., 7.07±0.71, and 24.39±2.02 ($p \leq 0.02$), respectively, for TRP (5 mg/kg), MS, and MS coadministered with TRP. This potentiation was also evident 30 minutes after drug administration when the latency in animals receiving the drug combination was still significantly longer. Motor coordination was not affected. Naloxone completely reversed the analgesic response of animals receiving MS and the MS-TRP combination.

The distribution of (N-methyl-^{3}H) morphine (30 μCi/kg) in the presence of TRP (4 mg/kg) was studied. Regional brain areas and plasma were sampled and dissolved in Soluene-350^R (Packard Instruments) before being counted for radioactivity. The levels of radioactivity in the striatum as expressed by tissue: plasma ratios for MS and MS-TRP respectively after 10 minutes were 3.2±0.4 and 1.9±0.2. After 30 minutes, the tissue to plasma ratio was 1.03±0.04 and 1.45±0.05 for MS and MS-TRP respectively. In the cerebral cortex the corresponding values were 0.58±.05, 0.67±0.1 for 10min samples and 0.50±0.03, 0.55±0.02 for the 30min samples. Similarly, the distribution of radioactivity in the hypothalamus, brain stem and plasma was not significantly different in the presence and absence of TRP.

The mechanism of the analgesic potentiation of MS by TRP does not appear to be due to changes in morphine distribution in plasma or in the brain.

261.4 NOCICEPTION IN DEVELOPING RATS. David M. Bronstein*, Mina Mir Mohammed Sadeghi* and Loy D. Lytle (SPON: R. W. Reynolds). Laboratory of Psychopharmacology, Department of Psychology, University of California, Santa Barbara, CA 93106.

Although there has been a great deal of research investigating the neuroanatomical and neurochemical mechanisms which mediate the pain responses of adult animals, relatively little is known about the development of nociception in those animals born immature. The purpose of the present study was to characterize the responses of rats of different ages following the intraperitoneal injection of a noxious hypertonic saline solution.

Groups of 55 male or female albino rats, bred in our colony from Sprague-Dawley derived rats obtained from Simonsen Laboratories (Gilroy, CA), were tested for 5 consecutive days beginning at ages 8, 13, 18, 28, 38, or 48 days following birth. All testing took place during the latter half of the light phase of the light:dark cycle. The testing procedure involved injecting each animal intraperitoneally with 1 ml/kg of one of 6 concentrations (3, 4, 8, 12, 16, or 20%) of hypertonic saline, and then observing them for the frequency and duration of a writhing response (a response in which animals show waves of rostral to caudal contractions of the abdominal musculature, and a stretching and/or arching of the back). The test session was terminated when an animal emitted no writhing response for a continuous 60 sec period.

In general, animals younger than 40 days of age showed a decreased responsivity/sensitivity to the noxious hypertonic saline treatment. For any given dose of saline, approximately 3 times as many animals that were 20 days of age or older emitted writhing responses following injection compared to 10 day old rats. Furthermore, the intensity of the writhing response increased both as a function of the age of the animal tested, as well as a function of the dose of hypertonic saline administered at any given age. Thus, the number of writhing responses an animal made and the total time an animal spent emitting the writhing responses gradually increased with age, until adult-like patterns were attained by 40 days of age. Further studies are planned to determine whether age-dependent changes in responsivity/sensitivity to hypertonic saline injections observed in this study might generalize to other noxious stimuli. However, our data thus far indicate that immature animals do not have fully mature, functional neuroanatomical and/or neurochemical mechanisms important for nociception. (Supported in part by NIMH grant MH-31134).

261.5 LEU-ENKEPHALIN EFFECTS ON ACQUISITION AND CONSOLIDATION OF AN ACTIVE AVOIDANCE TASK, R.C. Dana*, P. Conner* and J.L. Martinez, Jr., Dept. of Psychobiol., Univ. of Calif., Irvine, CA 92717. (SPON: J. A. Kusske)

Previously we reported that opioids are potent modulators of avoidance responding when administered prior to training (Neurosci. Abs.,1980,6:319). The purpose of these studies was to compare the effects of Leu-enkephalin (LE) on an active avoidance task when administered at different times relative to training.

Male Swiss-Webster mice (27-35 gm) were trained and tested in a two-compartment, trough-shaped alleyway. A white safe compartment was separated by a sliding door from a black footshock (0.8 mA) compartment. Mice were placed in the dark compartment facing away from the door. If the animal failed to cross to the safe compartment within 10 sec, the shock was turned on and terminated when the mouse escaped. 4 trials were run on Day 1, with a new trial being initiated every 30 sec. 24 trials were run on Day 2, and 10 trials were run on Day 5 with 15 sec to shock onset. Mice were injected with LE(200 ug/kg,I.P.), LE plus naloxone (Nx,200 mg/kg, I.P.) or saline (SAL) immediately after training on Day 1 (Expt. 1), or 1 min prior to training on Day 2 (Expt. 2).

MEAN AVOIDANCE RESPONSES, ± S.E.M., (n)

		Day 2	Day 5
Expt. 1	SAL	9.1 ± 4.3 (12)	4.8 ± 2.8 (15)
treatment on	LE	1.3 ± 2.0 (12)[a,b]	1.5 ± 1.8 (14)[a]
Day 1	LE + Nx	4.8 ± 5.2 (12)	2.9 ± 3.1 (7)
Expt. 2	SAL	8.8 ± 6.0 (29)	2.2 ± 2.5 (12)
treatment on	LE	3.7 ± 5.0 (26)[a]	1.0 ± 1.1 (10)
Day 2	LE + Nx	5.2 ± 5.2 (14)[a]	3.1 ± 1.5 (7)[b]

[a]Sig. diff from SAL, [b]Sig. diff. from LE, Dunnett's procedure.

In Expt. 1 LE impaired consolidation of the training experienced on Day 1. Animals treated with LE following training on Day 1 also exhibited impaired learning on Day 2 and Day 5 indicating that LE produces long-term effects. LE and NX given after training on Day 1 attenuated, but did not block the effect observed on Day 2. However, by Day 5 the LE + Nx group was indistinguishable from SAL. In Expt. 2 LE given before training impaired acquisition of the avoidance task, but the effect was not evident on Day 5 as it was in Expt. 1. Nx attenuated the effect of LE given before training on Day 2, but in contrast to Expt. 1, by Day 5 there was a clear cut antgonism of the LE effect.

LE was shown to impair acquisition and consolidation of an avoidance task. A high dose of Nx attenuated the actions of LE, particularly in the consolidation paradigm. Finally, the effect of LE given following training was long-term and was evident several days following administration. (Supported by ONR Contract N00014-82-K-0385 to J.L.M.)

261.6 BEHAVIORAL SIMILARITIES BETWEEN NALOXONE-PRECIPITATED MORPHINE WITHDRAWAL AND LOCUS COERULEUS STIMULATION IN MONKEYS. S. J. Grant, D. E. Redmond, Jr. Primate Research Laboratory. Yale School of Medicine, New Haven, Ct 06510.

Convergent evidence suggests that central noradrenergic systems contribute to the development of many of the physiological and behavioral manifestations of morphine withdrawal. However, behaviors elicited by stimulation of the noradrenergic nucleus locus coeruleus (LC) have not been directly compared with morphine withdrawal effects under identical conditions. In the present study, behaviors observed during naloxone-precipitated morphine withdrawal in chair-restrained Macaca arctoides were compared with behaviors elicited by electrical field stimulation of the LC.

Three female monkeys implanted with bilateral LC electrodes received continuous unilateral biphasic electrical field stimulation of the LC (50 Hz, 0.4-1.2 mAmp, 0.5 msec pulse width) for 30 minutes. Four female monkeys were addicted to morphine via subcutaneous slow release morphine pellets, while 3 female monkeys served as controls. Opiate withdrawal was precipitated by naloxone injections (0.002-0.016 mg/kg, I. M.) spaced at least 72 hours apart. Analysis of variance or covariance was used to evaluate the statistical significance of results.

LC stimulation produced a significant increase in the same restricted set of behaviors reported previously, without increases in general activity or distress behaviors. LC-related behaviors included oral movements, self-directed movements (e.g. hair and skin pulling), grasping of the chair, and jerky body movements.

Naloxone administration in the morphine-addicted monkeys increased the LC-related behaviors in a highly dose-dependent manner, but general activity did not increase significantly until the 0.016 mg/kg dose. Sedation and freezing behaviors which increased during morphine administration declined following naloxone injections. Control monkeys did not exhibit significant changes in any of the behaviors following naloxone administration.

Thus, behaviors associated with LC stimulation also increase during naloxone-precipitated morphine withdrawal. However, LC-stimulation produces a more specific increase in certain behaviors, while morphine withdrawal appears to produce a more general behavioral activation. These data are consistent with and suggest a behavioral consequence of the reported interactions of opioids with the LC at the molecular, intracellular, and cellular level (Redmond, D.E., Jr., editor, J. Clin. Psychiat. 43(6):1-48, 1982).

261.7 NALOXONAZINE: DOSE-DEPENDENT AND TEST-DEPENDENT EFFECTS UPON MORPHINE ANALGESIA. D. A. Simone,* R. J. Bodnar, and G. W. Pasternak. Dept. of Psychology, Queens College, CUNY, Flushing, NY and George C. Cotzias Laboratory of Neuro-Oncology, Memorial Sloan-Kettering Cancer Center and Dept. of Neurology and Pharmacology, Cornell University Medical Center, New York, NY.

The long-lasting opioid antagonist naloxonazine (NAZ), competes equally well with both endogenous and exogenous opioids for all opiate receptor sub-types for at least 48h. Morphine analgesia is eliminated by NAZ (10mg/kg) intravenously administered 24h prior to the opiate. The present study evaluated the dose-response relationships of intracerebroventricular (icv) administration of NAZ upon basal pain thresholds as well as morphine analgesia 24h following NAZ. Groups of six male albino Sprague-Dawley rats were matched according to baseline tail-flick latencies followed by jump thresholds which were determined over a four day period. Each group received only one NAZ dose (0, 1, 5, 50μg/10ul, icv) followed 24h later by one of the following morphine doses (5, 10, 15mg/kg, sc). Tail-flick latencies and jump thresholds were determined at 0.5, 1, 2, and 24h after NAZ administration and 0.5, 1, and 2h after morphine administration. An additional group received naloxone (50μg/10ul, icv) 24h prior to a morphine dose of 10mg/kg NAZ failed to alter either basal tail-flick latencies or basal jump thresholds at any post-injection interval. However, NAZ exhibited dose-dependent and test-dependent effects upon morphine analgesia. While all NAZ doses significantly attenuated the elevations in jump thresholds 0.5 and 1h after a 15mg/kg dose of morphine, only the 50μg NAZ dose was capable of significantly reducing morphine's (15mg/kg) effects on the tail-flick test. A similar antagonistic relationship of all NAZ doses upon morphine (10mg/kg) analgesia was observed with jump thresholds significantly reduced at all time points and tail-flick latencies altered by only the 50μg NAZ dose. Following 5mg/kg of morphine, elevations in jump thresholds were eliminated by NAZ (1 and 50μg) while again, only the 50μg NAZ dose significantly reduced tail flick latencies.

These date are discussed in terms of NAZ's long-term ability to antagonize opiate analgesia through opiate receptor blockade, the central site of action for such effects and the differential effects as a function of the pain test employed. (Supported by NIH grants GRSG 5S05RR07064 and DA02615).

261.8 LONG-TERM ADMINISTRATION OF MORPHINE REDUCES ADIPOSITY IN RATS N. D. Courtney, A. L. Riley, R. A. Gach* and S. C. Woods. Dept. of Psychology, Univ. of Washington, Seattle, WA 98195.

After starvation, when fat stores are depleted, rats will selectively increase dietary fat intake. Chronic morphine injection also leads to a selective increase in fat consumption by rats. Since it has been reported that endogenous opiods stimulate lipolysis, this suggests that the selective appetite for dietary fat in morphine-treated rats may be due to a morphine-stimulated loss of adipose stores. The present experiment was designed to determine the effects of chronic morphine injection on adipose tissue in rats.

Ninety-day-old Long Evans female rats (n=12) were divided into two groups. The first group received morphine sulfate (intraperitoneal 40 mg/kg) injections and the second group received equivolume injections of saline for 22 days. Both groups were given ad libitum access to standard Purina rat chow and water. Ovarian (OV) and retroperitoneal (RP) fat pad weights, fat cell numbers and lipoprotein lipase (LPL) levels were determined on the 23rd day.

	Morphine	Saline
BODY WEIGHT	237.2(8.1)	244.3(9.0)
FAT PAD WEIGHT (g)		
OV:	0.61(0.10)**	1.71(0.10)
RP:	0.27(0.03)**	0.73(0.04)
LPL (nmoles FFA/10^6cells/min)		
OV:	83.2(16.1)	82.0(18.5)
RP:	58.3(10.5)	51.6(9.0)

** =P <.05(t-test) mean(SEM)

Both fat pad weights were significantly decreased in the morphine treated rats compared to the controls, whereas LPL levels and body weights did not differ significantly.

This decrease in adipose tissue weight with no change in LPL levels in morphine treated rats, indicates that the reduced adiposity may not be due to decreased ability to store fat. It is possible that this decrease in adiposity is due to morphine induced stimulation of lipolysis. The lack of change in body weight with a concomitant decrease in adiposity with morphine injections, suggests a shift in caloric deposition from adipose tissue to lean body mass.

261.9 NEUROBEHAVIORAL RESPONSES OF INTACT AND CAUDATE NUCLEI LESIONED CATS DURING A CYCLE OF ADDICTION TO LOW DOSES OF MORPHINE. J.R. Villablanca, C.M. Harris, W. Burgess and I. De Andrés, Ment. Ret. Res. Ctr., Depts. Psychiatry & Anat., UCLA Sch. Med., LA, CA 90024

After 2 week baseline rectal temperature (RT) and body weight measurements, 5 intact and 5 cats with bilateral caudate nuclei lesions (acaudates) received a 12 day course of 3 mg/kg/day,i.p. morphine sulphate (MS), with 3 animals in each group continuing until 16 days. On day 12 and 16 respectively, the cats received 1.0 mg/kg i.v. naloxone (NX) 2½ hr after MS; NX alone was repeated 15-30 days after this first precipitated withdrawal. On days 1,5,11 and 15 and during NX days cats were placed in a one-way mirror, sound attenuated chamber for 2 hr prior and 5 hrs after MS (or 2 hrs after NX). Using a described video time-sampling procedure, the percentage time per sample and the per sample frequency of the following posture-movements were determined: walking, standing, sitting, crouching, lying down, discrete head and paw movements. Other items below were assessed from video samples or direct observations. RT was measured at the end of video sessions and 45 min after NX. Vomiting and weight were recorded daily. Intact cats showed little changes in above behaviors. Acaudates showed reduction of walking (26.5%) and increase in lying (67.1%) and head movements (16.2%), all non-significant, suggesting tolerance to activating effects. Sleep or drowsiness were not seen. There was tolerance to hyperthermia (intact p<.009, acaudates p<.02); vomiting was idiosyncratic to each cat and weight decreased (p<.01) during the withdrawal month for only acaudates. At the end of MS course all animals appeared slowed down, distressed, groomed poorly, vocalized plaintively and often salivated when handled but gross behavioral manifestations of caudate lesion (Exp. Neurol. 52: 389; 1978) were still present. After NX on the last day of MS, for about 10 min all cats appeared agitated (moving briskly, attempting to escape, backing, rearing, etc.) except for one acaudate (largest ablation) who stood immobile and developed pronounced catatonia; they showed panting, salivation, photosensitivity, urinated or sprayed, vocalized plaintively and some showed catatonic-like posturing for over 30 mins. For about 30 min, there were "wet-dog" body or head shakes. After 10-15 min cats calmed down, sat or crouched, but tachypnea continued for 60-100 min such that all cats slept only after that. Mydriasis and hyperthermia were blocked and, in a testing at 45 min, no signs of acaudate approaching syndrome were seen. Following the late NX injection, cats showed panting (N:2) or tachypnea (N:6) for about 20 min; most showed head shakes and fewer body shakes, vocalization, licking, mild activation and tail posturing. After saline injection, only sporadic vocalization and mild escape behavior were seen. In brief, the outstanding early and protracted withdrawal contrasted with mild signs of tolerance seen. (Grants DA-02518 & HD-04612).

261.10 LOW DOSES OF MORPHINE DEPRESS AFFECTIVE BEHAVIOR SCORES IN CATS. C.M. Harris and J.R. Villablanca. Mental Retardation Res. Ctr., Depts. Psychiatry and Anatomy, UCLA Sch. Med., LA, CA 90024

Feline affect has previously been studied with regard to reward and punishment related behavior. However, to detect drug-induced affective changes in cats not subjected to any strongly aversive or rewarding stimuli, we designed a test in which spontaneous and rater-elicited actions of freely roaming cats were observed. Nine mongrel adult male cats (3 intact, 6 brain-lesioned) were tested before, during and after a 16-day course of chronic morphine sulphate (MS), 3 mg/kg/day, ip. This dose is below that required for mania (see companion Abstract). The lesions included one cat with removal of one cerebral hemisphere, two with unilateral, and three with bilateral lesions of the caudate nucleus. The test battery included a checklist of 20 behaviors such as hiding and spontaneous approach, and a 7-item rating scale which indicated the rater's impression of states such as happy/sad and violent/gentle. Observations were made in a vivarium containing several racks of caged cats, a few dark niches and a large open-floor area. The rater refrained from interacting with the cat for 20 min while recording spontaneous activity. About 5 min were then devoted to interactions in which the rater called to the cat and engaged in petting and gentle play. If the cat did not approach when called, the rater spent about 5 min attempting actively to elicit purring and treading. The test battery was administered several times during the baseline periods, before and after chronic MS, and both before and 3 hrs after the injection on days 2, 7 and 14 of the treatment Paired comparisons between pre- and post-injection scores during the treatment and between pre- and post-treatment baseline scores were carried out with the Wilcoxon Signed Rank test. No striking differences were found among scores generated by five independent raters, two of whom were blind to the subjects' drug status Early in the course of treatment MS caused a significant lowering of test scores (p<.014, day 2), which suggests that affect was lowered by MS. This result is similar to the finding that, in humans, observer ratings indicate MS-induced mood-depression and decreased friendliness, although subjects report euphoria (Psychopharmacol. 75:124, 1981). Scores dropped each time the drug was administered and returned to pretreatment levels within 24 hrs. A comparison of change scores on days 2 and 14 indicated no tolerance to this effect, however tolerance may depend on surgical status, as the intact cats appeared to become more sensitive while the lesioned cats became less sensitive to the drug effect. A comparison of pre-treatment and post-withdrawal baseline scores indicated that no permanent change resulted from chronic treatment. (Supported by USPHS Grants DA-02518 and HD-04612).

261.11 SLEEP-WAKEFULNESS EFFECT OF SINGLE DOSES OF MORPHINE IN CATS. I. de Andrés and J. R. Villablanca, Dept. Morfología, Fac. Medicina, Univ. Autónoma, Madrid, Spain. Mental Retardation Research Ctr., Depts. Psychiatry and Anat. UCLA Sch. of Med. L.A., CA 90024

This report is a part of a continuing study of the neurobehavioral actions of low doses of morphine in intact and brain lesioned cats (Brain Res., 248: 159; 1982). Seven adult cats were implanted with neocortical and pontine, orbital and neck muscles standard electrodes to record EEG, EOG and EMG respectively. After recovering for 15 days or longer, four animals received i. p. injections of morphine sulfate at the dose of .5, 1.0 and 2.0 mg/kg. Each dose was administered only once per animal and the interval between injections was at least 15 days. The other 3 animals received a single injection of 3.0 mg/kg. All cats were continously recorded in a sound-attenuated chamber with one-way mirror for 1 hr. before and 72 hr. after morphine administration. The records were scored according to stablished poligraphic features defining wakefulness (W), drowsiness (D), NREM and REM sleep (S). Saline vehicle injections using each cat as its own control, were used for comparisons (Wilcoxon test) of the hourly values for the four S-W states during each daily cycle.

After morphine, both NREMs and REMs were suppressed for a time period which correlated with dose: NREMs, range=6-15 hr., r=0.63 $p<0.05$, REMs, range=9-25 hr., r=0.84, $p<0.01$. Thereafter, NREMs increased significantly starting by the 6th to 15th post-morphine hr. of the first day. REMs levels were restored but not rebound was seen. NREMs rebound continued through the second day, REMS values were non-significantly difference from controls, and W together with D remained significantly reduced (except for D at .5 mg/kg). Third day values for all stages were equivalent to controls, except for NREMs which, at the 3.0 mg/kg dose, stayed significantly increased for the first 6-7 hr. of that day.

In summary, there was a dose-dependent suppression of sleep with a protracted rebound for NREMs but not for REMs. In the context of our previous results in diencephalic and caudate nucleus lesioned cats, an interaction between brain stem and forebrain processed is proposed to understand S-W, and some behavioral effects of acute morphine administration in the cat (Supported by FISSS, Spain, Grant 51881 and USPHS Grants DA-02518 and HD-04612).

261.12 MORPHINE AND NALOXONE: EFFECTS ON THE DETECTION OF NON-REWARDING BRAIN STIMULATION. J.E.G. Williams*, K.R. Green*, H.S. Wheeling* and C. Kornetsky (SPON: D. Sax). Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118

Previous experiments in our laboratory demonstrated that morphine raises (Marcus, R. and Kornetsky, C. Psychopharmacology, 38: 1-13, 1974) while naloxone lowers (Sasson, S. and Kornetsky, C. Pharmacol. Biochem. and Behav., 18:231-233, 1983) the threshold for aversive electrical stimulation to the mesencephalic reticular formation. In order to determine whether or not these threshold changes are due to actions on a pain system rather than alterations in attentional or perceptual behavior, the effects of both morphine and naloxone on the detection of non-aversive stimulation to this same midbrain site were determined. The threshold level of stimulation for detection as employed in this procedure is by itself neither positively nor negatively reinforcing; however, this level of stimulation can be used as a discriminative stimulus in a simple instrumental task.

Male albino rats (CDF - Charles River Laboratories) were stereotaxically implanted with bipolar stainless steel electrodes aimed at the mesencephalic reticular formation (MRF) and the medial forebrain bundle - lateral hypothalamic area (MFB-LH). Following surgery, the animals were trained to make an instrumental response, a quarter turn of a wheel manipulandum, to a 0.5 sec MRF stimulation cue (S1). Responding to the cue within 7.5 sec was maintained by the delivery of a reinforcing contingent stimulus (S2) to the MFB-LH area. Absolute detection thresholds were determined by varying the current intensity of the brain stimulation cue (S1) according to a modification of the psychophysical method of constant stimuli. The contingent stimulus (S2) remained at a fixed highly rewarding intensity level. Preliminary results indicate that neither morphine (4.0-12.0 mg/kg) nor naloxone (4.0-16.0 mg/kg) will alter the detection threshold at doses that significantly raise or lower, respectively, the escape threshold for aversive stimulation to the MRF. These results suggest that these previously reported effects are not due to actions on attentional or perceptual systems but are due to direct effects on a pain system.

261.13 MORPHINE AND d-AMPHETAMINE: EFFECTS ON BRAIN-STIMULATION REWARD. C.B. Hubner*, G.T. Bain* and C. Kornetsky (SPON: R. Feldman). Laboratory of Behavioral Pharmacology, Boston University School of Medicine, Boston, MA 02118.

d-Amphetamine is often self administered with opiates in order to maximize its euphorigenic effects. Also, it has been shown that d-amphetamine potentiates the analgesic efficacy of morphine in man (Forrest, W.H., et al., New Engl. J. Med., 296(13):712-715, 1977) and the rat (Sasson, S., et al., Abstracts Society Neurosciences, 1983). Increased sensitivity for rewarding brain stimulation has been used as an animal model for drug-induced euphoria and is thought to be predictive of abuse liability. Individually, morphine and d-amphetamine at appropriate doses have been shown to significantly lower brain-stimulation reward thresholds (Marcus, R. and Kornetsky, C., Psychopharmacologia, 38: 1-13, 1974; Esposito, R.U., et al., Psychopharmacology, 69:187-191, 1980). In the present study doses of morphine and d-amphetamine which by themselves caused non-significant or just significant changes in threshold were tested together. Given the street use of d-amphetamine in combination with opiate drugs it would be expected that the results would reveal a synergistic action.

Male albino rats (CDF - Charles River Laboratories) were stereotaxically implanted with bipolar stainless steel electrodes aimed at the medial forebrain bundle. Determination of the brain-stimulation reward thresholds was accomplished by using a variation of the psychophysical method of limits. Various doses of morphine (0.125-4.0 mg/kg sc) and d-amphetamine (0.03-0.5 mg/kg ip) were tested separately in each animal. Ineffective or minimally effective doses of both morphine and d-amphetamine were then selected for each animal and tested in combination. The results indicate that minimally effective doses of morphine when combined with ineffective doses of d-amphetamine caused a lowering of the reward threshold far in excess of what has been observed by either drug at any dose. This synergistic effect is congruent with the reported effects of street use of the combination and probably contributes to the reported potentiation of the analgesic effect of morphine by d-amphetamine.

(Supported in part by NIDA grant DA 02326).

261.PO SUDDEN DEATH, ACUTE AND CHRONIC EXTRAPYRAMIDAL SYNDROMES INCLUDING TARDIVE DYSKINESIA AND SELF-MUTILATION INDUCED BY FLUPHENAZINE AND HALOPERIDOL IN MONKEYS. E.F. Domino, Dept. of Pharmacology, Univ. of Mich., Ann Arbor 48109 and Lafayette Clinic, Detroit, MI 48207.

For a number of years our laboratory has been studying various species of monkeys given fluphenazine and/or haloperidol in an attempt to develop a subhuman primate model of tardive dyskinesia. It has been possible to induce a syndrome of tardive dyskinesia in Cebus apella which we have reported previously (Kovacic and Domino, 1982, 1983). In the process of studying Macaca speciosa, several other syndromes were observed which are the subject of this report. A total of 8 adult animals, 3 males and 5 females, were studied. All of the animals were in excellent physical and neurological condition prior to neuroleptic treatment. Thus, any brain damage that might have been sustained because of their previous research history was minimal, if any. Each animal was given first 25 mg of fluphenazine decanoate and later the enanthate (3.2 mg/kg) i.m. every two weeks and 5 days a week haloperidol first i.m. and later orally. Haloperidol was given first in doses of 1.0 mg/kg and after several years of therapy reached 6.4 mg/kg/day. All of the animals developed severe bradykinesia and related acute extrapyramidal side effects. Gradually, over a period of months to years, these effects diminished so that larger doses of haloperidol were tolerated. Animals who survived gained weight. Three of the monkeys (Fifi, Pete and Sam) completed 3 to 5 years of uninterrupted neuroleptic treatment. Three (Babe, Bette and Brandy) died suddenly after 1 to 3 weeks of neuroleptic treatment. Two (Ben and Carol) developed self-mutilation syndromes after several months of neuroleptic therapy. These syndromes were so destructive (eating off fingers, chewing on testicles, chewing on the arms sufficient to expose bone, etc.) that neuroleptic treatment was discontinued for humane reasons. The three animals which completed several years of uninterrupted neuroleptic treatment never showed any tardive dyskinesia while on this medication. When neuroleptic treatment was stopped abruptly, there was an increase in alertness and loss of the bradykinesia and tremor. Within one month, two of the three monkeys showed an increase in mouthing and chewing movements which disappeared in Fifi in about two weeks. On the other hand, Sam developed marked mouthing and chewing movements, marked akathisia of the hands and feet which peaked in about 3 months and gradually diminished over a period of about one year after neuroleptic withdrawal. It is concluded that neuroleptics can induce in Macaca speciosa syndromes very similar to those described in man in addition to a self-mutilation syndrome which is clearly drug induced. Although Macaca speciosa in captivity are known to self-mutilate without any drugs, chronic neuroleptic medication dramatically enhances such behavior in some animals.

262.1 MORPHOLOGY OF PHYSIOLOGICALLY IDENTIFIED GANGLION CELLS IN THE CAT RETINA. L.R. Stanford and S.M. Sherman. Dept. of Neurobiology & Behavior, SUNY at Stony Brook, NY 11794.

Response properties of single cat retinal ganglion cells recorded in vivo via a transcleral approach have allowed us to classify these neurons as W-, X-, or Y-cells based on a battery of physiological tests. These tests included response latency to antidromic stimulation of the optic chiasm and tract, linearity of spatial and temporal summation, size and position of receptive field, type of receptive field (ON or OFF center/surround, direction selective, etc.), briskness of response, sustained or transient center response, and response to fast-moving (>200°/sec) targets. After electrophysiological testing and classification, the ganglion cells were impaled, re-classified, and iontophoretically injected with HRP. Following perfusion, the dissected retina was flat-mounted and reacted using the cobalt-intensified DAB protocol to demonstrate the HRP reaction product. This provided a Golgi-like filling of the soma, dendrites, and axon of each cell. To date, 15 ganglion cells have been successfully injected and recovered. These include 2 Y-cells, 7 X-cells, and 6 W-cells. Based on the morphological criteria of earlier Golgi studies, the 2 recovered Y-cells have been identified as alpha cells, having thick axons, large somata, and large dendritic fields. Of the 7 X-cells recovered, all but 1 had soma sizes and dendritic architecture previously ascribed to the beta cell class. The other X-cell had a soma size within the beta cell range but had dendrites that were similar to those previously described for gamma cells. All of our X-cells had medium-sized axons. Our injected W-cells showed the most variability in both soma size and dendritic architecture. These cells had thin axons and included some neurons with soma sizes within the previously described gamma cell range but others with somata within the size range of beta cells. All of our recovered W-cells had thinner dendrites and sparser dendritic fields than did our recovered X-cells. However, when compared with X-cells, the W-cell dendritic fields were more variable in size, and their soma positions were often eccentrically placed within the dendritic fields. Our results thus far support and extend the general structure/function correlations proposed by Wassle and colleagues.

262.2 IDENTIFICATION OF CELL TYPES IN RAT RETINA USING MONOCLONAL ANTIBODIES. C.J. Barnstable, K. Akagawa* and R. Hofstein.* Department of Neurobiology, Harvard Medical School, Boston MA and The Rockefeller University, 1230 York Avenue, New York.

We can label each major subclass of rat retinal cells by monoclonal antibodies raised against neuronal tissues.

Rod photoreceptors can be labelled with the previously described antibodies RET-P1, RET-P2 and RET-P3 as well as monoclonal antibodies raised against purified bovine rhodopsin such as antibody RHO-C7 (a gift from M. Applebury).

We have cloned two antibodies, RET-B1 and RET-B2, that label primarily bipolar cells. From the number of cells labelled and their terminal patterns in the inner plexiform layer it is likely that these antibodies are reacting with both ON and OFF bipolars. These antibodies also label the inner segments only of photoreceptors and a few cells at the inner edge of the inner nuclear layer.

Ganglion cells are the only cells in retina to express the cell surface antigen Thy-1. They can also be labelled with antibodies against neurofilaments.

A-type horizontal cells are the only other major cell class to be labelled with neurofilament antibodies. In addition these cells can be labelled with some antibodies that react with cytoplasmic antigens of glial cells -- making them unusual in expressing both glial and neuronal cell markers.

HPC-1, an antibody raised against rat hippocampus, selectively labels the amacrine cell layer and a few cell bodies in the ganglion cell layers. From double-labelling experiments with neurofilament antisera, the cells in the ganglion cell layer seem to be displaced amacrine cells.

The major glial cells in retina, Muller cells, can be labelled by a variety of membrane antibodies, RET-G1 - G6, most of which are not found elsewhere in the CNS. In addition we have produced a number of antibodies against intermediate filament proteins selective for Muller cells (and A-type horizontal cells).

One antibody, produced by in vitro immunisation of naive spleen cells, has been found that in retina is selective for the astrocytes of the optic nerve fibre layer.

These and other antibodies have been used to examine the postnatal development of the rat retina in terms of the expression of the individual cell-type specific antigens.

262.3 PUTATIVE SYNAPTIC CYTOSKELETAL COMPONENTS IN RETINA. S. D. Flanagan and B. Yost*. Division of Neurosciences, City of Hope Research Institute, Duarte, CA 91010.

Insolubility in non-denaturing detergents is an excellent operational means for the initial identification of cellular cytoskeletal components. When the cerebral membranes are subjected to the action of the bile detergent deoxycholate (DOC), two proteins, which have previously been identified as possible molecular components of postsynaptic densities (PSDs), are the predominant Coomassie blue staining species observed upon SDS-PAGE of the DOC-insoluble fraction (Flanagan, S.D. et al., J. Cell Biol., 94:743, 1982). One of the proteins, tubulin, has been localized to the PSD by immunocytochemical localization techniques, but is also a ubiquitous component of nonsynaptic microtubular structures. The second is a 51,000 M_r calmodulin binding protein, which has been co-purified in subcellular fractions enriched in PSDs.

The retina contains synapses that are morphologically homologous to those observed in the cerebrum as well as structures apparently unique to the inter- and outer-plexiform layers, e.g., ribbon synapses. If the DOC-insoluble fraction indeed reflects authentic synaptic cytoskeletal components, then apparent morphological differences in synaptic structures may be reflected in cerebral versus retinal DOC-insoluble fractions. Although the yields of DOC-insoluble protein from bovine retina and rat cerebral membranes were comparable (5.2% from bovine retina and 6.7% of the total membrane protein from rat cerebrum), there were several apparent differences in their protein compositions. The 51,000 M_r region on SDS-PAGE gels constituted only 2% of the retinal DOC-insoluble fraction based upon staining by Coomassie blue, as compared with 16% for cerebrum. The 51,000 M_r cerebral protein, a prominent calmodulin binding protein, may be visualized by overlay of SDS-PAGE gels with ^{125}I-calmodulin and subsequent autoradiography. In order to quantify the low levels of this protein in retina, we improved techniques for detection of calmodulin binding proteins, allowing the quantification of as little as 15 ng of the cerebral 51,000 M_r DOC-insoluble protein. This technique revealed a detectable level of 51,000 M_r calmodulin binding protein in both crude and DOC-insoluble fractions from retina, but at levels 30 to 35-fold lower than the comparable cerebral fractions. Other differences in the DOC-insoluble fractions from retina and cerebrum were the higher intensity of two proteins of 32,000 M_r and 43,000 M_r (actin or a closely related protein) in fractions from retina when compared with cerebrum.

262.4 STARBURST AMACRINE CELLS: INTERNUNCIAL CHOLINERGIC NEURONS SELECTIVE for ON and OFF PATHWAYS TO RETINAL GANGLION CELLS. E. V. Famiglietti, Jr. Dept. of Anatomy, Wayne State Univ. Sch. of Med., Detroit, MI 48201.

Starburst amacrine cells in rabbit retina have been demonstrated to have the salient morphological features of cholinergic retinal neurons which have been demonstrated autoradiographically by Masland and Mills ('79). Type a starburst amacrine cells have cell bodies in the amacrine cell layer and narrow dendritic stratification in sublamina a of the inner plexiform layer (IPL), while type b cells have cell bodies in the ganglion cell layer and stratification in the middle of sublamina b of the IPL (Famiglietti, '83).

By electron microscopy of serially sectioned, Golgi-impregnated cells, type a (OFF) and type b (ON) starburst amacrine cells are shown to have qualitatively the same synaptic connections: input from cone bipolar cells and from amacrine cells, and output exclusively to dendrites of ganglion cells.

Apart from mirror-symmetrical distribution, morphological differences between type a and type b starburst amacrine cells are slight. Asymmetry exists, however, in the synaptic input from bipolar and amacrine cells. In particular, type a starburst amacrine cells have more amacrine input than type b cells. Since a heavily labelled band of GAD (glutamic acid decarboxylase) positive synaptic terminals coincides with the substratum of type a starburst amacrine cells, but no corresponding heavily labelled band overlaps the substratum of type b starburst amacrine cells (cf. Brandon et. al., '81; Famiglietti and Vaughn, unpubl.), it is likely that a significant fraction of the input to starburst amacrine cells is GABAergic. Studies are underway to confirm this proposal, and to identify the morphological and functional types of ganglion cells which are postsynaptic to starburst amacrine cells.

(Supported by NIH grant no. EY 03547)

262.5 THE SHAPE OF THE CHOLINERGIC AMACRINE CELLS IN THE RABBIT RETINA: IDENTIFICATION BY INJECTING FIXED, FLUORESCENT NEURONS. Masaki Tauchi* and Richard Masland, Harvard Medical School, Boston MA.

A difficulty in studying the inner retina is the heterogeneity of the amacrine and ganglion cell populations. Depending on the method of classification, most mammalian retinas probably contain 10-20 morphologically and functionally distinct types of each. Because the density of each subtype is relatively low, a micropipette advanced through the retina encounters few examples of any given neuronal type. Moreover, the amacrine cells are quite small (8-14 um), so that only a direct hit with the micropipette is likely to yield successful penetration of the neuron.

We have been studying an amacrine cell, present in the rabbit retina, that synthesizes and releases acetylcholine. These neurons have been identified by autoradiography (Masland and Mills, 1979). Their shape is partly revealed by neurofibrillar staining (Vaney et al., 1981) and has been inferred by comparison of Golgi-stained cells with the distribution of acetylcholine revealed autoradiographically (Famiglietti, 1983). In an attempt to more definitively learn their shape, a method in which they are selectively injected with marker compounds after staining of their nuclei with a fluorescent dye has been developed.

The dye 4,6, diamidino-2-phenylindole (0.5 ug in H_2O) was injected intravitreally. Two days later the retina was removed, fixed for 15 minutes in 4% paraformaldehyde, and mounted flat. For unknown reasons, the blue fluorescent dye is selectively accumulated by the cholinergic amacrine cells (Masland, 1983). In a fluorescence microscope, the use of pipettes filled with lucifer yellow CH or a mixture of lucifer and horseradish peroxidase then allows penetration of the labeled neurons under visual control. Fixation of the retina does not destroy the integrity of the neuronal membranes, so that lucifer injected into a cell fills its processes. Neurons of retinas stored at 4^0 in 0.1M phosphate buffer could be filled successfully 1 month after fixation.

Eighty dye-labeled amacrine cells of the ganglion cell layer were successfully injected, at a variety of retinal locations. They were found to form a single morphological class, with unistratified dendritic arborization in a flat plane. They have very thin dendrites containing, in their distal third, abundant varicosities. A mirror-symmetric population of cells was identied in the inner nuclear layer. These neurons appear identical to the "starburst" amacrines seen in Golgi material, and to the matching populations identified by neurofibrillar staining.

Lucifer injection into fixed cells has been used here exclusively as an anatomical method. Because fluorescent dyes that stain living retinal neurons are available, the method can perhaps be employed for physiological studies as well.

262.6 D-ASPARTATE POTENTIATES THE EFFECTS OF BOTH L-ASPARTATE AND L-GLUTAMATE ON HORIZONTAL CELLS IN CARP RETINA. M. Ariel* and S. C. Mangel* (SPON: P. H. Hartline). The Biological Laboratories, Harvard University, Cambridge, MA 02138

It has recently been reported that D-aspartate potentiates the effect of L-glutamate on retinal horizontal cells by 15 times (Ishida and Fain, 1981). It was suggested that D-aspartate exerts this effect by saturating the high affinity uptake mechanisms for acidic amino acids known to be present in the retina. We have further examined the effects of D-aspartate and find that this drug enhances the effectiveness of both L-glutamate and L-aspartate upon carp horizontal cells.

D-aspartate, L-aspartate and L-glutamate were applied to the isolated carp retina by superfusion or by atomization. Upon the addition of D-aspartate (3 mM) to the superfusate, H1 horizontal cells were transiently depolarized by 5-15 mV. Subsequently, the responses of both L-aspartate and L-glutamate were potentiated. Additional applications of D-aspartate led to larger transient depolarizations with longer times required for membrane potential recovery. Application by atomizer of D-aspartate (25 mM in the atomizer) had little or no effect on the membrane potential or light response. However, the effects of both L-aspartate and L-glutamate were again greatly enhanced immediately following D-aspartate application. The increase in effectiveness of both these amino acids was observed in the atomization experiments in L-type and C-type cone horizontal cells, in dark-adapted and light-adapted retinas, and in Co^{++} treated retinas in which synaptic activity was blocked. Furthermore, in these experiments, L-aspartate and L-glutamate effects returned to normal within a few minutes. Since L-aspartate and L-glutamate are taken up by the same high affinity uptake mechanism (Marc and Lam, 1981; Drejer et al., 1983) our results are consistent with the idea that D-aspartate exerts its sensitizing effects principally by blocking amino acid uptake in the retina. The potent uptake system for acidic amino acids in the retina may be responsible for the 25-200 fold difference in L-glutamate sensitivity of horizontal cells in the intact retina, as compared to isolated horizontal cells (Mangel et al., 1983).

262.7 THE EFFECT OF 2-AMINO-5-PHOSPHONOVALERATE ON RESPONSES OF MUDPUPPY RETINAL GANGLION CELLS. P.D. Lukasiewicz* and J.S. McReynolds, Department of Physiology, The University of Michigan, Ann Arbor, MI 48109.

Responses to aspartate, glutamate and related amino acids may be mediated by pharmacologically different receptor sites, which have been classified as quisqualate (QA), kainate (KA) and N-methyl-D-aspartate (NMA) based on the relative sensitivity to these three aspartate/glutamate analogues.

We tested the relative effects of QA, KA and NMA on mudpuppy ganglion cells. All three substances caused depolarization and increased conductance. In all ganglion cells (ON-center, OFF- center and ON-OFF) the order of potency of the analogues was QA $\geq$ KA $>$ NMA. The specific NMA receptor antagonist 2-amino-5-phosphonovalerate (APV) blocked the light-evoked sustained excitatory and inhibitory responses of ganglion cells. Transient inhibitory responses at on and off were never blocked by APV. The transient EPSPs at on and off were greatly reduced in some ON-OFF ganglion cells but not in others. Furthermore, in some ON-center ganglion cells blocking the sustained depolarizing response revealed APV-resistant transient EPSPs at on and off. The responses of bipolar cells were not blocked by APV.

Thus, the sustained light-evoked responses and a subclass of excitatory transient responses in ganglion cells appear to involve NMA receptors. Whether the APV-sensitive receptors are located on amacrine, ganglion or both cell types is not yet known. The APV-resistant excitatory responses in ganglion cells may involve QA or KA receptors or transmitters other than amino acids. Additional work will be necessary to distinguish between several possible wiring schemes which are consistent with these results.

The sensitivity of ganglion cells to NMA, but not to QA or KA, was greatly reduced when transmission was blocked by 4 mM cobalt. This suggests that the NMA receptors, and hence the sites of APV sensitivity, are on cells which are presynaptic to ganglion cells and postsynaptic to bipolar cells, i.e., amacrine cells. However, we have not yet encountered cells of any type which responded well to NMA in the presence of cobalt. Alternatively, it is possible that ganglion cells do have NMA receptors which are directly blocked by a postsynaptic action of cobalt (Ault et al, J. Physiol. 307: 413-428, 1981).

Supported by NIH Research Grant EY 01653.

262.8 RETINAL AND HYPOTHALAMIC DOPAMINE BIOSYNTHESIS IN VITRO: EFFECT OF HYPERPROLACTINEMIA AND HYPOPHYSECTOMY. D.K. Sundberg*, B.A. Bennett* and W.K. O'Steen (SPON: D.J. Goode). Depts. of Physiol. & Pharmacol. and Anatomy, Bowman Gray Sch. Med., Winston-Salem, NC 27103.

Previous reports have demonstrated that prolactin augments light induced photoreceptor damage in the hypophysectomized rat. Prolactin also stimulates tuberoinfundibular dopaminergic (DA) activity. Since the retina possesses an active DA system, one might postulate the existence of a prolactin-amacrine-dopamine photoreceptor interaction. To investigate this hypothesis we examined the effect of 1) anterior pituitary autotransplant induced hyperprolactinemia and 2) hypophysectomy on the in vitro biosynthesis of retinal and hypothalamic DA. Male rats were made hyperprolactinemic by transplantation of pituitaries under each kidney capsule. Hypophysectomized rats were purchased from a commercial vendor. At sacrifice the retinas and medial basal hypothalamus (MBH) were removed and incubated in a balanced salt solution containing 5 μCi of 3H 2-6, tyrosine (30 Ci/mM). After incubation the tissue homogenates were extracted with alumina. DA was separated by reverse phase chromatography and measured by amperometric detection. Newly synthesized DA was determined by scintillation counting. Prolactin levels were increased by autotransplants coincident with an elevation of MBH DA synthesis. However, retinal DA biosynthesis was not affected by this manipulation. Hypophysectomy which alters the entire endocrine system stimulated both retinal and hypothalamic DA biosynthesis (see table).

	Retina (R)		MBH	
	DA ng/R	DA dpm/ng	DA pg/mg	DA dpm/ng
Control	3.9 ± 1.4	181 ± 18	877 ± 65	86 ± 16
Hyperprol.	4.5 ± 0.9	186 ± 22 NS	682 ± 11	179 ± 25*
Control	2.3 ± 0.3	662 ± 43	331 ± 33	97 ± 27
Hypox.	1.8 ± 0.3	946 ± 80*	270 ± 30	217 ± 7*

* = $p < 0.05$

These results suggest that the amacrine DA system is not involved in the augmentation of photoreceptor damage by prolactin.

(Supported by NIH grants HD 10900 to DKS and EY 02359 to WKO)

262.9 DO MAJOR PHYSIOLOGICAL RETINAL GANGLION CELL CLASSES HAVE DISTINCT MORPHOLOGIES? F.R. Amthor, C.W. Oyster and E.S. Takahashi. School of Optometry, Univ. of Alabama in Birmingham, Birmingham, AL 35294.

The rabbit retina has at least six major ganglion cell classes with complex response properties. These include two distinct direction-selective (DS) cell types, orientation selective cells, local edge detectors, large field units, and uniformity detectors. In addition, a number of concentric cell class subdivisions have been described. Anatomical classifications with as many as 23 distinct morphologies (cat retina: Kolb et al., Vis. Res. 21, 1981) implicitly suggest that major morphological differences should have some functional significance. The converse hypothesis is that cell classes with important physiological differences should have distinct morphologies.

To test this hypothesis, we have used intracellular recording and staining. Although our sample is still somewhat small, we have recovered ganglion cells representing many of the major physiological classes. The uniqueness hypothesis, and several other structure/function conjectures remain tenable. Specifically, 1) When the excitatory receptive field center response is On, Off, or On-Off, the corresponding ramification of the ganglion cell dendrites is in the inner IPL, outer IPL, or both, respectively. 2) Two types of On-Off responding cells (local edge detectors and On-Off DS cells) are distinguishable in both flat mount morphological characteristics and in IPL stratification pattern, although both cell types have dendrites in both the inner and outer IPL. Interestingly, although On-Off DS cells are distinguishable as a class from other morphologies, the preferred direction is not obviously apparent from their global dendritic tree structure. On-type DS cells, in contrast, are unistratified and have a less complex flat mount dendritic tree structure. 3) Present data suggest that uniformity detectors have a complex regional multistratification pattern with radially asymmetric locations of dendritic specializations.

Although the concentric cells recovered so far appear to be distinguishable as a group from the complex types, insufficient data has been obtained to argue for a unique morphology for each subclass. It is apparent, however, that at least three distinguishable morphologies underlie different concentric cell types. In contrast with other areas of the visual system, optical geometrical constraints and local circuit interactions may require that specific ganglion response properties be dependent on particular morphological structures.

262.10 CO-LOCALIZATION OF (^{3}H)-GLYCINE UPTAKE AND NEUROTENSIN-LIKE IMMUNOREACTIVITY IN SUSTAINED AMACRINE CELLS OF THE TURTLE RETINA. R. Weiler*, A.K. Ball* and W.K. Stell. Dept. of Anatomy and Lions' Sight Centre, University of Calgary, Calgary, Alberta, Canada. T2N 4N1

The eye of the turtle, Pseudemys scripta, was injected with (^{3}H)-GABA and (^{3}H)-glycine in order to identify amacrine cells which have a high affinity uptake system for these amino acids, and may use them as neurotransmitters. These retinas were then treated with antibodies against different neuropeptides using the Peroxidase-Antiperoxidase (PAP) technique to reveal immunoreactivity prior to autoradiographic localization of (^{3}H)-GABA and (^{3}H)-glycine.

(^{3}H)-glycine is accumulated by many cells whose somata are located in the amacrine cell layer. A small proportion of these cells also are neurotensin-immunoreactive. These doubly labeled cells have a small cell body and fine processes that spread diffusely throughout the inner plexiform layer (IPL). Neurotensin-immunoreactive cells of a second type, which do not accumulate (^{3}H)-glycine, have large cell bodies and one major neurite that projects to the mid-IPL where it forms a monostratified arborization. Neurotensin-immunoreactive cells that take up (^{3}H)-GABA were not observed.

In parallel experiments we attempted to learn the function of these cells by means of intracellular recording followed by injection of Procion Yellow or horseradish peroxidase. The marker-injected cells that most closely resemble the cells doubly labeled by neurotensin-immunoreactivity and (^{3}H)-glycine uptake respond to light with a sustained depolarization of their membrane potential.

262.11 ^{3}H-GABA RELEASE FROM MÜLLER (GLIAL) CELLS IN THE RAT RETINA. P. V. Sarthy. Dept. of Ophthalmology, Univ. of Wash., Seattle, WA 98195.

In several neural systems, glial cells appear to take up and release GABA upon depolarization. We have studied the release of ^{3}H-GABA from Müller (glial) cells in the rat retina by a double isotope-labeling procedure in which Müller cells are preloaded with ^{3}H-GABA while a population of neurons are prelabeled with ^{14}C-glycine. By autoradiography, we have confirmed that ^{3}H-GABA is taken up by the radially-oriented Müller cells while ^{3}H-glycine is accumulated by a subset of amacrine cells (neurons) in the rat retina. Using the double-labeling procedure, we have examined the effects of two depolarizing agents, high [K^+] and veratridine, and the GABA mimetic, ethylenediamine, on transmitter release from glial cells and neurons simultaneously. We found that (1) depolarization with 56 mM [K^+] released both ^{3}H-GABA and ^{14}C-glycine. About 70-80% of this release was blocked in Ca^{2+}-free medium; (2) 10 µM veratridine also released both the transmitters. This release was inhibited by 100 mM Tetradotoxin or 1 mM Procaine. Under Ca^{2+}-free conditions, < 20% isotope release was observed; (3) ethylenediamine (EDA) released ^{3}H-GABA readily while little ^{14}C-glycine release was observed. Removal of Ca^{2+} had no significant effect on the release of either transmitter. Further, in Na^+-free medium EDA failed to induce ^{3}H-GABA or ^{14}C-glycine release. These results suggest that high [K^+] and veratridine release ^{3}H-GABA from Müller cells by a Ca^{2+}-dependent vesicular process. Ethylenediamine, on the other hand, appears to induce ^{3}H-GABA release by a Ca^{2+}-independent, carrier-mediated exchange mechanism.

263.1 A NEURITE-PROMOTING ACTIVITY PRESENT IN HEART CELL CM ENHANCES THE NGF-INDUCED CONVERSION OF CHROMAFFIN CELLS TO NEURONS. A.J. Doupe and P.H. Patterson, Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

A variety of conditioned media (CM) contain factors which bind to substrates and markedly enhance neurite outgrowth of peripheral neurons in vitro. One such activity, from PC12 cell CM, is associated with a heparan-sulfate proteoglycan fraction (HeS)(Matthew et al., Soc. Neurosci. Abst. 8:83.4, 1982). Initial neurite outgrowth of sympathetic neurons on this HeS is independent of nerve growth factor (NGF), although NGF is required for long-term survival of these cells in vitro.

Adrenal chromaffin cells, like sympathetic neurons, are neural crest-derived, but do not have neurites and do not require NGF for survival. However, ~20% of newborn rat adrenal chromaffin cells respond to NGF administration in vitro by growing neurites and eventually becoming indistinguishable from mature sympathetic neurons (Doupe et al., Soc. Neurosci. Abst. 8:70,5, 1982). When we culture newborn chromaffin cells in the presence of NGF on a surface coated with serum-free rat heart cell CM, the percentage of cells that become neurons is greatly increased, as is the rate of conversion. Thus CM contains a factor which enhances the NGF-induced transformation. Administration of CM in the absence of added NGF also elicits a small amount of process outgrowth from chromaffin cells, although the cells do not progress to the completely differentiated neuronal phenotype. The conversion-enhancing activity appears to be similar to the neurite-promoting activity from PC12 cell CM. A monoclonal antibody (4H8) to the latter preparation, known to block directly the activity of PC12 cell CM on neurons (Matthew & Patterson, this vol.), also completely blocks the enhancement of chromaffin cell conversion to neurons when adsorbed onto the heart CM-treated surface.

Unlike cells from newborn medullae, few adult rat chromaffin cells grow processes in response to NGF. However, addition of heart cell CM markedly increases the number of cells that respond. Corticosteroid normally blocks the effect of NGF on chromaffin cells (Unsicker et al., PNAS 75:3498, 1978). In the presence of CM, on the other hand, dexamethasone is completely ineffective in blocking the neurite outgrowth. Our results suggest that, in addition to soluble environmental signals such as NGF and corticosteroids, extracellular matrix molecules like the HeS-associated activity described here also have important effects on developmental decisions in the sympatho-adrenal lineage.

263.2 EXPRESSION OF SOMATOSTATIN IMMUNOREACTIVITY IN NEURAL CREST CULTURES G.D. Maxwell, P.D. Sietz*, and S. Jean* Dept. of Anatomy, Univ. of Connecticut Health Center, Farmington, CT 06032

We are studying the development of neuronal properties by neural crest cells in tissue culture. Previous work has shown that some cells in neural crest cultures acquire the capacity to synthesize and store catecholamines and to take up [^{3}H]norepinephrine and release it in response to depolarization. We report here that a subpopulation of cells in neural crest cultures develop the capacity to express somatostatin-like immunoreactivity (SLI) after several days in vitro. Some cells in these cultures contain both catecholamines and SLI.

Neural crest cultures from the trunk region of quail embryos were prepared as described previously (Maxwell et al., 1982 J. Neurosci. 2:879-888). Growth medium contained 15% horse serum, 10% chick embryo extract, and 5 ng/ml 2.5S NGF. Using immunocytochemistry, cells with SLI are not detected prior to 5 days in vitro. At 5 days in vitro a few cells with faint immunoreactivity are observed. By 6 days in vitro the number of SLI positive cells has increased by an order of magnitude and the intensity of the immunoreactivity has increased markedly. At 9 days in vitro SLI positive cells constituted about 0.1% of the total cell population. The number of cells with SLI increased approximately linearly until 10 days in vitro (the latest time examined). The immunoreactivity is present in the cytoplasm and absent from the nucleus. SLI containing cells with and without processes are observed. The SLI positive cells are often clustered near one another.

Experiments which first detected catecholamine-containing cells histochemically followed by immunocytochemistry for SLI showed that some cells which contain catecholamines also contain SLI. Cells containing both traits were observed as early as 7 days in vitro and as late as 14 days in vitro (the earliest and latest times examined). On the average about 20% of catecholamine-positive cells were also positive for SLI. In these cultures treated to reveal catecholamines and SLI, the number of SLI positive cells was comparable to that seen in cultures processed for SLI alone.

These findings demonstrate that the expression of SLI by some neural crest cells can occur in vitro in the absence of their normal cellular environment. In addition, in some cases the same cells contain both catecholamines and SLI.

263.3 ADRENERGIC DIFFERENTIATION OF NEURAL CREST CELLS MAY BE DEPENDENT UPON A NEURAL TUBE DERIVED FACTOR. Marthe J. Howard* and M. Bronner-Fraser (SPON: M. Cahalan). Department of Physiology and Biophysics, University of California, Irvine, CA 92717.

Neural crest cells give rise to numerous derivatives including melanocytes, adrenergic and cholinergic neurons, and supportive cells of the nervous system. We have previously shown (Howard, et al. Soc. Neurosci. 8(1): 257, 1982) that cultured neural crest cells will differentiate into adrenergic neuroblasts or pigment cells when grown in medium containing 10% embryo extract. This effect was demonstrated for neural crest cells grown with or without the presence of the neural tube. However, when the embryo extract concentration is decreased to 2%, no catecholamine production (assayed by formaldehyde-induced-fluorescence) was observed. In the present study, we examine whether a factor or factors elaborated by the neural tube will support adrenergic differentiation.

Conditioned medium from neural tube, somite, or notochord cells was obtained by growing the respective cell type in culture in medium supplemented with horse serum and 2% embryo extract. The conditioned medium was harvested from these embryonic tissues every other day. Neural crest cells were subsequently fed the conditioned medium. When neural crest cells were grown in medium containing 2% embryo extract which was previously conditioned by neural tube, adrenergic neuroblasts were observed in all cultures. This effect appears to be at least partially specific since somite and notochord conditioned medium did not support adrenergic expression. Pigmented cells were present in all cultures, with or without neuronal differentiation, indicating the general health of the cells. To test the possible role of direct contact with the neural tube, neural crest cells were plated onto a layer of neural tube membranes in the presence of 2% embryo extract. No adrenergic differentiation was observed under these conditions.

The results indicate that: 1) the neural tube makes a factor or factors that will support adrenergic differentiation; and 2) contact with the neural tube is not required for expression of the phenotype.

263.4 IN VITRO DIFFERENTIATION OF QUAIL NEURAL CREST CELLS INTO SEROTONINERGIC, MET-ENKEPHALIN-IMMUNOREACTIVE AND SOMATOSTATIN-IMMUNOREACTIVE NEURONS. Maya Sieber-Blum. Department of Cell Biology and Anatomy, The Johns Hopkins University School of Medicine, Baltimore, MD 21205.

A wide variety of vertebrate cell types and tissues are the progeny of the same transient embryonic structure, the neural crest. They include much of the peripheral nervous system, nerve-supporting cells, pigment cells, endocrine cells, and head mesenchyme. Methods for the in vitro culture of neural crest cells holds promise for a detailed analysis of some aspects of neural crest cell development under well controlled conditions and insights into the underlying cellular and molecular regulatory mechanisms. However, thus far, only a few differentiated phenotypes have been identified among cultured neural crest cells: adrenergic neurons, cholinergic neurons, melanocytes and chondrocytes. In this communication, we report the in vitro differentiation of three additional neural crest-derived cell types: serotoninergic, met-enkephalin-immunoreactive and somatostatin-immunoreactive neurons. Serotoninergic neurons were identified by formaldehyde-induced histofluorescence and by indirect staining with an anti-serotonin antibody in both the presence and absence of the monoamine oxidase inhibitor, Parnate. No enhancing methods were used to identify peptidergic neurons by indirect immunofluorescence. The antibodies stained perikaryon and cell processes in all three cell types. Serotoninergic neurons were uni- or multipolar with short cell processes. Somatostatin-immunoreactive neurons were multipolar and had extremely fine and long cell processes with numerous varicosities and elaborate ramifications. By contrast, met-enkephalin-immunoreactive cells had few, very short and rather coarse processes. Contrary to expectations, serotoninergic neurons were found in neural crest cultures derived from all levels of the neuraxis, including the thoracic/upper lumbar level. In vivo crest cells from the thoracic/upper lumbar axial levels give rise to the sympathetic system which is predomonantly adrenergic. They do not contribute to the enteric ganglia which contain serotoninergic neurons. The results presented in this communication may indicate that the sympathetic nervous system of the quail contains serotoninergic cells. Alternatively, it is also conceivable that some restriction mechanisms that are active in vivo are abolished in culture and thus allow neural crest cells from certain axial levels to express a larger segment of their developmental potential. (Supported by NIH Grant HD 15311)

263.5 DIFFERENTIATION AND TRANSFORMATION OF NEURAL PLATE CELLS. R.W. Keane*, L.A. Lipsich*, and J.S. Brugge* (SPON: E.F. Barrett). Dept. of Physiol. Biophys. Univ. Miami School of Med., Miami, FL 33101, and Dept. of Microbiology Basic Health Sciences, SUNY at Stony Brook, Stony Brook, NY 11794

The developmental potential of presumptive neural plate cells of pre-streak chick embryos (stage 1) and primary-induced neural plate cells from definitive streak chick embryos (stage 4) has been examined in cell culture using specific markers which identify the major cell types in the vertebrate central nervous system. The pre-streak presumptive neural plate (PSPNP) cells, stage 1, which have not been determined, assume an epithelial appearance in vitro and synthesize cellular fibronectin, but do not express markers for the neuronal, astrocytic, melanocytic or oligodendrocytic lineages. Conversely, primary-induced definitive-streak neural plate (DSNP) cells are competent to express cell-type-specific markers for terminally differentiated neurons, astrocytes, and melanocytes, and synthesize an extracellular matrix of cellular fibronectin. Differentiation of DSNP cells in vitro can be prevented by infection with a temperature-sensitive mutant of Rous sarcoma virus, tsNY68. The development of DSNP cell transformants can be resumed by a temperature shift to the nonpermissive temperature. The morphological and biochemical changes associated with tsNY68 transformation are accompanied by alterations in $pp60^{src}$ kinase activity in the transformed cells.

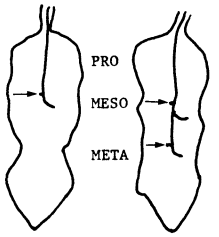
263.6 DUPLICATION OF NEURAL STRUCTURE IN BITHORAX FLIES. John B. Thomas* and Robert J. Wyman. Department of Biology, Yale University, New Haven, CT 06511 USA.

Homeotic mutations change the state of determination of one body part to that of a different body part. In Drosophila certain mutations within the bithorax gene complex (BX-C) transform metathorax into mesothorax. Although the cuticular transformations are well described, the effect of these mutations on internal tissues is less certain. This is due in large part to the lack of suitable internal markers for segmental identity.

The branching pattern of the Drosophila giant fiber neuron (GF) offers an unambiguous marker for the mesothoracic segment of the nervous system. The GF cell body lies in the brain; its axon descends into the thoracic ganglion. The axon has no branches in the prothorax and does not enter the metathorax (Brain Research 221:213). Within the mesothoracic neuromere it extends a tuft of small processes (arrows) which synapse onto the peripherally synapsing interneuron and it also bends laterally to synapse onto the tergotrochanteral motorneuron (J. Neurocytol. 9:753).

Mutant bithorax flies of the genotype abx bx^3 pbx/Df(3R)P2 (Drosophila Inf. Serv. 55:207) show nearly complete meta to mesothoracic cuticular transformation. In these flies the GF mesothoracic branches (revealed by intracellular injection of Lucifer Yellow) are duplicated in the metathoracic neuromere. Thus the normal mesothoracic cues involved in GF branching appear to be duplicated in the metathoracic neuromere of the BX-C mutant flies. These changes could be due to a direct affect of the BX-C mutations on the CNS or could be due to an inductive effect from other homeotically transformed tissues such as the cuticle or sense cells.

Giant Fiber Neuron in Thoracic Ganglion



263.7 REORGANIZATION OF SEGMENTAL FOUNDER CELLS IN THE LEECH EMBRYO FOLLOWING MICROBEAM ABLATION OF CELLS LABELLED WITH A FLUORESCENT LINEAGE TRACER. M. Shankland. Dept. of Molecular Biology, U. of California, Berkeley, CA 94720.

The egg of the leech Helobdella triserialis develops directly into the adult form through a stereotyped sequence of cell divisions, and it is possible to identify specific segmental founder cells, called blast cells, on the basis of their lineage. These blast cells lie in 5 parallel germinal bandlets, with each bandlet arising from a larger teloblast by a series of asymmetric divisions. Injecting teloblasts with cell lineage tracers shows that each bandlet gives rise to a distinctive set of segmentally iterated tissues, and that the blast cells within a bandlet are ancestral to segmentally homologous tissue complements. However, the blast cells within a given bandlet must give rise to slightly different descendant clones in order to account for the known differences between the individual segments.

Small groups of blast cells were ablated by means of a photosensitizing lineage tracer, fluorescein dextran (FDX), injected into and inherited from the parental teloblast. FDX does not interfere with development under normal conditions, but sensitizes cells to light within the fluorescein absorption spectrum. FDX-labelled blast cells were lesioned under an epi-fluorescence microscope equipped with a 50 W Hg arc light source and a narrow band exciter filter with peak transmittance at 480 nm. Using a 40X objective, a 20-60 sec exposure causes labelled blast cells to undergo rapid degeneration resulting within 2-10 hr in a loss of membrane integrity and dissipation of the tracer. This microbeam could be narrowed so as to selectively lesion 2 adjacent blast cells, thus sundering the labelled bandlet into separate rostral and caudal fragments. Unlabelled blast cells have negligible absorption at these wavelengths, and can be illuminated for up to 300 sec without any apparent damage.

There is normally a strict correlation between a blast cell's birth rank and its segmental fate. However, if a bandlet is photolesioned at the point where it merges with the other bandlets, the fragment caudal to the lesion is temporarily retarded and consequently slips out of its normal segmental register. The slipped bandlet is frameshifted so that its blast cells come to occupy segments caudal to those for which they are normally destined, where they produce their normal bandlet-specific complement of tissues. This segmental reorganization allows one to ask whether certain segment-specific features of the blast cell clones are determined by blast cell birth rank or by the position of the descendant clone along the rostrocaudal axis. The results show that at least one such segmental difference--the death of the supernumerary blast cells--is determined by position irrespective of birth rank.

263.8 DEVELOPMENTAL INDETERMINACY IN THE LEECH EMBRYO. D.A. Weisblat and M. Shankland. Molecular Biology, Univ. of Calif., Berkeley, Berkeley, CA 94720.

Identifiable neurons in the segmental nervous system of the leech derive from bilateral pairs of blastomeres, the left and right M,N,O,P and Q teloblasts. The teloblasts themselves are identifiable by size, position, or (except for O and P) by the order in which they arise during cleavage. The teloblasts make smaller blast cells in columns called germinal bandlets; these coalesce in a fixed manner ipsilaterally into left and right germinal bands, then rostrocaudally along the ventral midline into a structure called the germinal plate, from which the segmental tissues, including the ganglia of the ventral nerve cord, arise. Labeling individual teloblasts with cell lineage tracers revealed that each blast cell normally generates a distinct segmental complement of progeny, including neurons, which is characteristic of its teloblast of origin. This would suggest that neuronal fates might be determined at the time of teloblast formation, but in fact two lines of evidence have indicated that the O and P teloblasts (equivalent in their lines of descent from the egg) are also of equal developmental pluripotency, with the fates of their neuronal progeny being determined by a hierarchical interaction between blast cells in the germinal band (NS abst. 70.2, 1982). Firstly, in about one third of the embryos, positionally identified O teloblasts give rise to P teloblast progeny distribution patterns and vice versa; in fact it is the relative positions of the o and p germinal bandlets within the germinal band, not the position of the teloblasts, which correlates with the progeny distribution pattern. Secondly, in experiments where either an O or a P teloblast was ablated by DNase injection, the surviving ipsilateral P or O teloblast's progeny generated the P pattern of neurons, with the usual O progeny being absent.

Results to be presented, from experiments using the photoablation technique described in the previous abstract, confirm and extend the previous work as follows: firstly, when the posterior part of a bandlet whose anterior blast cells are already making the P pattern is caused to grow between the n and o bandlets of the contralateral germinal band, these posterior blast cells give rise to the O pattern of neurons, showing directly that P- as well as O-derived blast cells can make either the O or the P pattern; secondly, by lesioning p blast cells at various times after they have already entered the germinal band, we have found that the o blast cells become committed to making the O pattern at or near the time of their first mitosis.

263.9 REGULATION AND DETERMINATION OF NEURONAL PRECURSOR CELLS REVEALED BY CELL ABLATIONS IN THE GRASSHOPPER EMBRYO. Chris Q. Doe* and Corey S. Goodman (SPON: S. Glotzbach). Dept. of Biol. Sci., Stanford University, Stanford, CA 94305.

Each segmental ganglion of the grasshopper CNS arises during embryogenesis from a stereotyped pattern of neuronal precursor cells in the neuroepithelium: 61 neuroblasts (NBs) and 7 midline precursors. The NBs are arranged in two plates of 30 NBs, each composed of 7 NB rows, and 1 median NB. NBs are stem cells which divide repeatedly to produce families of neuronal progeny. Each NB can be individually identified according to its position and the highly stereotyped family of identified neurons it produces. We are interested in how the ectoderm gives rise to the NBs, and how the NBs acquire their unique identities.

Immediately following gastrulation the embryo is a thin strip of ventral ectoderm and dorsolateral mesoderm. The middle portion of the ectoderm becomes the neuroepithelium as cells delaminate and enlarge to form NBs. All 30 NBs within the plate do not form simultaneously. Rather, as the embryo grows, gaps develop between the initial NBs as additional ectodermal cells delaminate to form small clusters of 2-8 cells between the older NBs. Ultimately, only one cell within the cluster enlarges and becomes a NB; the remaining cells either die or form ensheathing cells around the NB and its progeny. In the 7th row, NBs 7-1 and 7-4 form first, followed by NB 7-2, and lastly NB 7-3. Before NB 7-3 appears, a cluster of 2-8 cells are situated between NB 7-2 and NB 7-4; one of these cells enlarges to become NB 7-3.

We have used either a laser microbeam or a microelectrode to ablate individual cells or specific groups of cells during the development of NBs 7-2 and 7-3. When we ablate the entire cluster of 2-8 small cells normally destined to form one of these NBs, no NB appears. When we ablate only a portion of the cluster, however, the NB forms. In particular, when we kill only the cell that is enlarging to form the NB, one of the remaining cells becomes the NB. It appears as if the NB can form from any one of the cells within the cluster, even after one cell has begun enlarging. We conclude that cell interactions within the cluster determine which cell becomes the NB, and that regulation can occur early in this process. However, once the enlarged NB begins its first division, no regulation occurs; ablation leads to a lack of the NB, despite the existence of delaminated cells adjacent to the ablated NB. Interestingly, when the mature NB 7-4 is ablated at a time when the cluster of cells for NB 7-3 is adjacent, NB 7-3 can appear but NB 7-4 is never replaced.

We conclude from these results that any cell within a cluster has the potential to make the correct NB (for that position within the neuroepithelium), but lacks the potential to make the adjacent NB. This suggests that particular clusters of delaminated ectodermal cells may represent precursor populations for a particular NB. Furthermore, by the time of its first division, the NB cannot be replaced; the remaining cells within the cluster, and the overlying epithelial cells, have either become commited to other fates, or are no longer capable of acquiring the NB fate. (Supported by a NSF predoctoral fellowship to CQD and a NIH grant to CSG.)

263.10 NEURONAL DETERMINATION DURING EMBRYONIC DEVELOPMENT: HIERARCHICAL FATE OF TWO SIBLING CELLS IN THE GRASSHOPPER CNS. J.Y. Kuwada and C.S. Goodman. Dept. Biol. Sci., Stanford Univ., Stanford, CA

We are studying the roles of cell lineage and interactions in the determination of identifiable neurons in the CNS of the grasshopper embryo. Two morphologically distinct sibling neurons, the H cell and the H cell sib, are the progeny from the symmetric division of midline precursor 3 (Goodman, Bate, & Spitzer, J. Neurosci., 1981). The two MP3 progeny are well suited for this study since they are easily identified by their unique location, can be filled intracellularly with dye, and can be easily manipulated. Here we describe the results following ablation of one of the two progeny at various stages after their birth. Cells were individually ablated with a microelectrode and the embryos allowed to develop in culture.

When the precursor cell divides, two progeny of equal size are produced which are located just ventral to the dorsal basement membrane. Ten hours later the first signs of differentiation appear: growth cones extend and one progeny moves away from the basement membrane making it ventral to its sibling. Thirty six hours following mitosis the two progeny are clearly distinguishable with different patterns of axons: the dorsal progeny is the H cell while the ventral progeny is the H cell sib. This pattern of development is reproduced in control ganglia when embryos are allowed to develop in a culture system.

When one of the progeny was ablated within 5 hours of the precursor mitosis and allowed to develop in culture for sufficient time, only one progeny was present and it possessed the H cell sib morphology in 11 of 14 cases and the H cell morphology in the remaining 3 cases. Thus at this time the embryo cannot number regulate, i.e., compensate for the loss of one progeny to restore the original number of progeny. Moreover, the progeny are not yet individually determined for the most part. Instead the surviving progeny appears to regulate its fate in response to the ablation of its sibling. However, when one progeny is ablated 10-15 hours following mitosis, the remaining progeny can be either the H cell or the H cell sib with equal facility. If the dorsal progeny was ablated, the survivor was the H cell sib (n=6); if the ventral progeny was ablated, the survivor was the H cell (n=2); and when one progeny was ablated and the dorsal-ventral relationship of the two progeny was not clear (n=10), 50% of the survivors were H cells and 50% H cell sibs. Thus as little as 5 hours later the progeny are determined and act autonomously in response to ablation of their sibling.

We conclude that within 5 hours of precursor mitosis, fate regulation can occur in response to ablation of one of the sibling progeny. This suggests that a hierarchy of cell fates governed by interactions with other cells or non-cellular elements exists for these sibling neurons. Additionally, the interaction occurs in a specified short period of time prior to the first signs of differentiation, number regulation does not occur, and the two progeny are not dependent on each other for survival. Presently neighboring neuronal progeny are being ablated in hopes of identifying possible cellular interactions. (Supported by NIH fellowship to JYK and an NIH grant to CSG.)

263.11 NEUROTRANSMITTER DETERMINATION: EMBRYONIC AND POSTEMBRYONIC DEVELOPMENT OF THE NEUROPEPTIDE PROCTOLIN IN THE GRASSHOPPER CNS. H. Keshishian and M. O'Shea. Committee on Neurobiology, The University of Chicago, Chicago, Il. 60637.

The development of the neuronal expression of proctolin was studied in embryos and nymphs of the grasshopper S. nitens, using immunohistochemistry, dye-fills, HPLC, bioassay and the incorporation of ^{3}H amino acids. About 45 postembryonic proctolin-IR neurons are present in the ventral nerve cord; somatic and neuropilar staining is stereotyped. The IR cell bodies appear either as clusters or as isolated individuals, a pattern which may reflect different modes of transmitter determination among clonally related neurons. The pro- and mesothoracic ganglia share a pattern of homologous transganglionic arborizations and a pair of ventral midline neurons. In the mesothorax there are also two ventral lateral pairs near the 1st and 2nd nerve roots. The metathoracic ganglion has two pairs of ventral midline interneurons, a pair of ventral neurons in the A3 neuromeres and 5-6 ventral lateral cells among the motorneurons projecting to nerves 3 and 5. On the dorsal posterior side two pairs of cells stain in the nerve 4 motor pool. The darker staining pair may be homologous to the proctolinergic Ds motorneuron of Periplaneta (O'Shea and Bishop, '79, J. Neurosci. 2, 1242). In the terminal ganglion there are two ventral midline clusters of 6-7 neurons each and either 1 large or 2 medium sized Dorsal Unpaired Median (DUM) neurons occuring with equal frequency. Embryonic staining starts at the 60% stage in the brain, with the mature pattern complete throughout the CNS at the 70% stage. The only staining evidence for supernumerary cells was the transient appearance at 70% of a pair of ventral metathoracic A2 neurons. Using C-18 purification levels of 15 femtomoles proctolin/embryo were assayed at the 50% stage. The levels increase with two plateaus; the 1st at the 70% stage after a 20-fold increment, and the 2nd at the 80-85% stage after a 5-fold rise. Peak levels are at the 90% stage, with a 3-fold decline by 100%. ^{3}H amino acid labelling of cultured embryos with HPLC resulted in the incorporation into proctolin during the 1st increment. The 2-stage increase of embryonic proctolin levels is synchronous with two ecdysone pulses and the 2nd and 3rd bouts of cuticulogenesis (Lagueux et al., '79, J. Insect Physiol. 25, 709).

Thus proctolin is a late arising embryonic phenotype that is expressed suddenly in a fixed population of identified post-mitotic cells.

263.12 **A MONOCLONAL ANTIBODY WHICH RECOGNIZES RADIAL GLIAL CELLS IN THE DEVELOPING VERTEBRATE CENTRAL NERVOUS SYSTEM.** **R. McKay and S. Hockfield, Cold Spring Harbor Laboratory, Cold Spring Harbor, N.Y. 11724**

The nervous system is derived from a plate of ectodermal cells which roll up in development to form a tube of approximately 10^{5} cells which proliferate and differentiate to generate the 10^{12} cells and many cell types of the adult vertebrate brain. The application of hybridoma technology to the analysis of the adult vertebrate nervous system has yielded many antibodies which distinguish discrete neuronal types in different areas of the central nervous system, but most of these antibodies failed to bind to the developing neurons. In order to define the major cellular features of the developing brain we have raised monoclonal antibodies to fixed embryonic day 15 spinal cord of rats. At this age the nervous system still contains both the rapidly profilerating epithelial cells and the recently differentiated neurons which have just begun to send out processes and receive input, where cellular differentiation of the neural plate and the initial events in axon outgrowth and synaptic recognition between neurons might be studied. Here we describe an antibody that recognizes a subset of cells in the developing CNS.

The antibody Rat 6-7G12 binds to an antigen which is expressed in radial cells in the columnar epithelium. These cells have the morphological characteristics of the neuroblast cells first described by the Golgi technique and called epithelial cells by Cajal. Immunoblots show the antigen to be a doublet of bands of approximately 180,000 daltons. Both biochemical and histochemical assays show the antigen to be absent in the adult rat brain. At the electron microscopic level the antibody recognizes an internal antigen in a subset of the E15 radial cells, some of these cells contain mitotic figures so we know they are dividing. Other cells in the embryo which express a related antigen are located in the region of the developing somites. Electron microscopy shows the antigen is present in the newly fused myotubes.

The antigens recognized by 7G12 are first apparent in the neural epithelium at the eleventh day of embryonic gestation (E11) and at this stage the majority of radial cells may bind the antibody. At day E15 however the antigen is only present in a subset of radial cells. As development progresses the number of 7G12-labelled cells diminishes, with very few remaining at birth. Antisera against the glial fibrillary acidic protein and vimentin also bind to radial cells in the developing spinal cord. However the antigens recognized by 7G12 have different molecular weights from vimentin and GFAP. Differential expression in early neuronal development of antigens such as these, will allow the analysis of events in neuronal differentiation.

263.13 SELECTION OF CELL-TYPE SPECIFIC MONOCLONAL ANTIBODIES INTERACTING WITH NASCENT POLYPEPTIDE CHAINS SYNTHESIZED *IN VITRO* BY CEREBELLAR mRNA. A. Safran*, Z. Eshhar* , D.M. Phillips* and H. Soreq. Dept. of Neurobiology, Weizmann Institute of Science, Rehovot, Israel.

Utilizing *in vitro* translation of cerebellar mRNA, we have previously found that the production of a number of abundant cerebellar polypeptides is regulated differently during ontogenesis of the cerebellum of normal rats (1), as compared to the irradiation-agranulated rat cerebellum (2) and to the cerebellum of *staggerer* mutants (3). Monoclonal antibodies (mAb) to such polypeptides should enable the assignment of the corresponding proteins to defined cell types and periods in cerebellar development. In order to study the regulation of synthesis of these proteins at the level of mRNA as well, the antibodies should recognize the polypeptide backbone of the proteins. To select for such antibodies, we immunized mice with cerebellar proteins eluted from regions in polyacrylamide gels, where differences in synthesis were observed. Hybridoma cell lines secreting mAb were obtained by fusion with NSO myeloma cells. The antibodies were screened against ^{125}I-labeled cerebellar proteins, that represent the total proteins in the cerebellum, including the contribution of incoming fibers. The mAb were also screened for their binding of ^{35}S-methionine labeled polypeptides, translated *in vitro* from cerebellar mRNA. These represent the biosynthetic potential of endogenous cerebellar cell bodies alone. mAb which were found to be positive by both selection methods were examined for their binding to frozen cerebellar sections by an immunofluorescence technique. In addition to mAb which stained most cell types, we identified mAb which selectively stained specific subcellular regions in various cell types. These include Bergmann fibers of Golgi type II epithelial cells, cell bodies of neurons in both the molecular and the granular layer, and meningeal cells. Such characterized mAb will serve as probes to follow the developmental regulation of the corresponding cerebellar antigenic markers, both at the protein and the mRNA level.

263.14 COMPOSITION OF THE PROLIFERATIVE SUBGRANULAR ZONE OF THE DEVELOPING AND MATURE DENTATE GYRUS IN THE RHESUS MONKEY: EM-IMMUNOCYTOCHEMICAL (anti-GFAP) AND AUTORADIOGRAPHIC (^{3}H-TdR) ANALYSES. M. F. Eckenhoff and P. Rakic. Sec. Neuroanat., Yale University School of Medicine, New Haven, CT 06510.

Previous studies using ^{3}H-thymidine (^{3}H-TdR) autoradiography revealed late labeled immature cells in the subgranular zone (SGZ) of the primate dentate gyrus, indicative of a protracted postnatal genesis (Rakic and Nowakowski,'81). A recent study using antiserum to glial fibrillary acidic protein (GFAP) as a glia-specific marker showed the presence of both glial and neuronal cells in the SGZ during prenatal and early postnatal periods (Eckenhoff and Rakic,'83). However, the kinetics of proliferation, the time-dependent changes in the proportions of glial and neuronal cell lines, and the nature of late generated cells needed to be determined. In the present study we employed immunocytochemical localization of GFAP at the EM level and ^{3}H-TdR autoradiography to examine the cytology and proliferative capacity of the SGZ in developing and mature rhesus monkeys.

Vibratome sections of the fixed hippocampus from monkeys at embryonic day 144 (E144), 3, 7, 18 postnatal months and an adult were reacted with GFAP antiserum by the Vectastain ABC procedure and processed for EM analysis. Animals of postnatal ages were injected with ^{3}H-TdR at least two months prior to sacrifice and sections are being processed by combined immunocytochemical and autoradiographic methods. In addition, 5 pairs of monkeys at ages comparable to the above were injected with ^{3}H-TdR and sacrificed either the same day to determine the site of cell genesis, or 2 months later to determine their nature. At E144, the SGZ is 3-4 cells wide and consists of immature GFAP-positive and GFAP-negative cells. These cells are presumably glial and neuronal precursors respectively, since ^{3}H-TdR labeling demonstrates that both cell lineages are generated in the SGZ at this age. At 3 and 7 months, the SGZ becomes 2-3 cells wide and contains a high percentage of GFAP-positive cells. Labeling by ^{3}H-TdR testifies to their proliferative capacity. In the 18 month specimen, the SGZ is reduced to 2 rows of immature cells virtually all GFAP-positive. In the adult monkey the SGZ remains 1-2 cells thick, and most, if not all, are GFAP-positive. So far, our material reveals that: (1) a vestige of the fetal SGZ persists in mature monkeys; (2) initially, the SGZ contains proliferative cells of both glial and neuronal lineages; (3) the number of neuronal cells declines with time such that in the adult virtually all immature and presumably still dividing cells are of astrocytic lineage; (4) in contrast to rodents, where neurons were reported to be added in substantial number to the adult dentate gyrus, in primates the late generated cells from the SGZ appear to be glia. Supported by NS14841.

FEEDING AND DRINKING: CUES FOR NEED STATE III

264.1 REGULATION OF PROTEIN/CARBOHYDRATE RATIO IN FOODS THAT RATS CHOOSE TO EAT. C.L. Thaell*, J.J. Wurtman*, and R.J. Wurtman. Laboratory of Neuroendocrine Regulation, M.I.T., Cambridge, MA 02139.

Ashley and Anderson (J. Nutr., 1975, 105, 1412) have presented evidence that protein intake is regulated separately from energy intake and is inversely correlated with plasma tryptophan/large neutral amino acid ratios. Fernstrom and Wurtman (Science, 1972, 178, 414) have shown that a carbohydrate meal increases the plasma trp/LNAA ratio, increasing brain tryptophan levels and serotonin synthesis, while a high-protein meal has the opposite effect. We have examined the possibility that the regulated aspect of food choice is not dietary protein or carbohydrate content, per se, but the same aspect as controls brain serotonin levels, i.e. the ratio of one nutrient to the other. Initially, we allowed rats to choose between two diets differing in CHO% and, simultaneously, in protein/CHO ratio. In the first two experiments, 12 possible diet pairs for diets containing 12, 32, 52, and 72% CHO were offered to rats, with CHO as either dextrin or sucrose and with diets either isoprotein/isofat (Experiment 1) or isoprotein/isocalorie (Experiment 2). In Experiment 3, 6 CHO diets ranging from 5-55% CHO (3.6-0.30 protein/CHO ratio) were paired with an isocaloric, isoprotein 65% CHO (0.28 ratio) diet. In Experiment 4, 6 CHO diets ranging from 5-65% CHO (3.6-0.28 ratio) were paired with an isocaloric, nonisoprotein 84% CHO (0.07 ratio) diet. Total food eaten was measured and grams of protein and carbohydrate eaten were calculated every 24 h.

The results of these experiments suggest that (1) caloric intake is regulated in deference to nutrient composition, at least with diets containing sufficient protein; (2) sucrose-fed rats consume more calories than dextrin-fed rats, emphasizing the need to consider the quality and not just quantity of the diet(s); (3) rats choose their foods so as to obtain a protein/CHO ratio ranging from 0.20-0.43, even when the possible range of ratios available to them is as wide as 0.07-3.6.

Pharmacological facilitators of serotoninergic mechanisms (fluoxetine, fenfluramine) have been shown to spare protein intake while decreasing caloric intake and, specifically, the self-selection for carbohydrate (Wurtman and Wurtman, Life Sci., 1979, 24, 895). The present study suggests that rats choose among available diets to obtain net protein/CHO ratios which will neither increase nor decrease brain serotonin.

264.2 INTESTINAL SATIETY IS ELICITED BY L- BUT NOT D-PHENYLALANINE. M.F. Lew*, J. Gibbs and G.P. Smith. Dept. of Psychiatry, Cornell Univ. Med. Coll. and E.W. Bourne Behav. Res. Lab., The New York Hospital, White Plains, NY 10605.

When rats provided with chronic gastric cannulas sham feed a liquid food following an overnight food deprivation, satiety is absent (Young et al, 1974). If a small amount of liquid food is placed directly into the small intestine of sham feeding rats, satiety reappears (Liebling et al, 1975). The mechanism(s) of this intestinal satiety are unknown, but we have postulated that endogenous peripheral circulating cholecystokinin (CCK) plays a role (Antin et al, 1978). Consistent with this hypothesis, gastric preloads of the L-isomer of phenylalanine (L-phe, a potent CCK releaser--Meyer & Grossman, 1972) reduce food intake in the intact rhesus monkey (Gibbs et al, 1976) and intact rat (Anika et al, 1977), while gastric preloads of the D-isomer (D-phe, a weak CCK releaser) do not reduce food intake in either species. To avoid the confound introduced by gastric preloads (activation of both gastric and intestinal satiety mechanisms), we tested the satiety potencies of L-phe and D-phe when they were delivered directly to the small intestine of sham feeding rats.

Five adult male Sprague Dawley rats were implanted with chronic stainless steel gastric cannulas and with chronic Silastic duodenal catheters, with tips 2.5 cm distal to the pylorus. After an overnight, 17-h deprivation of maintenance food (Purina pellets), gastric cannulas were opened and rats were offered a liquid food (50% BioServ) for sham feeding during a 1-h test period. Beginning 12 min after food presentation, a 3% solution of L-phe or D-phe, or of 0.15M NaCl as the vehicle control, was infused via duodenal catheters, at a rate of 1.2 ml-min^{-1} for 8 min. Sham feeding rates were recorded at 5 min intervals.

During the 40 min immediately following infusion on days when rats received intraduodenal 0.15M NaCl, they consumed a total of 70.6±6.2 ml (mean±SEm) at a relatively stable rate which ranged from 6.9±0.8 to 8.9±0.6 ml per 5-min interval. On days when rats received L-phe, they consumed 18.6±7.2 ml (difference $p < 0.005$ vs NaCl) at rates ranging from 0.6±0.6 ml to 3.8±1.5 ml. The latency to the onset of L-phe action was rapid: significant inhibition appeared before L-phe infusion ended. On days when rats received D-Phe, they consumed 58.2±12.3 ml (difference not significant vs NaCl) at rates ranging from 5.6±1.5 to 7.4±0.8 ml.

The results show that an intestinal load of L-phe produces a rapid and potent suppression of sham feeding, while an equivalent load of D-phe has no significant effect. We interpret these findings as additional evidence supporting a potent role for endogenous CCK in mediating intestinal satiety.

264.3 THE EFFECTS OF INTRAVENTRICULAR GLYCEROL INFUSION ON FOOD AND WATER INTAKE AND BODY WEIGHT IN YOUNG FEMALE RATS.
J. K. Nishita*, E. H. Ellinwood, Jr., W. J. K. Rockwell* (SPON: H. K. H. Brodie). Dept. of Psychiatry, Duke University Medical Center, Durham, North Carolina 27710.

Glycerol has been proposed as a humoral signal to the brain that relates the state of adipose tissue mass and its utilization. A variety of peripheral and central techniques have shown that glycerol can suppress food intake and reduce body weight in adult rats. Furthermore, these studies have shown that short-term administration of glycerol (7 days) produce transient effects on food intake and body weight; returning to normal levels within 3-4 days (Grinker et al., 1980). However, long-term glycerol treatment (13 days) may produce a permanent reduction in body weight but not in the rate of weight gain (Wirtshafter & Davis, 1977).

This study measured the effects of continuous short- and long-term intraventricular infusion of glycerol on body weight and 24 hour food and water intake in young female rats (37 days). Rats were implanted with 25 ga midline cannula aimed at the third ventricle. Following recovery and baseline measurements of body weight and ingestion, rats were implanted subcutaneously with Alzet osmotic pumps containing either 0.15 M glycerol at an osmolar concentration of 300 milliosmoles/l, or 0.15 M saline. Short-term infusions were made through a 32 ga cannula at a rate of 1.0 ul/hr for 7 days and long-term infusions were at a rate of 0.5 ul/hr for 14 days. Body weight and food and water intake were recorded daily during the infusion and for 10 days following pump removal. All rats then received 7 days of glycerol injections (40 mg/kg) followed by 7 days of no injection.

Glycerol produced reductions in body weight and food intake during both short- and long-term continuous intraventricular infusions. Both short- and long-term treated rats also showed a reduction in the rate of weight gain during infusion. Peripheral glycerol injections produced a more pronounced effect in glycerol-infused rats then in controls. These results suggest that intraventricular glycerol infusion in young maturing female rats may produce long-term effects in terms of sensitivity to glycerol.

264.4 Chronic Meal-Contingent Infusion of Insulin into Free-Feeding Rats Can Produce Hyperphagia and Accelerate Growth Rate.
D.B. West, K. Parmely, D.J. Braget and S.C. Woods. Department of Psychology, University of Washington, Seattle, WA 98195.

Bilateral lesions of the ventromedial hypothalamus (VMH) in rats leads to hyperphagia, hyperinsulinemia and obesity. VMH lesions also result in an exaggerated secretion of insulin during a meal. Pancreatic denervation by either vagotomy or transplantation of a pancreas into rats with chemically destroyed islets has been reported to block both this heightened insulin secretion and the obesity produced by destruction of the VMH. This suggests that neurally-mediated hypersecretion of insulin during feeding may contribute to the development of obesity in VMH-lesioned rats.

In order to test this hypothesis, adult, female Sprague-Dawley rats (n=5) were implanted with intraperitoneal catheters and habituated to computer-monitored enclosures which recorded food intake by a pellet detecting eatometer. Initially, at the beginning of each spontaneous meal, 0.27 ml of physiological saline was infused over a period of 150 seconds into 3 of the rats. The other 2 rats were given an equivilent number of random infusions by yoking their infusions to rats receiving meal-contingent drug administration. Saline infusion did not affect growth rate or food intake in either of the groups. When 27 mU of purified porcine insulin (INS, Nordisk) was infused at the start of each spontaneous meal over a 4 day period, food intake and rate of growth of both groups remained unaffected. With meal-contingent infusion of 135 mU of INS for 6 days, however, total daily food intake increased by an average of 26.9% (± 2.1) compared with baseline intake, and growth rate increased from 0.3 (±0.6) to 1.2 (± 0.6) g/day. This increase of food intake with INS infusion was due to larger meals (1.8 ± 0.1 vs 1.3 ± 0.1 g/meal) and not due to a change in feeding frequency (13.4 ± 1.6 vs 13.6 ± 1.3 meals/day) Rats receiving random infusions also increased their total daily food intake by 31.6% (± 0.7) and increased their growth rate from 0.3 (± 0.3) to 2.4 (±1.1) g/day. This increased food intake was due to more meals (14 3 ± 0.1 vs 12.2 ± 0.3 meals/day) and not due to larger meals (1.5 ± 0.4 vs 1.5 ± 0.3 g/meal).

These data support the notion that chronic enhancement of insulin secretion during a meal can lead to hyperphagia and obesity. The rather large dose of insulin infused in this study may have produced plasma values beyond the normal range for VMH rats. The observation that rats receiving random infusions of INS also increased food intake, but did this by increasing frequency of feeding, suggests that the hyperphagia of both groups may be due to insulin-induced hypoglycemia.

264.5 SYMPATHETIC BLOCKADE ALTERS MEAL PATTERN.
L.A. Campfield* and F.J. Smith*. (SPON: R.C. ROGERS). Depts. of Physiology and Engineering Sciences, Northwestern University, Chicago, IL 60611 & Evanston, IL 60201 and College de France, Paris.

Differential insulin secretory responses following dark and light phase meals suggest that prandial insulin response, and its autonomic modulation, may be an important variable in the dual periodicity of feeding. The role of sympathetic control of insulin secretion in the neuroendocrine mechanisms underlying feeding periodicity was examined using phentolamine, an alpha adrenergic blocking agent. Female Wistar rats were implanted with chronic femoral cannulas and were maintained on a 12 hr light/dark cycle with free access to powdered food and water. Food intake was continuously recorded by monitoring food cup weight. Following complete recovery, two studies were performed. In the behavioral studies, each rat received infusions of either isotonic saline or phentolamine (0.5 mg) at a rate of 3 µl/min during the last seven hours of the light phase on alternate days. Sixteen saline and eleven phentolamine trials were performed in five rats. Meals were defined using a 40 min criterion. Following phentolamine infusion, the size of the first dark phase meal was increased by 76±25% compared to saline infusion. The onset ratio of the second meal was also significantly increased (70±28%) following phentolamine. However, other parameters of the dark and light phase meal patterns as well as total food intake and body weight were not altered. Increased meal size and onset ratio observed early in the dark phase following phentolamine were typical of those observed at the end of the dark phase in saline treated rats. In the metabolic studies, identical infusion protocols were used except food was removed 2 hr prior to infusions. Three blood samples were collected from lightly heparinized, conscious rats prior to the beginning and the end of the saline or phentolamine infusion and 2 hr post infusion. Plasma glucose concentrations were similar after both infusions. However, plasma insulin concentration significantly increased (2.1±.6 vs 0.6±.1 ng/ml) during the phentolamine infusion returning to levels observed in saline treated rats within 2 hr post infusion. These data demonstrate that phentolamine infusion during the last portion of the light phase resulted in: 1) elevated plasma insulin concentrations; 2) increased size of the first dark phase meal; and 3) increased onset ratio of the second dark phase meal. These results suggest that elevation of insulin concentration during the last portion of the light phase may induce a shift in subsequent dark phase meal pattern. Therefore, the sympathetic nervous system, through its inhibitory action on insulin secretion, has the potential to modulate feeding periodicity.

264.6 EFFECTS OF CHOLECYSTOKININ ON RUNWAY PERFORMANCE.
J. E. Cox*, R. J. Toney*, and D. J. Wiebe* (SPON: C. Oyster). Dept. Psychology, University of Alabama in Birmingham, Birmingham, AL 35294.

Injections of cholecystokinin (CCK) reduce food intake. A prevalent interpretation is that injected CCK mimics a satiety-producing action of endogenous CCK, but many uncertainties remain as to the motivational sequelae of the injection. We investigated effects of CCK on appetitive motivation by examining runway performance for food reward after CCK injections.

Male, Sprague-Dawley rats (approximately 350 g) were trained to traverse a 4 ft runway for food reward after 20 hr food deprivation. Reinforcement was 0.2 ml of 10% sucrose. Two sequences of injection of CCK-octapeptide (Kinevac, Squibb) were then administered. In each case i.p. drug injections alternated on consecutive days with equivolemic doses of normal saline in a randomized cross-over design. Injections were given 10 min prior to the test trial on that day. In the first sequence, 6 rats received 5 doses of CCK-octapeptide. Mean (±SE) running speeds (ft/s) were:

	0.5	1.0	2.0	4.0	8.0 µg/kg
Saline	1.82±.19	1.43±.18	1.60±.20	1.73±.10	1.70±.09
CCK	1.90±.07	1.40±.20	1.40±.18	1.37±.14	1.45±.06

Analysis of variance (ANOVA) revealed no significant effects of Drug, Dose, or the interaction of Drug x Dose. Thus, CCK did not reliably alter running speed under these conditions.

In the second series of injections, 4 rats used above were given 2.0 and 8.0 µg/kg CCK alternating on consecutive days with saline injections. For these trials rats were allowed 30 min access to 10% sucrose once they reached the goal box. Percentage suppression of intake (compared to saline trials) after 2 and 8 ug/kg CCK was 29.0±5.7% and 70.0±6.7%, respectively ($p < .05$ for both doses compared to saline). Corresponding decreases in running speed were -10.0±13.7% and 30.8±9.0%. Thus, running speed was not at all reduced by 2.0 µg/kg CCK and decreased by almost one-third at 8.0 µg/kg. The latter effect was marginally significant ($p < .10$).

These results show that CCK-octapeptide is effective in significantly suppressing food intake at doses at which no slowing of runway performance is seen (2 µg/kg). Since running speed varies as a function of hunger and incentive value of the reinforcement (Bolles, 1975), CCK can apparently reduce intake in the absence of changes in these appetitive factors. This outcome is consistent with the proposal that motivational effects of CCK operate later in the appetitive sequence, perhaps interacting with food intake to enhance signals of satiety. However, because CCK may reduce running speed at higher doses (8 µg/kg), further decreases in feeding seen with increasing doses may be a function of additional factors.

264.7 CCK-8 DECREASES BODY WEIGHT IN ZUCKER RATS. R.G. Campbell* and G.P. Smith. Dept. of Psychiatry, Cornell Univ. Med. Coll. and E.W. Bourne Behav. Res. Lab., New York Hospital, White Plains, NY 10605

Cholecystokinin (CCK) has been shown to decrease meal size in animals and humans. CCK has not, however, been shown to produce body weight loss. We report here the results of chronic treatment with CCK on body weight in the genetically obese Zucker rat.

In the first experiment 10 genetically obese female Zucker rats were adapted to a 12 h reverse light/dark cycle with the dark phase beginning at 0700 h. The rats were restricted to three 0.5 h meals per day (0930-1000, 1230-1300 and 1530-1600) of Purina powder on Monday through Friday with tap water available at all times. On Friday at 1630, rats were given free access to twice the weight of powder they ate during the three Friday meals.

Following a five week diet restriction phase, rats were randomly assigned to control and experimental groups. The experimental group received intraperitoneal injections of CCK-8 (6 mcg-kg^{-1}) dissolved in 0.15M NaCl while the control group received intraperitoneal injections of 0.15M NaCl. Both groups received their injections prior to each meal for a three week period. Food intake(g) was measured for each meal and body weight(g) was measured Monday through Friday at 0900. A replication of the first experiment was done with eleven obese male Zucker rats.

CCK increased body weight loss and decreased food intake in both experiments without producing signs of toxicity.

Treatment	Body Weight[a]	Loss of Weight: Actual(g)	Loss of Weight: %Initial	Food Intake[b](g)
Experiment 1				
CCK (n=5)	422.6 ± 11.3	58.2±4.1**	13.9±1.2*	69.0±4.4*
Saline (n=5)	417.8 ± 31.7	33.6±5.7	8.6±1.9	107.4±11.7
Experiment 2				
CCK (n=6)	527.0 ± 19.3	77.2±6.6***	14.6±1.0***	70.5±5.0***
Saline (n=5)	529.6 ± 14.9	25.6±5.3	4.9±1.0	131.3±7.5

*p < .05, **p <.01, ***p <.001

[a]mean body weight prior to treatment
[b]mean food intake for Tue, Wed, and Thurs meals during three week treatment period.

We conclude that chronic CCK treatment in conjunction with a restricted diet enhances body weight loss in genetically obese Zucker rats. The increased loss of body weight appears to be due to the decreased food intake.

These results support the therapeutic potential of CCK for the treatment of obesity.

This research was supported by NIMH grants MH00149 and MH15455.

264.8 VAGAL AFFERENT AXONS MEDIATE THE SATIETY EFFECT OF CCK-8. G.P. Smith, C. Jerome* and R. Norgren (SPON: C. Pfaffmann). Cornell University Medical College, New York, NY 10021 and Penn State Univ. Col. of Medicine, Hershey, PA 17033

Bilateral abdominal vagotomy abolished or markedly reduced the satiety effect of peripherally administered CCK-8, but unilateral abdominal vagotomy did not. Since pharmacological "efferent vagotomy" by atropine methylnitrate did not block the satiety effect of CCK-8, we suggested that loss of vagal afferent axons was the critical lesion (Smith et al, 1981). To test this hypothesis, we unilaterally cut the afferent or efferent vagal rootlets intradurally as they approached the medulla. In a second operation, a unilateral abdominal vagotomy was performed that cut the abdominal vagal afferent and efferent fibers that project to and from the side of the medulla contralateral to the intradural section. The combination of cut afferent rootlets and unilateral abdominal vagotomy produced bilateral afferent abdominal vagotomy, but only unilateral efferent abdominal vagotomy. The combination of cut efferent rootlets and unilateral abdominal vagotomy produced bilateral efferent vagotomy, but only unilateral afferent vagotomy.

All rats were tested after 17 h food deprivation. CCK-8 (6 mcg-kg^{-1}, ip) or saline was administered just before rats were given a sweet milk diet and 30 min intakes were measured. After the food intake tests were completed, the afferent or efferent rootlet lesion was confirmed by the complete or almost complete loss of anterograde or retrograde HRP labeling in the medulla after application of HRP to the cervical vagus on the side of the rootlet lesion. The unilateral abdominal vagal lesion was verified anatomically under microscopic control. Six of 6 rats with verified bilateral afferent abdominal vagotomy failed to inhibit food intake after CCK-8, but 2 of 2 rats with verified bilateral efferent abdominal vagotomy and 1 surgical control showed the usual inhibition of food intake after CCK-8. These results confirm the hypothesis that vagal afferent axons mediate the satiety effect of peripherally administered CCK-8.

Support by grants MH15455, MH00149, and NS10150.

264.9 HEPATIC VAGOTOMY BLOCKS THE INHIBITORY EFFECT OF GLUCAGON, BUT NOT OF EPINEPHRINE ON FEEDING. N. Geary, M. Licht*, and L. Mac Isaac*. Department of Psychology, Columbia University, New York, NY 10027.

Peripheral administration of pancreatic glucagon or of epinephrine under appropriate conditions can inhibit feeding in rats. To investigate the involvement of the hepatic branch of the vagus nerve in these effects, we compared the potencies of glucagon and epinephrine to inhibit feeding in rats with selective vagotomis of only the hepatic branch of the abdominal vagus and in sham operated rats. Rats were maintained on tap water and ground Purina rodent chow under a reversed 12:12 LD cycle (lights off: 1200). On test days, rats were food deprived at 0900. At 1100 glucagon (100 mcg/kg), epinephrine (200 mcg/kg), or the vehicle solution alone (1 ml/kg 3% DMSO, 0.9% NaCl) was intraperitoneally injected and fresh food was presented. The rats were observed until they stopped feeding and retired to the rear of the cage to groom and rest. Meal size was then measured by weighing the food cups. Glucagon and epinephrine reduced meal size by comparable amounts in sham operated rats (median reduction as percent of control; epinephrine, 27%; glucagon, 20%; n=7). In hepatic vagotomized rats, however, the hormones had different effects. Hepatic vagotomy completely blocked glucagon's potency to inhibit feeding, but did not significantly change epinephrine's potency to inhibit feeding (median meal size reductions: epinephrine, 22%; glucagon, 5%; n=8). These data demonstrate that under conditions in which the hepatic vagus is necessary for pancreatic glucagon's satiety effect, it is not required for the anorexic effect of epinephrine. This does not support Russek and Racotta's (Front. Hormone Res. 6: 120-137, 1980) hypothesis that the effects of these two hormones on feeding are mediated by a common effect on hepatic metabolism

264.10 GLUCAGON'S SATIETY EFFECT IS ABOLISHED BY INTRAHEPATIC INJECTION OF ALLOXAN. B.Weick, S.Stone* and S.Ritter. College of Veterinary Medicine, Washington State University, Pullman, WA 99164-6520.

Work from several laboratories indicates that glucoreceptors capable of inhibiting food intake may reside in the liver. Furthermore, glucagon, a proposed satiety hormone, may exert its satiety effect by an action on the liver since hepatic vagotomy abolishes glucagon's satiety effect. Although the mechanism of glucagon's satiety effect is not known, it has been hypothesized that elevation of hepatic glucose subsequent to the release of glucagon during a meal might aid in the termination of feeding by activating hepatic glucoreceptors. We speculated that if glucoreceptors controlling feeding do in fact exist in the liver, they might be vulnerable to the toxic effects of alloxan, a substance which is toxic to some glucose sensitive cells in pancreas and brain. To test this idea, we injected a subdiabetogenic dose of alloxan (65 mg/kg) or vehicle solution (acidified saline, pH 3.0) directly into the hepatic portal system of rats in an attempt to damage the postulated hepatic glucoreceptors. The animals were then trained to drink a palatable liquid food (vanilla Instant Breakfast) and glucagon suppression of feeding was measured in a series of 30-min tests. On separate test days glucagon (400 or 800 ug/kg,i.p.) or vehicle injections were made 8 min after or 0, 4, 8, or 12 min prior to presentation of liquid food. Glucagon (800 ug/kg) significantly reduced food intake in controls when injected 0, 4 or 8 min prior to the test, but failed to suppress feeding in alloxan-treated rats. Under the most effective conditions glucagon suppressed intake in controls to 63.3 ± 19.3% of their baseline intake ($p < .01$), whereas alloxan-treated rats consumed 133.6 ± 19.3% of their baseline intake. Elevation of blood glucose during the 3 hr following glucagon was similar in both groups. In addition, cholecystokinin-induced satiety was not attenuated in alloxan-treated rats. The fact that alloxan abolished glucagon's satiety effect without impairing the ability of this hormone to elevate blood glucose suggests that hepatic-portal alloxan may damage a satiety mechanism which possibly operates by detection of glucose levels. This mechanism may involve hepatic vagal afferents, since hepatic vagotomy also abolishes glucagon satiety. If vagal afferents are damaged by hepatic-portal alloxan, the presumed damage must be limited to the hepatic innervation since cholecystokinin-induced satiety, which is mediated by the gastric vagus, was not impaired by this treatment. Finally, our alloxan treatment did not make animals diabetic or alter spontaneous weight gain. However, base-line intakes of the liquid food tended to be greater in alloxan-treated rats than in controls.

264.11 CCK-8 DECREASES SUCROSE INTAKE IN CHRONIC DECEREBRATE RATS. H.J. Grill, D. Ganster* and G.P. Smith (SPON: R. Murphy). Univ. of Pennsylvania, Philadelphia, PA 19104 and Cornell University Medical College, White Plains NY 10605.

Chronic decerebrate rats respond to the satiating effects of a gastric preload of nutrient by decreasing the intake of sucrose delivered through an intraoral catheter (Grill and Norgren, 1978). Such preloads stimulate preabsorptive and postabsorptive satiety mechanisms. CCK-8 is released by nutrients in the small intestine, and has a satiety effect in numerous animals and humans (Smith et al, 1981). To determine if endogenous CCK-8 released by a gastric preload could be one of the mechanisms that satiates the chronic decerebrate rat, we investigated the effect of exogenously administered CCK-8 on sucrose intake by chronic decerebrate rats.

Seven chronic decerebrate rats were prepared and maintained as described by Grill and Norgren (1978). After habituation to the test situation and the intraoral delivery of distilled water, decerebrate rats were tested in the light phase after 24 h of food deprivation. They received an ip injection of CCK-8 (6.3 to 8.3 $mcg\text{-}kg^{-1}$) or an equal dose of desulfated CCK-8 (which has no satiety effect in normal rats) just prior to the beginning of intraoral delivery of 0.1M sucrose at a rate of 0.82 $ml\text{-}min^{-1}$. Intraoral sucrose infusion was stopped when rats rejected the fluid. CCK-8 significantly decreased sucrose intake in all 7 rats: intake ($\bar{X}\pm SE$) after CCK-8 = 3.0±1.26 ml, intake after desulfated CCK-8 = 12.1±2.48 ml, $p< .02$. To compare the inhibition of sucrose intake by CCK-8 in decerebrate rats with the effect of CCK-8 in neurologically normal rats, we tested 6 normal rats under identical conditions. CCK-8 decreased intraorally delivered 0.1M sucrose intake in 5 of 6 normal rats: intake after CCK-8 = 6.4±1.34 ml, intake after desulfated CCK-8 = 19.7±3.78 ml, $p < .02$. These results demonstrate that the decerebrate rat has sufficient neural mechanisms to mediate the satiating effect of CCK-8 on sucrose intake and that endogenous CCK-8 could mediate part of the satiating effect of a gastric preload in decerebrate rats.

PERIPHERAL AUTONOMIC NERVOUS SYSTEM II

265.1 PATHOLOGICAL DISINHIBITION OF A SOMATOSENSORY-SYMPATHETIC REFLEX IN INDIVIDUALS WITH IDIOPATHIC HYPERIDROSIS, P. Marchettini,* E. Torebjörk,* W. Culp and J. Ochoa. Dartmouth Medical School, Hanover, N.H. and University of Wisconsin, Madison, WI, U.S.A.

The syndrome idiopathic hyperidrosis consists of excessive, often unmotivated and embarrassing sweating of palms, soles and axillae. Individuals of all ages and races may be affected. The cause of the disorder remains unknown; it is accepted that the condition is not a manifestation of neurosis. Among the many therapies attempted, the most effective is sympathectomy.

Below spinal cord lesions in man, there remains spinal reflex sudomotor activity in response to intense cutaneous thermal stimulation. In addition, under similar circumstances, reflex sweating is observed with bladder or rectal distention or following tactile or irritative cutaneous stimulation. These observations suggest the existence in man of dormant spinal sudomotor reflex arcs with mechanoreceptor rather than thermoreceptor afferents.

Taking advantage of the microneurographic technique (see Vallbo, et al,[1]), and of pulse plethysmography, we have studied pathophysiological phenomena in 3 otherwise healthy individuals exhibiting idiopathic hyperidrosis. By recording directly the neural autonomic outflow with intraneural microelectrodes in skin and muscle nerve fascicles, while monitoring equivalents of skin vasoconstriction and observing gross palmar sweating, we have made observations which reveal that these subjects have a) an abnormal increase in postganglionic sympathetic efferent activity under basal conditions, and b) an abnormal sweat reflex drive from skin afferents. The available evidence indicates that the abnormal circuitry impinges on sympathetic sudomotor outflow to skin, whereas vasomotor outflow to skin and muscle are unaffected.

Since autonomic subsystems have independent pathways, selective dysfunction of the sudomotor system in idiopathic hyperidrosis is readily explained. Analogous dysautonomia selective to other subsystems, perhaps Raynaud's syndrome from selective skin vasomotor dysfunction, should be demonstrable with the techniques applied in the present study.

A specific disorder of inhibitory interneurons is postulated for idiopathic hyperidrosis.

265.2 SYNAPTIC TRANSMISSION IN THE CHRONICALLY DECENTRALIZED MIDDLE CERVICAL AND STELLATE GANGLIA OF THE DOG. J.A. Armour, Dept. of Physiology and Biophysics, Dalhousie University, Halifax, Nova Scotia, Canada.

Afferent stimulation of one canine thoracic cardiopulmonary nerve generates compound action potentials (CAPs) in the efferent axons of other, ipsilateral cardiopulmonary nerves. This can occur before and after acute decentralization of the middle cervice (MCG) and stellate (SG) ganglia (Armour, 1976). These CAPs can be modified by a number of pharmacological agents (Armour, 1983). It was proposed that thoracic autonomic reflexes function via synaptic mechanisms located primarily in the MCG. It is not known if such reflex arcs are dependent upon two or more neurons which are located in the thoracic autonomic nervous system. Can some of these reflex mechanisms occur via neurons which are only in thoracic autonomic ganglia? A left thoracotomy was performed in twelve dogs following anesthesia (ketamine and pentobarbital) and the initiation of artificial respiration with a positive pressure device. The thoracic neural elements were identified. Connections between the left stellate ganglion and the central nervous system were cut. The upper thoracic vagosympathetic complex was cut as well. Thus, the SG and MCG were decentralized. The chest was closed. Fourteen days later the animals were anesthetised (ketamine and ∝chloralose) and the left thoracic autonomic nerves and ganglia exposed. The left cranial medial, intermediate medial, caudal medial and ventral lateral cardiopulmonary nerves were desheathed under oil and laid over bipolar stimulating and recording electrodes. Stimulation (0.5 Hz, 2-4 msec, 4-8 V) of one nerve generated CAPs in another ipsilateral nerve. In some experiments CAPs were modified by alteration of stimulation frequency or by the pharmacological agents hexamethonium, atropine, phentolamine and propranalol. In all experiments, CAPs were altered by local injections of chymotrypsin or manganese into the MCG (Armour, 1983). Injections of similar volumes of normal saline into the same regions had little, if any, effect on the CAPs. It is concluded that synaptic activity in thoracic autonomic ganglia generated by afferent nerve stimulation persists in chronically decentralized thoracic autonomic ganglia and that such activity can be modified by altered stimulation frequency and by pharmacological agents. It is proposed that afferent and efferent neurons exist in the thoracic autonomic nervous system which can function independently from the central nervous system.

265.3 PRE- AND POSTGANGLIONIC SYMPATHETIC PATHWAYS TO MESENTERIC ARTERIES IN THE GUINEA PIG. D. L. Kreulen, Dept. of Pharmacology, University of Arizona, College of Medicine, Tucson, AZ 85724.

The postganglionic mesenteric nerves emanating from the inferior mesenteric ganglion (IMG) of the guinea pig contain both pre- and postsynaptic nerve fibers. The purpose of these studies was to determine the contribution of the various ganglionic pathways to the neural outflow to mesenteric arteries. In vitro preparations consisting of the IMG with attached preganglionic [lumbar splanchnic (LSN)], postganglionic or mesenteric [lumbar colonic (LCN) and hypogastric (HGN)] and intermesenteric (IMN) nerves and mesenteric blood vessels (inferior mesenteric artery) were dissected from male guinea pigs and pinned to the floor of a recording chamber (Krebs, 37°C). Intracellular responses to stimulation of para-arterial nerves were recorded in smooth muscle cells of the inferior mesenteric artery and its secondary and tertiary branches. The recording sites were 10-15 mm away from the stimulating sites. Membrane potentials ranged from -70 to -85 mV. In response to single nerve shocks excitatory junction potentials (EJPs) were recorded in arterial smooth muscle cells; their amplitude ranged from 1-11 mV. All EJPs were blocked by tetrodotoxin (10^{-6}M) but not by phentolamine (10^{-6}M). For each arterial cell, the averaged EJP amplitudes (20-50 responses) were compared for each of the four nerve fibers. All cells studied gave responses to LCN (postganglionic) and LSN (preganglionic) stimulation, 40% to IMN stimulation and 22% to HGN stimulation. EJPs in response to LCN stimulation were always of the greatest amplitude. The amplitude of EJPs in response to LSN stimulation were 36% (± S.E.3%, n=15) of the EJPs in response to LCN, to IMN stimulation they were 38% (± S.E.12%, n=4) and to HGN stimulation they were 12% (n=2). IMN stimulation usually gave two EJPs of different latency in response to each stimulus. Repetitive nerve stimulation (2 Hz) resulted in an increase of EJP amplitude and a slow depolarization of the membrane potential. This facilitation was greater for stimulation of LSN than for LCN, indicating the additional facilitation at ganglionic synapses. Phentolamine (10^{-6}M) depressed the slow depolarization but increased the amount of facilitation. These studies demonstrate the participation of several ganglionic pathways in the neural control of mesenteric blood vessels. They also show that the IMG does not relay all presynaptic impulses to postganglionic fibers innervating the blood vessels. The activation of outflow to the vessels by HGN and IMN stimulation suggests a reflex pathway through the ganglia from the regions supplied by these nerves. *Support HL 27781.*

265.4 NEURONS WITH HIGH-AFFINITY GABA-UPTAKE SITES IN THE MYENTERIC PLEXUS OF THE GUINEA-PIG, RAT AND CHICKEN Saffrey, M.J.*, Marcus, N.*, Jessen, K.R.* & Burnstock, G.* (SPON: Anna B. Drakontides, Ph.D.)
Department of Anatomy & Embryology and Centre for Neuroscience, University College London, Gower Street, LONDON WC1E 6BT.

Autoradiographic techniques were first used to localize putative GABAergic (gamma-aminobutyric acid) neurons in the myenteric plexus of the guinea-pig caecum by Jessen et al. (Nature, 281:71, 1979), and subsequently in that of the ileum, by Krantis & Kerr (Neurosci. Lett., 23: 263, 1981). In order to determine whether such neurons are found throughout the enteric nervous system, we have examined the myenteric plexuses of the guinea-pig proximal and distal colon, the rat proximal colon and the chicken gizzard for the presence of neurons which take up ^{3}H-GABA.

Plexuses were isolated from the gut wall after enzyme treatment, and then incubated in 1.4×10^{-8}M ^{3}H-GABA and 10^{-3}M ^{3}H-GABA and 10^{-3}M Beta-alanine either immediately, or after maintenance in tissue culture for 7-14 days. Control preparations were incubated in the presence of 2,4-DABA, (2,4-diaminobutyric acid) a specific neuronal GABA uptake inhibitor. After incubation for 20 minutes at room temperature, the preparations were fixed, dried and processed for autoradiography.

Scattered neurons selectively labelled with ^{3}H-GABA were found in the myenteric plexuses from all the areas examined; control preparations contained no labelled neurons. these results show that neurons with high-affinity GABA uptake sites are widespread in the enteric nervous system. Recent biochemical and pharmacological evidence for GABA as an enteric neurotransmitter is discussed.

265.5 THE EFFECTS OF HYPOXIA-INDUCED STRESS ON CATECHOLAMINE CONTENT AND SYNTHESIS IN THE RAT SUPERIOR CERVICAL GANGLION. J.J. Brokaw and J.T. Hansen. Department of Anatomy, University of Texas Health Science Center at San Antonio, San Antonio, Texas 78284.

In addition to norepinephrine (NE)-containing principal neurons, the rat superior cervical ganglion (SCG) also contains numerous small intensely fluorescent (SIF) cells which store predominantly dopamine (DA). These paraneurons are thought to act as interneurons and/or in an endocrine capacity to modify ganglionic transmission. Hypoxia is reported to stimulate activity in other catecholamine (CA)-containing tissues such as the adrenal medulla, the carotid body and abdominal paraganglia. We wished to examine the effects of hypoxia-induced stress on CA content, turnover, and in vivo tyrosine hydroxylase activity in the rat SCG using high performance liquid chromatography with electrochemical detection. The steady-state SCG concentrations of NE and DA were 174.2 ± 4.7 and 17.8 ± 0.7 pmol/ganglion, respectively. Animals were rendered severely hypoxic by placing them in an enclosed chamber flushed with 5% O_2 - 95% N_2. Hypoxic exposure for 30 min resulted in a 128% increase in DA over control levels ($p < 0.01$). No change was seen in NE content. Turnover was determined by administering a selective inhibitor of tyrosine hydroxylase (α-methyl-p-tyrosine, 250 mg/kg, ip) and measuring the time-dependent decline in CA levels. The half-lives of SCG NE and DA were 1.6 hrs and <0.5 hrs, respectively. The turnover of NE was not altered by hypoxia, but DA turnover was too rapid to assess any changes by this method. Therefore, accumulation of DOPA following the blockade of L-aromatic amino acid decarboxylase by NSD-1015 (100 mg/kg, ip) was used as an in vivo index of tyrosine hydroxylase activity, another measure of synthetic capacity. DOPA levels in SCG from rats exposed to 30 min of hypoxia were increased 65% above air-breathing control levels ($p < 0.05$). Though the exact location of this increased activity cannot be ascertained, the hypoxia-induced increase in DA content, coupled with the inability of hypoxia to alter NE content or turnover, suggests that hypoxia may activate the relatively small population of SIF cells. 265.6 MUSCARINE INCREASES TYROSINE HYDROXYLASE ACTIVITY AND PHOSPHOLIPID METABOLISM IN THE SUPERIOR CERVICAL GANGLION OF THE RAT. J. Horwitz*, S. Tsymbalov*, and R.L. Perlman* (Spon: J. Townsel).
Department of Physiology and Biophysics, University of Illinois College of Medicine, Chicago, IL 60680

Muscarinic agonists increase DOPA accumulation and produce a stable activation of tyrosine hydroxylase (TH) in the superior cervical ganglion of the rat. These agents also increase phospholipid turnover in this tissue. Muscarine (100 μM) typically causes a 2 to 3-fold increase in DOPA synthesis and a 7 to 15-fold increase in the incorporation of $^{32}P_i$ into phosphatidylinositol (PI) in the ganglion. We have studied the relationship between muscarine-stimulated phospholipid turnover and the muscarine-induced activation of TH. Both of these actions are apparent within two min of incubation with muscarine, and both are independent of extracellular Ca^{2+}. Although muscarine causes a much larger increase in phospholipid labelling than in DOPA synthesis, the two processes show a similar dependence on muscarine concentration; muscarine produces half-maximal increases in both processes at a concentration between 1 and 10 μM. Muscarine is more potent and more effective than bethanechol both for the stimulation of DOPA synthesis and for the stimulation of phospholipid metabolism. Thus, the effects of muscarinic agonists on phospholipid turnover and on DOPA synthesis appear to be mediated through a single class of muscarinic receptors.

When ganglia are preincubated with [^{3}H]inositol to label inositol-containing phospholipids and then incubated in the presence of Li^+ (an inhibitor of inositol 1-phosphatase), muscarine increases the accumulation of inositol 1-phosphate in the ganglia. The primary effect of muscarine on phospholipid metabolism may be to increase the breakdown of inositol-containing phospholipids. Several lines of evidence support the idea that there may be a causal relationship between the muscarinic stimulation of phospholipid metabolism and the muscarine-induced activation of TH. Li^+ inhibits the muscarine-induced increase in DOPA accumulation. Other agents that promote phospholipid hydrolysis, including phospholipase C and deoxycholate, also increase DOPA synthesis in the ganglion [control, 121±11 pmol/ganglion/hour; phospholipase C (B. cereus, 7.5 units/ml), 749±130; deoxycholate (1 mM), 359±21]. Phospholipase C, like muscarine, causes a stable activation of TH in the ganglion. Changes in phospholipid metabolism may mediate the activation of TH by muscarinic agonists.

Supported in part by research grant HL 29025 from the National Institutes of Health. J.H. is the recipient of NRSA HL06701 from the National Institutes of Health.

265.7 PROTEIN PHOSPHORYLATION IN THE SUPERIOR CERVICAL GANGLION. Anne L. Cahill* and Robert L. Perlman* (SPON: R. Greenberg). Dept. of Physiology and Biophysics, University of Illinois College of Medicine, Chicago, IL 60680.

Cholinergic agonists, cyclic AMP analogues, and veratridine have all been shown to increase dopa synthesis in the superior cervical ganglion (SCG) of the rat. These agents all appear to produce a stable activation of tyrosine hydroxylase (TH) in the ganglion (Horwitz and Perlman, unpublished observations). We have investigated the role of protein phosphorylation in mediating the actions of these agents in the SCG. Intact ganglia were incubated in vitro in media containing $^{32}P_i$. Following this incubation, ganglionic proteins were separated by two-dimensional electrophoresis; phosphoproteins were identified by radioautography of the dried gels. Thirty-two phosphorylated polypeptides, ranging in apparent molecular weight (M_r) from 18,000 to 135,000 and in isoelectric point (pI) from 4.5 to 7.0, were consistently seen. Two of these phosphorylated polypeptides were identified as TH on the basis of their electrophoretic identity with immunoprecipitated TH. These two TH polypeptides migrated as a closely spaced doublet with M_r of about 60,000 and pI of approximately 6.1. Incubation of the ganglia with 50 μM veratridine, 100 μM dimethylphenylpiperazinium (DMPP), 150 μM muscarine, or 1 mM 8-bromo cyclic AMP increased the incorporation of $^{32}P_i$ into the two TH polypeptides. Veratridine, DMPP and muscarine also increased the incorporation of $^{32}P_i$ into six other polypeptides. The M_r (pI in parentheses) of these other phosphorylated polypeptides were 67,000 (5.0), 59,000 (5.7), 21,000 (5.6), 21,000 (5.8), 19,000 (5.0), and 19,000 (5.1). Veratridine caused the greatest increase in incorporation of $^{32}P_i$ into these polypeptides, followed by DMPP and then muscarine. 8-Bromo cyclic AMP also increased the incorporation of $^{32}P_i$ into the 59,000 (5.7) polypeptide, but not into the other peptides listed. Instead, 8-bromo cyclic AMP increased the incorporation of $^{32}P_i$ into 45,000 (6.4) and 43,000 (6.3) polypeptides. Thus, these various agents all increase protein phosphorylation in the SCG. 8-Bromo cyclic AMP presumably activates a cyclic AMP-dependent protein kinase in the ganglion; veratridine and cholinergic agonists may activate a cyclic AMP-independent protein kinase(s). TH can apparently be phosphorylated by both the cyclic AMP-dependent and the cyclic AMP-independent protein kinases. The stimulation of TH phosphorylation by cholinergic agonists, cyclic AMP analogues, and veratridine may underlie the effects of these agents on dopa synthesis in intact ganglia. (This work was supported by NIH Research Grant HL29025.)

265.8 HORMONAL REGULATION OF PEPTIDES IN PERIPHERAL SYMPATHETIC NEURONS. R.W.Hamill, L.C.Terry, L.A.Guernsey* and M.Zorza*. Monroe Community Hospital/Univ Rochester Med Ctr, Roch, N.Y. 14603 and V.A. Hospital/Univ Michigan, Ann Arbor, Michigan 48105

Previous investigations indicate that hormonal factors regulate the catecholaminergic neurotransmitter synthesizing enzyme tyrosine hydroxylase (T-OH) in peripheral sympathetic ganglia. One month after bilateral castration in male Sprague-Dawley rats T-OH activity declines 75% in the hypogastric ganglion (HG), a terminal noradrenergic ganglion which innervates androgen responsive pelvic sex organs. Recent studies indicate that neuropeptides are distributed throughout the neuraxis and may coexist with catecholamines in peripheral sympathetic ganglia. For instance, the undecapeptide substance P (SP) and the tetradecapeptide somatostatin (SRIF) are present in ganglia and may share regulatory influences with catecholamines. The present studies were designed to extend our earlier investigation and were based on the hypothesis that gonadal steroids may regulate peptidergic as well as catecholaminergic characteristics of peripheral ganglia.

Substance P-like immunoreactive (SPLI) and somatostatin-like immunoreactivity (SLI) were measured by radioimmunoassay in the hypogastric ganglia (HG) of male Sprague Dawley rats 2,4 and 10 weeks following castration. SPLI decreased significantly($p<.05$) by 2 weeks (28%) and remained so at 4 (22%) and 10 (21%) weeks. To substantiate the specificity of testosterone in these alterations, castrated and sham-operated animals were administered testosterone decanoate (20mg/kg) or vehicle. Testosterone restored HG SPLI to normal levels. In order to examine whether these effects of gonadal steroids were restricted to SP or whether other neuropeptides are influenced similarly, SLI was measured in the HG. There was no change in HG SLI whether examined 2 weeks (control 46.6±6.6 pg/gang; castrated 44.3±4.3 pg/gang) or 8 weeks (control 59.1±5.6 pg/gang; castrated 62.7±7.1 pg/gang) after castration. To define whether this regulatory influence of hormonal factors exist in other sympathetic ganglia, SPLI and SLI were examined in the pelvic ganglion another pelvic autonomic ganglion. Castration had no effect on either SPLI (control 411.2± pg/gang; castrated 414.8±36.4 pg/gang) or SLI (control 220.3±13.4 pg/gang; castrated 176.8±21.4 pg/gang) when examined 10 weeks after castration. These studies indicate that SP but not SRIF in specific peripheral sympathetic ganglia is under gonadal (androgenic) influences. Taken together with earlier studies, these observations suggest that catecholaminergic and specific peptidergic systems in sympathetic neurons are under hormonal control.

265.9 ON THE SUBCELLULAR DISTRIBUTION OF TYROSINE HYDROXYLASE IN BOVINE ADRENAL MEDULLA AND THE LOCUS OF EFFECT OF ACH IN SITU. J.W. Haycock#, R.J. George and J.C. Waymire. Dept. Neurobiology & Anatomy, University of Texas Medical School, Houston, TX 77225.

Acetylcholine (ACh), the physiological agonist of chromaffin cells, induces catecholamine secretion and a compensatory acceleration of catecholamine biosynthesis from bovine adrenal medulla. One mechanism for this compensatory increase in synthesis is the phosphorylation and activation of tyrosine hydroxylase (TH)[1], the first step in catecholamine biosynthesis. We have previously shown that a calcium-dependent kinase activity in the soluble fraction of medullary chromaffin cells is capable of mimicking the effects of ACh in situ[2]; however, recently it has been reported that TH and kinases capable of phosphorylating TH are present in bovine adrenal medullary chromaffin granule membranes[3]. Thus, the present studies investigated the subcellular locus of ACh's effects upon the phosphorylation of TH in purified, cultured chromaffin cells from bovine adrenal medullae.

First, we investigated the subcellular distribution of TH activity in both adrenal medullae and chromaffin cells purified from medullae. As reported by several other authors, a large portion of the TH activity (40-50%) from adrenal medullae was found in particulate fractions. However, with several different sonication media, over 90% of the TH activity associated with isolated chromaffin cells was soluble.

In addition, after labeling the cells with $^{32}P_i$, over 90% of the ^{32}P-TH was found in the soluble fractions. Stimulation of the cells with ACh increased the phosphorylation of TH but, again, over 90% of the increase was associated with soluble TH.

In an attempt to optimize detection of TH phosphorylation, crude homogenates, supernatant and particulate fractions from the chromaffin cells were prepared and phoshorylated in vitro in the presence of [gamma-^{32}P]ATP. Well over 90% of the phosphorylation of TH (and the stimulation thereof by cAMP and calcium) observed in the crude homogenate was also observed in soluble fractions. On the other hand, phosphorylation of a band which comigrated with TH in SDS-PAGE from particulate fractions was detectable only with very long autoradiographic exposures.

These data suggest then that although TH (and possibly kinases) can associate with particulate fractions when isolated from crude bovine adrenal medullae, the physiological effects of ACh are predominantly associated with soluble pools of TH and its attendant kinases.

265.10 GLUCOCORTICOID RECEPTORS AND THE REGULATION OF PNMT ACTIVITY IN CULTURED ADRENAL MEDULLARY CELLS. K.L. Kelner and H.B. Pollard. Lab of Cell Biology and Genetics, NIADDK, NIH, Bethesda MD 20205.

The activity of the adrenal medullary enzyme, phenylethanolamine N-methyl transferase (PNMT), is dependent on glucocorticoids secreted from the adrenal cortex. After withdrawal of glucocorticoid in vivo and subsequent loss of PNMT activity, the enzyme is known to require extremely high concentrations of glucocorticoids for reappearance of the activity. We are able to maintain isolated adrenal medullary cells in culture and measure PNMT levels in aqueous extracts of these cells. We could, therefore, ask whether PNMT activity in vitro was dependent on glucocorticoids and if so, whether high concentrations were necessary for activation. Maintenance of medullary cells in DMEM supplemented with 5% fetal calf serum and periodic measurement of PNMT indicates that after the removal of the cells from the animal, the specific activity of PNMT declines. There is an initial rapid decline in activity followed by a slower phase of loss of activity which approaches zero after 20-25 days in culture. PNMT activity can be increased 25 - 75% by glucocorticoids for up to 21 days in culture. Extensive dose response curves show maximal induction of PNMT at 10 μM dexamethasone in the presence of 5% fetal calf serum. Under these conditions maximal hydrocortisone stimulation occurs at 100 μM. In a serum free defined medium, maximal induction occurs at much lower concentrations of dexamethasone (10 nM) and hydrocortisone (10 nM). This may be due to the difference in availability of free steroid in a serum free defined medium and a 5% serum medium which contains the serum glucocorticoid binding proteins. Thus, unlike in vivo, in an in vitro situation adrenal medullary cells are capable of responding to very low concentrations of steroids.

Measurements of the affinity of the cytoplasmic glucocorticoid receptor indicate that, as expected, it has an extremely high affinity for its ligands. The K_d is 1.3 nM which is similar to the concentration of glucocorticoid needed for half maximal stimulation of PNMT. Therefore, the isolated adrenal medullary cell lacks the mechanism by which the organized adrenal medullary tissue maintains its apparent low sensitivity to glucocorticoids.

265.11 REGULATION OF CATECHOLAMINE RELEASE FROM FETAL ADRENAL MEDULLARY CELLS IN CULTURE: EFFECT OF HORMONES. Cecilia Y. Cheung. Div, of Perinatal Biol, Loma Linda Univ, Sch. of Med, Loma Linda, CA 92350

In the ovine fetus, circulating catecholamines as well as the hormones angiotensin II (AII) and prolactin (PRL) play a major role in the maintenance of cardiovascular homeostasis. We have recently observed that an i.v. administration of oPRL into ovine fetuses can induce increases in arterial pressure and heart rate (C.Y. Cheung, R.A. Brace, Soc. Gyn. Invest. Abs. #193, 1982). These responses occurred even in the presence of ganglionic blockade, suggesting that humoral agents rather than neural reflexes were responsible for the changes. To investigate the factors involved in the regulation of catecholamine release from fetal adrenal medulla, and to determine whether the effects of prolactin can be mediated through release of adrenal catecholamines, the direct effects of oPRL, AII and cortisol on the release of dopamine (DA), epinephrine (EPI), and norepinephrine (NE) from fetal adrenal medullary cells in culture were studied. The adrenal glands from ovine fetuses of 125-135 days gestation were used. The medulla was dissected free of the cortex and the tissues dispersed using 0.05% collagenase. The dispersed cells were allowed to plate for 18 h with 10^5 cells per well in Kreb's Henseleit buffer containing 0.5% BSA at 39.5°C in a humidified atmosphere of 95% air and 5% CO_2. Following a 6 h preincubation, fresh medium alone or containing oPRL (40 ug/ml), AII (40 ug/ml), or cortisol (10^{-6}M) was added to the cells and the incubation was carried on for 24 h. The medium was sampled at 3, 6, 18, and 24 h for measurements of DA, EPI, and NE using a radioenzymatic assay. oPRL enhanced the release of DA, EPI, and NE at 6 h by 103%, 75%, and 217%, resp. AII stimulated the release of EPI and NE at 6 h by 51% and 100%, resp., while decreasing the release of DA at 3 h by 47%. Cortisol selectively increased the release of EPI at 6, 18, and 24 h by 119%, 222%, and 167% resp., but had little effect on the release of DA or NE. In other experiments, the adrenal cortical cells were dispersed separately and recombined with medullary cells. The amount of DA, EPI, and NE released into the medium from medullary cells at 2 h was 43 ± 15, 565 ± 24, and 869 ± 75 pg/ml resp. However, in medullary cells recombined with cortical cells, the release of catecholamines was significantly elevated to 253 ± 25, 1510 ± 97, and 10,298 ± 825 for DA, EPI, and NE resp. The elevation in catecholamine release was maximal at 6 h, and continued to be observed at 24 h. The results suggest 1) oPRL can stimulate fetal adrenal medulla to release DA, EPI, and NE which could cause major hemodynamic effects on the fetal circulation, 2) AII and cortisol can enhance the release of NE and/or EPI from fetal adrenal medulla, and 3) recombination of fetal adrenal medullary cells with cortical cells can potentiate the release of all 3 catecholamines.

EPILEPSY: PHYSIOLOGY II

266.1 NEONATAL ALTERATION OF CENTRAL NORADRENERGIC AXONS ABOLISHES INHERITED SPIKE WAVE ABSENCE SEIZURES IN THE MUTANT MOUSE TOTTERING. Jeffrey L. Noebels, Departments of Neuropathology, Harvard Medical School and Neuroscience, Childrens Hospital, Boston, Massachusetts.

Tottering mice (tg) show in adolescence stereotyped spike-wave discharges with behavioral absence seizures. The sole CNS cytopathology as yet uncovered is a selective overgrowth of locus coeruleus axons, raising NE levels 100-200% within most LC terminal fields (Levitt and Noebels, PNAS 78:4683, 1981). To evaluate the pathogenetic significance of LC hyperinnervation with regard to the neurologic expression of the tg gene, homozygous tg/tg littermates were injected subcutaneously with the neurotoxin 6OHDA (100mg/kg) or saline on the 1st and/or 2nd postnatal days. EEG recordings were obtained daily from ages 18days-15weeks. In the untreated adult tg/tg, 6-7/sec spike-wave discharges (1-10sec., 300-400mV) occur at a mean rate of 50/hr.

Neonatal injections of 6OHDA entirely prevented the later appearance of cortical discharges and behavioral absence seizures without altering the otherwise normal EEG rhythms of freely behaving mice. In 5/9 tg/tg's, the effect was absolute; histofluorescence studies at age 15 weeks revealed complete absence of NE axons in all cortical laminae, paralleled by 94-97% decreases in cortical NE levels (assayed by HPLC-EC) with respect to untreated mutants. In the remaining 4 mutants, spike-wave bursts were delayed by 4 weeks, and developed at greatly reduced rates (1-2/hr), duration (0.3-1.0sec), and amplitude (100-200mv). Fluorescence surveys in these mice revealed scattered LC axon patches in all neocortical layers, suggesting that the initial lesion was incomplete.

To determine whether LC denervation could acutely reverse the abnormal CNS synchronization once the neurological traits of the tg gene were fully expressed, unilateral stereotactic injections of 6OHDA were made into the LC of 3 adult tg/tg mice. Initially (48hrs), discharge rate and duration increased sevenfold; over the subsequent 10 weeks, the rate decreased 82% (mean 12 vs 66 bursts/hr); 75% of the decrease ocurred in the first week.

These findings relate the inherited expression of abnormal synchronization and absence seizures to a gene-linked error within a single neuromodulatory cell group, the locus coeruleus. The data indicate that the clinical disease can be arrested prior to its natural phenotypic expression, and that there is probably no critical stage in development which irreversibly commits the affected neurons to abnormal firing patterns. Supported by the Klingenstein Foundation.

266.2 THE EFFECT OF PHENYTOIN ON POST-TETANIC POTENTIATION AT THE FROG NEUROMUSCULAR JUNCTION. M.E. Selzer, G. David*, and Y. Yaari*. Department of Neurology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104 and Department of Physiology, Hebrew University-Hadassah Medical School, P.O.Box 1172, Jerusalem, Israel 91010.

Phenytoin (diphenylhydantoin, DPH) is known to reduce post-tetanic potentiation of spinal reflexes. The mechanism for this effect is not known, but it has been suggested that it depends on a blockage of invasion of the action potential into nerve terminals at high frequencies of stimulation.

We studied the effects of DPH on the frequency dependent activity of the endplate potential at frog (R. ridibunda) sartorius and cutaneous pectoris neuromuscular junctions under conditions of low quantal release (0.4-1 mM Ca++, 4 mM Mg++). Both surface electrodes, which sampled the simultaneous endplate currents of several endplates, and intracellular microelectrodes were used. In both types of experiments, bathing the preparation for one hour in 0.2-0.4 mM DPH produced a dramatic reduction (up to 100%) in tetanic potentiation (TP) during a 30 sec - 30 Hz tetanus. Post-tetanic potentiation (PTP) was also greatly reduced, especially the early phase (augmentation). By contrast, facilitation was unaffected by DPH.

With intracellular recordings, it was found that the reduction of PTP (up to 100% for the early phase and 50% for the late phase) could occur even when there were no failures of endplate potentials during the tetanus. Thus, there were no failures of the presynaptic action potential.

Similar effects were seen at lower doses of DPH (.03-.1 mM) if the muscles were exposed to the drug for several hours.

It is concluded that at the frog neuromuscular junction: 1) DPH greatly reduces TP and PTP by a mechanism which does not require failure of invasion of the presynaptic terminal by the action potential during the tetanus; 2) the efects are specific for TP and PTP because under the present conditions, neither facilitation nor the mean quantal content of unpotentiated endplate potentials was reduced; and 3) the large doses of DPH often required to produce significant effects in acute experiments may reflect its slow onset of action.

266.3 PAROXYSMAL DEPOLARIZATION AND HYPERSYNCHRONICITY IN VIRAL INFECTED GANGLIA, by Jacob Zabara, Physiology/Biophysics, Temple University, Philadelphia, PA. 19140.

Hypersynchronicity and paroxysmal depolarization (PD) are observed in viral infected ganglia and related to neuronal discharge synchronization in epileptic seizures. The superior cervical ganglion, infected with pseudorabies virus, is investigated as an experimental model of seizure discharge as occurs in focal or generalized epilepsy. In this preparation, the development of seizure-like discharges can be observed in a relatively isolated synaptic region where electrophysiological techniques can be used to monitor the underlying processes. The superior cervical ganglion is infected by intraocular viral (pseudorabies) inoculation of the right eye of rats. Recordings are performed either in situ or after excision of the ganglion which is suspended on Ag-Ag Cl electrodes in a humidified chamber containing a modified Ringer's solution and equilibrated with 95% O_2, 5% CO_2. Recordings are performed of evoked potentials (by rectangular pulses applied to the presynaptic nerve), and of potentials generated by viral replication, with d.c. amplifiers and oscilloscope. PD's begin as a consequence of viral replication in the postsynaptic cell bodies. These PD's have a characteristic rise time of approximately 50 msec., a duration of approximately 200 msec. and occur at a frequency of approximately .5Hz. Spike bursts are superimposed on the rising phase and peak of the PD's. Perfusing the superior cervical ganglion with acetylcholine decreases the PD interval time and amplitude but does not disrupt the rising or falling phases of the PD's. An analysis of time delays indicates that there is no single pacemaker cell or group of pacemaker cells from which the PD originates. These observations support the possibility that the PD represents a field potential which acts externally (i.e., ephaptically) in a relatively large population of cells to synchronize spike discharges in the cell population. This synchronization is related to viral replication since as the infection proceeds, increasing waves of oscillatory depolarization occupy the population of neurons producing field bursts of increasing amplitude and duration. A slow IPSP appears to be associated with the PD's in early stages of infection. The slow IPSP progressively diminishes with time until a later stage of infection when oscillatory waves of depolarization make their apperance. It is possible that inhibitory neurons within the ganglion (SIF cells) are involved in the increasing synchronization of spike discharges. Thus the PD's and hypersynchronicity could have their origin in viral replication within inhibitory cell bodies.

266.4 ACTION OF TUNGSTIC ACID GEL ON CAT LUMBAR MOTONEURONS. W. Spain*, P. C. Schwindt* and W. E. Crill. Depts. Physiology & Biophysics and Medicine, University of Washington; Veterans Administration Medical Center, General Medical Research (151), Seattle, WA 98108.

Injection of tungstic acid gel (but not pH adjusted saline) into the cat lumbar ventral horn results in spontaneous, epileptiform bursts of action potentials in motoneurons surrounding the injection site. The abnormal motoneuron activity consists of waves of repetitive grouped discharges, or bursts, of action potentials. Each burst is composed of 3-6 action potentials where action potentials subsequent to the first one are triggered from the delayed depolarization of the preceding action potential. The same kind of multi-action-potential, high frequency bursts can be triggered by brief intracellular injected current pulses which evoke single action potentials in normal motoneurons. Rhythmic, repetitive bursts of the same type are evoked by long-lasting injected current pulses. Thus, altered neuronal membrane properties are responsible for the bursting activity. The character of the bursts observed after tungstic acid application differ markedly from those seen during strychnine- or penicillin-induced spinal seizures and is likely to result from different cellular mechanisms. It is hypothesized that the alteration of fast-activated ionic conductances and/or dendritic properties underly the tungstic acid-induced bursting as opposed to the alteration of slow ionic conductances which are involved in penicillin-induced bursting.

266.5 NEURONAL ACTIVITY IN AREAS OF CHRONIC CORTICAL INJURY. J.W. Lighthall* and D.A. Prince (SPON: M. Scher). Dept. of Neurology, Stanford Univ. Sch. of Medicine, Stanford, CA 94305.

We used in vitro techniques (37°C) to study neurons in guinea pig sensory motor neocortical slices (500 μm) obtained from chronic epileptogenic freeze lesions made 1-3 wks earlier. Intracellular recordings were obtained from 42 neurons in cortical laminae located directly beneath the site of the freeze lesion. The properties of 18 neurons examined in detail were as follows: V_m = 69.8 ± 11.8 mV; spike amp = 8.10 ± 13.3 mV; and time constant = 11.5 ± 3.8 msec. Following orthodromic (intracortical or subcortical) stimulation, 16 of these neurons generated fixed short latency bursts of action potentials superimposed on long duration (62.5 ± 15.2 msec) graded multiple component depolarizations. Three of 18 neurons exhibited variable (75-150 msec) latency bursts of 1-6 action potentials. The duration and amplitude of both fixed and variable latency depolarizations, and the number of spikes varied with stimulus intensity and frequency. Both types of depolarizing events resembled PSPs in their response to changes in V_m. Similar depolarizations and burst responses could not be evoked by intracellular current injection, nor were they observed in 10 layer IV neurons recorded in normal guinea pig neocortex. Four neurons exhibiting a short latency graded burst response were intracellularly labelled with HRP. These consisted of 3 layer IV medium-sized spiny pyramidal neurons and 1 layer III multipolar spiny stellate neuron. Dendrites of these cells which subtended the lesion site showed no gross morphological abnormalities.

These preliminary data indicate that neurons in the area of a chronic freeze lesion possess unusual orthodromic response characteristics. Both short and variable latency burst responses were unlike the all-or-none intrinsic bursts observed in some normal layer IV neurons (Connors et al., J. Neurophysiol. 48:1302, 1982). The long variable latency depolarizations and bursts had properties similar to those of neurons in chronic epileptogenic cortex of man (Prince and Wong, Brain Res. 210:323, 1981) and depolarizing shifts in neurons of penicillin-treated neocortical slices (Gutnick et al., J. Neurophysiol. 48:1321, 1982). Our data suggest that the burst responses in chronic freeze lesions are the result of modified synaptic impingement; alterations in intrinsic membrane properties may also be present, but have not as yet been identified. The role of such cellular behavior in the generation of epileptiform events in the chronic focus in vivo is unclear.

266.6 INTRACELLULAR RECORDINGS FROM HUMAN EPILEPTIC CORTEX: *IN VITRO* MAINTENANCE OF SPONTANEOUS RHYTHMIC ACTIVITY. P.A. Schwartzkroin and W.D. Knowles, Dept. Neurological Surgery, Univ. Washington, Seattle, WA 98195

The *in vitro* slice preparation has made it possible to obtain intracellular recordings from neurons in cortical tissue removed from a suspected epileptic focus in human epilepsy patients. Our earlier studies on slices from lateral temporal neocortex, however, yielded little convincing evidence that epileptiform activity could be maintained *in vitro* (Ann Neurol 13:249-257, 1983). We now report results of more recent experiments in which unusual (epileptiform?) activity has been observed.

Human tissue was obtained during neurosurgical procedures to remove focal epileptic regions of temporal lobe in patients with medically-intractable seizures. Cortical biopsy samples from both lateral and mesial temporal lobe were cut into slices 700-800 μm thick, and studied electrophysiologically. Spontaneous cellular activity was present in both lateral and mesial tissue samples, but there were no spontaneous field potential events suggestive of epileptic 'spikes'. Stimulation in the white matter region of the slice evoked synaptic inputs in cortical neurons consisting of both EPSP and IPSP components. Average cell resting potential, action potential amplitude, and input resistance were similar for cells in lateral and mesial cortex.

The most striking activities recorded in these experiments were spontaneous, rhythmic postsynaptic potentials. These PSPs, consisting of both depolarizing and hyperpolarizing components, were seen most often in the tissue from mesial temporal lobe. The depolarizing component of the PSP was sometimes sufficiently large to trigger action potentials. Stimulus-evoked and spontaneous PSPs had a similar appearance, with similar reversal potentials for their respective hyperpolarizing components. Spontaneous PSP frequency was not dependent on cell resting potential, but PSPs were blocked when TTX was focally applied near the recording electrode. Simultaneous intracellular recordings from two cells were obtained from several tissue samples in which this rhythmic activity was apparent; in all cases, these spontaneous events occurred synchronously, or with a close phase-locked relationship, over a wide area of a slice.

The mechanism(s) underlying these events is unclear. There may be some pacemaker region in the tissue, and/or the synchronous activity may be the result of unstable circuit interactions. It appears that the requisite cells and circuitry are more likely to be contained in thicker slices, and in tissue from mesial temporal cortex than in thinner and/or lateral cortex slices. These spontaneous, rhythmic, synchronous PSPs may reflect the epileptogenic nature of the tissue from human foci.

266.7 MECHANISMS IN HIPPOCAMPAL CA3 REGION WHICH PROTECT AGAINST SPREADING DEPRESSION. M.M. Haglund and P.A. Schwartzkroin Dept. of Neurological Surgery, University of Washington, Seattle, WA 98195.

Using the slice preparation of the developing rabbit hippocampus, we have studied spontaneous spreading depression (SD) episodes that occur at highest frequency at 8-13 days postnatal. These spontaneous SD events are primarily limited to the CA1 region. The present investigations were aimed at elucidating the "protective" mechanisms among the CA3 cells which prevent the spread of depolarization into this region.

Simultaneous intracellular recordings from the CA1 and CA3 regions were obtained to analyze the sensitivity of the two regions to spontaneous SD episodes and their thresholds to incoming SD. In order to control the onset of SD, 2 M KCl was applied with pressure ejection (30 psi) from a microelectrode (2-5 µm tip, 50-150 msec) located in stratum pyramidale either 100 µm away from an intracellular electrode or midway between the two intracellular electrodes. The SD episodes elicited with this technique had similar chracteristics to those SD episodes which occurred spontaneously (see Neurosci. Abstr. 8:1017,1982). The SD episodes induced by KCl application in the CA1 region led to two types of activity in the CA3 cells: 1) The CA3 cell would increase its spontaneous firing rate, then hyperpolarize 5-10 mV, and finally return to resting membrane potential level as the CA1 cell repolarized; or 2) Ictal activity began in the CA3 region 5-20 seconds after the onset of a SD episode in the CA1 region. The CA3 seizure consisted of a 10-20 mV depolarization which developed into rhythmic discharges. Upon repolarization of the CA1 cell, the ictal activity in the CA3 region ceased, and synchronous afterdischarge bursts were observed.

That the CA3 region has a higher threshold to the SD was confirmed in experiments in which potassium applications were made between the two cell regions. In most cases, the potassium application triggered SD in the CA1 region, while the CA3 cells either hyperpolarized or generated ictal activity. Potassium pulse durations of 50-100 msec elicited SD in the CA1 region, whereas durations of 200-300 msec (through the same electrode) were needed to trigger a SD episode in the CA3 region. Frequency of SD episodes in both the CA1 and CA3 regions was increased when the $[Cl^-]_o$ of the bathing medium was lowered from 120 to 20 mM; the spontaneous and potassium-elicited SD events were eliminated by blocking synaptic transmission ($[Ca^{++}]_o$ to 0.5 mM and $[Mg^{++}]_o$ to 8.0 mM). These results indicate that SD episodes are dependent upon synaptic transmission and suggest a critical role for local inhibitory mechanisms. The IPSPs in CA3 cells, which are potent much earlier in development than CA1 IPSPs, may account for the CA3 resistance to SD.

266.8 KAINATE LESIONED HIPPOCAMPI BECOME EPILEPTOGENIC. J.E. Franck* and P.A. Schwartzkroin (SPON: M. Anderson) Department of Neurological Surgery, Univ. Washington, Seattle, WA 98195.

It is well known that kainic acid creates an hippocampal lesion remarkably like that seen in Temporal Lobe Epilepsy. In clinical material, hippocampal necrosis appears as a selective loss of discrete pyramidal cell subfields; other subfields, as well as the dentate granule cells, are left apparently viable. The kainate model provides an opportunity to study whether such a selective pattern of cell death, and the intrinsic reorganization that occurs in remaining neurons, is a benign by-product of repeated seizures or if it also may contribute to epileptogenesis.

The CA3-CA4 region of the rat hippocampus was destroyed by unilateral, intraventricular kainate injection (0.5ug in 1ul saline, pH=7.4). Three weeks later pyramidal cells in the CA1 region were studied in the in vitro slice preparation.

Subfield CA1, in lesioned slices, generated both multiple population spikes and synchronous afterdischarge activity to orthodromic stimulation. When individual neurons from these slices were examined, there was a considerable attenuation of the afterhyperpolarization (AHP) that normally follows current induced repetitive firing. Often this was replaced by a depolarizing afterpotential (DAP). Prolonged DAPs were also seen following spontaneous activity. These DAPs often induced additional spike firing which, in some cells, progressed to seizure activity riding on a long depolarizing envelope.

There were numerous, apparently healthy, interneurons in slices with afterdischarge activity. However, the IPSP normally seen in pyramidal cells following antidromic stimulation was difficult to elicit, and was sometimes replaced by multiple EPSPs or additional orthodromic spikes.

The AHP and DAP observed in pyramidal cells normally control the occurrence and frequency of burst firing. The prominence of the DAP in cells from lesioned hippocampi may be a mechanism for alterations in excitability in these neurons. In addition, while interneurons are present, the relative absence of IPSPs in pyramidal cells suggests that pyramidal cell-interneuron connectivity has been altered. These data indicate that, at this survival period, lesioned hippocampi have become progressively epileptogenic and that this response is due to a loss of both intrinsic damping mechanisms and extrinsic inhibitory control.

266.9 HIPPOCAMPAL ELECTROPHYSIOLOGY AFTER KAINIC ACID TREATMENT: A CHRONIC MODEL OF FOCAL EPILEPSY. B. Lancaster,* H.V. Wheal,* and T.J. Ashwood.* (SPON: P.R. Adams). Dept. of Neurophysiology, University of Southampton, Southampton SO9 3TU, U.K.

The neurotoxin kainic acid (KA) can produce acute seizure activity, and intracerebral KA produces lesions which resemble the pathology often associated with temporal lobe epilepsy. However, there are few studies on the chronic epileptogenic effects of KA-induced lesions. This report describes some electrophysiological changes seen in CA1 pyramidal neurones in the KA-lesioned hippocampus. Unilateral lesions of the CA3/CA4 area were made by stereotaxic injection of KA into one lateral ventricle of an anaesthetized rat (Lancaster & Wheal, J. Comp. Neurol. 211:105). At post-operative day seven, transverse slices of the hippocampus were prepared. Control slices were obtained from the contralateral, unlesioned hippocampus or from untreated animals. The potential KA model was evaluated by comparison with preparations in which GABA-mediated inhibition was blocked by bicuculline.

Intracellular recordings from CA1 pyramidal neurones showed that synaptic stimulation normally evoked only a single action potential (AP), followed by a biphasic afterhyperpolarization (AHP). In common with previous observations (Nicoll & Alger, Science 212:957) the first phase of the AHP, and also the recurrent IPSP evoked by stimulation of the alveus were blocked by bicuculline, suggesting that they are GABA-mediated. This loss of inhibition was accompanied by synaptically evoked bursting activity. In the KA-lesioned hippocampus, CA1 pyramidal cells displayed values for resting potential, input resistance and AP amplitude which were indistinguishable from controls; however, synaptic activation evoked burst responses in 55% of neurones studied. All of these cells showed changes in the characteristic orthodromic AHP. The first phase was either markedly reduced or more usually absent (80%); and the second phase was also significantly reduced. The recurrently evoked IPSP was reduced or absent in comparison to control recordings.

KA treatment is known to induce spontaneous, recurrent seizure activity (Pisa et al., Brain Res. 200:481). In addition, it produces a characteristic pathology and a reduction in GABA-mediated inhibition associated with burst discharges. The results suggest that the KA-lesioned hippocampus may be a suitable chronic model of epilepsy.

Supported by a Wellcome Trust grant (HVW) and travel grant (BL), and the MRC (UK). HVW is a Wellcome Trust Senior Lecturer. Present address of BL; Dept. of Neurobiology & Behavior, SUNY at Stony Brook, New York 11794.

266.10 ELECTROPHYSIOLOGY OF KAINIC ACID (KA) INDUCED EPILEPTIFORM ACTIVITY IN THE RAT HIPPOCAMPAL SLICE. R.S. Fisher* and F.E. Alger, Dept. Physiol., Univ. Maryland Sch. Med., Baltimore, MD 21201.

Depression of GABA-mediated IPSPs has been proposed to be a crucial factor in the onset of epileptiform activity in most models of epilepsy. To test this idea, we induced epileptiform activity by bath application of 0.3-1 µM KA in the rat hippocampal slice. Repetitive field potential firing, spontaneous or evoked, occurred during exposure to KA. Intracellular records from 30 CA1 pyramidal cells during changes between control saline and saline containing 1 µM KA indicated that KA depolarized cells an average of 5 mV and caused a 15% decrease in input resistance. In several cells the tonic effects were preceded by a transient phase of sporadic, spontaneous depolarizations of 2-10 mV which lasted 50 - 200 ms. These small depolarizations, which could trigger action potentials, were blocked by membrane hyperpolarization. Action potentials and current-induced burst afterhyperpolarizations did not change significantly.

The major effect of 1 µM KA was a reversible depression of both fast, GABA-mediated IPSPs and slow, potassium (K) dependent IPSPs. These IPSPs were reduced, respectively, to 20% and 31% (corrected for resistance change) of control values. IPSP depression correlated closely with the onset of burst potential firing in reponse to synaptic stimulation. KA did not increase EPSP amplitudes. Similar observations were made on 6 CA3 cells, although these cells were affected by lower doses of KA.

The mechanism of IPSP depression was studied by using KCl filled electrodes to invert small spontaneous IPSPs into depolarizing potentials. In 9 CA1 cells the rate and amplitude of spontaneous IPSPs transiently increased, but then decreased in conjunction with evoked IPSP depression. Possible KA effects on postsynaptic GABA responses were investigated with GABA iontophoresis. In KA hyperpolarizing GABA responses were variably decreased but these changes could not account for KA induced IPSP depression measured concurrently.

KA-induced alterations in extracellular K were assessed in 6 slices with ion-sensitive microelectrodes and in 2 slices with glial cell penetrations. The increases of approximately 0.5 mM in extracellular K could not explain the effects of KA.

We conclude that KA induces epileptiform activity in hippocampus principally by a presynaptic block of IPSP pathways. Supported by NIH Grant NS17539 and a McKnight award (E.E.A.) and by TIDA 5K07NS00697 (R.S.F.).

266.11 CL 218, 872 BLOCKS KAINIC ACID-INDUCED CONVULSIONS AND NEUROPATHOLOGY, J.F. Bates*, L.J. Standish* and T.W. Hall*. (SPON: A. Trehub).

The convulsive behavior and neuropathology associated with human status epilepticus can be induced in laboratory rats with intraperitoneal injections of kainic acid (KA), a rigid analogue of glutamic acid with neuroexcitatory properties. A benzodiazepine, diazepam (DZ), is the drug of choice in treating status epilepticus. DZ has been reported to prevent KA-induced convulsions in laboratory rats at a dose of 20 mg/kg i.p., as well as reducing the extensive limbic system neuropathology that accompanies KA-induced status epilepticus. Triazolopyridazines (TPZs) are a novel class of drugs with potent anti-anxiety effects in experimental animals and selective affinity for Type I benzodiazepine receptors. We compared the anti-epileptic effects of CL 218,872, a potent TPZ, and DZ with respect to behavioral and neuropathological protection against the epileptogenic action of KA.

Rats were infected intraperitoneally with KA alone (12 mg/kg), or pretreated with either CL 218,872 (1.7, 25, 50, or 150 mg/kg) or DZ (20 mg/kg) prior to KA (12 mg/kg). Behavior was scored every 10 minutes over a 6 hour period, using a scale of 0-15 (normal to grand mal convulsion). Following a 7 day survival period, animals were perfused intracardially with formalin. Tissue was subsequently sectioned and stained using a modified Fink-Heimer silver degeneration procedure. Coronal 40 μ sections were analyzed by light microscopy for the presence of degenerating cells and necrosis.

KA treatment resulted in severe (generalized tonic-clonic) convulsions and extensive brain damage in limbic system structures (hippocampus, amygdala, lateral septum, midline, medial and lateral thalamic nuclei and limbic cortex) and several neocortical areas. Pretreatment with CL 218,872 produced dose-dependent effects. Doses of 50 and 150 mg/kg significantly reduced the severity of KA-induced convulsions, as well as reducing, or preventing, neuropathology. In contrast to previous reports, DZ pretreatment did not significantly reduce convulsion severity, nor did it protect against KA-induced neuropathology.

CL 218,872 is a potent anti-epileptic drug with respect to both convulsions and neuropathology associated with KA-induced status epilepticus. In addition, this TPZ was more effective than DZ. These results suggest that CL 218,872 in particular, and TPZ's in general, may be of clinical value as anti-epileptic agents in the treatment of status epilepticus.

266.12 PROPERTIES OF RECURRENT EXCITATION IN THE CA3 REGION OF THE HIPPOCAMPUS. R. Miles* and R.K.S. Wong (SPON: J.J. Stewart). Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

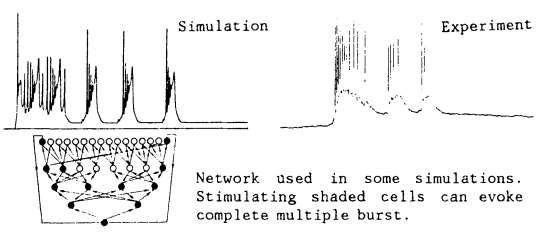
Local circuit interactions are of great importance in modulating neuronal activity. In the hippocampus the existence of recurrent inhibition is well established. However although local excitatory connections are thought to exist much less is known about them. In this study we have attempted to demonstrate and define the characteristics of recurrent excitatory synapses between pyramidal cells in the CA3 region of guinea pig hippocampal slices.

In order to test for recurrent excitation between CA3 neurones we stimulated in the stratum oriens or radiatum of the CA1 region where axonal collaterals of CA3 cells are known to project. A proportion of CA3 neurones were antidromically activated while in most other cells an epsp followed by an ipsp was recorded. The ipsp was blocked in the presence of 10^{-4} M picrotoxin leaving a series of epsp's which often initiated an epileptiform burst. Increasing Mg to 8 mM allowed a pure epsp to be examined in the absence of synchronized activity. This synaptic potential could result from the stimulation of cholinergic septal fibres or commissural fibres from the contralateral hippocampus. However it could still be evoked in the presence of 10^{-6} M atropine and in slices prepared from guinea pigs where commissural fibres had been allowed to degenerate following a midline lesion. Based on its latency and frequency following ability and on the fact that the epsp could still be evoked in 14 mM Mg when di-synaptic recurrent inhibition was blocked we conclude that this synaptic potential results from monosynaptic recurrent connections between CA3 neurones.

With low intensity stimulation 'minimal' synaptic events of varying amplitude interspersed with a proportion of transmission failures could be evoked. These synaptic potentials were comparatively slow with mean time to peak of 8.9 msec and mean duration at half amplitude of 32.2 msec. Their mean amplitude in the presence of 8 mM Mg was 0.9 mV (n=17). The application of paired stimuli separated by times from 20 to 1000 msec revealed a potentiation of 57% at 20 msec which declined exponentially with time constant 92 msec (n=8). The determination of these properties of recurrent excitatory synapses provides a basis for the exploration of their role in local integration processes in the CA3 region of the hippocampus. (Supported by NIH grant NS18464).

266.13 SIMULATION OF IN VITRO EPILEPTIFORM MULTIPLE BURSTS, R.D. Traub, W. D. Knowles, R. Miles, R.K.S. Wong and R. Linsker*. IBM Watson Research Center, Yorktown Heights, NY 10598 and UTMB, Galveston, TX 77550.

When the hippocampal slice is bathed in convulsant agents (e.g. penicillin), synchronized neuronal bursting occurs. We have shown how chemical excitatory synaptic interconnections can lead to a long-latency single population burst (Traub and Wong, Science 216 (1982) 745-747). In the presence of the GABA-blocker picrotoxin (0.1mM), more complex spontaneous events occur: multiple bursts rather than single bursts. All cells observed participate in each event. Multiple bursts consist of a sustained (about 150 ms) primary burst followed by a series of 1 to 5 or more afterdischarges occurring every 50-65 ms. Multiple bursts are synchronized. As for synchronized single bursts, both the primary burst and the afterdischarges of multiple bursts are synaptically elicited (R. Miles and R.K.S. Wong, Soc. Neurosci. Abs. 8 (1982) 910). Synchronized activity can be partially entrained and the rhythm reset by intracellular stimulation of some, but not all, CA2-CA3 cells. In simulation studies, we used a single compartment model for each neuron, because the soma and apical dendrites are synchronized during multiple bursts. We made parameter changes in the model neuron that were forced by the experimental data. These allowed for shortening the interburst interval, slowing the kinetics of burst termination, changing the burst afterhyperpolarization to a depolarization, and preventing depolarization block. We made networks of model neurons connected by excitatory synapses. Synaptic inhibition was not included, because of its presumed blockade by picrotoxin. Randomly connected networks lead to realistic multiple bursts in individual cells, but without synchronization between cells. Tree-like networks containing loops generated, after stimulation of some single cells, synchronized multiple bursts similar to those observed experimentally. Decreasing synaptic strength produced, as required, a decreased number of afterdischarges.



Network used in some simulations. Stimulating shaded cells can evoke complete multiple burst.

266.14 CHANGES IN BRAIN WATER CONTENT AND PERMEABILITY OF THE BLOOD-BRAIN BARRIER (BBB) IN CONVULSIVE SEIZURES. R. Cahn*, T. Kuroiwa*, C. Nitsch*, W. D. Lust and I. Klatzo. Lab. of Neuropathology and Neuroanatomical Sciences and Lab. of Neurochemistry, National Institutes of Health, Bethesda, MD 20205.

The purpose of this study was to evaluate the effect of short epileptiform seizures on brain water content and behavior of the BBB. The convulsive seizures were induced by intravenous injection of 40-50 mg/kg of pentylenetetrazole (PTZ). The behavior of the BBB was assessed with 2% Evans Blue (EB) tracer (0.5 ml intraven.). Brain water content was evaluated by modified specific gravity (SG) measurements; also, osmolarity and levels of lactate were assessed in the plasma. Two groups of animals: A) awake, non-paralyzed, spontaneously breathing, and B) anestnesized, paralyzed and artificially ventilated, were subjected to PTZ seizures lasting usually between 10-20 minutes and were sacrificed at various time intervals up to 6 hours following induction of the seizures.

Both groups of animals showed circumscribed areas of EB extravasation, most common in hypothalamus, cerebellum, thalamus and pallidum. In the non-paralyzed group there was a significant increase in SG values, more pronounced in EB-negative than in EB-positive regions, which reached its peak at 30 minutes and returned to normal after 3-6 hours. The increase in SG, indicating dehydration of the brain, coincided with a marked increase in blood osmolarity, which showed a sharp increase already 5 minutes after the onset of seizures and then gradually returned to normal, approximately 4 hours after convulsions. The plasma lactate changes in non-paralyzed animals parallel those concerning osmolarity with the peak at 5 minutes and return to normal at 4 hours.

In paralyzed, artificially ventilated animals the PTZ seizures produced similar changes in BBB, but no changes in osmolarity or plasma lactate. The SG values in EB-negative areas were normal, whereas those in EB-stained regions revealed significantly lower levels at 6 hours after the seizures.

Our investigations indicate that the epileptic seizures associated with strong tonic-clonic convulsions induce a marked elevation of blood osmolarity, presumably mainly due to a rapid increase in lactate and this leads to a significant transient decrease in water content of the brain. The opening of the barrier associated with extravasation of serum proteins leads to edematous water increment in areas with barrier damage.

267.1 A COMPARISON OF VISUAL CALLOSAL CONNECTIONS IN NORMAL, NEONATALLY BLINDED AND CONGENITALLY ANOPHTHALMIC MICE. R.W. Rhoades, R.D. Mooney, G. Yuen* and S.E. Fish. Dept. of Anatomy, UMDNJ-NJSOM & RMS, Piscataway, NJ 08854 and Neurobiology Program, N.E.O.U.C.O.M., Rootstown, OH 44272.

To assess the consequences of prenatal versus postnatal eye "removal" upon the development of visual callosal connections, the organization of this pathway was examined using HRP transport in normal adult C57BL and DBA mice, adult C57BL mice enucleated bilaterally within 12 hr of birth and adult ZRDCT-an congenitally anophthalmic mice.

In normal animals labelled callosal neurons and anterograde transport indicative of callosal terminals were located primarily at the borders of area 17. In the 17-18a border area labelled cells were located in primarily layers II, III and V. Anterograde transport was dense in layers V and VI, light in lamina IV and moderate in layers I-III. In addition, moderate anterograde labelling and a few retrogradely labelled cells were visible in lamina VI of the medial striate cortex.

In animals bilaterally enucleated on the day of birth and examined as adults the callosal projection was markedly abnormal. Both callosal cells and anterograde labelling had the same laminar distribution as in the normals, but they extended well into the medial part of area 17.

In adult, anophthalmic mice callosal cells and terminals were also visible medially, particularly in the rostral part of area 17. Here, this labelling took the form of discrete patches, approximately 275μm in width which were separated by regions of approximately the same size that were largely free of labelled callosal cells or terminals. In serial sections, these patches formed bands which paralleled the 17-18a border. The laminar distribution of labelled cells and fibers at the 17-18a border in these animals matched that in the normals. In the more medial patches, however, labelled cells were restricted primarily to layers II and III.

The above results suggested that the presence of the retinae prenatally may have some influence upon the development of visual callosal connectivity. Surprisingly, however, the distributions of callosal cells in normal and anophthalmic animals examined on postnatal day 3 were identical and extended uniformly over the mediolateral extent of the posterior neocortex.

267.2 COGENERATION OF SUBPLATE AND MARGINAL ZONE CELLS IN THE CAT'S PRIMARY VISUAL CORTEX. M.B. Luskin and C.J. Shatz. Department of Neurobiology, Stanford, CA 94305.

During the development of the cerebral cortex, the Retzius-Cajal cells are among the earliest generated, and come to lie within the marginal zone (MZ)--future layer 1. These cells are numerous throughout embryonic life, but only a few survive into adulthood (Edmunds, S.M. and Parnavelas, J.G., J. Neurocytol., 11:427, 1982). We reported (Neurosci. Abst., 8:3, 1982) that another sparse population of early generated cells was present below layer 6 embedded in the white matter. These cells are generated throughout the period between embryonic day 24 (E24) and E30 in the cat (gestation is 65 days) that largely precedes the neurogenesis of the cellular layers of the cortex. We wondered if, like the Retzius-Cajal cells, these white matter cells also might be more abundant during embryogenesis. Therefore intrauterine injections of ^{3}H-thymidine were made into 24 fetuses between E24 and E30, and autoradiographs of the regions of the occipital were examined at progressively later developmental ages from E34 through birth.

At every age a bistratified labeling pattern was found. Radioactively labeled cells were confined to one zone immediately deep to the cortical plate (CP), and another one within the MZ. In contrast to the extremely sparse cell labeling found in adults, extensive labeling of both zones was seen at every embryonic age. The deep zone is the subplate, a loosely packed layer of large darkly staining cells underlying the radially aligned densely packed cells of the CP. In cresyl violet stained sections, this zone appears by E30, the earliest time that the CP itself can be identified, and persists at least until birth.

This bistratified labeling pattern indicates that cells of the subplate and MZ are cogenerated in time. If so, then do the two sets of cells originate as a single population? To address this question, we injected a series of fetuses at E24 (a time well before genesis of the CP) and examined them at E30, E34, E41, E57 and adulthood. As before, the characteristic bistratified pattern was present in all animals aged E34 and older. However, at E30 the distribution of labeled cells was not bistratified. Instead, a single zone of labeling extended from the pial surface inward to the outer border of the ventricular zone.

These findings show that the subplate and MZ cells are generated concurrently as a single population, and later are split apart by the subsequent accretion of cells forming the CP. Thus, both sets of early generated cells may provide a framework for the development of the cortical plate that largely disappears when the process is complete.

267.3 MONOCULAR DEPRIVATION EFFECTS IN THE VISUAL SYSTEM OF SQUIRREL MONKEY. M. Tigges, A. E. Hendrickson and J. Tigges . Yerkes Regional Primate Research Center, and Depts. of Anatomy and Ophthalmology, Emory Univ., Atlanta, GA 30322, and Dept. of Ophthalmology, Univ. of Washington, Seattle, WA 98195.

Four squirrel monkeys had their right eyelid sutured at or shortly after birth and survived from 9 to 40 months of age. Their brains were studied with various anatomical techniques, including the 2DG method, the transneuronal 3H amino acid and retrograde HRP transport techniques, and the cytochrome oxidase (CO) and Nissl stains. In all 4 monkeys, neurons in the deprived laminae of the LGN were considerably smaller in size compared to the neurons in the undeprived laminae. The retrograde transport of HRP after injections of this tracer into area 17 revealed that the cortical projections originating from the deprived laminae were still present since HRP filled neurons in the LGN extended in the typical shape of a wedge throughout all LGN laminae. The striate cortex proved remarkably resistant to extraneous manipulation. No changes in cell size and cell density were found in layer IVC of area 17 in Nissl stained sections. Also, CO staining resulted in a "puff" pattern in layers II-III, undistinguishable from that found in normal animals. Layers IVC and IVA were uniformly stained and, thus, were identical with the normal pattern. Transneuronal transport of monocularly injected 3H amino acid did reveal changes in the deprived striate cortex; these include the occurrence of irregularly spaced dense "patches" of silver grains over layer IVC in the ipsilateral striate cortex in the calcarine fissure. Compared to undeprived monkeys, layer VI in the deprived monkey contained only grains at background levels. Ipsilateral layer IVA in deprived animals was indistinguishable from that in normal monkeys. In layer IVC of contralateral area 17, a very few faint "patches" superimposed on a background of uniform labeling were found. Long stretches of contralateral layer IVA were unlabeled, except for a short strip in the anterior calcarine fissure, adjacent to the 17/18 border. After monocular visual stimulation of the deprived eye, 2DG labeling showed crisp patches of dense label in layer IVC superimposed on a uniformly high background; these were present in both hemispheres. These modest changes after monocular deprivation in squirrel monkey contrast with the dramatic effects on ocular dominance columns reported in infant macaca monkeys.

267.4 THE PATTERN OF OCULAR DOMINANCE COLUMNS IN AREAS 17 AND 18 OF NORMAL AND VISUALLY DEPRIVED CATS AS REVEALED IN TANGENTIAL SECTIONS OF THE UNFOLDED CORTEX. P.A. Anderson*, J. Olavarria* and R.C. Van Sluyters. School of Optometry and Neurobiology Group, University of California, Berkeley, CA 94720.

We have used a procedure for unfolding and flattening the cortex (see Olavarria and Van Sluyters, this meeting), in combination with the transneuronal transport of horseradish peroxidase-wheat germ agglutinin conjugate (WGA-HRP), to study the overall pattern of ocular dominance (OD) columns in tangential sections through the full extent of areas 17 and 18 of the cat. In contrast to the autoradiographic method, use of WGA-HRP as a tracer allowed us to see the cortical OD pattern, which consisted of densely labeled regions alternating with relatively unlabeled regions, only 4 days after a monocular injection (1 mg in 20 ul saline). In addition, our procedure for flattening the cortex allows large extensions of the OD pattern in areas 17 and 18 to be visualized in a single section, thereby permitting us to reconstruct the entire pattern from only 3-5 sections.

We studied normal cats as well as cats reared with strabismus or monocular deprivation (MD). In both normal and strabismic cats, the label accumulates in the cortex in isolated patches or branching bands whose shapes are highly irregular. The boundaries of these labeled regions appear somewhat sharper in cats exposed to a prolonged period of strabismus. In MD cats, the labeled regions observed following injection of the deprived eye are more fragmented and much smaller in size, so that they appear dot-like over all of area 17. Although our results indicate that significant input from the deprived eye remains after almost 2 years of MD, preliminary analysis suggests that the total cortical area occupied by this input is noticeably less than that occupied by either eye of normal or strabismic cats. In all cats, the labeled pattern tended to be more filled-in in the contralateral hemisphere than in the ipsilateral hemisphere and, in both hemispheres, there was a tendency for regions of area 17 containing the peripheral visual field representation to be more filled-in than those representing the central visual field. In contrast to the monkey, the overall pattern of OD columns in area 17 of the cat is irregular and cannot be described as easily. In area 18, labeled regions are wider and more bar-like than those in area 17, and their orientation is roughly perpendicular to the 17/18 and 18/19 borders. While area 19 appears relatively unlabeled, regions of moderate labeling are observed in visual areas located in the medial bank of the lateral suprasylvian sulcus.

267.5 THE EFFECT OF DARK-REARING UPON cAMP-METABOLISM IN THE VISUAL CORTEX OF CATS. C. Aoki* & P. Siekevitz. Lab. of Cellular Biology, The Rockefeller University, New York, N.Y. 10021.

The evidence from many labs indicate that the neuronal plasticity of the postnatally developing visual cortex is dependent on visual experience. Recently, Kasamatsu et.al. have reported evidence indicating that this form of plasticity is influenced by the local concentration of l-norepinephrine (NE) in the visual cortex. Further, Cynader's group has reported that the plastic period, which spans the first 3 to 4 months after birth, can be extended at least a year, so long as the animal is completely deprived of visual experience during that time. Our goal was to study the molecular mechanism by which NE modulates visual cortical plasticity of this type. We have examined in homogenates from areas 17 and 17 plus 18 of the visual cortex the ontogenetic changes of three enzymes involved in cAMP metabolism, namely 1)cAMP- and cGMP-phosphodiesterase (PDE); 2)cAMP-dependent protein kinase and 3)adenylate cyclase. In addition, we have studied the protein species phosphorylated by the kinase. The kittens used were reared under three different conditions: 1)light-reared(LR); 2)dark-reared (DR) and 3)dark-reared followed by light-reared condition (DLR), and sacrificed at the same time of day.

During the 6 mos. postnatal period, both cAMP-PDE and cGMP-PDE specific activities increased 2½-3 fold. No difference was observed on the cGMP-PDE among the LR, DR and DLR animals. A significant decrease in cAMP-PDE was observed at 2 mos. in the LR but not in the DR or DLR kittens. Protein kinase activity was determined by examining autoradiograms of the phosphorylated proteins after ^{32}-P-ATP incubation. Differences were observed in the basic phosphorylation pattern during development and in the pattern between LR and DR animals. A cAMP-dependent protein kinase was present in the LR, DR and DLR visual cortex. The addition of cAMP caused an increase in the phosphorylations of synapsin I under all the rearing conditions. The addition of calmodulin caused an increase in the phosphorylations of 51,000M_r and a 60,000M_r protein under all the rearing conditions. The adenylate cyclase of the visual cortex was similar to the activity in other tissues in being activated by GTP, Mn^{2+} and GppNHp and by dopamine and NE. The specific activity in LR kittens was very low at birth and increased to adult levels by 4-mos.; the percentage activation by the activators was the same in 5-day to 6-mos. tissues. The activity in DR kittens is being studied. The possible role of cAMP in visual cortical plasticity will be discussed.

267.6 CLONIDINE AND VISUAL CORTICAL PLASTICITY: NEW EVIDENCE FOR NORADRENERGIC INVOLVEMENT. S.B. Nelson*, Marjory Schwartz*, and J.D. Daniels, Division of Engineering and Center for Neural Sciences, Brown University, Providence, RI 02912.

We have shown previously that acute but not chronic administration of 6-hydroxydopamine is capable of preventing the visual cortex ocular dominance plasticity normally expected after monocular deprivation in kittens (Bear et al. Nature 302:245 (1983)). Those results, and the fact that non-plastic adult cats have significant levels of cortical norepinephrine (NE) indicate that plasticity cannot be correlated solely with tissue NE levels. We believe NE's facilitatory effect on plasticity may require elevated transmitter release and post-synaptic receptor response. To investigate the importance of transmitter release we studied monocularly deprived kittens treated with the alpha-2 adrenergic agonist clonidine (CLON). CLON inhibits firing of noradrenergic locus coeruleus neurons and hence inhibits release of NE in cortex.

CLON (400 ug/kg) was administered by i.p. injections given every 4 hours beginning 2 days prior to lid suture and continuing through a 5 day period of monocular deprivation. In one litter, three kittens all received CLON, in 2 other litters, 3 kittens received CLON and 2 kittens given an identical schedule of saline injections served as controls. For these last five kittens, recording was performed blind and the drug code was broken only after final histograms were generated.

In the control animals, 73% of the units (N=104) were driven predominately by the open eye, while only 16% were driven by the deprived eye. In the CLON treated animals, the number of units driven by the open and deprived eyes were nearly indentical, being 42% (N=218) and 39% respectively. Thus CLON treatment did prevent the expected ocular dominance shift seen in controls. We also found that CLON itself, in doses up to 800 ug/kg given i.v. during physiological recording, had no acute effect on single unit responses.

In order to insure that CLON was in fact inhibiting NE release, we assayed CSF levels of MHPG, the primary central NE metabolite. 0.3cc samples of cisternal CSF were withdrawn before, during and immdiately following CLON treatments. HPLC analysis revealed that in the 6 CLON treated animals, MHPG levels declined 48% over the 7 day period, from an average of 8.65 ng/ml to an average of 4.43 ng/ml.

Our results provide new evidence that NE can modulate plasticity in kitten visual cortex, and that proper release of the NE may be crucial for its action.

Supported by ONR Contract N00014-81-K-0136.

267.7 RESTORATION OF NEURONAL PLASTICITY IN CAT VISUAL CORTEX BY ELECTRICAL STIMULATION OF THE LOCUS COERULEUS. T. Kasamatsu, K. Watabe, E. Schöller* and P. Heggelund.* Div. of Biol., Calif. Inst. Tech., Pasadena, CA 91125, USA; and Neurobiol. Lab., Univ. of Trondheim, Trondheim, N-7055, Norway.

We have studied a role of central norepinephrine (NE)-containing system in regulating neuronal plasticity in cat visual cortex. We use changes in the distribution of ocular dominance as a simple yet reliable assay of plasticity present in a given cortex. Previously, we manipulated function of NE terminals within the visual cortex by direct perfusion of either a catecholamine (CA)-related neurotoxin, 6-hydroxydopamine (6-OHDA) or exogenous NE or both. Chemical degeneration of CA terminals due to 6-OHDA led to a loss of neuronal plasticity. The cortical sensitivity to alterations in visual experience was restored by the NE perfusion into either the kitten cortex pretreated with 6-OHDA or the adult visual cortex which had lost its plasticity due to outgrowing of the postnatal susceptible period.

In the present study, we wanted to show the restoration of visual cortical plasticity in old kittens (17~ wks old) and adult cats by direct stimulation of NE cells in the locus coeruleus (LC), thus leaving the cerebral cortex totally intact. The animals were monocularly exposed to a laboratory environment in the light for 2 hrs everyday during which time the LC was electrically stimulated by a train of 4 pulses (0.05 msec width, 50 Hz, every 3.3 sec, ~1.5 mA). Otherwise, the animal was housed in the dark. This brief monocular exposure combined with LC stimulation lasted for 6 days, attaining a total of 12 hrs of monocular experience.

When we recorded from these animals on the 7th day, we found the significantly lower (30%~) number of binocular cells than normal. The plasticity-restoring effects of LC stimulation were mediated through NE terminals in the visual cortex, since no such effects were obtained if the visual cortex had been priorly perfused with 6-OHDA. Some animals were revived from the first recording, returned to the preceeding routine without accompanying electrical shocks to the LC and recorded a second time after variable time intervals. There was a sign of gradual disappearance of the restored plasticity at a rate of a 21% loss every 7 days. However, in animals subjected to the usual form of monocular lid suture and kept in our cat colony (17L/7D cycle) after reviving from the first recording, the altered distribution of ocular dominance sustained or binocularity further decreased. The present paradigm in restoring plasticity was free from nonspecific actions of exogenous chemicals as well as some pathology due to the chronic implantation of a metallic cannula directly into the cortex. These results strengthened the NE hypothesis of visual cortical plasticity. Supported by EY-03409

267.8 THE SENSITIVE PERIOD FOR MODIFYING VISUAL CALLOSAL CONNECTIONS IN THE RAT. R. Malach*, J. Olavarria* and R.C. Van Sluyters (SPON: J.F. Metcalf). School of Optometry and Neurobiology Group, University of California, Berkeley, Ca 94720.

In the normal mature rat, visual callosal connections are distributed tangentially in a band that runs along the 17/18 border and in several rings that lie in extra-striate cortex. Enucleation of one or both eyes at birth results in the development of an altered pattern of callosal connections. The most striking effect of monocular enucleation (ME) is the appearance of an additional callosal band, situated roughly in the center of area 17, in the hemisphere contralateral to the enucleated eye, while binocular enucleation (BE) leads to the appearance of acallosal regions within the 17/18 band and irregularly shaped extensions that invade well into area 17. We have shown that, in the rat, the pattern of callosal connections achieves its adult form by 12 days of age, and that enucleation at birth alters the pattern of normal development without changing its time course (Olavarria, et al, Invest Ophthal, 24, ARVO Abst Suppl, 9, 1983).

In the present study we investigated the effect of delaying the time at which enculeation was performed in order to characterize the sensitive period for modifying the pattern of callosal connections. Fifty pigmented rat pups were subjected to ME or BE at ages ranging from birth to 11 days. After a survival period of several weeks, one cortical hemisphere received multiple injections of horseradish peroxidase (HRP) spread evenly across the cortical surface. The rats were perfused after 24 hrs, and the opposite hemisphere was flattened and sectioned tangentially. Sections were reacted for HRP histochemistry to reveal both anterogradely and retrogradely transported label. Our results indicate that the sensitive period for modification of callosal development ends by 6 days of age in both BE and ME rats, since rats enculeated at this age develop a pattern of callosal connections that is indistinguishable from normal. It is important to note that this sensitive period ends at a time when development of callosal connections is far from complete. Indeed, in 6-day-old normally reared littermates of these enucleated pups, the distribution of callosally projecting cells was clearly immature -- large numbers of filled cells still were present throughout area 17. Pups enucleated at 5 days of age develop a pattern of connections that is partially disrupted, while pups enucleated at 4 days of age exhibit a degree of abnormality comparable to that found in pups enucleated at birth, suggesting that the sensitive period for modifying callosal connections in the rat terminates rather abruptly. Possible factors involved in determining the duration and characteristics of this sensitive period will be discussed.

267.9 Corpus Callosum and Development of Striate Binocularity: Complete Critical Period Within Three Postnatal Weeks. Andrea J. Elberger. Dept. of Neurobiology and Anatomy, Univ. of Texas Medical School at Houston, Houston, Texas 77025, and Earl L. Smith, III* College of Optometry, Univ. of Houston, Houston, Texas 77004.

Abnormal visual experience during development has been shown to result in alterations of the visual system. For example, induced conditions such as strabismus, monocular deprivation, astigmatism, and anisometropia result in reduced levels of striate binocularity, as well as deficits in visual acuity (amblyopia). The period of time within which the developing visual system is susceptible to abnormal visual experience is known as the critical period. For these particular conditions the critical period extends from the second week through 4-6 months, postnatally. Previously, section of the corpus callosum (CC) was also shown to affect the normal development of the visual system, however the critical period for callosum section to produce amblyopia was limited to the first postnatal month (Elberger, Soc. Neurosci. Abstr. 82.2, 1982). To more fully investigate the possibility that the callosum may have a different critical period than that for abnormal visual experience, we explored the length of time that callosal section has an effect on the development of cortical binocularity.

To date, we have examined 30 cats which had the posterior CC sectioned between 13 days and 14 weeks after birth. We have performed extracellular single unit recording in striate cortex within 2 years after the surgery, with a minimum time between surgery and recording of 10 weeks in the 14 week CC cats. Within each age group the results were consistent and demonstrated an extremely restricted period of time during which CC section had any effect on altering the level of striate binocularity. The greatest change in ocular dominance was in the 13 day CC cats, with a minimum of 20% of the cells retaining binocular activation. The proportion of binocularly excited neurons gradually increased in the 14, 15 and 18 day CC cats. By 19 days after birth, CC section no longer resulted in any abnormal distribution of ocular dominance. For 17 cats with CC section at 19 days-14 weeks the proportion of monocularly activated cells averaged 10-17%. In all groups of cats, all other receptive field parameters were qualitatively normal.

The results show a distinct critical period for corpus callosum to influence the development of cortical binocularity, which is remarkably similar to that for the development of acuity. This callosal critical period is the first three postnatal weeks. During this time period, CC section produces the same range of alterations of binocularity and acuity as does abnormal visual experience. However, the critical period for the latter is much longer, and hardly overlaps the critical period for the corpus callosum.

267.10 THE SENSITIVE PERIOD FOR THE LOSS OF BINOCULAR DEPTH PERCEPTION IN KITTENS. Brian Timney. Department of Psychology, University of Western Ontario, London, Canada, N6A 5C2.

Kittens' binocular depth discrimination abilities improve rapidly during the sixth and seventh week, at a time when cortical disparity-tuned neurones are acquiring adult-like characteristics (Timney, 1981). Recently, I showed that periods of monocular deprivation lasting from the time of natural eye opening until 35 days or older resulted in a complete breakdown of binocular depth perception. Prolonged deprivation imposed after the age of four months had no effect (Timney, 1983), suggesting the existence of a sensitive period occurring during the first few months of life. The present study was designed to obtain a profile of that sensitive period.

Kittens were subject to 10-day periods of monocular deprivation beginning at different ages. Deprivation was accomplished by suturing the eyelids of one eye using conventional procedures. The deprivation periods were begun at the ages of 30, 40, 50, 60, 70 and 80 days. After a recovery period following eye opening monocular and binocular depth thresholds were obtained for each kitten using the jumping stand technique. Briefly, the kittens were trained to jump from a platform toward the closer of two patterned surfaces. Normal kittens can do this under binocular viewing conditions with virtually no training and typically can discriminate separations corresponding to less than 5 minutes of retinal disparity. When viewing monocularly, performance is almost invariably much worse, allowing the inference that normal kittens possess stereopsis.

In the present experiment, deprivation from 30 to 40 days led to generally poor binocular performance, although binocular thresholds were slightly better than monocular. Deprivation between 40 and 50 days completely abolished binocular superiority, but the effect was progressively less pronounced as deprivation was applied at later ages. By 70 days the deprivation had little effect. These results indicate that the sensitive period begins between days 30 and 40 and is almost completely over by day 70. Unlike resolution acuity, the impairment of stereoacuity appears to be permanent. Studies are now underway to determine the minimum amount of deprivation necessary to cause a breakdown in binocular depth perception.

267.11 BINOCULAR INTERACTION IN CORTICAL CELLS OF MONOCULARLY DEPRIVED KITTENS. R. D. Freeman and I. Ohzawa*. School of Optometry, University of California, Berkeley, CA 94720.

Several lines of evidence suggest that some input from the deprived eye to visual cortex remains following monocular deprivation. In previous work, we attempted to find evidence of such input using sinusoidal gratings presented to each eye so that one was phase shifted with respect to the other (Freeman & Robson, Exp. Brain Res. 48:296-300, 1982). For normal cats, this stimulation procedure generally results in marked phase specific binocular interactions involving both facilitation and inhibition. But we did not observe these effects in cats that were studied following long-term monocular deprivation.

In the current investigation, we have pursued the possibility of binocular interaction in monocularly deprived kittens by using relatively brief periods of deprivation (from 3 to 21 days). For single-unit study, we plotted receptive fields for each eye if possible and estimated ocular dominance qualitatively. Next, we conducted quantitative tests of orientation and spatial frequency tuning using sinusoidal gratings. Finally, we determined responses to binocular stimulation using optimal grating parameters. Relative spatial phase was altered to one eye and the set of phases was interleaved randomly with monocular presentations to each eye so that direct comparisons could be made between monocular and binocular responses.

Our results show a variety of binocular interactions. First, a large proportion of cells that appeared monocular or nearly so were influenced by input from the other eye. This influence was often phase specific especially for simple cells. In other cases, phase non-specific suppression was observed. Suppression of the non-deprived eye by the deprived eye was observed more frequently than the reverse case. However, this bias may simply reflect the effects of the rearing procedure which produces an ocular dominance shift to the non-deprived eye. Interestingly, phase non-specific suppression was also observed when the stimulus to the silent eye was orthogonal to the preferred orientation of the dominant eye indicating that the effect was not orientation specific. For binocular cells, a full range of phase-sensitive responses were observed and these were not obviously abnormal or distinguishable from responses found in the normal kitten or adult cat. We conclude that during the early stages of monocular deprivation, binocular connections remain which cannot be demonstrated using monocular excitation.

267.12 DARK REARING DOES NOT PROLONG SUSCEPTIBILITY TO THE ANATOMICAL EFFECTS OF MONOCULAR DEPRIVATION. G.D. Mower and C.J. Caplan*. Dept. of Neurology, Children's Hospital, Boston, Ma. 02115.

Several recent studies have shown that dark rearing extends the period of susceptibility to the physiological effects of monocular deprivation (MD) in visual cortex. Does dark rearing also prolong susceptibility to the anatomical effects of MD?

Eye injections of tritiated proline were used to label ocular dominance (OD) columns in cortical layer IV. Studies were done in cats who experienced only prolonged (4 mos) dark rearing (DR cats, N=2) and in cats who experienced 3 mos of MD after 4 mos of dark rearing (DR-MD cats, N=4). Results from these cats were compared with those from normal (N=2) and MD (N=2) cats.

In DR cats, there was little evidence for OD columns. Label was nearly continuous in layer IV with only very slight fluctuations in grain density. In normal cats, OD columns were clearly evident as alternating patches of high and low grain density. This result suggests that visual input is necessary for normal segregation of geniculocortical afferents.

The DR-MD cats allowed us to address two issues: 1) can the overlapping afferents (after dark rearing) segregate into OD columns with delayed visual experience? 2) will such delayed segregation reflect the nature of the visual input? Surprisingly, injection of either the open (N=2) or the closed (N=2) eye in DR-MD cats resulted in uniform label throughout layer IV, similar to the pattern seen in DR cats. MD cats showed the expected expansion of columns from the open eye and contraction of columns from the closed eye. Measurements of cell sizes in the lateral geniculate nucleus indicated marked shrinkage of cells innervated by the closed eye in MD cats, but no shrinkage in DR-MD cats. Single unit recordings in area 17 of both DR-MD and MD cats showed a dramatic takeover by the open eye. These results suggest that delayed physiological plasticity in DR-MD cats is not paralleled by delayed anatomical plasticity.

Overall, it appears that formation of OD columns requires visual input occurring during early life. Dark rearing prolongs susceptibility to the physiological but not the anatomical effects of MD.

268.1 SIMULTANEOUS MONITORING OF ACTIVITY OF MANY NEURONS IN BUCCAL GANGLIA OF PLEUROBRANCHAEA AND APLYSIA. L.B. Cohen and H.S. Orbach. Dept. of Physiology, Yale University School of Medicine, New Haven, CT 06510.

Optical methods, using potential sensitive dyes, might allow simultaneous monitoring of the activity of all the neurons in ganglia with a few hundred neurons. Pleurobranchaea californica and Aplysia californica have interesting behavior and have the relatively large neurons that are necessary for optical measurements. In previous experiments, poor dye penetration of the connective tissue sheath caused difficulty. Dyes that penetrated and stained routinely in nudibranchs did not stain every Pleurobranchaea preparation and did not stain Aplysia at all. We find that staining is better with the dimethin analogue, 433, of the merocyanine dye, XVII (Ross et al., 1977), and that reducing the divalent ion concentration by 50% during staining also improved the results.

In preliminary experiments carried out on dissected buccal ganglia of Pleurobranchaea, stimulation of the stomatogastric nerve resulted in rhythmic bursts of action potentials recorded from roots 1 and 3 that are correlated with rhythmic movements of the buccal mass (Davis et al., 1973). Simultaneous optical measurements detected activity in 20-30 neurons. Some neurons had activity that was phase locked to the burst on the roots, other neurons had activity that was correlated with the stimulus, while activity in a third group of neurons did not seem to be correlated with either the root bursts or the stimulus. Preliminary experiments on Aplysia ganglia showed that optical signals could be detected from many neurons in response to electrical stimulation of buccal nerves.

We hope that the technique can be developed to the point that all the neurons active during feeding can be monitored simultaneously. Supported by NIH Grant NS08437.

268.2 THE HISTAMINERGIC NEURON C2 OF APLYSIA IS A MECHANOAFFERENT CELL WHOSE OUTPUT CAN BE GATED SYNAPTICALLY. K.R. Weiss, H.J. Chiel and I. Kupfermann. Center Neurobiol. & Behav., NY State Psych. Instit.; Depts of Physiol., Anat.& Cell Biol., and Psychiat., Columbia P&S, and Schl. Dent. & Oral Surgery, N.Y.

The histaminergic cell C2 provides excitatory input to the MCC, a neuron that mediates aspects of food arousal. In a semi-intact preparation C2 fires when food is applied to the lips and contributes to the activation of the MCC. Activity of C2 occurs each time that the jaws close, and is not dependent on the continued presence of food as long as rhythmic buccal movements persist. The spiking of C2 is always preceded by prepotentials that are axon spikes conducted from the periphery and are blocked at a point electrically distant from the soma. The A spikes were reduced in size by hyperpolarizing the soma, and simultaneous intracellular and extracellular recording revealed that mechanical pressure stimulation of the mouth elicited spikes, each of which appeared first in the nerve, followed by an A spike in the soma. Mechanical stimuli were effective in high Mg^{++} low Ca^{++}, indicating that C2 may be a primary mechanoafferent neuron. Since the A spikes show temporal and spatial summation, they are functionally similar to EPSPs. Functional meaning of this mechanism is suggested by the finding that C2 receives powerful inhibitory input that can prevent the A spikes from bringing the cell to the threshold for soma spikes. Furthermore, recording from C2 and the MCC or other followers revealed that synaptic output of C2 only occurs when a full soma spike is triggered. We found that at the point of trifurcation of the axons of C2, the main axon rapidly increases in diameter, creating a region of low safety. Synaptic output of C2 occurs between the trifurcation and the cell body. Thus, spikes which fail at the trifurcation can not produce synaptic release. In summary, C2 is a highly unusual proprioceptive cell that is normally in a state in which it fails to pass information into the nervous system. If its axon input occurs at a high rate, it switches into a transmitting mode and passes the proprioceptive information to an arousal system, as well as to cells involved in motor patterning (Chiel et al.). Synaptic input operating at a central locus can function to modulate the level at which this gate opens. [Grants 1 ROl MH36730, 5 ROl MH35564]

268.3 AN IDENTIFIED HISTAMINERGIC NEURON ACTS PRE- AND POST-SYNAPTICALLY TO INHIBIT THE OUTPUTS OF IDENTIFIED BUCCAL-CEREBRAL INTERNEURONS. Chiel, H.J. Weiss, K.R. and Kupfermann, I. Center Neurobiol., Behav., NYPI; Depts of Physiol., Anat.& Cell Biol., and Psychiat., Columbia P&S, and Schl. Dent. & Oral Surg., New York, NY 10032.

Feeding in Aplysia requires the coordinated activity of the buccal and cerebral ganglia. We have identified two buccal interneurons, B17 and B18, (buccal-cerebral interneurons, BCIs) that may participate in this coordination, since they send axons into the buccal-cerebral connective, and provide monosynaptic excitatory or inhibitory inputs to the cerebral ganglion. We found that the identified histaminergic neuron, C2, which is a cerebral mechanoafferent cell (Weiss et al., these abstracts), modulates the outputs of the BCIs. C2 and the buccal cells are reciprocally connected. The BCIs produce monosynaptic IPSPs in C2, and, in turn, C2 reduces the size of the PSPs that the BCIs evoke in cerebral neurons. C2 acts in two ways: 1) it polysynaptically inhibits the spiking of BCIs, which results in all or none block of the PSPs, and 2) it monosynaptically inhibits the PSPs in a graded fashion. To study the mechanism of the graded inhibition, we determined the coefficient of variation of control PSPs and of PSPs that were reduced in size by firing C2. The reduced PSPs showed an increased coefficient of variation. Estimates of m and q based on this analysis suggest that firing of C2 can produce a reduction of quantal number (m) of 50-80%, while quantal size (q) remains virtually unchanged. Thus, the reduction in the PSP is not due to a postsynaptic factor that produces a constant percentage reduction of PSP size, e.g., an increase of postsynaptic membrane conductance, and is therefore likely to be due to presynaptic inhibition. Since the BCI as well as C2 are active during the generation of "feeding motor programs" induced by tonic stimulation of an esophageal nerve, and C2 is activated during feeding-like behavior in a semi-intact preparation (Weiss et al., these abstracts), these cells may contribute to coordination of functional activity between the buccal and cerebral ganglia during feeding. 268.4 SEROTONIN CONTROLS FEEDING BEHAVIOR IN THE MEDICINAL LEECH. C.M. Lent, M.H. Dickinson* and C.G. Marshall* Center for Neuroscience, Brown University, Providence, R.I. 02912.

We investigated the effects of serotonin (5-HT) upon feeding behavior by Hirudo medicinalis. Three behaviors are significantly altered after a bath in 5-HT (3×10^{-5}M, 20 min): 1) leeches initiate swimming toward vibration with a shorter latency, 2) they bite a 35°C surface more frequently, and 3) they ingest larger blood meals than controls. Exposing dissected leeches to micromolar 5-HT produced four physiological responses: jaw movements resembling biting, a constriction of the crop, an increase in secretion of saliva from between the paired teeth on the jaws, and a rhythmic pharyngeal peristalsis. Salivation and peristalsis are peripheral effects, and both the volume of saliva, as well as the frequency and strength of the peristalsis, increase with 5-HT concentration (10^{-8} to 10^{-6}M). Thus, 5-HT enhances feeding behavior and activates some of its physiological systems.

We examined the electrophysiological responses of identified serotonin-containing neurons in the C.N.S. to inputs and outputs which could be associated with feeding. Segmental sensillae bear hair cells which detect water vibration (Young, S., et al., J. Comp. Physiol. 114:111, 1981), and their mechanical stimulation synaptically excited the Retzius cells (RZ) in segmental ganglia. Thermal stimulation of the prostomium synaptically excited RZ within the subesophageal ganglion (SubEG) substantially increasing their impulse frequency. The intracellular stimulation of RZ within the SubEG usually produced salivation. Further, stimulation of the large, lateral (LL) cells within the anterior SubEG, which contain 5-HT, reliably produced pharyngeal contractions. Thus, serotonin neurons are excited to higher impulse levels by stimuli which evoke feeding, and increasing their impulse activity produces salivation and pharyngeal pumping.

We attempted to reduce 5-HT levels in the leech by injecting them with 5,7 dihydroxytryptamine. Six of 9 injected leeches would neither bite a warm surface nor feed. Glyoxylic acid histochemistry revealed that all the peripherally projecting, 5-HT cells (RZ & LL) were selectively and completely ablated in the non-feeding leeches. Bathing these depleted leeches in 10^{-4}M 5-HT for 10 min, restored their biting behavior. Well-fed leeches do not bite or feed and 5-HT exposure restores their biting behavior as well. Thus, biting behavior can be restored in leeches whose behavior has been abolished by pharmacological or physiological methods by exposure to exogenous serotonin.

Serotonin has a central role in organizing and controlling the complex feeding behavior of the medicinal leech. (Supported by NIH grant NS-14482 and NSF grant BNS 79-15108 to C.M.L.).

268.5 THE SLUG LIMAX MAXIMUS SHOWS POST-INGESTIVE FOOD AVERSION LEARNING TO AMINO ACID DEFICIENT DIETS. K. Delaney* & A. Gelperin, Dept. Biology, Princeton University, Princeton, NJ 08544 and Bell Laboratories, Murray Hill, NJ 07974.

The capacity of a generalist herbivore, the pulmonate mollusc Limax maximus, to modify its feeding behaviour on the basis of post-ingestive cues was examined. The storage of a sensory representation of a diet for several hours which can occur with this type of learning may provide an opportunity for examination of cellular mechanisms of short term memory.

An artificial diet which contained free amino acids as the nitrogen source was suspended in agar and presented to cultured slugs kept individually in 15 cm Petri dishes. The ratios of the free amino acids present approximated those reported for cabbage, a food normally eaten by Limax. Deficient diets differed from the complete diet in that they lacked a single "essential" amino acid, e.g., methionine. An aversion was assessed on the basis of how much diet was eaten by animals given the deficient diet alone versus animals given only the complete diet. In addition, the amount of diet consumed by "naive" slugs was compared to that consumed by slugs after they had experienced the diet for at least 7 days. The latency to feed was assessed by examining the number of slugs which had eaten a portion of the diet within 2-2.5 hrs of its presentation. Initially, the amounts of deficient & complete diets eaten were equivalent. While control animals maintained or increased the amount of complete diet they ate over the course of the 7 days, animals provided with the deficient diet reduced their consumption and increased their latency to feed. Using groups of only 6-8 animals, significant differences in consumption between slugs eating complete and deficient diets were found by the second day of feeding. By the third day, if a meal was eaten by animals fed the deficient diet, it was only 30-40% of the amount eaten by control animals. The amount of a third diet, rat chow in agar, eaten by animals previously provided with the amino acid deficient diet for one week was greater than or equal to that eaten by control animals. This indicates that the depressed appetitive and consummatory behaviour of slugs fed the deficient diet was specific to the deficient diet. Animals which had developed an aversion to the deficient diet would also initially show an aversion to the complete diet but, after an initial small meal, they increased their consumption on subsequent feedings to a level equal to that of animals fed only the complete diet. Animals fed the complete diet and then switched to the deficient diet consumed the deficient diet initially as if it were complete but then reduced their consumption over several days. Animals returned to a diet of rat chow after one week on the deficient diet retained a significant aversion to the deficient diet for more than 2 weeks.

268.6 CHANGES IN SPECIFIC INTERNEURONS PRESYNAPTIC TO COMMAND NEURONS UNDERLYING ASSOCIATIVE LEARNING IN PLEUROBRANCHAEA. J. A. London and R. Gillette, Dept. of Physiology and Biophysics, Univ. of Ill., Urbana, IL 61801

Food avoidance conditioning of the predatory marine slug, Pleurobranchaea californica, using a paired food-shock paradigm causes suppression of the paracerebral feeding command neuron (PCNs) activity in response to food (Davis and Gillette, 1978). These command neurons are usually excited by food and act to initiate and sustain feeding (Gillette, Kovac and Davis, 1978); in conditioned animals, food stimuli cause tonic inhibition of the PCNs via a prolonged barrage of IPSPs. We previously documented a pathway mediating cyclic inhibition to the PCNs during feeding activity. This pathway is composed of serially connected interneurons driven both by chemosensory inputs and cyclic activity in the feeding oscillators (London and Gillette, 1983). The Interneuron 1s (Int-1s) make monosynaptic inhibitory connections on the PCNs. We find that Int-1s are active during food stimulation of conditioned animals and that hyperpolarization of a single Int-1 reduces the inhibition seen in the PCNs, indicating their role in the learned suppression of feeding behavior. A second population, the Int-2s, potently excite the Int-1s and synchronize Int-1 activity. Hyperpolarization of a single Int-2 in trained animals decreases the amplitude and duration of PCN inhibition in response to food. The excitatory depolarization of the neurons following measured food stimulus application persists significantly longer in conditioned that in control subjects. An analysis of variance comparing the amplitude, duration, and area under the depolarization of conditioned versus naive animals showed significant difference between the groups ($p < 0.001$). A Scheffe test of the means indicated that the basis of the difference was due to the duration and the area of the depolarization response. The averaged response duration for naive animals stimulated by 0.5 ml of squid homogenate applied to the oral veil over 10 seconds was 10.9 ± 1.3 s; that for conditioned animals was 19.4 ± 1.7 s ($p < 0.001$). The response area was 281 ± 17.8 mV·Sec for naive and 516.8 ± 21.3 mV·Sec for conditioned animals ($p < 0.001$). A comparison of the amplitudes showed no significant difference, suggesting that there is no change in the early sensory input. The mechanisms underlying the learning-induced alteration in Int-2 responsiveness are under investigation.

This research was supported by NSF BNS 79-18329 to R. G. and NIH GM07283 to J.A.L.

268.7 MOTIVATION TO FEED AFFECTS ACQUISITION OF FOOD-AVOIDANCE CONDITIONING IN PLEUROBRANCHAEA. Martha L. U. Gillette, J. A. London and Rhanor Gillette. Dept. of Physiology and Biophysics and Neural and Behav. Biol. Prog., University of Illinois, Urbana, IL 61801.

Motivation has a particularly significant effect on task performance in learning situations. A distinct inverted-U shaped relationship between arousal (the motivational variable) and task performance characterizes mammalian learning (Yerkes and Dodson, 1908; Hokanson, 1969). Mammals which are at extremes of the arousal state show low motivation to learn while those partially aroused acquire the task relatively rapidly. The neurophysiological mechanisms underlying these motivational variables have remained unamenable to analysis in these complex organisms. The simple nervous system of the marine mollusc Pleurobranchaea has been useful for examining reflections of motivation in feeding command cells as well as the central neuronal changes underlying food-avoidance conditioning (Davis and Gillette, Science, 1978; Gillette and Gillette, J. Neurosci., 1983; London and Gillette, this volume). We report here that Pleurobranchaea shows motivational affects on task acquisition similar to mammals.

We were alerted to this phenomenon while performing food-avoidance conditioning studies in which animals were observed for acquisition and retention of the task over a period of weeks. Some animals initially would not feed. When retested after one week, they fed with moderate feeding thresholds (as determined by that concentration of food which elicited feeding); they also acquired the task more rapidly than animals with low thresholds. Upon dissection, these animals were found to have food in the posterior gut suggesting that initially they had been satiated. A more careful examination of the phenomenon demonstrated an inverted U-shaped relationship between both feeding experience and threshold vs task acquisition: animals which were either fed to satiation (very high threshold) or held without feeding (very low threshold) were much poorer at acquiring the food-avoidance task than those which had been partially fed and showed moderate thresholds for food. In fact some animals acquired aversion to food in only one food-shock trial. These results suggest an adaptive relation for motivation in learning. For animals which are satiated and **not** aroused by food or those voraciously hungry and overaroused by food, it may be maladaptive to associate food with a negative simulus. However, in animals aroused by food stimuli but not starving, the adaptive value inherent in feeding may be less important than the negative stimulus with which it is associated. The neurophysiological correlates of these phenomena are under investigation. Supported by NSF BNS 79-18329.

268.8 HABITUATION CORRELATED WITH A SHIFT IN THE VOLTAGE DEPENDENCE OF MECHANORECEPTOR CHANNELS IN THE PROTOZOAN, STENTOR. D.C. Wood, Psychobiology Program, Department of Psychology, University of Pittsburgh, Pittsburgh, PA 15260.

The ciliate, Stentor coeruleus, contracts to 40% of its extended length in 10 msec after application of a suprathreshold mechanical or electrical stimulus. During repeated mechanical stimulation the probability of contracting progressively decreases. This decrement in response probability exhibits 7 of the 9 parametric characteristics of habituation but does not show dishabituation.

Mechanical stimuli elicit graded (<25 mV) receptor potentials which are capable of triggering action potentials. Action potentials trigger contractions. When recording at room temperature repeated mechanical stimulation produces a progressive decrement in receptor potential amplitude which is highly correlated with the decrement in probability of an action potential occurring. Action potential amplitude is not altered.

Records from cells cooled to 10°C typically reveal receptor potentials (<15 mV) which are insufficient to elicit action potentials. Under these circumstances repeated mechanical stimulation does not produce a decrement in the receptor potential. Similarly repeated elicitation of action potentials using depolarizing current pulses does not produce a receptor potential decrement. However, if the mechanical stimulus is following in 200 msec by a current elicited action potential then the receptor potential undergoes a progressive decrement. Thus habituation of the mechanoreceptor potential appears to be contingent on action potential production.

Repeated presentation of combined mechanical and electrical stimuli also produces a significant reduction in mechanoreceptor current. This current reduction was characterized by generating I-V plots for cells before and after habituation. Before habituation mechanoreceptor currents have a reversal potential at +20 mV and their conductance is voltage dependent reaching a maximum at -10 to +20 mV while being only 25-40% maximal at resting potential (-50 to -55 mV). After habituation the reversal potential and maximal conductance are not significantly altered but the curve for the voltage dependent conductance is shifted to depolarized values. At resting potential the conductance is now less than 20% maximal. This shift indicates that the unresponsive form of the mechanoreceptor channel which is normally present at hyperpolarized potentials has become more prevalent. This conclusion is reinforced by the observation that significantly more labelled d-tubocurarine binds to habituated than to control cells, since d-tubocurarine has previously been shown to bind selectively to the unresponsive form of the mechanoreceptor channel.

268.9 IMMUNOCYTOCHEMICAL STUDIES OF NEURONS PRODUCING PRESYNAPTIC FACILITATION IN THE ABDOMINAL GANGLION OF APLYSIA CALIFORNICA H. B. Kistler, Jr., R. D. Hawkins, J. Koester, E.R. Kandel, and J.H. Schwartz. Center for Neurobiology & Behavior, Columbia College of Physicians & Surgeons and The New York State Psychiatric Institute, New York, N.Y. 10032.

Sensitization of the gill withdrawal reflex in Aplysia is a simple form of learning resulting in part from presynaptic facilitation of the LE mechanoreceptor neurons of the abdominal ganglion. Previous work has established that facilitation can be produced by application of serotonin, stimulation of the pleuroabdominal connectives or direct stimulation of members of the L29 cell cluster. In addition, earlier electron microscopic studies have shown that L29 cells are similar morphologically to known serotonergic neurons and take up ^{3}H-serotonin with high affinity. It therefore seemed likely that LE sensory neurons receive facilitatory serotonergic input from L29 cells.

Serial 16-um cryostat sections of 7 abdominal ganglia were examined using serotonin antiserum (provided by Harry Steinbusch, Free University, Leiden) and indirect rhodamine immunofluorescence. Serotonin-immunoreactive fibers bearing varicosities closely apposed both the cell bodies and the initial segments of physiologically identified sensory neurons marked by intracellular injection of Lucifer Yellow. Although these observations suggest that sensory neurons receive serotonergic innervation, the origin of these immunoreactive fibers is not the L29 cells. No immunoreactive cell bodies appeared on the ventral surface of the left hemiganglion, the location of L29 cell bodies, whereas identified serotonergic RB cells and several previously unidentified cell clusters were brightly immunofluorescent. Furthermore, when single physiologically identified L29 cells in 3 ganglia were marked with Lucifer Yellow, their cell bodies and processes exhibited no serotonin immunofluorescence. As a control, injection of dye did not interfere with serotonin immunofluorescence in cell bodies or processes of RB cells.

Although sensory cells appear to receive serotonergic innervation, these data indicate that it is not provided by the L29 cells. Our results are consistent with the idea that L29 neurons produce facilitation either by exciting as yet unidentified serotonergic interneurons or by acting in parallel with serotonergic facilitator neurons, using a related amine or another transmitter substance.

268.10 APLYSIA SIPHON SENSORY NEURONS SHOW TERMINAL-SPECIFIC FACILITATION. G. A. Clark* (SPON: E. R. Kandel). Center for Neurobiology and Behavior, Columbia Univ., and New York State Psychiatric Institute, New York, NY 10032.

Classical conditioning of the siphon withdrawal response in Aplysia involves activity-dependent enhancement of heterosynaptic facilitation at terminals of siphon mechanosensory cells onto siphon motorneurons. While activity-dependent enhancement can provide a mechanism for the stimulus and temporal specificity of classical conditioning, the mechanisms underlying response specificity remain unclear. In the present study, we examined the hypothesis that single siphon sensory cells can exhibit facilitation at synapses onto one set of followers without showing facilitation at synapses onto other followers. Although there is as yet no behavioral evidence that Aplysia exhibits response specificity, terminal-specific facilitation would provide a potential mechanism for conditioning one group of motor responses without affecting others.

To test for terminal-specific effects, we compared facilitation at two different sets of synapses of a single sensory neuron: one onto a central motorneuron (located in the abdominal ganglion), and the other onto a perpiheral siphon motorneuron (located on the distal end of the siphon nerve, several mm away). Central and peripheral neuropils were perfused independently, and monosynaptic excitatory postsynaptic potentials (EPSPs) evoked by intracellular stimulation of a siphon sensory cell (once every 40 seconds) were recorded in one central and one peripheral motorneuron. Following 10 trials, 0.1 mM serotonin (the putative transmitter of some of the facilitator interneurons) was perfused over either the central or peripheral neuropil, and washed out while testing continued. After 10 more trials, serotonin was perfused over the other neuropil.

Results showed that serotonin could facilitate transmission at either central or peripheral synapses independently. Application of serotonin onto the central neuropil caused a marked facilitation of EPSPs in central motorneurons, while peripheral EPSPs showed slight habituation from repeated stimulation of the sensory neuron (154% increase vs. 10% decrease, N = 10, $p < .05$). Similarly, application of serotonin onto the peripheral neuropil facilitated peripheral but not central EPSPs (62% increase vs. 10% decrease, N = 10, $p < .01$).

To determine whether activation of endogenous facilitators could produce terminal-specific facilitation, we stimulated the left abdominal connective (6 Hz, 4 sec) at the end of five experiments. Connective shock caused a striking enhancement of EPSPs in central but not peripheral motorneurons (251% increase vs. 6% decrease, $p < .05$).

Since both serotonin and connective stimulation can produce terminal-specific facilitation in siphon sensory neurons, we plan in future experiments to determine whether this mechanism is actually utilized by the nervous system to confer the types of response specificity evident during many forms of learning.

268.PO PERSISTENT CHANGES IN HERMISSENDA B PHOTORECEPTOR MEMBRANE PROPERTIES WITH ASSOCIATIVE TRAINING: A ROLE FOR PHARMACOLOGICAL MODULATION. A. McElearney* and J. Farley, Dept. of Psychology, Princeton U., Princeton, NJ 08544 (spon: S. Harnad)

Previous accounts of long-lasting conductance changes (e.g. I_A reduction; Alkon et. al., Science, 1982) produced in Type B photoreceptors by associative training with light and rotation have emphasized voltage-dependent inactivation and intracellular Ca^{++} accumulation as mechanisms responsible for persistent changes in Type B cell currents. Three lines of evidence suggest that pharmacological modulation of ionic currents - by a substance as yet unidentified within the optic ganglion - may also contribute to B cell membrane changes with training.

Simulation of light-rotation training sequences in the isolated nervous system by administering five simultaneous pairings of light and depolarizing current stimulation of the caudal hair cell produced significantly greater B cell depolarization and increased input resistances (R_m) than did pairing light with comparable direct current-produced depolarization of the B cell [8.2 ± 1.9 vs. 5.7 ± 1.1 mV; 45% vs. 29% MΩ increases; n=9; $p < .05$]. This indicates that the cumulative depolarization and enhanced input resistance which B cells normally undergo during pairings of light and rotation cannot be entirely reproduced by substituting current-induced depolarization for synaptically-induced depolarization of B cells. Perfusion of ligated B cells with a crude optic-ganglion homogenate resulted in a mean depolarization of 5 mV and an average increase in input resistance of 33% (n=8), while a crude extract made from the pedal ganglion had no consistent effect. The optic ganglion has previously been demonstrated to contain the type S/E cell which is the source of EPSPs in B photoreceptors.

As a preliminary step towards a thorough characterization of the pharmacological sensitivity of B cells and to delimit the possibilities of agents which may play an active role in mediating the effects of training in B cells, we have assessed the effects of various neuromodulatory agents upon membrane properties of Type B cells. In the dark, serotonin (30 μM; 5HT) produced an average 25% increase in input resistance and an average 4 mV depolarization of the Type B cells (9/9 cells; ranges 10-83%, -1 to +9mV), while octopamine and dopamine had no detectable effects in 6 and 11 different cells tested, respectively. 5HT also clearly enhanced both the peak and steady state light response of B cells. Norepinephrine produced a slow depolarization (mean = 3.1 mV, 6 cells) accompanied by decreased input resistances (mean = -10%), as did arginine-8-vasopressin (means = 2.8 mV, -14% % decrease in R_m; 5 cells).

268.PO TEMPORAL ORDER SENSITIVITY OF ASSOCIATIVE LEARNING IN HERMISSENDA. L. Grover* and J. Farley, Dept. of Psychology, Princeton U., Princeton, NJ 08544 (spon: B. Campbell)

Previous research has established close correspondences between many of the cardinal features of associative learning in vertebrates and the associative suppression of phototaxic behavior in Hermissenda produced by light-rotation pairings. These similarities include: pairing-, stimulus-, and contingency-specificity, reversibility, and both short- and long-term forms of memory. Our present results indicate a potentially important discrepancy, however. Unlike vertebrates, Hermissenda's most profound associative neural and behavioral changes occur when trained with light-rotation pairings involving simultaneous onsets and offsets. Forward pairings (i.e. light precedes rotation onset by 30 sec) produce no appreciable neural or behavioral change.

Exposure of intact animals to a standard 3-day associative conditioning procedure [50 light-rotation pairings/day; light intensity = 4.5×10^{-3} ergs. cm^{-2} sec^{-1}; rotation = 2.24g; each stimulus 30" in duration, ITI=2 min] in which light onset either coincided with (simultaneous), preceded by 30 sec (forward), or followed by 30 sec (backward) the onset of rotation resulted in significant suppression of phototaxic behavior at a 24 hr test interval for the simultaneous arrangement alone (median=.29; n=9). Forward and backward conditioning groups were not suppressed (.54, .42; n's=10,6 respectively).

Simulation of these training sequences in the isolated nervous systems of previously untrained animals by pairing light with depolarizing current stimulation of a caudal hair cell (cf. J. Farley and D.L. Alkon, J. Neurophysiol., 1983 in press) revealed a similar pattern for cumulative depolarization of Type B cells. These cells are causally related to phototaxic suppression (Farley et al., Science, 1983, in press). Five simultaneous pairings resulted in an average 7 ± 2 mV depolarization, which significantly exceeded that produced by forward (1.0 ± 1.7 mV; $p < .05$), backward (1.6 ± 2.0 mV; $p < .05$), and random control (2.0 ± 1.8 mV; $p < .05$) conditions. Consistent with previous results, the cumulative depolarization for the simultaneous arrangement arises in large part from increased positive synaptic feedback from the S/E optic ganglion cell and disinhibition from the caudal hair cell. Both are unique outcomes of terminating visual and hair cell stimulation simultaneously. For forward pairings, the asynchronous offsets of visual and statocyst stimulation results in post-light hair cell inhibition of the B cell, and substantially reduced and delayed positive synaptic feedback. For backward pairings the sole source of positive synaptic feedback is that attributable to light-alone.

268.PO EXTINCTION OF ASSOCIATIVE LEARNING IN HERMISSENDA: BEHAVIOR AND NEURAL CORRELATES William Richards, Joseph Farley, Dept. of Psychology, Princeton Univ., Princeton, NJ 08544 and Daniel L. Alkon, (spon: R. Cholewiak) NINCDS, NIH, MBL, Woods Hole, MA 02543

Long-term, pairing-, and light-specific reductions in Hermissenda phototaxic behavior have repeatedly been demonstrated for animals exposed to light-rotation pairings. The reversible nature of this form of associative learning is illustrated here by our findings that animals exposed to 25 non-reinforced light steps, immediately following the end of two daily sessions of standard light-rotation pairings (50/day), exhibited significantly reduced levels of phototaxic suppression (suppression ratio score: .44 ± .05), at a 2 hr retention interval, when compared to animals which received pairings only (.29 ± .05; $p < .05$). Extinction animals were no different from random control animals (.54 ± .05). Similar results were obtained at both 2 and 24 hr retention intervals in a second experiment, indicating a lack of spontaneous recovery of the extinguished phototaxic suppression. To test the possibility that habituation contributed to the extinction effect, an additional group of animals was exposed to the same total number (125) of light presentations as extinction animals, but were found to be unchanged by the experience (.56, .47; ± .05:2,24 hr. respectively). The absence of both habituation and sensitization of phototaxis, coupled with the failure to demonstrate spontaneous recovery, suggests that extinction in Hermissenda involves a reversal of the original neural substrates of acquisition and retention. This conclusion was supported by the results of intracellular recordings from isolated Type B photoreceptors from trained animals. These cells have previously been shown to be causally related to the learned suppression of phototaxis (Farley et al., Science, 1983 in press). Paired-condition animals exhibited significantly greater: 1) peak- (26.5 ± 1.4 vs. 19.9 ± 2.5 mV) and steady -state (20.3 ± 1.8 vs. 12.7 ± 2.3 mV) light-induced generator potentials, 2) greater input resistances (33.3 ± 8.9 vs. 25.2 ± 7.1MΩ) when compared to random control or naive animals. Extinction-animal light-responses (20.5 ± 1.5 mV, 15.3 ± 1.5 mV peak and steady-state) and input resistances (14.7 ± 2.5 MΩ) were no different from controls, but significantly less than paired animals ($p < .05$). Thus, Type B cells encode for extinction as well as acquisition and retention of associative learning. Additional results implicate primary neural changes to occur with acquisition and extinction training in Type A photoreceptors as well. Isolated Type A cell steady-state light responses were less for paired (14.4 ± 1.7 mV) vs. extinction (18.3 ± 2.5 mV) and naive or random control (17.2 ± 1.6 mV) animals.

HUMAN NEUROPSYCHOLOGY II

269.1 INTENSITY-TIME FUNCTIONS FOR PATTERN DISCRIMINATION IN RHESUS MONKEYS AND A HUMAN SUBJECT: EVIDENCE FOR SUPERSUMMATION. Andrew Glover*, Pedro Pasik and Tauba Pasik (Spon: Catherine Mytilineou), Dept. Neurol., Mount Sinai Sch. Med., CUNY, N.Y., N.Y. 10029.

Bloch's Law states that intensity (I) and exposure time (T) can be reciprocally interchanged below a certain critical duration (tc) to produce a constant visual behavioral response. This relationship is termed temporal summation. In general, for $T > tc$, I remains constant for the same effect. In addition, there is evidence suggesting that response latencies are similar below tc. Most studies on temporal summation have used single or double light flashes in human subjects. We sought to obtain this type of data using patterns in both normal monkeys and human observers.

Low contrast (12%) circle-triangle pairs were presented at several luminance levels, and subjects were required to initiate forced-choice trials. In Experiment I, tachistoscopic thresholds were obtained for two monkeys at two luminance values (2.9 and 0.2 cd/m^2), by both the descending staircase and the constant stimuli methods. Stimulus and adapting fields were flux-equated for each level. Thresholds (means of 14 and 34 msec, respectively) were found comparable across procedures. The 1.2 log attenuation of the luminance resulted in only a 0.4 log increase in liminal duration. Similarly, less energy (E = IT) was needed at the lower luminance value, the difference being 0.8 log Talbot.

In Experiment II, thresholds were determined in three monkeys and one human subject by the descending staircase method. Eight luminances were used in 0.3 log unit steps. Contrary to Experiment I, the adapting field was held constant and flux-equated to the highest stimulus value (2.9 cd/m^2). For the same monkeys used in Experiment I, a 1.2 log decrease in luminance resulted in about 1.0 log increase in threshold duration, the energy difference being approximately 0.3 log Talbot. For all subjects, function analyses of the log I vs log T relationships showed a region of reciprocity (slope = -1.0), in agreement with Bloch's Law, for brief durations. However, at longer exposures the slopes were not of the expected 0.0 value (failure of summation) and, therefore, no tc was evident. Instead, the slopes became steeper than -1.0, i.e., T was more effective than I for eliciting the criterion response. Latencies remained relatively constant for high luminance, brief duration stimuli, and became progressively longer at lower luminances and longer durations.

The results of both experiments indicate that, at longer exposures, T is a more significant stimulus property than I for a pattern discrimination task. This effect has been termed supersummation. The inflexion point between reciprocity and supersummation may serve as a marker for separating different processes used to solve similar visual tasks. The phenomenon has been only rarely found in physiological and behavioral studies probably because no complex stimuli (patterns) were used. Apparently, light adaptation influences the magnitude of the supersummation effect, given the differences found across the present experiments. (Aided by NEI #EY-07014 and EY-01867.)

269.2 BRAIN ORGANIZATION EXPLAINS DUAL-TASK INTERFERENCE: A DEVELOPMENTAL STUDY. M. Kinsbourne* M. Hiscock* (SPON. J. Warsh). Eunice Kennedy Shriver Center, Waltham, MA. 02254

We have attributed the detrimental effect of performing two tasks at the same time ("time-sharing")to the need to engage a mechanism that obviates interfering neuronal activity ("cross-talk") between the concurrently active cerebral processes. If so,the time sharing decrement should be a function of the extent to which the relevant areas of central cortex are connected or customarily interact. Specifically, it should be greater in, but not limited to, the situation in which both tasks are programmed within the same hemisphere. Should cross-talk be incompletely inhibited, this should manifest as intermittency in task performance. This should be more apt to happen in the immature brain.

Seventy-three righthanded children in grades one through four engaged in speeded finger tapping of the right and of the left hand, each while 1. speaking, 2. memorizing, 3 not otherwise performing. Both concurrent tasks reduced tapping rate relative to control 1. in proportion to task difficulty, 2. of the right hand more than the left, 3. in inverse proportion to age. Gross intermittency characterized the time shared tapping of grade one children only. Ability to time share increased with age, but the degree to which interference was lateralized did not.

The results indicate greater ability to isolate active central processors from each other when they are located indifferent hemispheres and when the brain is relatively mature. Time sharing engages neural activity additional to that which controls the concurrent performances. This activity becomes more efficient with increasing age.

The results do not readily lend themselves to interpretation in terms of unitary or multiple resource models of capacity limitation.

269.3 ENHANCED DUAL TASK PERFORMANCE FOLLOWING TRANSECTION OF THE CORPUS CALLOSUM IN HUMANS. J. D. Holtzman* and M. S. Gazzaniga. Div. of Cognitive Neuroscience, Cornell Univ. Med. Col., N.Y., N.Y. 10021.

Surgical transection of the corpus callosum in humans, so-called "split-brain" surgery, has profound effects on the perception of the visual environment. In essence, when the accurate performance of a task requires the detailed analysis of visual pattern, callosal surgery renders each hemisphere perceptually blind to visual stimuli in the ipsilateral hemifield, i.e., the right hemisphere only perceives left field stimuli, the left hemisphere only perceives right field stimuli. As a consequence, split-brain patients are unable to perceptually compare stimuli appearing in different hemifields. Based on these findings, we hypothesized that under conditions of maximal perceptual load, in which stimuli are distributed between the hemispheres, the apprehension of visual stimuli by split-brain patients would be superior to that of neurologically intact observers.

The present findings confirmed this prediction in one split-brain patient at a spatial memory task. The background visual display for these experiments consisted of two 3 X 3 cell matrices, one displayed to the left and one to the right of a central fixation stimulus. On each trial, a bilaterally displayed "X" moved among 4 cells, either through the same or a different sequence of cells in the two matrices. A unilateral probe sequence subsequently appeared, and the observer indicated whether it matched the original sequence for the probed field. The split-brain patient's performance was comparable under the two conditions ($z = .69$; $p > .05$), whereas neurologically intact observers were significantly more accurate when the same pattern appeared in the two hemifields ($z = 9.42$; $p < .001$). Moreover, the split-brain patient performed better than the control observers when different sequences were presented in the two matrices ($z = 4.70$; $p < .001$). This latter finding implies that under experimental conditions that maximize interfield perceptual load, surgical transection of the corpus callosum can enhance the information processing capacity of the organism.

269.4 OPPOSITE HEMISPHERE LATERALIZATION OF EXPRESSIVE AND RECEPTIVE SPEECH MECHANISMS: AN UNUSUAL CASE STUDY OF CROSSED DOMINANCE. D. Buchholz,* D. Ratusnik,* L. Bieliauskas,* and F. Morrell. Departments of Psychology, Speech Pathology and Neurological Sciences, Rush Medical College, Chicago, Il. 60612.

Early brain injury to the dominant hemisphere frequently results in a shift of speech dominance to the opposite side. Most commonly such shift involves all aspects of language processing. It has been suggested, however, that the shift may be selective for one or another facet of speech (Rasmussen and Milner, Ann. N.Y. Acad. Sci. 299: 355, 1977) although such selectivity has rarely been documented by pre and post-operative examination. We present a study of a 33 yr old left handed accountant who had sustained a perinatal left hemisphere injury resulting in chronic epilepsy. A large porencephalic cyst replaced much of the posterior inferior parietal and posterior temporal lobe on the left. When the seizures became medically intractible, he was hospitalized for evaluation for surgical therapy.

Intracarotid amytal injection into the left carotid artery resulted in complete cessation of ongoing speech, despite retained comprehension of verbal commands. The patient also recalled verbal material given during the drug effect including names of objects and a test phrase. Right carotid injection of amytal did not result in cessation of counting or other serial verbal tasks. Verbal production was fluent but aphasic and he could not follow commands given during the drug action. The test phrase was not recalled.

Pre and post-operative neurological, neuropsychological tests as well as the Boston Diagnostic Aphasia Examination confirmed the interpretation of the amytal studies.

This case offers additional support to the notion of Rasmussen and Milner (1977) that brain injured patients may have receptive speech function in one hemisphere and expressive speech in the other.

269.5 THE CORPUS CALLOSUM IS LARGER IN LEFT HANDERS. S. F. Witelson. Dept. Psychiatry, McMaster Univ. Hamilton, Canada, L8N 3Z5

Linear and planimetric measurements of the corpus callosum exposed in midsagittal section were made in 33 consecutively obtained formalin-fixed specimens acquired from clinical post-mortems. They included 12 men and 21 women, ranging in age from 25 to 67 years (mean = 49 yr) at time of death. The direction, degree and family history of hand preference were available from direct testing of these cases who are being studied as part of a larger study on the relationship between neuroanatomical variation and neuropsychological test performance. All anatomical measurements were made without the knowledge of handedness or sex of the individual.

It was found that individuals with left- or mixed-hand preference (n=11) (as defined in Annett, Quart. J. exp. Psychol, 1967, 19, 327) had a larger corpus callosum than did right handers (n=22). The two hand subgroups, by chance, proved comparable in age, sex distribution and brain weight. Mean total area of the callosum was 6.7 vs 7.9 cm^2 for the right and left handers, respectively. Mean brain weight was similar for right and left handers, 1311 vs 1359 g, respectively. Callosal area relative to brain weight (x1000) was also significantly different between groups, 5.1 vs 5.8, respectively ($p<.01$). This difference between hand groups was present within each sex group, particularly for men. Maximal antero-posterior callosal length was 7.1 vs 7.4 cm for right and left handers, respectively (nonsignificant).

Callosum size was found also to be associated with sex, as previously reported (de Lacoste-Utamsing & Holloway, Science, 1981, 216, 1431). In the present study, the sexes were found to differ, not in callosal area (7.2 vs 7.0 cm^2), callosal length (7.3 vs 7.1 cm) or maximal splenial width (1.5 vs 1.4 cm), but only in callosal area relative to brain weight x1000 (5.0 vs 5.6, $p<.05$); in all cases, men vs women, respectively. Rank order of callosal area relative to brain weight in the four subgroups indicates that right-handed men have the smallest corpus callosum (4.6) and left-handed women, the largest (5.9).

Hemispheric representation of cognitive functions is well documented to be more diffusely represented bilaterally in left handers compared to right handers; some evidence indicates that females also have greater bihemispheric representation of cognition compared to men (Witelson, In Language Functions and Brain Organization, Segalowitz (ed) 1983). The larger corpus callosum found in left handers and also in females may be a morphological basis for individual differences in laterality and for the greater bihemispheric representation of cognition in some individuals.

269.6 NON-HEMORRHAGIC LESIONS OF THE THALAMUS: NEUROPSYCHOLOGICAL, NEURORADIOLOGICAL AND ELECTROPHYSIOLOGICAL FINDINGS IN HUMANS. Authors: Neill R. Graff-Radford*, Hanna Damasio*, and Thoru Yamada*, (SPON: A.E. Applebaum). Department of Neurology, University of Iowa Hospitals, Iowa City, Iowa 52242

Eighteen patients with non-hemorrhagic thalamic infarctions were independently studied by three investigators with: (a) comprehensive clinical and neuropsychological testing (NG-R); (b) computerized tomography (CT) (HD), and (c) somatosensory evoked responses (SER) (TY). The patients were divided into five groups corresponding to the probable vascular territories of the infarctions. These include (i) entire geniculothalamic territory (n = 4), (ii) partial geniculothalamic territory (n = 3), (iii) tuberothalamic (n = 3), (iv) deep interpeduncular profunda (n = 2), (v) anterior choroidal (n = 6).

Severe neuropsychological deficits were seen in the tuberothalamic and deep interpeduncular profunda groups. Language, verbal and visual memory, verbal and performance IQ and visuospatial deficits were seen in the left tuberothalamic patients, whereas language, verbal memory and verbal IQ were preserved with right tuberothalamic lesions. Left anterior choroidal cases had language and verbal memory deficits, whereas the right anterior choroidal had visual memory deficits. The geniculothalamic groups had normal neuropsychological performance unless the posterior cerebral artery was also occluded.

SER's were absent after P14 (brain stem) over the ipsilateral hemisphere in the complete geniculothalamic artery group, possibly corresponding to destruction of the primary sensory nuclei (VPL and VPM) and to the clinical finding of multimodal sensory loss. In the partial geniculothalamic group pinprick loss and proprioception retention were associated with normal N17, N19 and N20 but delayed N32 and N60. This indicated that the stimulation of medial lemniscal pathways probably caused waves N17, N19 and N20. But lesions in the tuberothalamic territory, which does not include the primary sensory nuclei, cause a delay of these waves. This may result from a disturbance of intrathalamic pathways or disturbance of the gating by the reticular nucleus of the thalamus situated anterior to VA. This area is considered important in gating evoked responses in the cat.

269.7 COGNITIVE DEFICITS ASSOCIATED WITH RIGHT HEMISPHERE DAMAGE: COMMON PROCESSES UNDERLYING VISUOSPATIAL ABILITIES AND STORY COMPREHENSION? Kenneth L. Moya*, Larry I. Benowitz, David M. Levine* and Seth Finklestein*. Mailman Research Center, McLean Hospital; Depts. of Psychiatry and Neurology, Harvard Medical School; Massachusetts Rehabilitation Hospital; Massachusetts General Hospital.

Visuospatial abilities and story comprehension were tested in 18 right brain-damaged (RBD) patients and in 10 age-matched controls. Performance for both the story comprehension and visuospatial tasks was evaluated for recall of details and for appreciation of overall form and relationships among elements, using a quantitative scoring protocol developed for these studies. In addition, the frequency of various error types such as perseverations, intrusions, substitutions, and confabulations were analyzed. In accordance with other research, our results showed that RBD patients were impaired on all aspects of visuospatial performance. RBD patients also performed significantly worse on story comprehension than controls, and these deficits were correlated with the degree of visuospatial deficits. The ability to appreciate relationships among story elements showed the greatest impairment after right brain damage and was the most significant verbal correlate of visuospatial performance. These results indicate (a) that certain aspects of language transcend the capabilities of the isolated left hemisphere, and (b) that the involvement of the right hemisphere in appreciating complex linguistic material may utilize processes similar to those involved in visuospatial abilities. We propose that both story comprehension and visuospatial abilities reflect a general role for the right hemisphere in organizing and/or evaluating schemata. Supported by an Alfred P. Sloan Foundation Fellowship to Dr. Benowitz, and an American Heart Association Clinician-Scientist Award to Dr. Finklestein.

269.8 NEUROPSYCHOLOGY OF MILD HEAD INJURY. H.M. Eisenberg, H.S. Levin, R.M. Ruff,* S. Mattis,* L.F. Marshall and K. Tabaddor.* Div. of Neurosurgery, Univ. Texas Med. Branch, Galveston, TX 77550; Div. of Neurosurgery, Univ. Calif., San Diego, and Div. of Neurosurgery, Albert Einstein College of Medicine, Bronx, NY.

In an ongoing three-center study, we have investigated the recovery of 76 consecutively admitted patients with mild closed head injury (CHI). The head injuries were considered mild according to research diagnostic criteria; no other major injuries were present. The neuropsychological measures consisted of the Mattis-Kovner selective reminding test, the Benton Visual Retention Test, Digit Span, a visuomotor speed test (Coding), and the Paced Auditory Serial Addition Test (PASAT).

In comparison with a control group (n=52), the mild CHI patients were impaired on all measures at the time of the baseline exam within 1 week of injury. According to a criterion of the worst control score, nearly 50% of the mild CHI patients had defective verbal memory, a third had poor visual memory and about 25% evidenced deficits on digit span, Coding, and the PASAT.

Thirty one mild CHI patients have been examined at 1 month postinjury. Their performance improved on all measures ($p<.001$) and showed only a nonsignificant trend of deficit as compared to the controls. Review of individual cases and each test, however, disclosed that 10% to 30% of the mild CHI patients were still impaired.

269.9 AUTOMATIC AND EFFORTFUL PROCESSING IN DIABETICS. W. Lichty. Psychology Department, University of Missouri, Columbia, MO 65211

Two aspects of information processing, effortful and automatic processing, were investigated in 32 Type I (insulin-dependent, ketone-prone) diabetics and 32 control subjects matched for age, sex, and education. Effortful processing efficiency varies with organismic and environmental influences such as aging, mood, and stress; whereas, efficiency for automatically processed information is relatively constant. The purpose of the present experiment was to investigate effortful and automatic processing in diabetes, a disease which is subject to neurological influences involving acute effects of blood glucose level and chronic effects related to cardiovascular complications and to segmental demylination of Schwann cells, and in some cases, oligodendrites.

As anticipated, on a task requiring effortful processing, a paired-associate learning task, diabetics attained lower scores when WAIS vocabulary scores were partialed out in an analysis of covariance ($p<.05$). On the automatic processing task, a frequency judgment task, null effects were found ($p=.61$), in agreement with the hypothesis that automatic processes are stable under physiological alterations.

Additional investigations of the diabetic group revealed possible effects immediate blood glucose level and long term diabetic control may have on effortful processing. Correlations of blood glucose level and paired-associate learning scores increased over trials and eventually attained significance, thus suggesting a positive influence high glucose availability in the brain may have on effortful processing. Diabetic control may also have a strong impact on effortful processing, as suggested by superior performance of subjects who reported high frequency of hypoglycemic reactions ($p<.05$). Since frequency of hypoglycemic reactions is a rough indication of general level of diabetic control and since general level of control relates to development of complications, it is possible that the results relate to neurological degeneration.

269.10 DISPROPORTIONATE DECLINE IN VISUOSPATIAL MEMORY IN HUMAN AGING, H.S. Levin and G.J. Larrabee*. Div. of Neurosurgery and Dept. of Neurology, Univ. Texas Med. Branch, Galveston, TX 77550.

In view of the frequent finding of memory deficit and visuospatial impairment early in the course of dementia of the Alzheimer type (cf. Sim, M. & Sussman, I. J. Nerv. Ment. Dis., 135:489, 1962), we postulated that long term memory (LTM) declines more rapidly as a function of age for visuospatial information as compared to verbal material. We employed the selective reminding test (Buschke, H. & Fuld, P.A. Neurology, 24:1019, 1974), which measures storage and retrieval of 12 words across 12 trials. We also administered a visuospatial selective reminding task in which the subject reproduces the spatial locations of marbles over 12 trials. Consistent long term retrieval (CLTR) summed across the 12 trials was the measure of LTM. We studied 50 high school students, 22 subjects in the 60-69 year old range, 24 subjects in the 70-79 year old range, and 17 subjects at least 80 years old (mean =83) who had adequate vision and hearing and no history of major health problems.

We transformed the CLTR scores of the elderly subjects to standard (T) scores based on the CLTR distribution of the high school students (T score mean = 50, SD = 10). The T transformation of CLTR scores on the verbal and visuospatial selective reminding tasks in the 60-69 year old group yielded means of 39.7 (SD=13.5) and 19.2 (SD=27.7), respectively which differed significantly ($t=3.13$, $p<.005$). In the 70-79 year old group visuospatial memory (mean=5.4, SD=33.4) was significantly below verbal memory (35.0, SD=9.1), $t=4.14$, $p<.001$. The pattern of more rapid decline in visuospatial memory was also confirmed in the subjects who are at least 80 years old (verbal CLTR=28.9, SD=10.9; visuospatial CLTR=1.41, SD=27.5), $t=3.73$, $p<.002$.

Impairment of CLTR, i.e., a score which fell at or below the 5th percentile of the students, was present in 8 of the 60-69 year olds (36%) on the spatial selective reminding as compared to 4 (18%) failures on the verbal procedure, a nonsignicant difference. In the 70-79 year old group, 9 subjects (38%) were impaired on the spatial task as compared to only a single subject (4%) on the verbal measure, a difference in proportions which was significant ($\chi^2=6.19$, $p<.02$). Of the subjects at least 80 years old, 5 (29%) had impaired visuospatial memory as compared to 2 (12%) with verbal LTM deficits, a nonsignificant difference.

We suggest that learning and retention of visuospatial information is more vulnerable to the effects of normal aging than memory of verbal material. The disproportionate decline in visuospatial memory in normal aging may represent an analogue of the memory disorder associated with dementia of the Alzheimer type.

269.11 COMPUTED TOMOGRAPHY MEASURES OF CEREBRAL ATROPHY AND COGNITIVE DECLINE IN AGING AND DEMENTIA: T. L. Jernigan and L. M. Zatz*. Veterans Administration Medical Center, Palo Alto, CA 94304.

We have obtained measures from computed tomography (CT) of sulcal widening, ventricular enlargement, and mean attenuation values in white and gray matter samples in over 175 normal adults and over 40 demented patients. In two independent studies of older adults, using different CT scanners, white and gray matter values declined with age. This change appears to be more strongly associated with sulcal widening than with ventricular enlargement, and occurs quite evenly across the different structures sampled. Like the global atrophy measures, the white and gray matter values are modestly, but significantly correlated with measures of recent and remote memory, and psycho-motor speed.

In our investigations of the normal elderly, specific relations between regional CT measures and various cognitive test scores have been only weakly supported. For example, we hypothesized that frontal white matter values would be more strongly associated with psychomotor speed while temporal white matter values would better predict performance on a figure learning task. The simple correlations were as follows:

	Frontal White	Temporal White
Psychomotor Speed	.28*	.20
Figure Learning	.28*	.42**

While the results are not inconsistent with our hypotheses, regression analyses reveal that the difference between the contributions of the CT values does not approach significance for either cognitive measure. That is, no specific relationship is observed between frontal white and psychomotor speed, or temporal white and figure learning.

With CT, we can not yet rule out a model in which parenchymal values decrease and sulcal widening occurs diffusely due to a single global process. This process would appear to be weakly associated with pervasive mild intellectual decline. Analyses of data from demented patients are currently in progress. These results will be compared to those obtained in normal aging.

*p<.05, **p<.01.

269.12 NEUROPSYCHOLOGICAL FUNCTION AND REGIONAL CEREBRAL GLUCOSE UTILIZATION IN HEALTHY AGING AND DEMENTIA. C.L. Grady*, J.V. Haxby*, R. Duara*, S.I. Rapoport and N.R. Cutler. (SPON: A.F. Mirsky), NIH/NIA, Laboratory of Neurosciences, Bethesda, MD, 20205.

To assess the relation between behavioral and physiological measurements of brain function, we have compared performance on the Luria Nebraska Neuropsychological Battery (LNNB) with regional cerebral metabolism, as measured by [^{18}F]fluoro-deoxyglucose and positron emission tomography (PET). Thirty-seven healthy male subjects between the ages of 21-83 yr (mean age 49.9) were PET scanned with reduced visual and auditory input. The regional cerebral metabolic rates for glucose (rCMRglc) and ratios of rCMRglc to whole brain CMRglc (Q scores) were calculated and correlated with age and the clinical scales of the LNNB. The LNNB scores also were arranged into localization scales, which are thought to represent function of large brain areas, such as the frontal lobes, and the rCMRglc values and Q scores were also grouped into corresponding regions. These measures were then correlated with age and with each other. None of the rCMRglc values or Q scores was correlated with age but the clinical scales of the LNNB, with the exception of reading, writing, and arithmetic, were significantly correlated with age. Few rCMRglc values or Q scores were correlated significantly with any LNNB scale, and these could have been due to chance. The localization scales were significantly correlated with age, with the exception of the left parieto-occipital scale, while none of the combined metabolic values was related to age. Only one localization scale was significantly correlated with the corresponding metabolic value, that of the left parieto-occipital scale with the corresponding Q score.

A similar analysis was conducted on the data from 4 patients with a diagnosis of Alzheimer's disease (mean age 57.7 yr) who were also PET scanned in an unstimulated state. In 3 patients there was close correspondence between abnormally elevated LNNB localization scales and metabolic deficits, particularly in the parieto-occipital areas. A fourth patient showed a marked right parietal deficit on the LNNB and a predominantly left parietal metabolic deficit.

The findings suggest that in healthy subjects there is little relation between neuropsychological function as measured by the LNNB, and rCMRglc in an unstimulated state. In patients with dementia, however, there is a correspondence between these two measures, particularly in the parieto-occipital areas, suggesting that both instruments may be useful in assessing gross deficits in brain function.

269.13 RETENTION OF ORIENTING REACTION HABITUATION IN PATIENTS WITH NIGHT TERRORS. R. Rogozea and V. Florea-Ciocoiu+. Inst. Neurol. Psychiat., Bucharest, ROMANIA.

A polygraphic study on habituation of the somatic (EMG), autonomic (finger plethysmogram, galvanic skin reaction, pulse, EKG) and EEG (acoustic-evoked potential and EEG-blocking reaction) components of the orienting reaction elicited by a repetitive auditory stimulus during successive (weekly) sessions was performed in 36 patients with night terrors and in 72 matched subjects in two control groups (41 normal subjects and 31 patients with symptomatic epilepsy).

The study evidenced significant retention disturbances of orienting reaction habituation (i.e. of learning), the "saving" of stimulations achived from one session to the other to obtain the habituation criterion, being lesser in patients with night terrors than in normal subjects of control group I. However, the "saving" of stimulations was significantly bigger than in patients with symptomatic epilepsy of control group II.

The severity of these habituation retention disturbances in patients with night terrors depended on the patients' age at seizure onset, the frequency of nocturnal episodes and their etiology, as well as on the features of spontaneous EEG activity. Thus, the most marked deficit in retention of the orienting reaction habituation was noted in patients with early onset of the nocturnal episodes (i.e. undes the age of 9), in patients with frequent seizures (i.e. with daily seizures), in patients with nocturnal episodes on organic background (i.e. with meningoencephalitides, craniocerebral traumata, neonatal diseases in their history) and in patients with interictal EEG tracings displaying signs of hyperexcitability, diffuse or focal pathological graphoelements and especially EEG signs of immaturity.

These habituation retention disturbances may be ascribed to the nervous functional disordes induced by psychological factors (mental stress, strong emotional states, environmental (sociofamilial) negative stimuli) or/and by organic disordes (caused by post-meningoencephalitic or post-traumatic lesions) which determine, apart from night terrors seizures, disturbances in the activity of the neural structure and pathways involved in the regulation of the nervous system diffuse excitability and, implicitly, in the control of repetitive sensory messages and in learning.

269.14 TOWARD A THEORETICAL NEUROPSYCHOLOGY: BRAIN SYSTEMS AS MICROFIBRATIONS. W. C. Hoffman. Dept. of Mathematical Sciences, Oakland University, Rochester, MI 48063.

The topological structure of microfibration (a "total space" coupled to and from a "base space" by projection mappings) appears to be the common structural and functional element of the CNS. In the case of the posterior perceptual systems, these fibrations constitute so-called equivariant dynamical systems, owing to the known invariances of form perception. For such cognitive functions as semantic memory and problem solving, the fibrations consist, according to information processing psychology, of semisimplicial microbundles embodied in the structure of the prefrontal cortex, inferotemporal cortex-hippocampus, and the higher brain stem. The latter constitutes the base space for subcortical integration of higher brain functions at the conscious level. Specific features of LTM, STM, and working memory and of problem solving behavior are analyzed in terms of the structure of the category of semisimple fibrations.

270.1 HAIR FOLLICLE INPUTS CONVEYED TO THE FIRST SOMATIC SENSORY AREA (SI) VIA THE DORSAL FUNICULUS ARE REQUIRED FOR THE PERFORMANCE OF A HAIR DISPLACEMENT DISCRIMINATION BY RHESUS MONKEYS.
Richard J. Schneider and David P. Friedman. Laboratory of Neuropsychology, Bldg 9 Rm 1N107, NIMH, Bethesda, MD 20205.

The role of the dorsal funicular input to SI in hair displacement and electrocutaneous stimulus discrimination was explored. Three rhesus monkeys were trained to discriminate between two amplitudes of displacement of hair groups on the anterior calf and between two frequencies of electrical pulse trains applied to the skin over the peroneal or sural nerves. A go-no go design was employed. Each animal was required to press a manipulandum in response to the go stimulus (a specific amplitude of hair displacement or frequency of pulse train) and to refrain from pressing it for the no-go stimulus (a lower amplitude of hair displacement or frequency of pulse train). The discriminations were made ambiguous so that each animal made errors while performing the task. The stimuli were presented successively (10 sec. interstimulus interval) and pseudorandomly. After reliable control values were established, animals were retested with peripheral nerve block (PNB) followed by unilateral dorsal funiculus (DF) lesions at the T1 level. Following the DF lesions and testing, single and multiunit recording in SI was carried out in one animal. Contralateral to the lesion, all of the denervated and some of the innervated portions of SI were explored. In the opposite SI, similar regions were examined.

Prior to the tractotomy, discriminative ability of monkeys on the hair displacement and electrocutaneous tasks produced mean d' scores, the measure of sensory capacity in signal detection theory, of 2.21 and 1.29, respectively. With PNB, responding to both types of stimuli ceased distal to the block, but not proximal to it. By contrast, following DF tractotomy, there was a marked diminution in the d' score below the level of the lesion on the hair displacement but not on the electrocutaneous task. Contralateral to both the PNB and DF tractotomy, there was no change in d' scores. In the region of SI deprived of DF input (lower body representation), no cells were found which responded to hair displacement and none was driven electrocutaneously. Both stimuli drove cells in the arm representation on the ipsilateral side and the leg representation contralaterally.

The results suggest that: (1) SI is supplied with hair displacement input exclusively via the DF; (2) Hair receptor input to SI is required for hair displacement discrimination; and (3) Electrocutaneous input to SI also arrives exclusively via the DF but this input is not required for the discrimination of pulse train frequency.

270.2 GLUTAMIC ACID DECARBOXYLASE CONTAINING NEURONS IN THE DORSAL COLUMN NUCLEI OF THE CAT. A. Rustioni, D.E. Schmechel*, S. Cheema., and D. Fitzpatrick,* Depts of Anatomy and Physiology, Univ. of NC at Chapel Hill, and Dept. of Neurology, Duke Univ. Durham, NC

The retrograde transport of horseradish peroxidase (HRP) and immunocytochemistry for glutamic acid decarboxylase (GAD) have been employed to verify whether interneurons exist in the dorsal column nuclei and whether these may be GABA-ergic. Observations were focused on the dorsal part of the middle cuneate nucleus (MCd) since this region has been previously shown to contain projecting neurons whose axon terminate almost exclusively in the contralateral thalamus. After injections of HRP or lectin conjugated HRP (WGA-HRP) in the ventrobasal complex of the feline thalamus the majority of neurons in MCd are labelled. These represent 88.9%, as counted in frozen, 40 µm thick sections, and 69.7% as counted in plastic-embedded 2.5% µm thick sections, of the neuronal population of MCd. Unlabelled by the same injection are few medium to large neurons at the dorsal rim of MCd but, most characteristically, small (X=±250 µm^2) neurons at the periphery of the cell clusters formed by thalamic-projecting neurons. These small neurons rep-resent 10-12%, as counted in frozen, 40 µm thick sections, and 29.3%, as counted in plastic-embedded 2.5 µm thick sections, of the neuronal population of MCd. The same class of neurons are also unlabelled after injection of the retrograde tracer in the pretectal area, the inferior and superior colliculi, the inferior olivary complex and/or spinal cord. These injections however re-sult in labelling of neurons along the dorsal rim of MCd and/or in other regions of the cuneate nucleus.

In adult, colchicine treated, cats, the use of anti-GAD-serum reveals a population of labelled neurons uniformly distributed throughout the DCN. In MCd, these are small (X = 220µm) neurons found mainly at the periphery of cell clusters and they represent about 27% of the neuronal population of this nuclear subdivision as counted in plastic-embedded 2.5 µm thick sections. Labelled processes densely infiltrate the cell clusters and labelled varicosities appear to cover the soma and dendrites of unlabelled neurons.

At the electron microscopical level, most labelled profiles contain vesicles and correspond to F-boutons usually involved in "axo-axonic" contacts with terminals of dorsal root afferent and presynaptic to dendrites. Other vesicle-containing, GAD-positive endings also seem to correspond to the P-boutons described by Ellis and Rustioni (1981) and are believed to be, at least in part, of dendritic origin. It is suggested that GAD-positive neurons are GABA-ergic interneurons and that these can mediate both pre- and post-synaptic inhibition although their integrative role is likely to be more complex than postulated by previous electrophysiological studies. Supported by USPHS grant NS 12440.

270.3 CLASSIFICATION OF SLOWLY-ADAPTING PROPRIOCEPTIVE NEURONS IN THE CUNEATE NUCLEUS OF THE CAT. D.J. Surmeier*and A.L. Towe. Dept. of Physiology and Biophysics, Univ. of Washington, Seattle, Wa.98195

Muscle spindle afferent fibers from the forelimb project to the cuneate nucleus of cats (Rosen,J.Physiol.,205:209-236,1969). Amassian and Giblin (J.Physiol.,243:353-385,1974) reported that proprioceptive cuneate neurons rarely produced spike trains with more than two periodic components, and suggested that such neurons are strongly driven by no more than two periodically discharging muscle afferent fibers. We examined this assertion by analyzing the spike trains of cuneate neurons with both time and frequency domain methods. In addition, we attempted to characterize the cutaneous receptive fields of these cells.

Single unit activity was recorded with tungsten microelectrodes from domestic cats anesthetized with alpha-chloralose and paralyzed with decamethonium bromide. Spike and stimulus trains were led into waveform discriminators interfaced with a TI 990/12 computer that recorded event times on magnetic disk. All units had slowly-adapting responses to alterations in forelimb position, and could not be driven by gentle probing or stretching of the skin. The spike train produced in the absence of cutaneous stimulation was recorded with the limb held fixed. Then, electrical stimuli were delivered to the skin through needle bipolar electrodes. The stimuli were Poisson distributed, with mean rates of 2.5-10 Hz. Responses were assessed by cross-correlation.

Three types of proprioceptive neuron were found. The most common type (26/56) had unimodal interval and joint interval distributions and one, or a few, closely spaced spectral components. Only one of twelve units tested responded to cutaneous stimulation. The second type (11/56) had bimodal interval distributions and joint interval structures indicative of two or more strong periodic inputs. Spectral analysis revealed from two to five periodic components. Two of four cells tested had cutaneous receptive fields. The third type (19/56) produced spike trains which "reset" following a non-modal interval. These trains rarely had fewer than three dominant spectral components, and commonly had four or five. Of eleven cells tested, ten responded to cutaneous stimulation. Thus, while all proprioceptive neurons sampled displayed periodicities, the majority had one, or two, dominant components. A significant number of cells appeared to receive input from more than two muscle afferent fibers and from afferent fibers of cutaneous origin.

270.4 DIFFERENCES IN THALAMIC- AND SPINAL-PROJECTING NEURONS IN CAT DORSAL COLUMN NUCLEI. R. J. Budell* and K. J. Berkley (SPON: J. E. Tunkl). Dept. of Psychology, Florida State Univ., Tallahassee, FL 32306.

In addition to ascending projections, neurons in the dorsal column nuclei (DCN) have descending projections to the spinal cord (Dart, 1971; Kuypers & Maisky, 1975; Burton & Loewy, 1977). Recent electrophysiological studies have demonstrated that 70% of the spinal-projecting DCN neurons have ascending collaterals (Bromberg et al., 1981). The purpose of the present study was to determine, anatomically, if these ascending collaterals terminate in the ventroposterolateral nucleus of the thalamus (VPL).

Spinal- and VPL-projecting neurons were compared using single and double autoradiographic or fluorescent retrograde labeling techniques. The labels which were injected into the rostral spinal cord (C2, C4-8, T4) and VPL included: ^{3}H-inactivated horseradish peroxidase, ^{3}H-N-acetyl wheatgerm agglutinin and wheatgerm agglutinin:horseradish peroxidase conjugate, or the fluorescent dyes fast blue and nuclear yellow. In comparisons of the labeling patterns in 16 cats, spinal-projecting neurons differed in both their morphology and location from VPL-projecting neurons. Whereas, as expected from previous studies, round "clustered" neurons were labeled after injections confined to VPL, the majority of labeled neurons following spinal injections were fusiform, triangular or stellate. Furthermore, VPL-projecting neurons were grouped, as expected, into "cell nests" in the dorsal portion of the caudal and middle levels of DCN, whereas spinal-projecting neurons were concentrated ventrally in the same levels, as well as in distinct regions between the gracile and cuneate nuclei. At rostral levels of DCN, where VPL-projecting neurons were more scattered, spinal-projecting neurons remained ventral or ventromedial to the VPL-projecting neurons.

These results indicate that ascending collaterals of spinal-projecting DCN neurons probably do not terminate in VPL, but instead terminate in one or more of DCN's other targets. Because of their location and morphology, it is likely that this target, or targets, may be the pretectum, as well as perhaps the pons, cerebellum or tectum (Bull & Berkley, 1981; May & Berkley, this vol.).

The ventral portion of DCN receives sensory input from muscles and other deep structures, whereas the region between the gracile and cuneate nuclei receives input from thoracic segments (Rosén, 1969; Keller & Hand, 1970; Bakker et al., 1982). The present results together with previously reported results on pretectal- and pontine-projecting neurons (see above) suggest that the spinal-projecting neurons may be part of an efferent system originating in DCN that is involved in some aspect of sensorimotor integration such as the control of postural adjustments.

270.5 A COMPARATIVE STUDY OF THE THALAMIC DISTRIBUTION OF GAD IMMUNOREACTIVE NEURONS. G.R. Penny, M. Conley, I.T. Diamond and D.E. Schmechel*. Neurobiology Program and Department of Psychology, and Division of Neurology, Department of Medicine, Duke University, Durham, NC 27706.

In earlier papers we described the distribution of neurons immunoreactive for glutamic acid decarboxylase (GAD) in the dorsal thalamus of the cat and the bushbaby, Galago senegalensis. The significance of these experiments relies on the fact that GAD is the synthetic enzyme for GABA and therefore that GAD immunoreactivity is a marker for inhibitory GABAergic neurons. One striking result was the similarity between these two distantly related groups. In both species the small GAD neurons were distributed throughout the dorsal thalamus with the exception of the centre median-parafascicular complex, where GAD neurons were absent. In both cat and Galago 20-30% of the neurons in the lateral geniculate and ventral posterior nuclei were GAD immunoreactive, and in both species the GAD neurons were identified as local circuit neurons (i.e., they did not project to cortex). In the present study we examined two additional species (opossum and rabbit), chosen because they might reveal some basic principles of the organization of thalamus in all mammals: Specifically, we asked, "are the similarities between cat and Galago common to all mammals or, on the contrary, does cat and Galago each reflect derived features differing from those displayed by the living conservative mammals (such as opossum)?"

The answer to this question was immediately apparent from the finding that in opossum, GAD neurons are chiefly confined to the lateral geniculate and the lateral extremity of the lateral posterior nucleus. The distribution of GAD neurons in rabbit is curiously intermediate between that found in opossum on the one hand and cat and Galago on the other. Like opossum, about 25% of cells in the lateral geniculate nucleus are GAD immunoreactive. Unlike opossum, however, as many as 18% of the cells in the ventral posterior nucleus are GAD immunoreactive, and scattered cells are also labeled in other thalamic areas, such as the medial geniculate and the lateral group. These results support the idea first put forward by Cajal that local circuit neurons proliferate with the course of evolution of complex mammalian brains. If we can assume that the opossum retains characteristics reflecting an early (or primitive) stage of mammalian evolution, the results suggest that thalamic local circuit neurons evolved first in the visual thalamus and only later in evolution spread throughout the whole thalamus.

270.6 INTRACELLULAR STAINING OF ELECTROPHYSIOLOGICALLY IDENTIFIED NEURONS AND FIBERS IN VENTROBASAL THALAMUS (VB) OF CAT. C.-T. Yen and E.G. Jones. James L. O'Leary Division of Experimental Neurology & Neurological Surgery, and McDonnell Center, Washington University School of Medicine, St. Louis, MO. 63110.

Horseradish Peroxidase (HRP) filled microelectrodes have been used to reveal fine morphological details of physiologically characterized VB neurons and medial lemniscal fibers (ML) in barbiturate anesthetized cats. Cuff electrodes were used to stimulate the contralateral median and sciatic nerves. Natural stimuli were applied to skin, hairs and deep tissues. The ipsilateral ML was stimulated electrically at its medullary decussation and the ipsilateral first somatosensory cortex was stimulated over the forelimb representation. High impedance microelectrodes were filled with 10% Tris-buffered HRP. A high voltage electrometer was used to record and to inject. Frozen or Vibratome sections were reacted with cobalt intensified Diaminobenzidine. Twelve VB neurons, 12 ML fibers and one neuron in the reticular thalamic nucleus (RTN) have been stained.

Ten VB neurons were confirmed as thalamocortical relay cells (TC neurons) with a range of modality properties. Soma diameters ranged from 20 to 50 microns and dendritic fields 200-400 microns. Larger TC neurons with thick axons have thick proximal dendrites ending abruptly in a tuft of finer branches but no spines or protrusions. Smaller TC neurons have thinner, less highly but evenly branched dendrites with thin spines. No TC axons gave off local collaterals inside VB; several had collaterals ending in the RTN. Latencies of antidromic spikes of TC neurons ranged from 0.4 to 1.4 msec. Two small VB neurons which were not characterized physiologically had 3 to 4 thin twisted processes with occasional varicosities and may represent interneurons. The RTN neuron had a somatosensory receptive field. It had long, thin, sinuous dendrites. The thin axon collateralized profusely with many enpassant endings in RTN, VB and adjacent nuclei.

ML fibers demonstrated a range of modality properties and latencies of 0.5 - 1.3 msec. Individual fibers had 1 - 4 termination fields in VB. Within each field, densely packed boutons of variable size and shape were found (33 to 1240 per field). Almost all boutons were found within 50 - 400 micron long, rod-shaped termination field. Isolated boutons were rare. We conclude provisionally that TC neurons of VB have no intranuclear collaterals, but have collaterals in the RTN. There seem to be two morphological types of TC neuron and an interneuron. ML fibers terminate in very restricted but often multiple patches. Somatosensory RTN neurons terminate diffusely in VB and other nuclei.

270.7 THREE-DIMENSIONAL RECONSTRUCTION OF THE TOPOGRAPHY OF THALAMOCORTICAL PROJECTIONS IN THE RAT. J.K. Chapin, D.S. Schlusselberg, W.K. Smith, and D.J. Woodward. Dept. of Cell Biology, U. Tex. Hlth. Sci. Ctr., Dallas, TX 75235.

This study was conducted to define the topographic relationships between the thalamus and precisely defined areas within the frontal and parietal cortex of the rat. Discrete injections of horseradish peroxidase (HRP) were made into the following cortical zones: fronto-medial agranular (FMAG), fronto-lateral agranular (primary motor (MI) cortex), granular zones (GZ's; containing the hindpaw, forepaw, and face areas of primary somatosensory (SI) cortex), dysgranular zones (DZ's; containing the limb and trunk areas of SI cortex), and SII cortex. Locations of retrogradely labelled neurons and thalamic nuclear boundaries, observed in serial coronal sections through the thalamus, were digitized with a graphics tablet. A computer was used to reconstruct this data into three-dimensional views of the thalamocortical organization.

Corticotopic patterns of labelled neurons were observed in the ventro-lateral (VL), ventral postero-lateral (VPL) and -medial (VPM), ventro-medial (VM), and posterior (Po) thalamic nuclei (defined in "The Rat Brain", by Paxinos and Watson, Acad. Press, 1982). After HRP injections into the different SI cortical GZ's, labelling was observed mainly within the VPL (paw areas) or VPM (face areas) in rostro-caudally oriented comma -shaped arrays of cells. The fore- and hindpaw arrays, but not the face arrays, widened rostrally into the VL, and formed the dorso-lateral edge of both VL and VPL nuclei. Injections in the DZ (SI limb areas) produced labelling in the dorso-medial part of rostral VL. Caudally, this labelling divided into a lateral branch in the dorsal (limb) area of the VPL and a medial branch in the lateral Po, just medial to the dorsal aspect of VPM.

Injections in MI cortex resulted in heavy labelling predominantly in the ventral region of the rostral VL. Caudally, this crescent-shaped continuous array of labelled cells divided into a ventral branch extending into VM, and a dorsal branch extending into the same general region in the lateral Po as was seen after DZ cortical injections. Specifically, neurons projecting to the SI forelimb cortex appeared to overlap with those projecting to the MI forelimb cortex. Injections into FMAG cortex produced similar crescent shaped patterns as MI injections, but more ventro-medial in VL and VM, and more medial in Po. Labelling from SII cortex was corticotopic but diffuse throughout VP and Po.

To summarize, these reconstructions indicated that thalamocortical projection neurons exist in rostro-caudally oriented arrays that may pass continuously through different cytoarchitecturally defined thalamic nuclei. Supported by grants NIAAA 3901, NS18041, and the Biol. Humanics Found.

270.8 THALAMIC CONNECTIVITY OF THE SOMATOSENSORY CORTICAL FIELDS OF THE LATERAL SULCUS OF THE MONKEY. D.P. Friedman, E.A. Murray and J.B. O'Neill*. Laboratory of Neuropsychology, NIMH, Bethesda, Md. 20205.

The thalamic connections of the cortical fields of the somatosensory system of macaques were investigated by making injections of tritiated amino acids or horseradish peroxidase into those fields. Injection sites in individual fields were initially selected by recording multi- and single-unit responses to mechanical stimulation of the body surface, or in a few cases, by direct visualization. The location of each injection was later verified on the basis of cytoarchitectural and connectional criteria. Additional monkeys with thalamic injections or cortical lesions supplied supplementary data.

There were three major findings: (1) The second somatosensory area (SII) receives its major thalamic input from the ventro-posterior inferior thalamic nucleus (VPI), with additional inputs arising from the parvocellular portion of the medial dorsal nucleus and from the central lateral nucleus. Previously reported inputs to SII from the caudal division of the ventroposterior lateral nucleus (VPLc) could not be confirmed. If they exist, they may arise only from the most ventral and caudal portions of VPLc that are adjacent to VPI, and from the ventroposterior medial nucleus (VPM). The finding in the monkey that SI and SII receive different thalamic inputs is consistent with the hypothesis that they process information in a sequential, rather than parallel manner, a notion that was based on previous reports that both fields received their inputs from VPLc. (2) Area 7b and the granular (Ig) and dysgranular (Id) insular fields, all now implicated in somesthesis, receive projections from the medial pulvinar (Pulm). Thus, the cortical territory that receives inputs from Pulm is much larger than previously believed and includes the somatosensory system. (3) Id receives major thalamic input from a continuous band of neurons that runs caudolaterally from the basal ventromedial nucleus (VMb) through VPI and the posterior nucleus (Po) to the anterior portion of the medial geniculate body. Additional inputs to Id arise from nucleus reuniens and the intralaminar nuclei.

We have confirmed the projections to area 7b from the oral nucleus of the pulvinar, to Ig from the suprageniculate and limitans nuclei, and to the retroinsular area from Po. Reciprocal thalamocortical and corticothalamic labeling was seen in each case where combined labeling was available.

Taken together, these results suggest that there is a complex array of thalamic inputs to individual cortical somatosensory fields outside of SI and that individual thalamic nuclei may project to a number of cortical fields within the somatosensory system.

270.9 CYTOARCHITECTONIC ORGANIZATION OF THE BRAINSTEM TRIGEMINAL NUCLEI IN THE MOUSE: CORRELATION WITH VIBRISSAL INPUTS AND POSTNATAL DEVELOPMENT. P.K.M. Ma* & T.A. Woolsey. Dept. of Anatomy & Neurobiology and McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, MO 63110.

Representations of the facial vibrissae in the brainstem trigeminal nuclei of the mouse have been identified using histochemical staining methods. We have found that they can also be seen using routine Nissl staining methods. In Nissl stained celloidin sections of brainstems of both adult and neonatal mice, cytoarchitectonic organization was identified within subnuclei principalis, interpolaris, and caudalis in all three cardinal planes. The overall cytoarchitectonic patterns are identical to those seen using histochemical staining for succinate dehydrogenase. No distinct cytoarchitectonic pattern can be seen in subnucleus oralis. These patterns can first be observed by at least the third postnatal day in all three subnuclei. By the fifth or sixth postnatal day, a relatively mature pattern is present. Postnatal damage to vibrissal follicles by electrocautery altered these cytoarchitectonic patterns appropriately in all three subnuclei. Electrocautery of all the vibrissae at birth completely prevents the formation of the cytoarchitectonic pattern in all subnuclei. These results demonstrate that cytoarchitectonic representations of the facial vibrissae exist in all stations of the sensory pathway from the brainstem to the cortex. Identification of the cytoarchitectonic organizations in the brainstem trigeminal nuclei opens up new possibilities for studying development, function and plasticity of the trigeminal system using techniques with which histochemical staining methods are not compatible. (Supported by NIH Grant NS-17763 and the McKnight Foundation.)

270.10 INCREASED ^{14}C 2-DEOXYGLUCOSE UPTAKE IN CEREBELLUM, BRAINSTEM, AND THALAMUS DURING SENSORY STIMULATION OF RAT VIBRISSAE. F.R. Sharp, M. Gonzalez* and K.L. McKeown. Dept. of Neurosciences, UCSD School of Medicine, La Jolla, CA 92093

We have recently described the regions of rat brain which increase ^{14}C 2-deoxyglucose (2DG) uptake during stimulation of the "vibrissae" region of rat motor cortex (Sharp et al., JCN 208:255, 1982). In that study it was not possible to state if sensory feedback played a significant role in the 2DG changes observed. The present work was aimed at describing the changes of 2DG uptake in rat brain during mechanical sensory stimulation of the vibrissae.

Adult female Sprague-Dawley rats were briefly anesthetized and restrained to an animal board with tape. Animals were allowed to recover from anesthesia at least 12 hours. ^{14}C 2-deoxyglucose (20uCi/100 gm) was injected intravenously and stimulation of the right vibrissae begun. Stimulation was carried out with a mechanical, hand-held stimulator at 2-4 times per second in an anteroposterior direction to all of the vibrissae for 45 minutes. Animals were sacrificed and their brains frozen, sectioned, and autoradiographed as described previously.

The largest increases of ^{14}C 2DG uptake occurred ipsilateral to the stimulation in the ventral portions of the nucleus of the spinal tract of the trigeminal nerve including pars oralis (NTS_{VO}), pars interpositus, and pars caudalis. The ventral portion of the principal sensory trigeminal nucleus was also activated. Several regions of the cerebellar granule cell layer were activated ipsilateral to stimulation including large parts of crus II, and smaller parts of crus I, paramedian lobule, lobulus simplex, and anterior lobe hemisphere. 2DG uptake increased in deep layers of the superior colliculus contralateral to the side of stimulation. Other contralaterally activated structures include the posterior (PO) nucleus of thalamus, medial ventrobasal nucleus of thalamus (VB), and perhaps lateral parts of the medial posterior (POm) nucleus of thalamus. A broad increase in 2DG uptake also occurred in primary somatosensory cortex (SI) particularly layers IV and Vb.

Our data show that sensory stimulation of the vibrissae activates different structures than does stimulation of the vibrissae region of motor cortex. The only regions which appear to be activated by both include NTS_{VO}, ?POm, SI, and portions of the cerebellar hemisphere.

270.11 THE REPRODUCIBILITY OF 2DG PATTERNS IN MONKEY SI AND THEIR RELATIONSHIP TO SINGLE UNIT MAPPING DATA. S.L. Juliano, O. Favorov*, B.L. Whitsel, Dept. of Physiol., Univ. of N. Carolina, Chapel Hill, NC 27514.

This series of experiments sought to determine to what extent the complex, strip-like pattern of metabolic activity evoked by a controlled stimulus was reproducible from animal to animal. We also sought to define the relationship between the distribution of metabolic labeling and that of SI neurons possessing distinguishable functional properties. Extracellular microelectrode mapping penetrations were carried out in SI on the same animals which were used in metabolic mapping experiments. Four monkeys (macaca fascicularis) received an intermittent vertical displacement stimulus (15 hz) on the volar tip of digit 2. Two animals underwent the metabolic mapping procedure alone; 2 others were studied neurophysiologically and then underwent the 2DG procedure. Two additional animals underwent both microelectrode and 2DG mapping, but the 2DG experiment differed in that constant velocity (20 cm/sec) brush strokes were delivered to the volar radial hand. Reconstructions of the SI labeling patterns for the 4 animals stimulated with the flutter stimulus reveal remarkable similarities. Moreover, individual autoradiographs from comparable levels of SI for the different animals subjected to the same stimulus are nearly identical. The relationship of metabolic activity to single neuron properties is not simple. Metabolic label only occurred at cortical locations where the neurons possessed functional properties consistent with their activation by the stimulus used during the 2DG experiment. However, the single neuron observations obtained at loci between patches of 2DG label indicated that the properties of neurons in these sites were, in a number of instances, quite similar to those in the neighboring regions containing metabolic label. These findings suggest that the highly reproducible pattern of metabolic activity produced in SI by somatic stimulation is determined by multiple factors. Since labeling only occurs in regions where the single neurons possess RFs and submodality properties matching the stimulus, these properties must be a major determinant of the pattern. RF properties are clearly not the sole factor, however, since many neurons in the regions separating the strips possess properties consistent with activation by the 2DG mapping stimulus. We are currently investigating the possibility that an intracortical inhibitory mechanism together with the static properties of single SI neurons determine the spatial pattern of activity which uniquely represents a given somatic stimulus. (Supported by NS 10865 & ONR N0014-83K-0387)

270.12 DISCHARGE PATTERNS OF SOMATOSENSORY AND PERIARCUATE NEURONS IN AN ALTERNATING ATTENTION PARADIGM. G.Gücer, L. Viernstein,*R. Szymanski.* Dept. of Neurological Surgery, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Neurons of the somatosensory cortex S1 decrease their responsiveness to vibratory stimuli during sleep, particularly during REM sleep. To determine if such an inhibitory mechanism as involved in sleep can also reduce the responsiveness of post central neurons while the monkeys are attending to sensory input other than the vibratory system; we have recorded from 122 pre- and postcentral neurons while monkeys were engaged in an alternating attention paradigm. Monkeys were trained to discriminate between different frequencies of an auditory and also a vibratory stimulus. They were rewarded for pressing a lever for the contingent frequency and not the other. The discriminative nature of the task assured that they had to attend to each stimulus before making a decision. These auditory and vibratory games were alternated as cued by different colored lights.

The discharge pattern of 59 neurons located in Brodman's area 1, 2 and 3 did not reveal any significant change in the entrainment nor the strength of entrainment as monkeys shifted their attention back and forth between the vibratory and auditory stimuli. In two of our trained monkeys we extirpated the S1 cortical region and S1 plus areas 5 and 7 by subpial suction after single cell recording failed to show any significant changes in entrainment or responsiveness as animals shifted their attention between modalities. The day after surgery the monkeys played an alternating game and were capable of discriminating between 10 HZ and 100 HZ vibration as well as they did preoperatively. Our preliminary finding in 63 neurons in areas 4 and 6 showed two basic types of neural discharge. First, neurons that discharge rhythmically related to the rhythmic movement of the hand pressing the key. This neural response was independent of which modality was receiving the attention.

Secondly, we found neurons which started to discharge 200 to 300 MSECS after the onset of either the contingent auditory or contingent vibratory stimulus but not for both. Neurons of this type did not discharge rhythmically with the key hits but rather in a uniform manner but uniquely for the contingent auditory or vibratory stimulus. One other effect was seen as the attention was shifted, namely, the mean impulse rate of latter type neuron responding to vibration was compared with the neuron impulse rate while responding to tone for repeatable trials. For those neurons that enable for vibration a significantly lower impulse rate was found in the vibratory game than in the tone game. Neurons that enabled for tone had a significantly lower impulse rate in the tone game than in the vibratory game.

270.13 TACTILE DIRECTION DISCRIMINATION IN PRIMATES, G.K. Essick* and B.L. Whitsel. Dept. of Physiology, School of Medicine, Univ. of North Carolina at Chapel Hill, 27514.

The capacity of single S-I neurons of macaque monkeys and the capacity of human subjects to distinguish opposing directions of movement across the skin was studied employing experimental paradigms and data analyses based on sensory decision theory. A major advantage of this approach is that one obtains comparable behavioral and neurophysiological indices of directional sensitivity (i.e., they have the same metric).

A relative operating characteristic (ROC) curve, providing estimates of directional sensitivity, was generated for each of 18 neurons by using the responses of each neuron to multiple replications of the two opposing directions of movement. The rate-related neural response dimension which yielded the most directional information was determined. It was shown that even when the neural data sample is too small for ROC curve construction, reliable estimates of sensitivity can be computed since the distributions of neural responses are available to the experimenter.

ROC curves were generated for each of 5 human subjects who participated in a cutaneous direction discrimination task. It was shown that the SDT "Gaussian equal-variance" hypothesis was applicable to the data. Furthermore, experimental designs which account for among-subject as well as among-session differences in perceptual sensitivity possess power sufficient to allow quantitation of the influences of variations in a single stimulus parameter on tactile directional sensitivity.

Data from 90 S-I neurons and 9 human subjects were consistent with the following conclusions. Cutaneous directional sensitivity of human subjects and of one class of S-I neurons, the "direction invariant" neurons, (i) is maximal when the stimuli move between 5.0 and 30.0 cm/sec, and (ii) increases as the length of skin traversed is increased. Furthermore, human cutaneous directional sensitivity is greater on body regions receiving a dense cutaneous innervation and is independent of the orientation of the moving tactile stimulus. Members of a second class of directionally selective S-I neurons, the "direction variant" neurons, signal movement toward or away from a given region within the receptive field, and thus do not unambiguously encode stimulus direction on the skin.

Of the two classes of directionally sensitive S-I neurons studied, only the direction invariant neuron class appears to possess properties consistent with human tactile directional sensitivity and its dependency on stimulus parameters.

AGING I

271.1 INTRACELLULAR STUDIES OF THE AGE-RELATED DEFICIT IN HIPPOCAMPAL FREQUENCY POTENTIATION: APPARENT CALCIUM SATURATION IN SYNAPSES OF AGED RATS. P.W. Landfield, T.A. Pitler*, M.D. Applegate* and J.H. Robinson*. Dept. of Physiol. & Pharmacol., Bowman Gray Sch. Med., Winston-Salem, NC 27103.

In another paper at this meeting (Pitler & Landfield) we report that hippocampal frequency potentiation appears to depend upon residual Ca^{2+} accumulation in presynaptic terminals. In this report we describe quantitative analyses of the timecourse of synaptic and membrane events associated with frequency potentiation in hippocampal slices from aged and young rats.

The data were obtained in intracellular recordings from approximately 60 neurons in the CA1 pyramidal cell layer (stratum pyramidale) from 15 aged rats (27-30 mo-old) and 20 young-mature rats (5-8 mo-old). Barrier-reared, male Fischer rats from the NIA colony at Charles River were used. Aging animals exhibiting overt pathology were not included in these studies. Cells were excluded from analysis if they failed to meet our criteria for healthy cells, or for stable penetrations (e.g., less than 15 Mohm input resistance, less than 50 mV stable resting potential, less than 60 mV spike, cells held for less than 15 min).

In each cell, EPSP amplitude, input resistance and membrane potential were measured before, during and following a 4 min period of 10 Hz stimulation of the Schaffer collaterals. Measures were obtained at 5, 15, 30, 45 and 60 sec, and at 2, 3 and 4 min of 10 Hz stimulation.

A highly significant reduction was found in the amount of EPSP potentiation in cells from aged rats, both in terms of maximal potentiation and in the duration of potentiation. As noted in a separate report in this meeting, potentiation of EPSP amplitude during stimulation is closely correlated over time with increased membrane conductance changes. This conductance change is apparently due to a Ca^{2+}-activated K^+ conductance, and therefore argues that EPSP potentiation is also dependent on intracellular Ca^{2+} concentration.

In cells from aged rats, this correlation was maintained, and both EPSP potentiation and membrane K^+ conductance changes were "blunted" during stimulation. These findings suggest that Ca^{2+}-activated processes in hippocampal neurons are less responsive in aged animals. We previously found that elevating Mg^{2+} in the bathing medium, which is believed to reduce Ca^{2+}-binding at active intracellular sites, strongly increased frequency potentiation in slices from aged rats (Landfield, Soc. Neurosci. Abstr., 1981). Taken together, these data are consistent with the hypothesis that hippocampal synaptic frequency potentiation is blunted in aging because of Ca^{2+}-saturation of available Ca^{2+} sites in synaptic terminals. Such saturation could result from an elevation of intracellular $[Ca^{2+}]$. (Supported by AG 01737)

271.2 DIFFERENCES BETWEEN AGED AND YOUNG MICE IN REACTION TO CAFFEINE AND IN ADENOSINE RECEPTORS. L.D. Middaugh, N.S. Buckholtz and D.K. Ingram.* Medical University of South Carolina, Dept. of Psychiatry and Behavioral Science, Charleston, SC 29425 and Geront. Res. Center, Baltimore, MD 21224.

Several reports indicate that the elderly have atypical responses to numerous drugs. Although the stimulatory effect of caffeine on the elderly presumably differs from that on younger individuals, a systematic comparison is unavailable. Recent evidence suggests that caffeine-induced changes in locomotor activity of rodents is mediated by its antagonist action on adenosine receptors. In the present study, we examined the effect of caffeine on locomotor activity of young (10 to 12 mos.) and aged (28 to 36 mos.) C57BL/6J mice and also compared the two age groups on the binding of N^6-cyclohexy [^{3}H] adenosine ([^{3}H]CHA) in four brain regions.

Locomotor activity was assessed for three hours following intraperitoneal injections of caffeine (5, 15, 20, or 45 mg/Kg) into mice previously habituated to the activity monitoring apparatus for one hour. Activity of both age groups was elevated by the 15 mg and 30 mg/Kg doses; however, the extent of elevation above pre-drug levels was greater for aged than for young mice. This was particularly evident at later time periods when ratios of post- to pre-injection activity counts ranged from 1.5-2.0 for aged mice compared with 0.8-1.0 for young mice. In spite of the greater degree of activity elevation for the aged group, the time course for elevated activity was similar for both groups.

Adenosine receptor binding was determined in cortical, hippocampal, striatal, and cerebellar tissue from mice in the above age groups using [^{3}H] CHA as the ligand. For both age groups, the greatest amount of binding occurred in hippocampus and cerebellum. Binding did not differ according to age in the cortex, hippocampus, or striatum; however, it was 15% higher in cerebelli of aged than young mice

Although young and aged mice appear to differ in their reaction to caffeine and in [^{3}H] CHA binding, whether or not the two age differences are functionally related remains to be determined. (Supported in part by P.H.S. Grant MH37747 to N.S.B.)

271.3 VOLUME OF THE DENTATE GYRUS MOSSY FIBER PROJECTION SYSTEM IN REGIO INFERIOR OF AGING F344 RAT. V.B. Moyer*, P.D. Coleman, M.J. West, and S.J. Buell* (SPON: T. Pasternak). Depts. of Anatomy and Neurology, University of Rochester Medical Center, Rochester, New York 14642 and Institute of Anatomy B, Aarhus Univ., Aarhus, Denmark.

The volume of the mossy fiber projection from dentate gyrus to regio inferior of the hippocampus was measured in seventeen male F344 rats at ages from 4 to 33 months. The mossy fiber system was visualized with the Timm stain. Volumes were determined stereologically from coded horizontal sections by the point count method. The hilus region was excluded. The average total volume determined for all animals was 2.36 mm^3 throughout the entire dorso-ventral extent of the mossy fiber system. The average values for each age in mm^3 were 2.22, 2.53, 2.20, 2.18 and 2.52 for ages 4, 12, 20, 27 and 33 months, respectively. Measures of the infra-, intra- and supra-pyramidal subdivisions of the mossy fiber system gave mean volumes of 0.34, 0.21 and 1.81 mm^3, respectively. Volumes of these subdivisions in individual animals varied in parallel with the volumes of the total mossy fiber system.

Supported by the National Institute on Aging (AG1121 and AG2680) and by The Institute of Anatomy, Aarhus University

271.4 VOLUMES OF THE SUBDIVISIONS OF THE DENTATE GYRUS AND HIPPOCAMPAL REGION IN AGING F344 RAT. M.J. West and P.D. Coleman. Institute of Anatomy B, Aarhus Univ., Aarhus, Denmark and Department of Anatomy, University of Rochester Medical Center, Rochester, NY 14642.

Much of the recent data on cells, synapses and other structures in the dentate gyrus and hippocampus as a function of age are density or volume fraction data. In order to estimate total numbers, volumes or surface areas of cells, synapses, vessels, etc. as a function of age the total volumes of the subregions of the dentate gyrus and hippocampus must be known. These volumes have been determined in four 12 and four 33 month old male F344 rats (data for intermediate ages will be available at the presentation of this paper). The subdivisions were visualized with the Timm stain. Boundaries of the following regions were manually traced from 35-40 coded horizontal sections for each animal through the dorso-ventral extent of the dentate gyrus and hippocampus: 1) hilus, 2) layer of granule cells, 3) commissural-associational zone of dentate gyrus molecular layer, 4) perforant path zone of molecular layer and 5) hippocampus plus subiculum (all layers). The resulting drawings were automatically traced by an image dissector and PDP-11 computer system. The computer derived three dimensional reconstructions and volumetric quantifications on the basis of these data. Volumes in mm^3 were: hilus, 12 mo. (Y)-2.65, 33 mo. (O)-2.73; layer of granule cells, Y-2.41, O-2.61; commissural-associational, Y-2.42, O-2.47; perforant path, Y-7.30, O-7.39; hippocampus & subiculum, Y-40.64, O-43.27. Volumes were always greater in the 33 month animals than in the 12 month animals with old/young x100 ranging from 101% (perforant path zone) to 108% (layer of granule cells). Analysis of variance showed a significant region main effect, a non-significant age main effect and a significant age x region interaction. These data suggest that some of the regions analyzed beome significantly larger with age while others do not. In those regions which become significantly larger with age the interpretation of density or volume fraction data may require modification. Data from intermediate ages will clarify whether changes in volume as a function of age are linear.

271.5 REGENERATION OF CENTRAL CATECHOLAMINE FIBERS IN AGED RAT BRAIN. Carol Phelps and John R. Sladek, Jr. Dept. of Anatomy, University of Rochester School of Medicine and Dentistry, Rochester, N.Y. 14642.

Aging is often accompanied by degenerative changes in the CNS which can include a loss of neurons, synapses and/or transmitter content. However some evidence suggests that central catecholaminergic (CA) neurons may retain a degree of plasticity in response to alterations in their target neurons. This response is manifested by an apparent hyperinnervation of peptidergic targets in the hypothalamus (Sladek et al., Peptides 1:141, 1980). In addition, an earlier study demonstrated regenerative capacity in a CA pathway in young rats (Turpen and Sladek, Cell. Tiss. Res. 187:449, 1978). Taken together, these observations suggested that regenerative and/or sprouting activity may occur in aged brain. To test this hypothesis, CA histofluorescence patterns in the area of a neurosurgical lesion were evaluated.

Transection of the ascending medial forebrain bundle (mfb) was accomplished using rotation of a handhewn knife, positioned vertically in the brain according to three-dimensional stereotaxic coordinates (Paxinos and Watson, 1982), achieving partial loss of the CA innervation of the supraoptic (SON) and paraventricular (PVN) nuclei. The area damaged by surgical intervention was examined in 3, 20, and 30 month-old male Fischer 344 rats, at matched intervals after lesion placement. Brains were prepared for fluorescence histochemistry by formaldehyde/glutaraldehyde (FAGLU) and aluminum/formaldehyde (ALFA) perfusion fixation.

Two simultaneous processes were evident in the lesion site: CA fibre degeneration and vigorous regrowth of axons. By 4 days following surgery, fine varicose fiber growth was observed, passing into and through the scarred region. Further regenerative activity was progressive, in rats of all ages, between 4 and 14 days after lesion placement. Although the lesion site showed greater necrosis and inflammatory reactivity in aged animals, regrowth was demonstrable, by these sensitive histofluorescence methods, in the mfb-lesioned areas of aged brains. In fortuitous sections, new fibers could be clearly identified as growth from damaged axons.

Progressive growth, and fiber invasion of a surgically scarred area, imply robust plasticity in CA pathways, which persists in aged brain. Possible reinnervation of target sites, at longer postsurgical intervals, is currently being evlauated.

Supported by USPHS Grant AG 00847 (JRS).

271.6 EFFECT OF DEVELOPMENT AND AGING OF THE RAT ON UNIDIRECTIONAL PALMITATE FLUX INTO BRAIN. H. Tabata, A.S. Kimes, J.M. Bell, and S.I. Rapoport. Lab of Neurosciences, Gerontology Res. Ctr., Natl Inst on Ag., NIH, Baltimore City Hospitals, Balto., MD 21224.

Palmitate flux into a stable 4 hr-brain compartment is proportional to the regional cerebral metabolic rate for glucose (rCMRglc) (Kimes et al., Brain Res. in press) and can be reduced by barbiturate anesthesia (Kimes and Rapoport, Neurosci. Abst. 8: 1003, 1982). Because palmitate flux is proportional to rCMRglu, it was of interest to measure flux in awake Fischer-344 rats at the ages of 1,3,12, 24 and 34 mo. In addition, because rCMRglc and regional cerebral blood flow (rCBF) show different patterns for aging animals, it was of interest to determine if palmitate flux varied with development and aging like either rCBF or rCMRglc.

Femoral arterial and venous catheters were implanted under ether anesthesia. Rats were allowed 4 hr to recover from anesthesia, following which 450 µCi/kg [14C]palmitate was injected i.v., and timed arterial blood samples were collected. At 4 hr after injection, rats were killed and brains were frozen. Brain radioactivity was determined in 43 regions by quantitative autoradiography. Plasma radioactivity due to [14C]palmitate was determined by extraction and thin layer chromatography. Unesterified plasma palmitate was determined by gas chromatography. Unidirectional flux of plasma palmitate into the brain (J, µmol/g.sec) was calculated from the equation: J=kCplasma, where k=transfer constant for plasma palmitate to brain, and Cplasma= plasma concentration of palmitate. k was determined by the equation $k=C^*brain/\int_0^t C^*plasma\,dt$, where C*brain = the brain radioactivity at 4 hr after injection and $\int_0^t C^*plasma\,dt$ = integral plasma [14C]palmitate between 0 and 4 h.

J declined 15 to 30% between 1 and 3 months in all regions, rose 15 to 35% between 3 and 12 months and then declined 20 to 30% by 24 months. Changes in regional J between 3 and 12, 12 and 24, and 24 and 34 months were similar to changes in rCBF as reported by Ohata et al. (Brain 104:319-332, 1981) although rCBF increased between 1 and 3 mo. Unlike both rCBF and rCMRglc, regional palmitate flux at 1 mo was higher than that at 3 mo. Considering the fact that the maximum rate of myelin deposition for rats occurs at 20 days of age (W.T. Norton and S.E. Poduslo, J. Neurochem. 21: 759-773,1973), a higher flux at 1 mo than at 3 mo is related possibly to myelinization. This is supported by a significantly larger flux into white matter compared to gray in 1 mo versus the older animals ($p < .05$). The ratios of palmitate flux into white matter as compared to gray matter was 0.61 at 1 mo, 0.49 at 3 mo, 0.51 at 12 mo, 0.46 at 24 mo, and 0.50 at 34 mo.

271.7 NEUROMUSCULAR JUNCTION REMODELING IN THE RAT SOLEUS DURING AGING: A MORPHOMETRIC STUDY. C. A. Cardasis* and D. M. LaFontaine* (SPON: E. Taber-Pierce) Dept. of Anatomy, Univ. of Mass. Medical School, Worcester, MA 01605.

Ultrastructural remodeling of neuromuscular junctions (NMJ), with evidence of focal denervation and reinnervation occurs in normal rat soleus during aging (Cardasis & Padykula, '81; Cardasis, Anat. Rec., in press). From 3 to 9 months (Group I) this may relate to body growth and increased workload. When growth slows (11-19 months, Group II) the balance between de- and reinnervation changes: NMJs with exposed junctional folds (focal denervation) increase from 61% to 100%. We sought to quantitate junctional fold exposure in individual NMJs, to characterize spacing of normally innervated versus exposed folds using TEM, and to compare soleus with diaphragm, which undergoes less intense age-related reorganization, by study of ChE stained whole mounts. Morphometric analysis of longitudinally oriented EM composites of 20 Group I and 21 Group II NMJs showed, in Group II, significant increase in fold exposure in individual NMJs (Group I = 20%, Group II = 69%, $P<.0001$.), and a trend toward clustering of normal folds and separation of exposed folds (Distance (μm) between normal folds: I = 0.562±0.12, II = 0.451±0.10. P=.038. Exposed folds: I = 0.554±0.12, II = 0.685±0.16. P=.024). This data suggests increased area of postsynaptic membrane in the normal folds of Group II. The area of soleus and diaphragm endplates was determined in ChE preparations in 3 rats each at 1, 3, 7, 11, and 15 months, measuring 20 NMJs/muscle/rat/age:

Soleus:	246±62	677±214	728±102	1399±495	930±142 μm
Diaphragm:	198±22	408±34	763±28	799±58	842±131 μm

With age, there was increase of endplate area, myofiber size, and complexity of branching of primary folds. In the soleus by 11 months degeneration was evident, as suggested by diffuse rather than discrete localization of ChE reaction product, or sometimes both within an individual NMJ, and wide separation (approximately 3 μm) of multiple NMJ regions on individual muscle fibers. Diaphragm NMJs did not become as complex nor degenerate as rapidly as soleus. The net effect of remodeling of soleus NMJs appeared to be increase of normal synaptic area during the first year and decrease of normal synaptic area during the second year.
Supported by NSF Grant #BNS-8207829.

271.8 SPONTANEOUS NEURONAL ACTIVITY IN THE NEOCORTEX AND STRIATUM OF YOUNG AND OLD RATS. W.C. Stern, W. Pugh*, and P.J. Morgane. Burroughs Wellcome, Research Triangle Park, NC 27709 and Worcester Fndn. Exptl. Biol., Shrewsbury, MA 01545.

The present study compared the spontaneous activity of single units in the frontal cortex and the striatum of 20 young (5-11 mo.) and 10 old (25-31 mo.) Fisher 344 albino male rats. These structures were selected because of their importance in cognitive and motor events, measures which often change during aging, and because they represent regions of low (cortex) and high (caudate) spontaneous discharge rates.

Rats were anesthetized with 1000 mg/kg urethane i.p., and single neurons were recorded extracellularly using glass micropipettes. The major findings obtained from computer analyses of spike activity are summarized in the table below:

	Frontal Cortex		Striatum	
	Young	Old	Young	Old
# Cells	105	121	42	28
Spikes/Sec	4.1±.4	3.3±.3	18.2±1.8	12.3±1.9*
ISI (msec)	634±87	1088±190*	218±74	728±393
Variability Ratio	1.26±.04	1.28±.05	.66±.06	1.16±.13***
% Bursts	9±1	7±1	10±2	17±3
% Pauses	13±1	11±1	6±1	8±1

*p < .05, **p < .01, ***p < .001 (2-tailed t-tests): Above values are mean ± S.E.; ISI = inter-spike intervals, variability ratio = mean/SD of the ISI

These results show a 20-35% decrease in average discharge rate and a consequent lengthening of the mean ISI in the cortex and the striatum of old rats. Also, the variability of discharge rates was markedly increased in the striatum of the old rats. In young rats, most striatal cells exhibit a sustained high rate of discharge, often 15-25/sec. However, these rates were not sustained in many of the striatal cells from the older rats.

The present results from cortex and striatum are consistent with two prior studies which showed a decrease in the average discharge rate for locus coeruleus neurons (Olpe, Brain Res. 1982) and for Purkinje cells of the cerebellum (Rogers et al., Neurobiol. Aging, 1980). This suggests that in the aged rat, decreased rate of neuronal discharges are likely to be characteristic of many brain regions. Moreover, these changes may be associated with a decreased metabolic rate observed in the aged nervous system. (Supported by NIA contract N01-AG-0-219 and funds from Burroughs Wellcome Co.).

271.9 CONDUCTION VELOCITY OF CORTICALLY-PROJECTING NUCLEUS BASALIS NEURONS DECREASES WITH AGE. J. Rogers,[2] G. Aston-Jones,[1] T. Dinan,[1]* R. Shaver,[1]* and D.E. Moss.[3] [1]Center for Neurobehavioral Sciences, SUNY, Binghamton, NY 13901, [2]Dept. of Neurology, U. Mass. Medical School, Worcester, MA 01605, [3]Dept. Psychology, U. Texas, El Paso, TX 79968.

Cholinergic neurons of the basal forebrain (nucleus basalis of Meynert in primates, nucleus basalis magnocellularis in rodents)(nBM) have come under recent experimental scrutiny because of their possible involvement in the etiology of Alzheimer's Disease. A parallel study (Aston-Jones et al., this volume) has examined normative conduction characteristics of cortically-projecting nBM fibers. In the present research, we extend those data to changes with age. Single nBM units were antidromically driven from a frontal cortex stimulating electrode in chloral hydrate anesthetized rats, 3 mos, 18 mos, or 28 mos old. The collision technique was used to verify antidromicity of driven spikes and to insure that segments of the same axon were being tested at different cortical depth placements of the stimulating electrode. By sampling conduction latencies from superficial to deep cortex in 300 u increments, it was possible to derive estimates not only for overall conduction velocity of cortically-projecting nBM fibers, but also for conduction velocity within gray matter (i.e., superficial to deep cortex) and white matter (i.e., deep cortex to nBM). All antidromically driven cells were histologically localized to the globus pallidus area, corresponding to anatomic maps of acetylcholinesterase-positive cells. Sixty-five such neurons are included in the present report.

Overall, conduction latencies for young rats were significantly shorter ($P < .001$) than for middle-aged and old rats. Further analysis at the various stimulating electrode depths, however, revealed that the conduction velocity in gray matter was virtually identical for all age groups. The difference in overall latencies was therefore due almost entirely to a two- to four-fold decrease with age in subcortical conduction velocity.

Since the estimated white matter conduction velocity for young rats (2.3 m/sec) is consistent with fine, myelinated fibers, one possible explanation for our data is that aging occasions a partial demyelination of cortically-projecting nBM axons. Further research, particularly on the ultrastructure of nBM axons, will be necessary to determine the cellular bases for age-related decline of nBM cortical afferents.

271.10 CHOLINE EFFECTS ON NEUROMYAL TRANSMISSION IN MATURE AND AGED CBF-1 MICE.
Hiroshi Hasuo, Alexander G. Karczmar and Tashihiko Nishimura, Dept. of Pharmacology, Loyola Univ. Med. Center, Maywood, Il.

This study concerns the effects of choline, one of acetylcholine precursors, on neuromyal transmission in mature (1 year old) and aged (2 year old) inbred CBF-1 mice (Hill, Charles River Digest, 20:1, 1981). Isolated phrenic nerve-diaghragm preparations were employed and microelectrodes were used to measure miniature endplate potential frequency (mEPPf) and quantal content (QC). We have previously shown that presynaptic function and effectiveness of neuromyal transmission are decreased in aged animals (Hasuo & Karczmar, Soc. Neurosci. Abstracts, 8:440, 1982; Fed. Proc. 42:750 1983). At this time we tested whether or not choline can improve the presynaptic function in vitro and whether the effect, if any, is age-related. Higher (0.5mM) concentrations of choline evoked immediate postsynaptic effects; in confirmation of earlier data (cf., eg., Adams, 1975), these effects included depolarization and/or curarimimetic action. At concentrations of 0.05 to 1mM, choline did not exert appreciable effects on QC or mEPPf whether in mature mice or old mice which exhibit depressed mEPPf and QC values (Hasuo and Karczmar, o.c.). However, at concentrations of 50 and 300μM, choline prevented or reversed decrease in QC and in mEPPf induced by prolonged (2 hrs.), repetitive (10Hz) presynaptic stimulation. In non-treated animals the decrease in QC induced by repetitive stimulation amounted to 34 and 21 percent of control values in mature and aged mice, respectively; similarly induced, decrease of mEPPf amounted to 30 and 25 percent of controls in mature and old mice, respectively. Depression of QC induced by repetitive stimulation was diminished in 50μM and reversed in 300 μM choline solution in mature animals; it was reversed in 300μM choline solution in both mature and old mice. Similarly, choline 300μM, prevented mEPPf decrease induced by repetitive stimulation. Repetitive stimulation did not have a significant effect on mEPPf amplitude in either age group, nor did choline superfusion affect this parameter. These preliminary data suggest that 1) decrease of QC and mEPPf values after stimulation was smaller in aged than in mature mice, and 2) antagonism of these effects by choline was not significantly different in the two age groups. As in resting state exogenous choline seems to be incorporated into phospholipids rather than ACh (Kindel et al., Fed. Proc. 42:1983), present data suggest that increased activity augments choline participation in presynaptic ACh pool.

Supported in part by BRSG Grant No. 104, and Potts Foundation Grant. CBF-1 mice were kindly supplied by NIH Institute on Aging

271.11 PHYSIOLOGICAL CHARACTERISTICS OF PLANTARIS MOTOR UNITS OF YOUNG AND OLD RATS. F. Pettigrew* and P.F. Gardiner, Neuromuscular Research Group, University of Montreal, Montréal, Qué., Canada, H3C 3J7

Several alterations in adult neuromuscular structure and function with aging have been previously reported, including losses in spinal motoneurones, physiological and structural changes at the neuromuscular junction, and biochemical and physiological changes in skeletal muscles. These changes would be expected to manifest themselves functionally at the level of the motor unit. In this study, the isometric contractile characteristics of plantaris (PL) single motor units (MU) were studied in 6 young (3 mos) and 4 old (33 mos) male Fisher rats. MU were functionally isolated by stimulation of single PL axons following dissection of ventral root filaments in the lumbar spinal cord (L4-L5) MU characteristics are presented in the Table below as means ± S.D., with range in parentheses. PL from old rats were slightly (16%) smaller in wet weight, while whole-muscle tetanic tension was 56% smaller ($p < 0.01$). The variability in tetanic tensions among fast MU was higher in old animals, due to the presence of a significant number of high-tension units (> 30 g) in the latter. Old fast MU showed CT and fatigue resistance characteristics comparable to those in young rats. Slow MU were more easily obtainable from old (10 of 22 MU) than young (2 of 29 MU) animals, and generated larger tetanic tensions in the former. As with the fast MU, no differences were apparent in slow MU, CT or fatigue characteristics between the age groups. The data are consistent with a scheme of neuromuscular remodelling occurring during aging which includes motoneurone death, subsequent sprouting of remaining motoneurones, and muscle fiber-type conversion.

Supported by grants from MRC Canada, and NSERC Canada.

		CT (ms)	Tetanic tension (g)	Tetanic tension (% muscle)	Fatigue index

271.12 3,4-DIAMINOPYRIDINE PARTIALLY REVERSES THE AGE-RELATED DECLINE IN SYNAPTOSOMAL CALCIUM UPTAKE. C. Peterson and G.E. Gibson, Cornell Univ. Med. Coll. Burke Rehabilitation Center, White Plains, NY 10605

The molecular basis of the age-related cognitive changes is unknown. Since several lines of evidence suggest that senescence may alter calcium homeostasis, calcium-45 uptake was determined in brain synaptosomes from aged rats. Incubations were terminated by vacuum filtration after the addition of EGTA/ruthenium red. In low potassium (5 mM-KCl) media, aging decreased calcium uptake from 100.0% (6 months) to 76.7% (15 months) or 58.6% (27 months). In 31 mM-KCl media uptake declined when the age increased from 6 (100.0%) to 15 (67.8%) or 27 (55.8%) months. Since our previous studies demonstrated that 3,4-diaminopyridine stimulates synaptosomal calcium uptake, we tested its efficacy on these age-related deficits in calcium metabolism. 3,4-Diaminopyridine elevated the potassium-stimulated calcium uptake in high K^+ media 13.1%, 23.8% or 140.0% in synaptosomes from 6, 15, or 27 months old rats, respectively, when compared to non-drug treated synaptosomes of the same age. The calcium that is bound to the plasma membrane externally was measured with incubations that are terminated by ruthenium red and filtration. This binding increased with age from 100.0% (6 months) to 116.1% (15 months) or 141.4% (27 months). 3,4-Diaminopyridine reduced this superficial binding at 15 or 27 months to 109.3% or 121.4%, when compared to the 6 month old rats. Thus, age-related changes in calcium homeostasis that may alter neuronal metabolism can be ameliorated by treatment with 3,4-diaminopyridine.

Supported in part by grants NS16997, NS03346 and the Winifred Masterson Burke Relief Foundation.

271.13 RAPID INDUCTION OF CEROID FORMATION IN RAT HIPPOCAMPUS BY LEUPEPTIN. G.O. Ivy, F. Schottler, M. Baudry, and G.S. Lynch. Dept. of Psychobiology, Univ. of California, Irvine, Irvine, CA 92717.

The accumulation of pigmented lipid particles in the brain has long been known to coincide with aging, as well as with various metabolic disorders, such as neuronal ceroid lipofuscinosis. While the large lipid conglomerates are thought to arise in lysosomes, the series of events leading to their formation remains unclear. We now report that an inhibitor of thiol proteases, leupeptin, causes the rapid accumulation of lipofuscin-like material in both normal and denervated rat hippocampus.

Continuous infusion of leupeptin (20µg/hr) or saline (.05 µl/hr) into the lateral ventricle of 40-90 day old rats was accomplished with an indwelling cannula connected to an osmotic minipump. The rats were sacrificed from 3 to 14 days later and their brains prepared for electron microscopy using conventional procedures. Light microscopic examination of semi-thin sections stained with toluidine blue revealed the presence of numerous dense bodies in a perinuclear position in the several types of hippocampal neurons. Astroglial cells also contained accumulations of this material. Preliminary studies suggest that this effect does not occur in cerebellum. Electron microscopic analysis indicated that the perikarya and dendrites of hippocampal neurons from drug treated animals contained electron dense bodies that in size and appearance closely resembled lipofuscin. Denervation of the dentate gyrus by removal of the entorhinal cortex resulted in deposits of lipofuscin-like material throughout the dendritic trees, as well as in the granule cell bodies and in numerous glial cells in rats treated with leupeptin. None of these effects was obtained in rats infused with saline.

It should be noted that the cannula caused some damage to the hippocampal fimbria and thus the observed effects may reflect an interaction between leupeptin and denervation, even in the animals without entorhinal lesions. Experiments with cannulae implanted at various sites in brain combined with analysis of several brain regions are now in progress.

Since leupeptin blocks thiol proteases, known to be present in lysosomes, these results suggest that inhibition of lysosomal activity causes a rapid accumulation of ceroid material in the brain. It is possible that these findings have significant implications for the origins of the ceroid substances that accumulate during aging and disease.

271.14 ELEVATED ^{3}H-IMIPRAMINE BINDING IN AGED HUMAN AND MOUSE BRAIN. J.A. Severson. Department of Psychiatry, University of Southern California, School of Medicine, Los Angeles, CA 90033.

The tritiated form of the antidepressant imipramine binds to a site on serotonergic nerve terminals that modulates serotonin reuptake. This site is assumed to be a locus of the clinical efficacy of imipramine. The brain binding site and a pharmacologically similar site on platelet membranes appear to be regulated similarly and, therefore, the platelet site has been suggested to reflect the state of brain imipramine sites. Although conflicting evidence exists concerning the brain site, the number of platelet imipramine sites is reduced in clinical depression.

The elderly, as a group, are more prone to depression and suicide than the general population. An analysis of imipramine binding sites in brain might determine if alterations in this depression-related biological marker reflect a predisposition in the elderly to depression.

Binding sites for ^{3}H-imipramine were determined by filtration assay using washed membrane preparations. In a sampling of 24 human brain specimens ranging from 17 to 100 yr., hypothalamic ($r=0.76$, $P<0.0001$), frontal cortical ($r=0.63$, $P<0.002$) and parietal cortical ($r=0.60$, $P<0.002$) imipramine Bmax was elevated with increasing age. The Kd of the site for ^{3}H-imipramine was unchanged with age. In all three regions, Bmax doubled between 17 and 100 yr. Analysis of covariance confirmed the age effect on Bmax and determined that other factors associated with human autopsy specimens, such as time from death to autopsy, length of storage as frozen tissue, cause of death and sex, did not significantly affect binding. Hypothalamic samples were also analyzed for the regulation of ^{3}H-imipramine sites by Na^+ and Cl^-. The ability of Na^+ to enhance ^{3}H-imipramine binding was impaired with age ($r=-0.43$, $P<0.04$), but Cl^- enhancement of binding was intact ($r=0.04$, n.s.).

Cerebral cortical ^{3}H-imipramine Bmax was elevated 45% in 26 mo. male C57BL/6J mice, relative to 3 and 10 mo. mice. The Kd for imipramine was similar in the three ages examined. This suggests that the aged mouse can serve as a model for changes in human ^{3}H-imipramine binding during aging. In general, the data suggest that elevations in imipramine sites and impaired regulation of the sites may contribute to alterations in central serotonin function and, in turn, may predispose the elderly to depression.

271.15 POSTSYNAPTIC SEROTONIN BINDING SITES IN POSTMORTEM HUMAN BRAIN THROUGHOUT THE LIFESPAN. J Marcusson*, DG Morgan*†, B Winblad* and CE Finch†. (SPON: SP Bessman). Dept of Pathology, Univ. of Umea, Umea S-90187, Sweden, and †Andrus Gerontology Center, Univ. of Southern California, Los Angeles, CA 90089-0191, USA.

Postmortem human material was analyzed for S-1, S-2, S-2A, and S-2B binding sites in frontal cortex and hippocampus, and 5-HT, and 5-HIAA levels in frontal cortex and hypothalamus.

S-1 binding was assessed with ^{3}H-serotonin using 1 mM nonradioactive serotonin to define nonspecific binding. The density of S-1 sites declined with age in both frontal cortex (n=20; r=-0.49; p<0.05) and hippocampus (n=14; r=-0.62; p<0.02). Linear regression analysis indicated a 30% decline between the ages of 20 and 100 years. The average B_{max} in both regions was 470 fmoles/mg protein and the K_d was 3.70 nM. No age related change in K_d was observed.

S-2 binding was determined with ^{3}H-spiperone. For the total S-2 site, 0.5 µM ketanserin was used to define nonspecific binding. To discriminate S-2A from S-2B binding, displacement curves with methysergide were performed on the same tissue (see Morgan et al, this meeting, for definition of S-2A and S-2B binding). The total S-2 binding declined by 41% (20-100Y) in frontal cortex (n=24; r=-0.73; p<0.01) but not in hippocampus. The average B_{max} for total S-2 binding was 360 fmoles/mg protein in frontal cortex, and 162 fmoles/mg protein in hippocampus. No correlation was found between the two regions. The K_d for ^{3}H-spiperone was approximately 1 nM in both brain regions, and K_d was not affected by age.

In the frontal cortex, S-2A sites decreased in density with age (n=19; r=-0.65; p<0.01), while S-2B sites did not change. The S-2A site was the predominant subtype in this brain region with 60% more sites on the average than the S-2B subtype. Within the frontal cortex, total S-2, S-2A, and S-2B binding correlated with the S-1 density (r = 0.472, 0.514, and 0.504 respectively).

In the hippocampus, the S-2A sites also declined with age (n=21; r=-0.46; p<0.05), and as in cortex, there was no change in S-2B binding. However, the hippocampus contains twice as many S-2B sites as S-2A. This preponderance of the age stable S-2B subtype in the hippocampus may explain why the total S-2 site fails to change with age in this region. No correlation with S-1 binding density was obtained for the hippocampal S-2 site or its subtypes. In addition, hippocampal S-2 binding was not correlated with frontal cortical S-2 sites.

The levels of 5-HT and 5-HIAA did not show any age related trends in either frontal cortex or hypothalamus.

271.16 DISTRIBUTION OF NEURITIC PLAQUES IN THE CORTEX OF AGED RHESUS MONKEYS. R. G. Struble, L. C. Cork*, D. L. Price, Jr.*, D. L. Price and R. T. Davis*. Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; Dept. of Psychology, Washington State Univ., Pullman, WA 99164.

Neuritic plaques (NP) occur in aging and Alzheimer's disease and, in the latter, correlate with the severity of dementia and magnitude of cortical cholinergic deficits. NP are composed of enlarged neurites surrounding a core of amyloid. It has been suggested that NP evolve from a neurite-rich, immature stage to a neurite-poor, amyloid-rich end stage (Wisniewski, H.M. and Terry, R.D., Progress in Neuropathology, Vol. II, pp 1-26, 1973).

Aged nonhuman primates are an important model for testing hypotheses about the evolution and significance of NP. In this study of six rhesus monkeys, aged 23-31 years, who had been behaviorally tested for many years, NP were counted in ten formalin-fixed hemisections of brain per animal. The types and distributions of NP were mapped using an XY plotter.

In prefrontal cortex, plaque densities varied from 0.03 to 2.79/mm^2, while in midportions of neocortex, they varied from 0.001 to 0.85/mm^2. Caudal levels had fewest NP. End-stage plaques varied from 27% to 73% with higher plaque densities associated with a high percentage of end-stage plaques.

We conclude that: 1) in animals with few NP, the immature form of NP predominates; 2) in areas of low density, NP appeared in clusters but, as plaque densities increased, clustering was obscured; 3) NP were not evenly distributed throughout various cortical regions (e.g., prefrontal and temporal cortex, particularly the inferior portions, had high densities, while area 17 showed low densities). The amygdala and hippocampus had high and low densities, respectively. This preferential distribution for NP in aged monkeys shows parallels with those seen in human brain.

Statistical analysis of these monkeys' performance on a delayed response test did not show significance between the group of 31-year old animals and their progeny (23-26 years old). However, comparison of NP densities to performance within each animal disclosed that the 26-year old monkey, which performed poorly on the test, had plaque densities comparable to those in the older group. These data suggest that, on this test, plaque densities, rather than chronological age, are better predictors of abnormalities of performance.

271.17 DENDRITIC PLASTICITY IN AGING CAT AUDITORY CORTEX: GROWTH IN COLONY CATS, REGRESSION IN CASTRATED PETS. Arnold B. Scheibel and Anne S. Kaplan. Brain Research Inst., U.C.L.A., L.A. CA 90024.

We have previously reported finding greater total dendritic length (TDL) in auditory cortex neurons from young (YP) but not old (OP) pet cats, when compared to young colony (YC) cats (Kaplan and Scheibel, Soc. Neurosci. Abst. 1981). This suggests that the relatively enriched environment in which pet cats live, and/or their peri-pubertal castration, may have a positive effect on dendritic extent, which is reversed by moderate old age.

We next added an old colony (OC) group, expecting its TDL to be at least as low as that of OP and YC. All pets (both sexes) were neutered. Old cats were 10 to 18 years of age. Basilar dendrite systems of pyramidal neurons from Layer III of the midectosylvian gyrus were drawn. Five neurons from each of five cats from each group were chosen by strictly random criteria, drawn with a drawing tube and measured on a computer graphics tablet.

The results for TDL and its two main factors, mean branch length and total number of branches, are shown below. Rather than having the least TDL, OC equalled YP in these measures. Two-way ANOVA showed no age or environment effect (p>.60), but a highly significant interaction (p= .0001) between the two variables. Post hoc t-tests between OP and OC, YP and YC, OP and YP, and OC and YC were also all significant (p<.05). Thus, aging had opposite effects in the two environments.

The 28% increase in TDL in group YP, relative to group YC, resulted from both more branches per dendritic tree (+12%), and longer bifurcating (+16%) and terminal (+14%) branches, with no change (+1%) in number of trees per cell. For group OC, on the other hand, the same TDL increase was a function of 13% more trees per cell, and of a 20% increase in lengths of terminal branches, with no changes in the number of branches per tree (+1%) or length of bifurcating branches (-3%). Thus, the patterns of dendritic growth differed between young pets and old cage raised cats.

Finally, group OP did not differ from YC by more than 10% on any measure. OP had fewer (-14%) and slightly shorter (-6%) branches than YP, suggesting dendritic dying back. OP also had far greater variance than OC for many measures. Whether such differential aging is related to the castration of the pets, or to some other variable (e.g. nutrition), remains to be determined.

271.18 MORPHOLOGICAL CHANGES IN THE TASTE BUDS OF THE ELDERLY. L.Gaitan*,G.Espinosa*,J.Espinosa* and J.P. Machado-Salas. Lab.Neuromorfologia.Neurociencias.UIICSE,ENEP Iztacala. UNAM.Tlalnepantla.Edo. de Mexico.54030.MEXICO.

Decline of sensory functions is commonly seen in the elderly.Previous studies have shown changes in the architecture of the central nervous system.Some of these changes can account for some of the sensory modifications of aged people.Nevertheless, the extent to which they participate is unknown since the anatomofunctional changes shown by peripheral structures have not been exhaustively studied.We have undertaken a series of studies aiming to approach this issue.

In this report, we describe the morphological changes observed in the taste buds of the elderly.Samples from:a) tip of the tongue, b)lingual posterolateral region, and c) lingual "V" region, were promptly removed from recently dead subjects.The age of the experimental group was over 65 years, and that of the control group between 20 and 50 years.Subjects with oral pathology or trauma were not considered for this study.All the samples were frozen-cut and processed with:Nauta-Gygax, Cajal's reduced silver nitrate and Gallego's trichromic methods. The aging human taste buds were characterized by:1)loss of the usual barrel-shaped silhoutte, which became substituted by s-shaped, cone-shaped or kinked forms, 2)degenerative changes of the cytoplasm and nuclei, of both, sustentacular and gustatory cells, 3)the taste pore region was frequently distorted and sometimes misoriented,4)also, some clear-cut degenerative changes were seen at the initial portion of the afferent nerve fibres, and 5) our statistical data have shown that the vertical diameter of aging taste buds tends to be longer than those of younger subjects; paradoxically, the depth at which the taste pore is located in the elderly is larger than that of controls. Finally, we found that the number of sustentacular and gustatory cells is similar in both groups.

It is our impression that these changes do have an important role in modifying taste perception in old age.We shall discuss some of the putative involved mechanisms.

272.1 STRIATAL DOPAMINE RECEPTOR SUPERSENSITIVITY AND THE ALTERATION OF MOTOR BEHAVIORAL DEFICITS IN THE SENESCENT RODENT, J.A. JOSEPH, S. SEASACK*, R.T. BARTUS, D. CLODY*, +D. MORGAN*, AND +C. FINCH. CNS BIOLOGY, LEDERLE LABS, PEARL RIVER, N.Y. 10965 +Dept. of Physiology & Biophys, USC Med. Sch., Los Angeles,CA 90033.

Previous reports (Joseph et al Life Sci., 29 575, 1981; Joseph et al Aging, 22, 1983) have indicated that the induction of development of striatal dopamine (DA) supersensitivity in senescent animals with 6-hydroxydopamine lesions or prevention of striatal DA receptor loss via dietary restriction retards age-related declines in rotational behavior, suggesting that alteration of striatal DA receptor number may be important in influencing motor behavioral performance in senescence. The present study extended these findings to other motor behaviors. Young (6-8 mo; n=7) Middle (15-18 mo, n=10) and Old (25 mo; n=10) Fisher 344 rats were implanted sc. with 2 Alzet osmotic pumps containing either vehicle (0.5N HCL)or haloperidol (.12 mg/ul in 0.5 N HCL 2.88 mg/day/pump). Pumps were left in place for 14 days, removed and 3 days later the animals were given a battery of 4 motor tests (horizontal rod walking; wire hanging; plank walking on wide medium, and narrow planks; hanging on screen inclined at 60°). Tests were carried out sequentially and later the same day the animals were given 0.5 mg/apomorphine ip. and 10 min later stereotypy assessed for 10 min (sniffs, licks, grooms, and cage crosses) Animals were sacrificed one day later, striata dissected and DA receptor activity assessed using [^{3}H]spiperone binding with domperidone (1 uM) used to determine non-specific binding. Six concentrations of [^{3}H] spiperone were used per analysis (25 to 800 p moles). Results showed that there were age differences in the vehicle treated animals on the inclined screen ($P < .05$ Kruskal Wallis Analyses of Variance) rod walk ($P < .001$) wide plank ($P < .001$ and medium plank ($P < .005$, with old animals showing significantly smaller scores (times) than young animals ($P < .05$ (Mann Whitney tests). Analyses of the difference scores computed between pairs of vehicle-treated and haloperidol treated animals revealed no age-related group differences on any of the motor tasks, indicating that all animals treated with haloperidol and withdrawn were able to show equivalent performance regardless of age on the 4 tasks. These findings were reflected in the binding data which showed that although there was a trend toward lowered receptor binding as a function of age ($P < .05$; Bmax Y = 451 ± 27, M = 420 ± 34, O = 393 ± 28 f moles/mg protein) no such trend was seen in haloperidol treated animals Y = 613 ± 36, M = 471 ± 18; O = 502 ± 35f moles/mg protein; haloperidol enhancement; Y = 36% M = 12%, O = 28%). Stereotypy scores showed enhancement in both old and young animals (e.g., grooms vehicle Y = 0.80 ± 0.80; O = 1.42 ± 0.60; haloperidol Y - 9.55 ± 4.71; O = 11.57 ± 8.17 $p < .05$ within age Mann Whitney test comparisons).

272.2 INTRACEREBRAL GRAFTING IN THE AGED RAT BRAIN. F.H. Gage, A. Björklund, U. Stenevi*, S.B. Dunnett[1]*. Department of Histology, Lund University, Lund, Sweden. Department of Experimental Psychology, Cambridge University, Cambridge, England[1].

Recent data suggest that impairments in dopaminergic and cholinergic neurotransmission, respectively, may contribute importantly to the decline in sensorimotor and cognitive function associated with the aging process. We have previously shown that lesion-induced impairments of dopaminergic and cholinergic transmission in young rats can be partially reversed both biochemically and behaviorally by grafts of embryonic dopaminergic or cholinergic neurons, and recent reports suggest that neuronal transplants can survive also in aged rat brain. In the present study we report that mesencephalic dopamine neurons and septal cholinergic neurons, taken from rat embryos, can be grafted with excellent survival to the neostriatum and hippocampus, respectively, in the brains of aged rats, and that the intrastriatal dopamine-rich transplants can ameliorate the impairments in motor coordination seen in these animals. The study employed female rats 21-23 months of age and young adult controls 2-3 months of age at the beginning of the study. One group of old rats received dissociated cell suspension grafts of embryonic septum bilaterally into the dorsal and ventral hippocampus while another group received grafts of embryonic substantia nigra bilaterally into the caudate-putamen. Behavioral testing was conducted on all rats immediately prior to and again 11-14 weeks following transplantation surgery. After the final behavioral test the animals were taken for histochemical evaluation. Surviving grafts were found on both sides of the brain in all grafted animals. Graft survival rate, volume, and histological appearance were more variable and selectively different from those previously observed in young adult host, but extensive outgrowth and cell survival were clearly apparent. Additionally the intrastriatal DA grafts were associated with a significant improvement in motor coordination abilities in the aged rats. These results suggest that the intracerebral grafting technique may provide a new tool for the exploration of the role of dopaminergic deficits in neurological and behavioral impairments associated with aging.

272.3 ACETYLCHOLINE RECEPTOR BINDING CHARACTERISTICS AT THE NEUROMUSCULAR JUNCTION OF MATURE ADULT AND AGED RATS. Michael R. Chapman and Dean O. Smith (SPON: D. Gilboe). Department of Physiology, University of Wisconsin, Madison, WI 53706.

At the rat diaphragm neuromuscular junction, there is an age-related increase in the number of nerve terminals and a corresponding rise in the amount of transmitter released. To determine if these changes are associated with altered ACh receptors, the binding characteristics were assayed using ^{125}I-labeled α-bungarotoxin. After iodination via the chloramine-T method, the labeled toxin was chromatographed on columns of Sephadex G-25 and C-25 to obtain the pure monoiodinated form. The specific activity was then determined by competition binding using solubilized Torpedo ACh receptors. Whole muscle samples from Fischer 344 rats aged 10 and 28 mos were incubated in labeled toxin. When the toxin concentration was 0.8 nM, similar to K_D, the time to half-maximal binding was 1 hr for both age groups. For the concentration ranges studied, maximal binding was attained after 2 hr at 37°C. Therefore, subsequent saturation experiments involved 2-hr incubations at 37°C in labeled toxin concentrations ranging from 0.1 to 30 nM. Binding was then assessed by Scatchard analysis. The average (±s.e.) values of B_{max} were 6.3 (±1.1) and 15.6 (±2.3) fmol/mg protein in the 10- and the 28-mos animals, respectively. Furthermore, the average (±s.e.) values of K_D were 1.1 (±0.12) and 2.7 (±0.16) nM in the younger and the older rats, respectively. Both of these age-related differences were highly significant statistically (0.01 level). Thus, the aged animals appear to have significantly greater numbers of receptors which exhibit a lower binding affinity. Supported by NIH grants AG01572 and NS00380 (R.C.D.A. to D.O.S.).

272.4 SELF-STIMULATION IN AGED RATS: EFFECTS OF AMPHETAMINE AND HALOPERIDOL. E. S. Valenstein & H. Altman. Dept. Psychology, Univ. of Michigan, Ann Arbor, MI 48109 and Lafayette Clinic, Detroit, MI 48207.

Sprague-Dawley male rats of three different age groups were tested for lateral hypothalamic self-stimulation rate at current intensities ranging from below threshold to supra-maximal levels. No differences in response rate or reward threshold was found between young (3-4 months), mature (8-9 months), and old (22-25 months) animals. When tested following injections of amphetamine (1 mg/kg) young animals displayed the anticipated increase in self-stimulation rate, but the rate of old animals tended to decrease. The response of mature animals given amphetamine was intermediate. When tested following injections of a relatively low dose of haloperidol (.06mg/kg) the self-stimulation rate of old animals was significantly more depressed than that of the young animals. Results indicate that the reward maintaining lateral hypothalamic self-stimulation in old animals is less responsive to activation by amphetamine and more vulnerable to dopamine blockade than that of young animals. It is hypothesized that the substrate of the reward system of older animals may display less reserve capacity when challenged.

272.5 PROGRESSION OF AGE CHANGES IN SYNAPTIC TRANSMISSION AT MOUSE NEUROMUSCULAR JUNCTIONS. N. Robbins and S.S. Kelly*, Dept. Anatomy, Case Western Reserve Sch. Med., Cleveland, OH 44106.

Prior physiological studies on synaptic aging have been confined to comparisons of young and old animals (e.g. Banker, Kelly & Robbins, J. Physiol., 1983). Thus, the changes observed could be agonal, secondary to aging of other organs, or alternatively, slowly progressive through life. Therefore, the progression of age-related changes in neuromuscular function was investigated in muscles from CBF-1 mice between 7 and 32 months of age. Endplate potentials (EPPs) were recorded in extensor digitorum longus (EDL), soleus, and diaphragm muscles after neuromuscular transmission was blocked with either (+)-tubocurarine chloride (curare) or high magnesium/low calcium Krebs solutions. Between 10 and 31 months of age in EDL and soleus but not in diaphragm there was an increase in EPP amplitude with age. In soleus, the maximum increase was approximately two-fold in curare and three-fold in high magnesium solution. Increase in EPP amplitude in curarised preparations took place between 20 and 28 months of age in EDL and between 28 and 31 months of age in soleus. Indirectly elicited twitch responses were used to determine the time-course of age-related changes in sensitivity to magnesium block. Increased resistance to block appeared between 15 and 19 months of age in both EDL and soleus (in which the increase was more gradual). In magnesium-blocked preparations, increased quantum content (measured directly) accounted for the increased EPP amplitude. Spontaneous miniature endplate potential (MEPP) frequency in old soleus muscles was not sensitive to low calcium/high magnesium solutions although frequency in young soleus and young and old diaphragm was significantly reduced.

The diaphragm shows no age-related changes in the physiologic parameters measured here. In limb muscle, age-related changes in evoked transmitter release begin in mid-life and take place more rapidly in EDL than in soleus. This may be due to the difference in muscle type or to the different usage of these muscles. In both muscles, age changes appear before any significant mortality or organ pathology is evident. Decreased sensitivity of transmitter release to low calcium/high magnesium is therefore an early sign of altered synaptic transmission in aging mouse limb muscle. This work was supported by NIA AG 00795.

272.6 TIME-SERIES ANALYSIS OF MORPHOLOGICAL CHANGES AT THE NEUROMUSCULAR JUNCTION OF FUNCTIONALLY DIVERSE MUSCLES DURING AGING. J.L. Rosenheimer and D.O. Smith. Dept. of Physiology, Univ. of Wisconsin, Madison, WI 53706.

The end-plate regions of the diaphragm, a phasic muscle which remains active during the aging process, and of the extensor digitorum longus (EDL) and soleus, phasic and tonic hindlimb muscles, respectively, which most likely suffer from disuse atrophy with aging, were examined in rats. Neuromuscular junctions were located following cholinesterase staining of the end plate and silver-gold impregnation of the axon and its terminal arborization. The number of terminal branches and the frequency of occurrence of sprouting and degeneration were then recorded. The mean values of 60 measurements from 5 animals of each age group (in 3-mos intervals) ranging from 10 to 31 mos were obtained. Nonlinear data smoothing techniques, according to the methods of J.W. Tukey, were applied to analyze trends. Changes in branch number were examined and compared with relative changes in sprouting and degenerating terminals.

At the diaphragm neuromuscular junction, a pronounced increase in terminal branch number was observed between 16 and 25 mos of age. Consistent with this observation, the number of sprouting terminals remained greater than the number of degenerating terminals throughout. However, sprouting decreased steadily, while degeneration increased until approximately 19 mos of age, when these trends appeared to reverse. Nerve-terminal branching within the EDL end plates decreased steadily until approximately 25 mos. The occurrences of sprouting and degeneration likewise declined with age. Sprouting remained slightly ahead of degeneration until about 25 mos of age, when degeneration was observed more frequently. Soleus neuromuscular junctions exhibited a steady decrease in branch number until approximately 19 mos; then the trend reversed, and a steady increase was seen. Accordingly, both sprouting and degeneration decreased at nearly the same rate until 19 mos. This was followed by a slight increase in sprouting through 31 mos of age. In general, these age-related changes were least pronounced in soleus, the tonic muscle. Conversely, they were more extreme in the phasic muscles. However, the number of terminal branches may be influenced by the relative amount of activity. Supported by NIH grants AG01572 and NS00380 and an NIH training grant to the Neurosciences Training Program.

272.7 TRANSMITTER RELEASE FROM CYTOPLASMIC AND VESICULAR SOURCES AT THE NEUROMUSCULAR JUNCTION OF MATURE ADULT AND AGED RATS. Dean O. Smith. Department of Physiology, University of Wisconsin, Madison, WI 53706.

At the diaphragm neuromuscular junction, there is an age-related decrease in transmitter (ACh) per nerve terminal and a corresponding increase in the number of nerve terminals per end plate. To assess correlated changes in synaptic responses, transmitter leakage and release was measured at the neuromuscular junctions of rats aged 10 and 28 mos using electrophysiological and biochemical techniques. Leakage of ACh from cytoplasmic sources was determined by measuring the hyperpolarization following application of d-tubocurarine. The hyperpolarizing responses were of similar magnitude (1 mV) in both age groups; however, the older rats were less sensitive to ACh, indicating that cytoplasmic leakage was greater in the 28-mos animals. Miniature end-plate potentials were significantly smaller in the older rats; they also occurred more frequently in the aged animals, but this increase could be attributed to the increased terminal number. In curarized preparations, end-plate potentials were recorded intracellularly during repetitive stimulation at rates ranging from 5 to 50 Hz. Synaptic depression was observed to be more extensive in the older animals. In both age groups, depression could be described quantitatively by models based strictly on depletion of transmitter. Estimates of release probability, p, were derived from these data, and the average values were 0.17 and 0.16 in the young and the old rats, respectively. As these values were significantly greater than zero, quantal release could be described using binomial statistics. Average quantal content, m, was 75 and 116 in the 10- and the 28-mos rats; this difference is significant at the 0.05 level. However, the corresponding average values are 6 and 7 per nerve terminal, and this difference is not significant statistically. Furthermore, the binomial parameter n was estimated to be 444 and 817 in the young and the aged rats, respectively; when normalized for the number of nerve terminals per end plate, however, the values were 34 and 47, which are not significantly different (0.17 level). Biochemical assays revealed that 3.2 and 3.9 fmol of ACh were released per end plate in response to 1000 presynaptic action potentials in the young and the older rats, respectively; this difference is significant at the 0.05 level. The corresponding values per nerve terminal were 0.24 and 0.22 fmol, which are not significantly different. Furthermore, in the aged animals this represents a significantly larger fraction of the total ACh present in the nerve terminals. These results indicate that an age-related increase in transmitter release may be attributed to greater numbers of nerve terminals within the end plate. Supported by NIH grants AG01572 and NS00380.

272.8 SELECTIVE REDUCTION IN THE HIGH AFFINITY OPIATE BINDING SITES IN THE PEDAL GANGLIA OF MYTILUS EDULIS DURING AGING. A. Chapman*, G. B. Stefano, M. Leung* and R. Martin[1]*. Depts. Biological Sciences and Chemistry, SUNY/College at Old Westbury, New York 11568 and [1]Electron Microscopic Section, Univ. Ulm, D-7900, West Germany.

It is expected that if specific age-related changes in neuronal function occur, these changes will be reflected in and possibly due to changes in specific neurotransmitter or neuromodulator systems and/or in other neurochemical properties. The characteristics of opioid receptors were studied in pedal ganglia (Pg) membrane suspensions of 1,2, and 4-year-old animals using both ^{3}H-etorphine and ^{3}H-naloxone. Specific and saturable high and low affinity binding was demonstrated for all age groups. When the binding data were analyzed by Scatchard plot the K_D values (high affinity 3.1nM; low affinity-11.2nM) were quite similar, however the high affinity site receptor density in older organisms was significantly reduced (young 51.0 pmol/g of protein ; old 38.0) while the density of the lower affinity sites did not change (163 pmol/g of protein). Examination of the enkephalin-like immunoreactivity in the Pg of young (1-yr) and old (4-yr) organisms revealed identical localization, however the enkephalin immunoreactivity was not as pronounced in older organisms. In an effort to resolve this observation the Met/Leu enkephalin and Met-enkephalin-Arg-Phe levels were estimated by HPLC analysis (Beckman 334, 210 sample injector, C RIA integrator on a Brownlee RP-300 column). In previous studies these opioids were isolated and sequenced from M. edulis Pg acid extracts. The levels of these opioids in this preliminary evaluation were found not to vary with age. In conclusion the high affinity opiate density appears to be selectively reduced in this organisms Pg during the aging process. Other age-related decreases in opioid regulation of dopamine levels in M. edulis have been described earlier. The significance of this selective reduction in high affinity opiate binding densities in older organisms has yet to be determined, however, such studies are important for our understanding of biological continuity, diversity and evolution.

Supported by NIH-MBRS Grant RR 08180

272.9 A GOLGI STUDY OF SUPRAOPTIC NUCLEUS TRANSPLANTS IN THIRD VENTRICLE OF YOUNG AND OLD RATS. Anne S. Kaplan, Paul D. Coleman, and Don M. Gash. Department of Anatomy, University of Rochester Medical Center, Rochester, N.Y. 14642

The supraoptic nucleus (SON) was dissected from 17-day F344 rat fetuses, and transplanted into the third ventricle of 5- and 25- month old male F344 rats. The hosts were killed 3 months later and their brains were stained by the Golgi-Cox method and sectioned coronally. Every third section was Nissl-counterstained.

The transplants were found in varying positions within or along the ventricle. The host-transplant border was sometimes distinct with a ventricular wall or capsule, and sometimes blurred, which suggests that *the two tissues had become structurally integrated.*

Nissl-stained sections showed that some but not all cells in the transplant were SON-like in appearance. Cells tended to cluster in the center or along one side of the transplant.

Golgi-stained somata varied widely in location, shape and size, but had many characteristics typical of SON neurons (see Flood and Coleman, this meeting). Their processes could usually be differentiated into dendrites and axons. A typical cell had 2 or 3 dendrities, with 0 to 3 bifurcations, for a total of 2 to 8 branches. Somata and dendrites often had long, hairy thorns. Branches from the same cell or even the same branch point differed greatly in their thickness and morphology. Many branches were studded with varicosities, which were often numerous and large. Dendrities sometimes ended with a varicosity, or with a bristly, diffuse, wide mass, suggestive of a growth cone.

The path of some of these processes was very tortuous, akin to those seen in normal SON. Many however, especially those running in cell-poor areas of the tissue, were quite direct. These tended to be much longer than normal SON dendrites. Processes from cells in or near the wall or capsule tended to stay there, running in parallel, or to turn to enter the donor tissue. Some even turned to enter the host tissue. Dendrities originating from cells within the center of the transplant tended to head towards the ventricle floor (median eminence) or towards ventricle or capsule walls. There, most either terminated or turned to follow the wall, but some, again, penetrated the graft-host interface, projecting into the host parenchyma. In addition, some host cells sent processes to or through the transplant wall, although most host fibers in the vicinity of the graft simply ran alongside it.

In summary, both old and young host rats were able to support hypothalamic transplants, with cells that appeared quite robust and normal in form. Further, there was some evidence of two-way anatomical interaction between host and transplant tissues.

272.10 DENDRITES OF DENTATE GRANULE CELLS AND HIPPOCAMPAL PYRAMIDAL NEURONS IN HUMAN AGING AND DEMENTIA. S.J. Buell*, C.H. DeFiore, G.J. Horwitz* and P.D. Coleman. Dept. Neurology, Univ. Rochester Sch. Med. & Dent., Rochester, NY 14642.

We have extended our finding of dendritic growth in layer II pyramidal neurons of the parahippocampal gyrus in normal human aging but not in aging with dementia (Buell & Coleman, Science 206:854, 1979) by assessing dendritic extent in the granule cells of the dentate gyrus and pyramidal neurons of sector H-1 (approximately CA1) of Ammon's horn. From over sixty cases obtained at autopsy, five normal adults (avg. age=51 yr.), five aged cases (avg. age=79 yr.) and five cases with senile dementia of the Alzheimer type (avg. age=76 yr.) were selected. All cases were free from significant neurological or psychiatric disorder, except the cases in the latter group had a well documented history of late stage Alzheimer's disease. All cases were also free from significant neuropathology at autopsy, except that the cases in the latter group had abundant senile plaques and/or neurofibrillary tangles in the hippocampus and adjacent neocortex. Neurons were selected randomly for analysis from coded 200um thick sections of tissue prepared by the Golgi Cox method. The groups did not differ significantly in post mortem time (PMT) which averaged 12 hrs. Dendritic extent tended to be greater in the aged than the adult or demented cases in both the granule cells of the dentate gyrus and the pyramidal cells of Ammon's horn. Dendritic trees of demented cases were slightly smaller than those of the adults. Differences among groups tended to be greater in terminal than in non-terminal segments and were largely confined to the middle range of somatofugally-ordered segments. The magnitudes of the differences among groups were nearly identical in these two cell types and are very similar to the group differences we saw previously in layer II pyramidal neurons of the parahippocampal gyrus. Analysis of covariance showed that when total dendritic length was corrected for effect of PMT, differences among groups were not statistically significant. However, this form of analysis showed that the groups did differ significantly in dendritic extent in the middle range of somatofugally-ordered segments in the dentate granule cells ($p < 0.05$) but not in the hippocampal pyramidal neurons. Values for the aged group were significantly larger than those for the adult and demented (t-test, $p < 0.02$ and $p < 0.01$, respectively) which did not differ significantly from each other. This accentuation of differences among groups in middle dendritic orders has been a consistent finding in our studies of dendrites in aging and dementia. Supported by NIH Grant AG 02680.

272.11 DENDRITIC EXTENT OF LAYER II PYRAMIDS IN ENTORHINAL CORTEX OF AGING F344 RAT. P.D. Coleman and S.J. Buell*. Departments of Anatomy and Neurology, University of Rochester Medical Center, Rochester, New York 14642.

Previous work from our laboratories has indicated apparent dendritic growth of Golgi-Cox stained layer II pyramidal neurons in parahippocampal gyrus of aged as compared to middle aged humans (Buell and Coleman, Science, 1979; Brain Research, 1981). Interest in developing an animal model of this phenomenon led us to quantify the same cell type in the same layer in a comparable cortical area (entorhinal) of the aging male F344 rat. Tissue was stained by the Golgi-Cox method. Section thickness and random cell selection procedures from coded slides were similar to those used in our earlier human study. Dendritic trees were traced by means of a drawing tube. These tracings were quantified with the aid of an Apple II+ microcomputer with a drawing tablet. The data show no significant differences between mean dendritic measures at 12 months and 30 months. Total dendritic length per cell at 12 months was 2,189 um; at 30 months 2,205 um. However, the within animals standard deviation for total dendritic length averaged 578 um for the 12 month and 951 um for the 30 month old animals ($p<0.05$ one tailed). Increased variance in older animals is a usual finding in aging studies. Within the context of the present study this increased variance suggests that cells whose dendritic lengths depart more from the mean are more common in 30 month than in 12 month animals. To maintain the same average dendritic length in the two age groups cells with regressing dendritic trees seem to be balanced rather precisely by cells with expanding dendritic trees in the 12 to 30 month period. Data available to date suggest significant species differences in aging of cortical neurons in relation to life span as defined by survival curves.

272.12 AGE-RELATED CHANGES IN DENDRITIC EXTENT OF NEURONS IN SUPRAOPTIC NUCLEUS OF F344 RATS. D.G. Flood and P.D. Coleman. Dept. of Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642.

Dendrites and cell numbers were examined in the supraoptic nucleus of male F344 rats ranging in age from 3 to 32 months. Cells with a visible nucleolus were counted in every 20th cresyl violet stained 10 um section in rats aged 12, 20, 27, 30, or 32 months. No change was found in cell numbers as a function of age. These data extend those of Hsu and Peng (Gerontol. 24, 434-440, 1978), who studied female Sprague-Dawley rats. In rats aged 3, 12, 20, 27 or 30 months, dendritic trees of supraoptic neurons were examined in Golgi Cox impregnated tissue. Generally, the impregnated neurons were found in the posterior and superior portions of the nuclei. The neurons had dendrites that projected ventrally, seldom branching. Because of their simple structure, quantitative changes occurred only in dendritic length measures and not in measures of branching. Between 20 and 27 months of age, dendritic length was drastically reduced. No further reduction occurred between 27 and 30 months. These data suggest that dendritic atrophy is not necessarily a prelude to cell death. Between 12 and 20 months of age, Sladek et al. (Peptides 1, Suppl. 1, 141-157, 1980) have found a decline in the noradrenergic innervation of the ventral portion of the supraoptic nucleus. These data suggest that partial deafferentation may be producing the age-related dendritic atrophy seen in this system. Supported by PHS grants AG 01456 and AG 01121.

272.13 DENDRITES IN EXTREMELY OLD MOUSE CORTEX. L. Magagna*, P.D. Coleman and S.J. Buell*, (SPON: E.D. Caine). Dept. Neurology, Univ. Rochester Sch. Med. & Dent., Rochester, NY 14642.

Dendritic regression has been reported in a number of studies in which the aged animals were very old in terms of species or colony life span characteristics. Dendritic growth has been reported in studies in which aged subjects were relatively younger. We have analyzed dendritic extent in spiny stellate neurons of the posteriomedial barrel subfield of C57Bl/6NNia mice at 36 and 45 months-of-age for comparison with our earlier series of mice at 4, 12, 22, 26, and 30 months-of-age. In this earlier series we observed stability of dendritic extent throughout the 26 month portion of the life span studied (Buell et al., The Gerontologist 22:234, 1982). In both the previous and the present study 140 micron sections impregnated by the Golgi Cox method and counterstained with Cresyl violet according to Ramon Moliner were coded before analysis. Five randomly selected neurons from each of three animals at each age were studied for a total of 30 cells at 36 and 45 months-of-age and a total of 105 from 4 to 45 months-of-age. Dendritic extent was estimated from camera lucida drawings entered into a microcomputer via a digitizing tablet. Our results gave no indication of dendritic regression even at 45 months-of-age(the published 1% survival age for this colony is 33 months). Qualitatively, there was no detectable difference in appearance of the impregnated dendritic trees in any of the old animals when compared to the young. Likewise, there was no quantitative evidence for dendritic regression in any of the old animals. On the contrary, there was evidence for significant dendritic growth (ANOVA, $p<0.05$) in the middle range of centrifugally ordered dendritic segments as a function of advancing age from 4 to 45 months. Inspection of the group data revealed than mean value for each of the three oldest groups (30, 36, 45 months) was greater than the mean values of all of the four youngest groups (4, 12, 22, 26 months). We conclude that dendritic regression is not an inevitable consequence of advancing age, even in extremely old individuals. Some potential for dendritic growth appears to be preserved even at very late stages in the life span of this colony. Supported by NIH Grant AG 02680.

272.14 QUANTITATIVE ELECTRON MICROSCOPY OF DENDRITIES IN LAYERS I AND II OF ENTORHINAL CORTEX OF AGING F344 RAT. M.N. Sheridan*, T. Langow* and P.D. Coleman (SPON: V. Laties). Departments of Anatomy, Uniformed Services, University of Health Sciences, Bethesda, MD 20814, and University of Rochester Medical Center, Rochester, NY 14642

Dendrites were quantified in electron micrographs of layers I and II of lateral entorhinal cortex of male F344 rats aged 4, 20 and 32 months. Brains were fixed by perfusion with buffered aldehydes, post fixed in osmium tetroxide, dehydrated in alcohol and embedded in Epon. Electron micrographs were prepared at a final magnification of 17,500. Over 13,000 dendritic profiles were counted and measured. Dark dendritic profiles were included in the sample. Profiles too small to be positively identified as dendrites were excluded from the sample. The average cross sectional area of dendrites in layer I was 1.75 μm^2; in layer II it was 1.91 μm^2. Average circumference per dendritic profile in layer I was 5.69 μm; in layer II it was 5.70 μm. In layer I there was an average of 0.115 dendrities per μm^2 and the volume fraction of dendrites was 0.20. Analysis of variance showed no significant age-related trends in any of the measures taken. These electron microscopic data are consistent with Golgi-Cox data showing no significant age-related changes in dendritic extent in entorhinal cortex of the male F344 rat.

Supported by the National Institute on Aging (AG1121) and by USUHS Grant CO7024.

272.15 THE EFFECTS OF AGING AND EXERCISE UPON REGIONAL BRAIN GLUCOSE OXIDATION. R.P. Farrar*, C.M. Ardies*, P.E. Gilliam, H.L. Dodd* & W.W. Spirduso. Dept. of Physical and Health Education, University of Texas, Austin, Texas 78712.

As rats age there is a progressive decline in spontaneous motor activity. Concomitmant with this decline is a reduction of capillarization and blood flow in the caudate, a decline in oxidative metabolism in the brain, and a decline in reactive capacity. Previously we have measured an attenuation of the decline in reactive capacity in rats that initiated running at 18 months and continued until 24 months when compared to their sedentary controls. Due to the shifts in blood flow induced by regional brain activity it was hypothesized that a regular running regime might better maintain regional blood flow and oxidative metabolism in the caudate, motor cortex, and cerebellum. Sedentary male Fisher 344 rats 3,6,12,18, and 24 months of age were compared to rats 18 and 24 months of age that had run on a treadmill 5 days/week, 30 min/day, from the age of 3 months. The caudate exhibited a significantly greater rate of glucose oxidation, 18.94 $\pm$ 0.6 umoles of glucose/mg/30 min at 3 months, than did the motor cortex, 12.79 $\pm$ 0.53, or the cerebellum, 10.85 $\pm$ 0.54. The caudate also exhibited the greatest decline in oxidation down to 10.11 $\pm$ 1.24 umoles at 18 months compared to 7.67 $\pm$ 0.54 umoles for the motor cortex, and 6.92 $\pm$ 1.01 umoles for the cerebellum. Surprisingly, glucose oxidation did not decline from 18 to 24 months in any region and exercise did not significantly attenuate the decline in any region at either 18 or 24 months.

273.1 SLOWLY DEVELOPING HYPERRESPONSIVENESS OF CRAYFISH NON-GIANT ESCAPE CIRCUITRY FOLLOWING NERVE CORD TRANSECTION. M.T. Lee and J.J. Wine. Dept. of Psychol., Stanford Univ., Stanford, CA 94305.

In intact crayfish, gradually applied tactile stimulation of the abdomen can evoke a series of tailflips, i.e., alternating, rapid flexions and extensions of the abdomen. The production of this behavior does not involve the giant axons (MG and LG); instead, it appears to be dependent upon activity in other axons that travel in the dorsal part of the nerve cord. Transection of the cord below the subesophageal ganglion immediately abolishes "non-giant" tailflips. The cord does not regenerate across the lesion, and normal non-giant tailflips never return. However, sensory-evoked activity in the abdominal fast flexor (FF) muscles develops within a few weeks. We have begun to analyze the cellular basis of this return of function.

The nerve cords of crayfish (Procambarus clarkii) 7-11 cm in length were transected completely between the 5th thoracic and 1st abdominal ganglia. At various times after the operation, abdominal nerve cords were isolated along with the tailfan, which was left attached to the 6th ganglion via its nerve roots. In acutely transected preparations, intracellular recordings from the FF motoneurons reveal only very small depolarizations in response to tactile stimulation of the tailfan. By 7 weeks after transection, these same stimuli produce intense barrages of EPSPs, sufficient to evoke copious spikes in many of the FF motoneurons. Although spike output varies greatly among cells, increased responsiveness has been found in all FF motoneurons examined in abdominal ganglia 2-5 of chronically transected preparations. During flexor bursts, the telson flexor motoneurons and the peripheral inhibitor of the fast extensor muscles also burst strongly. In contrast, the fast extensor motoneurons are silent, and the fast flexor inhibitor fires either weakly or not at all. Moreover, elements restricted to the giant escape circuitry (MG, LG, segmental giant, and motor giant) are also silent. These results suggest that changes occurring within the isolated abdominal nervous system specifically enhance the excitability of the non-giant escape circuitry. The enhancement appears to be limited to the flexion portion of non-giant escape, although this may be merely the result of the method of stimulation or the type of preparation used. Further experiments are under way to determine the sites of these changes.

Supported by NIH postdoctoral fellowship NS 07033-01 (M.T.L.) and NSF grant BNS 81-12431 (J.J.W.).

273.2 NEONATAL 6-OHDA TREATMENT OF RATS: CHANGES IN DOPAMINE (DA) RECEPTORS, STRIATAL NEUROCHEMISTRY AND ANATOMY. Richard B. Mailman, Andrew Towle, David W. Schulz, Mark H. Lewis, George R. Breese, Diane L. DeHaven and Martin R. Krigman. Biol. Sci. Res. Center, Depts. of Psychiatry, Pharmacology and Pathology, University of North Carolina Sch.of Med., Chapel Hill, NC 27514.

Within 18 hrs of birth, Long-Evans rats were given an intracisternal injection of 6-hydroxydopamine [(OHDA) 30mg/10 mL ascorbate-saline] 30 min after 20mg/kg DMI, and then sacrificed at 45-50 days of age. Three separate experiments were performed with N_{6OHDA} = 13, 4, 3 rats, and $N_{control}$ = 10, 4, 3 rats, respectively per experiment. The striatum was dissected into two regions. That part of the caudate putamen in a coronal section ca. 1.6 -2.6 mm anterior from bregma formed what is termed "striatum". All rostral portions of the striatum were termed "head of the caudate". In the "striatum", there was a significant decrease in neuropil, as well as in the total number of synapses. Moreover, there were very few remaining fibers with tyrosine hydroxylase immuno- reactivity (TH-IR). However,the binding of [^{3}H]-dopamine (5nM) was decreased by 62%, 50%, and 67% for the three experiments, respectively. Interestingly, there were no detectable changes in either [^{3}H]-spiperone binding, or in the sensitivity of dopamine stimulated adenylate cyclase. In the same animals, the concentrations of DA in the "head of the caudate" was decreased by 98%, 98% and 99%, whereas the concentration of 5-hydroxytryptamine (5-HT) was increased by 62%, 50% and 67%, in the three experiments respectively. The latter finding confirms earlier work noting that neonatal 6-OHDA treatments significantly increase 5-HT in this area of the striatum (Stachowiak et al., Soc. Neurosci. Abstr. 8:304, 1982). It is presently unknown what the exact nature is of the binding sites for spiperone or dopamine, although dopaminergic agonists and antagonists clearly have markedly different affinities for those binding sites that are common. In the present experiments, the persistent (i.e., for at least 45 days after treatment) decrease in [^{3}H]-dopamine binding occurs in the absence of any changes in the binding of [^{3}H]-spiperone, or in the sensitivity of adenylate cyclase to dopamine. This suggests that the loss of [^{3}H]-dopamine binding sites are predominately from populations other than the ones normally designated as D_1. Similiar treatments to those used here cause profound "receptor supersensitivity" (i.e., apparent increase in behavioral potency of dopamimetic drugs), yet no "receptor up-regulation" was detected in these experiments. The reasons for this are certainly relevant to the general question of the physiological meaning of changes in receptors as measured by radioligand binding.

(Supported in part by ES01104, HD/MH16834 and HD03110.)

273.3 DEVELOPMENTAL CHANGES IN THE NEURAL CIRCUITRY FOR TOUCH SENSITIVITY IN CAENORHABDITIS ELEGANS. M. Chalfie[1], J.E. Sulston[2*], J.G. White[2*] and J.N. Thomson[2*]. [1]Department of Biological Sciences, Columbia University, New York, NY 10027, [2]MRC Laboratory of Molecular Biology, Cambridge, England.

We have used selective cell killing and reconstruction from serial section electron micrographs to analyze the neural circuitry involved in touch-mediated movement in the nematode Caenorhabditis elegans. This circuitry is modified during C. elegans development by the addition of cells and the loss of specific synapses. For both the anterior touch response (resulting in backward movement) and the posterior touch response (resulting in forward movement) the pattern of synapses is similar: the touch cells form gap junctions and apparent chemical synapses to the major ventral cord interneurons. These, in turn, synapse onto the motor neurons of the ventral cord. Using laser microbeam killing of cells of each of these classes, we have determined that the gap junctions are the most important synapses for touch-mediated movement. Thus, touch receptors in the tail form gap junctions to interneurons (the PVCs) which in turn synapse onto motor neurons that make the animal move forward. In the young larvae a similar circuit occurs in the head: the touch cells form gap junctions to interneurons (the AVDs) that synapse onto motor neurons that make the animal move backward. However, midway through larval development, a postembryonic touch cell (AVM) sends branches to each of the pre-existing touch cells in the head (ALML and ALMR) and forms gap junctions with each. AVM appears to serve two functions: 1) it joins with ALML and ALMR to form a nerve net of touch receptors (this may be required in C. elegans because the cells do not have intricate branching patterns and 2) it provides this nerve net with chemical synapses onto an additional class of interneurons, the AVBs. These AVB synapses appear to be important since in adults the gap junctions between these touch cells and the AVD interneurons are lost. As a result of this loss, animals which lack AVM (by prior laser killing) become touch insensitive in the head 3-4 days after becoming adults. The loss is quite stochastic: in nine experimental animals, some were virtually touch insensitive, others were almost wild type. This loss is quite specific since both the touch cells and the AVD interneurons retain gaps junctions with other neurons, and, in the case of AVD form additional gap junctions to other neurons. These changes in the touch circuitry appear to be part of what may be extensive respecification of the C. elegans nervous system during development.

273.4 PROPERTIES OF GLUTAMIC ACID DECARBOXYLASE IN HOMOGENATES OF CRAYFISH CNS TISSUE AND EFFECTS OF CRUSH ON ENZYME ACTIVITY. R.M. Grossfeld, S.W. Yancey* and D.B. Hansen*. Zoology, Dept., North Carolina State University, Raleigh, NC 27650.

Glutamic acid decarboxylase (GAD) activity is maintained for 2 weeks in isolated peripheral nerves of crayfish despite the coincident loss of CAT and AChE activities (Sarne et al., Brain Res. 110:91-97, 1976). Our goal was to examine the stability of GAD activity in isolated CNS tissues of crayfish.

GAD activity was measured in homogenates of crayfish abdominal nerve cord. Our procedure reliably estimates GAD activity and yields data consistent with that of Wu et al. (Trans. Am. Soc. Neurochem. 7:190, 1976). GABA and CO_2 were produced in roughly equimolar amounts. Product formation was linear for 10 h. at 11-32° and had an optimal pH of 7-10. There was no significant catabolism of product. Decarboxylation of L-glutamate was inhibited 35% by 5 mM D-glutamate or α-ketoglutarate but less than 12% by substrate analogs of varying chain length. There was an optimal concentration for stimulation by pyridoxal phosphate, 2-mercaptoethanol, or potassium phosphate. Sodium phosphate altered the stimulatory effect of potassium phosphate. Inhibition by the carbonyl trapping agent aminooxyacetic acid (AOAA), the sulfhydryl reagent DTNB, the product GABA, or chloride was competitive with substrate. AOAA also competed with coenzyme. Product analogs of varying chain length were ineffective inhibitors. SCN^{-1}, I^{-1}, Zn^{+2}, and Mn^{+2} were the most potent inhibitory ions. Acetate, F^{-1}, and phosphate were stimulatory. EDTA, Mg, NAD, and nicotinamide had no significant effect. GAD in homogenates of crayfish CNS tissue behaves like a typical neural GAD I rather than like the non-neural GAD II, but is distinct from GAD I of other species.

We examined GAD activity in CNS connectives and ganglia which had been crushed at each end to isolate them in vivo from central and peripheral connections, and in comparable tissues from sham-operated control animals. The lesions produced about a 30% decrease in the total and specific activities of GAD in the isolated connectives and ganglia during the first 2 post-operative weeks; however, there was little or no change during the ensuing 6 weeks. During this time, there was no apparent recovery of function. GAD activity appears to be conserved for at least 2 months after injury of crayfish CNS tissues, even in those isolated tissues (connectives) in which there are no known nerve cell bodies. (Supported in part by Grant 2036 from N.C. Board of Science & Technology and by N.C. Agricultural Research Service Project 5490).

273.5 DENERVATION-INDUCED ELEVATION OF ENDPLATE BAND ACETYLCHOLINE RECEPTORS. T.A. Levitt-Gilmour and M.M. Salpeter. Section of Neurobiology & Behavior, Cornell Univ., Ithaca, NY 14853.

Studies using gamma counting reveal that the number of acetylcholine receptors within the endplate band doubles by 2 days after denervation (C.C. Chang et al., J. Physiol. 250:161, 1975; A. Olek et al., Brain Res. 214:429, 1981; T.A. Levitt-Gilmour & M.M. Salpeter, unpublished data). By 8 days after denervation, no such increase is seen. The endplate-band label is obtained after subtraction of non-endplate band counts on a per weight basis, assuming a uniform distribution of extrajunctional label. Therefore, the early increase in the endplate-band specific label could be due to an increase in the site density of receptors localized in the postjunctional folds, or to a non-uniform development of extrajunctional receptors after denervation.

We treated 4 day denervated sternomastoid muscle of female albino mice in one of two ways: 1) the muscle was saturated with ^{125}I-α-bungarotoxin (^{125}I-α-BGT) 4 days after denervation, or 2) the muscle was pretreated with unlabelled BGT just before the nerve was cut, and 4 days later, fixed and labelled with ^{125}I-α-BGT, thereby labelling only newly inserted receptors. For an internal control, the innervated muscle of each mouse was saturated with ^{125}I-α-BGT. All tissue was then processed for EM autoradiography. We determined the site density of receptors in 3 regions: within the junctional folds (junctional receptors); in extrajunctional membrane within the endplate band; and in non-endplate regions (which by our dissection was at least 2 mm from the endplate). The site density of junctional receptors was the same for innervated and denervated muscles. In denervated muscle pretreated with unlabelled toxin, the junctional site density was that expected from replacement of receptors degrading with a slow half-life (∿8 days). On the other hand, the site density of extrajunctional receptors within the endplate band was ∿150 sites/μm^2, and similar to that seen in non-innervated muscle (S. Bevan & J.H. Steinbach, J. Physiol. 267:195, 1977), whereas the site density in the non-endplate band was ∿3 times lower (∿40 sites/μm^2). This difference represents a gradient of extrajunctional receptors away from the junction, similar to that reported during development (Bevan & Steinbach, 1977; S. Burden, Dev. Biol. 57:317, 1977). We calculate that the increased extrajunctional site density over the area of membrane in the endplate band is large enough to account for the elevated receptor values obtained by the 4 day gamma count experiments. In conclusion, our data show that after denervation there is no increase in junctional receptors, but extrajunctional receptors first develop near the junction and by 8 days are distributed throughout the membrane, giving rise to a "spread of supersensitivity."

273.6 BEHAVIORAL AND ANATOMICAL CONSEQUENCES OF PERIPHERAL NERVE LESIONS WITH POSSIBLE RELEVANCE TO DEAFFERENTATION PAIN. B. E. Rodin and L. Kruger. Depts. of Anatomy and Anesthesiology, UCLA Center for the Health Sciences, Los Angeles, CA 90024.

I. The hypothesis that autotomy - self-inflicted damage to a deafferented body part - is a pain-related behavior was tested by comparing the incidence/severity of autotomy in adult rats subjected to bilateral lesions of the saphenous and sciatic nerves and either (1) no additional special treatment (control) or (2) neonatal treatments that compromised the fiber systems believed to contribute to deafferentation pain. Unmyelinated primary somatosensory axons were destroyed in one group of animals by treatment with capsaicin; postganglionic sympathetic fibers, reported to play a role in ectopic impulse generation in injured sensory axons, were destroyed in a second group by treatments with 6-hydroxydopamine. The efficacy of the neurotoxins was determined by electron microscopic or immunohistochemical studies of dorsal root, spinal cord and superior cervical ganglion. Neither neonatal treatment reduced the level of post-denervation autotomy relative to control behavior, a result indicating that pain is probably not an etiologic factor in autotomy.

II. The potential reinnervation of denervated cutaneous zones with collateral sprouts from nearby intact nerves was examined in adult rats by labeling dorsal root ganglion (DRG) cells with a lectin-horseradish peroxidase (WGA-HRP) conjugate for transport labeling of cutaneous sensory fibers. The distribution of saphenous nerve sensory axons in the plantar skin of the hind paw was studied at acute (control; 2 days) or long (2 wks-6 mos) intervals following section of the ipsilateral sciatic nerve. Behavioral testing included responsiveness to hemostat-pinch of the plantar skin throughout the postoperative survival period. Since the sensory innervation of the rat hind paw originates in the L4 and L5 DRG, these ganglia were injected with WGA-HRP; two days later the animals were sacrificed and the DRG and plantar skin were reacted with tetramethyl benzidine. Control material consisted of labeled skin from the hind paw contralateral to the chronic lesion or from the ipsilateral hind paw in different animals.

Behavioral and anatomical evidence indicated that under normal circumstances the saphenous nerve projects to the medial third and the sciatic to the lateral two-thirds of the hind paw. Following sciatic lesions, the saphenous projection to lateral plantar skin gradually increased and, by 6 mos, was dense across the entire plantar surface of the paw. The nature of the sprouting fiber population is currently under investigation by re-examining sprouting in animals treated neonatally with capsaicin.

273.7 NEURAL REGULATION OF NORMAL AND DYSTROPHIC AVIAN MUSCLE. S. Howlett* and T.B. Hoekman* (SPON: C. Harley). Basic Sci. Div., Fac. of Med., Memorial Univ. of Nfld., St. John's, Nfld, Canada A1B 3V6.

The etiology of muscular dystrophy has been variously described as either primarily neurogenic, myogenic or vascular in origin. One current view is that a generalized membrane abnormality is the primary defect and different tissues are affected to varying extents. To evaluate the neural regulatory role in avian dystrophy, the contractile responses of innervated and denervated muscle to acute close intra-arterial (IA) injections of acetylcholine (ACh) were examined in normal (Line 412) and dystrophic (Line 413) New Hampshire chickens. The in vivo nerve-muscle preparation of the avian extensor digitorum communis muscle was used (Howlett, S.E. & Hoekman, T.B. Exp. Neurol., In press, 1983) with four study groups; normal control (NC), dystrophic control (DC), normal denervated (ND), and dystrophic denervated (DD). Acute IA drug injections were administered as 30 ul volumes during continuous direct twitch stimulation. Two contractile measures were examined, the % twitch depression and the baseline contracture (% maximum twitch).

Denervation caused a 100-fold shift to the right for the ACh log dose-response curves for both twitch and contracture responses in normal and dystrophic muscle. This is consistent with the extrajunctional ACh sensitivity which develops in denervated muscle. The contracture response was significantly increased ($p<0.05$) in the ND group when compared to the DD group although the contracture response was similar in NC and DC groups. In the control group the % twitch depression was significantly greater ($p<0.05$) in NC than in DC birds and in the denervated group, the twitch response was depressed in ND when compared to DD birds. These data suggest that differences in the neural regulation of the muscle response to ACh exist in normal and dystrophic avian muscle. To determine whether these differences reflect alterations in either the receptor properties or in excitation-contraction coupling, the acute responses to IA injections of caffeine and KCl are currently being investigated.

This work was supported by grants from the Medical Research Council of Canada (MA 6477) and the Muscular Dystrophy Association of Canada.

273.8 **METHYLPREDNISOLONE PRESERVATION OF CAT MOTOR NERVE FUNCTION DURING EARLY ANTEROGRADE DEGENERATION.** E.D. Hall and D.L.Wolf, CNS Diseases Research, The Upjohn Company, Kalamazoo, MI 49001.

Previous work has demonstrated that intensive pretreatment with the glucocorticoid triamcinolone in cats (8 mg/kg i.m./day for 7 days) acts to preserve the function of cat soleus motor nerve terminals during early anterograde degeneration (Hall et al., Ann. Neurol. 1:263, 1977; 2:404, 1977; Exp. Neurol. 79:488, 1983). The present study was undertaken to determine whether this effect of high dose glucocorticoid treatment is peculiar to triamcinolone or whether it can be duplicated by a structurally distinct glucocorticoid. Accordingly, 4 cats were treated with methylprednisolone (MP) acetate (Depo-Medrol^R) in a regimen of 8 mg/kg i.m./day for 7 days. On the 7th day, one leg was denervated by aseptic sciatic nerve section at the hip under pentobarbital anesthesia, and 48 hr later a bilateral in vivo soleus nerve-muscle preparation was performed as described in the above refs. Several neuromuscular functional parameters were examined in the 48-hr nerve sectioned and the contralateral non-nerve sectioned soleus muscles in both MP-treated and untreated (N=4) cats.

The mean ratio of the isometric contractile responses to supramaximal nerve stimulation at 0.4 Hz of the 48-hr nerve-sectioned soleus muscle to that of its contralateral non-nerve sectioned muscle was 0.2± 0.14 in the untreated cats vs 0.68±0.20 in the MP-treated animals ($p< 0.1$). Thus, MP treatment appeared to result in a 3-fold greater number of functional soleus motor units at 48-hr after nerve section. Secondly, the degree of maintenance of maximal tetanic muscle tension during brief high frequency stimulation (100 Hz/10 sec) was only 35.7± 13.1% in the untreated 48-hr preps vs 84.4±7.3% in the MP-treated 48-hr ones ($p < 0.05$). Furthermore, a post-tetanic potentiation (PTP) of contractile strength was observed in 4/4 MP-treated 48-hr nerve-sectioned soleus muscles, indicative of the occurrence of a stimulus-bound repetitive discharge (SBR) of the trophically-compromised motor nerve terminals, while SBR-PTP never occurred in the untreated 48-hr preps. Similarly, the MP-treated 48-hr degenerating motor nerve terminals were significantly more responsive to the facilitatory effects (SBR generation) of a 200 μg/kg i.v. dose of edrophonium. Finally, a 150 μg/kg i.v. test dose of d-tubocurarine produced a mean 91.3±5.4% decrease in contractile tension in the untreated 48-hr nerve-sectioned preps vs only a 26.6±8.0% transmission block in the MP-treated degenerating ones ($p < 0.001$).

In conclusion, intensive pretreatment with MP, as shown previously with triamcinolone, acts to preserve the excitability and transmitter function of degenerating motor nerve fibers, thus showing that this is a common effect of high-dose glucocorticoid treatment that may be useful in the treatment of certain degenerative neuromuscular disorders.

273.9 DEGENERATION OF PERIPHERAL NERVE IN THE RAT TRIGEMINAL SYSTEM. W. E. Renehan* and B. L. Munger* (SPON: B. Hwang). Dept. of Anatomy, College of Medicine, Pennsylvania State University, Hershey, PA 17033.

While a great deal of attention has been focused on the study of myelinated axons following a transection or crush lesion, relatively little information is available concerning the course of degeneration at the level of the peripheral axon terminal. In light of the importance of this data to both the clinician and the neuroscientist, we chose to examine sensory terminal degeneration using the highly ordered and dense innervation of the rat vibrissa. Adult Sprague-Dawley rats were subjected to transection or crush of the infraorbital nerve approximately 2mm distal to the infraorbital fissure. Animals were sacrificed at 6, 12, 15, 18, 24 and 72 hours following surgery, and perfused with a Forssmann's rinse followed by a 2% glutaraldehyde-2% paraformaldehyde fixative. Individual vibrissae were dissected from the mystacial pad, embedded in araldite (Durcupan, Fluka), and examined with a Philips 400 transmission electron microscope. The Ruffini terminals, free nerve endings (FNE's), and lanceolate-like terminals in the loose connective tissue at the roof of the ring sinus, Merkel cell-neurite complexes of the outer root sheath, lanceolate terminals of the mesenchymal sheath and free nerve endings (FNE's) below the ringwulst were monitored for evidence of degeneration. No observable changes were detected until 18 hours after surgery, at which time some large diameter myelinated axons displayed moderate to severe axoplasmic disruption and focal myelin breakdown. Occasional Merkel and lanceolate terminals evidenced axoplasmic vacuolization with mitochondrial clumping and distention. The Ruffini terminals and FNE's displayed no degenerative changes at this time. At 24 hours, virtually all the Merkel cell-neurite complexes and lanceolate receptors were deafferented. Large diameter sensory axons showed severe degenerative changes, including vacuolization of cytoplasm and myelin breakdown. The Merkel cells themselves were unchanged, but the Schwann cells associated with the lanceolate receptors contained electron-dense amorphous inclusions, presumed to be phagocytosed axon terminals. The Ruffini complexes and FNE's still displayed no degenerative changes at 24 hours. At 72 hours, however, both Ruffini terminals and FNE's were no longer present. Many of the residual Schwann cells displayed reduplication of basal lamina and contained remnants of phagocytosed myelin. We conclude that the sequence of degeneration is first observed in those receptors innervated by large diameter myelinated axons, with those supplied by small diameter myelinated and unmyelinated axons persisting for a significantly greater period of time. (Supported in part by USPHS HD-11216.)

273.10 NEUROTROPHIC REGULATION OF THE AUTOPHOSPHORYLATABLE REGULATORY SUBUNIT OF PROTEIN KINASE TYPE II (RII). S.P. Squinto*, J.A. McLane and I.R. Held. Depts. of Biochemistry and Pharmacology, Loyola Univ. Med. Center and V.A. Hospital, Hines, IL 60141.

The motor nerve transmits regulatory information to the contiguous muscle cell through the impulse-directed and spontaneous release of ACh or through the release of neurotrophic factors which are synthesized in the neuronal perikarya and delivered to the neuromuscular junction by axoplasmic transport. The molecular mechanism(s) by which the muscle cell translates these non-impulse mediated neural messages into biological responses is not known. Previously, we reported that the in vitro phosphorylation of a 56,000-dalton soluble cytosolic protein is increased early (3 hr) after denervation of the slow-twitch soleus muscle of the rat and that this phosphorylative modification is temporally correlated with the length of distal nerve stump left attached to the muscle (J. Neurosci., in press, 1983). Additionally, we have tenatively identified the 56,000-dalton phosphoprotein as RII (Proc. Int. Soc. Neurochem., in press, 1983), the autophosphorylatable regulatory subunit of cyclic AMP-dependent protein kinase. Autoradiographs of ^{32}P-labeled tryptic fragments produced by limited proteolysis of the 56,000-dalton phosphoprotein and resolved by 15% SDS-polyacrylamide slab gel electrophoresis according to Cleveland et al. (JBC, 1977) yielded minor phosphopeptides of M_r=52,500, 31,000, 24,000, 16,500 and 12,000 and a single major 39,000-dalton phosphopeptide. The peptide map of the 56,000-dalton phosphoprotein was compared to the peptide map of a commercial preparation of RII (phosphorylated in vitro in our assay system) generated by limited tryptic proteolysis. Points of overlap were observed for the 56,000-dalton protein, the 52,500 and 16,500-dalton phosphopeptides and the major 39,000-dalton phosphopeptide which has been identified as the autophosphorylated RII peptide (Takio et al., FEBS Lett, 1980). Also, the denervation-induced change in the cytosolic protein phosphorylation (171 ± 13.4%) can be accounted for by the increased phosphorylation of the 39,000-dalton peptide (157.1 ± 7.3%). These results suggest that some non-impulse mediated neural influence is exerted through the autophosphorylation of RII. Supported by the V.A. Medical Research Service and BRSG funds from Loyola Univ.

273.11 DENERVATION INDUCED DEGENERATION OF NEUROMUSCULAR JUNCTION: THE ROLE OF NICOTINIC INTERACTIONS. S. Rochel-Landau and N. Robbins. Dept. of Anatomy, Case Western Reserve University, School of Medicine, Cleveland, Ohio 44106.

The objective of this study is to evaluate the neurotrophic role of nicotinic acetylcholine (ACh)-transmission in the development of denervation dependent fall of muscle resting membrane potential (RMP). If spontaneous (quantal or non quantal) or, action potential evoked ACh release by the motor nerve were the major or only requirement for RMP maintenance, then the denervation induced fall in RMP should be accelerated by nicotinic blockers, which would supply an "instant denervation". Therefore, rat hemidiaphragms with (+N) or without (-N) a 2 cm nerve stump were incubated for different periods of time in organ culture in the presence or absence of nicotinic blockers α bungarotoxin (αBTX, 5 μg/ml) or d-tubocurare (3 μg/ml). Upon completion of the incubation period RMPs and miniature endplate potentials (MEPPs) were measured.

Spontaneous miniature endplate potentials disappeared 12 hrs after nerve section in -N diaphragm strips, and after 18 hrs in +N strips. A 10 mV fall of RMP was attained after 24 hrs in -N strips and after 28 hrs in +N strips, in agreement with in vivo studies (Card, Exp. Neurol. 54, 251, 1977).

Nicotinic transmission was blocked from time zero in αBTX or curare treated muscle, but there was no advance in the time of RMP fall in -N muscles in vitro. Moreover, the nerve stump effect of delaying the RMP depolarization persisted in the continuous presence of αBTX or curare.

Thus, with respect to neuronal regulation of RMP, neither the effects of denervation nor of the long nerve stump are entirely explicable by a nicotinic mechanism. Corresponding in vivo experiments are now in progress. This work was supported by NS 18694 and an NIH Training Grant NS 07118-04.

274.1 DUAL ARBORIZATION OF SINGLE PARASYMPATHETIC AXONS IN THE SPHINCTER AND DILATOR MUSCLES OF THE MOUSE IRIS, Patrick C. Jackson.† Dept. Physiology & Biophysics, Washington University, St. Louis, MO 63110

The intrinsic muscles of the mammalian eye have been found to contain axonal profiles typical of autonomic cholinergic terminals (Nishida & Sears 1969). These are generally accepted as arising from parasympathetic ciliary ganglion neurons. Given that the sphincter and dilator of the iris have opposing actions, one of the possibilities suggested by these observations is that there are groups of neurons within the ciliary ganglion that project separately to these regions. Previous studies of the innervation of the iris have treated the whole population of ciliary ganglion neurons together and do not address this issue. Thus the purpose of the present study was to examine the projection of electrophysiologically and morphologically identified neurons to their target(s) using the intracellular marker horse-radish peroxidase (HRP). The adult mouse was chosen as the preparation for this work.

The eye was dissected from the orbit in continuity with the ciliary ganglion and a length of the occulomotor nerve. In most cases, a single ganglion neuron was impaled with a microelectrode containing HRP. The degree of convergence onto the impaled cell was estimated by recording EPSPs evoked by graded stimulation of the pre-ganglionic axons. Of 101 neurons impaled, 37 were sufficiently well filled to reveal that these neurons exhibit a range in dendritic complexity and that the most complex also received the largest number of inputs. (see also Purves & Hume 1981). The axons of thirteen single neurons were stained and followed to the irides of thirteen preparations. Of these, seven produced fine collateral branches exhibiting varicosities. Six axons arborized and produced terminal varicosities in both the sphincter and the dilator; one produced an arbor only within a small region of the ciliary processes near the root of the iris. There was no obvious relationship between the degree of convergence onto a ciliary ganglion neuron and the size or location of its terminal arbor in the iris.

Injection of HRP into single ganglion neurons with depolarizing current often produced an observable response in the iris; this was always an asymmetric constriction of the pupil. A simple speculation as to the physiological significance of dual distribution of a single axon to the antagonist sphincter dilator muscles is that impulse activity gives rise to a contraction of one and a relaxation of the other. Nishida, S. and Sears, M. (1969) Exptl. Eye Res. 8:292-296. Purves, D. and Hume, R.I. (1981) J. Neurosci. 1:441-452.

274.2 CHANGES IN THE INNERVATION OF CARDIAC GANGLION CELLS ACCOMPANYING NEURONAL GROWTH IN POST-METAMORPHIC XENOPUS LAEVIS. Peter B. Sargent. Department of Structural Biology, Stanford University School of Medicine, Stanford, CA 94305.

Cardiac ganglion cells in Xenopus laevis are innervated by axons which terminate upon both the ganglion cell body and its axon in a number of swellings, called synaptic boutons. Previous work in mature frogs has shown that the number of boutons on the ganglion cell body is directly correlated with its surface area (J. Physiol. 342, in press). Thus bouton density is similar for large and small cells in mature frogs. The experiments reported here were designed to address the question of whether bouton density remains constant during the increase in ganglion cell size that accompanies post-metamorphic growth.

Synaptic boutons terminating on ganglion cell bodies were stained at several stages following metamorphosis with zinc iodide and osmium (ZIO), which by electron microscopy was shown to stain all synaptic boutons. The ZIO procedure also impregnates preganglionic axons and thus permits visualization of the entire presynaptic arborization. Ganglion cells taken from frogs completing metamorphosis have an average diameter of about 15 μm and an average of approximately 4 synaptic boutons on their somata. Both ganglion cell size and bouton number increase continuously throughout post-metamorphic life. The increase in bouton number is accompanied by a marked elongation of the preganglionic axon(s) in contact with the ganglion cell body and by the presence of ZIO-stained growth cones on the cell body. Ganglion cell bodies in frogs nearing sexual maturity have several times the surface area and several times the number of boutons as cells from animals just completing metamorphosis. By contrast, the density of boutons, expressed per unit of somatic surface area, increases only slightly during this same interval. Thus most, but not all, of the increase in bouton number that takes place following metamorphosis occurs in parallel with an increase in cell body size. Although the mechanism generating this "compensatory" growth of both cell size and bouton number is unknown, its effect might be to maintain adequate safety factor for synaptic transmission during the neuronal growth that accompanies post-metamorphic life.

Supported by the National Science Foundation, The March of Dimes Birth Defects Foundation and The Dysautonomia Foundation.

274.3 **TRANS-SYNAPTIC REGULATION OF THE DEVELOPMENT OF CATECHOLAMINE CONTENT IN THE RAT SUPERIOR CERVICAL SYMPATHETIC GANGLION.** A.J. Smolen, T. Lindley*, and L.L. Wright. Dept. of Anatomy, Med. Coll. of Pa./E.P.P.I. Division, Philadelphia, PA. 19129.

It has been shown (Black et al., '72, J. Neurochem., 19:1367) that denervation of the superior cervical ganglion (SCG) of the mouse prevents the normal developmental increase in the activity of tyrosine hydroxylase, the rate limiting enzyme in the synthesis of norepinephrine (NE). A similar finding has been reported in the rat (Thoenen et al., '72, Brain Res., 44: 593), although the time course was not defined. The present experiment was designed to determine if the development of catecholamine content is regulated trans-synaptically by examining SCGs of rats after neonatal ganglionic denervation when reinnervation was either permitted or prevented.

There was no effect on total protein content of the SCG following any of the surgical procedures. In unoperated or sham operated control animals, NE content rose rapidly and reached adult values by one month after birth. In denervated ganglia, NE content failed to increase for the first two weeks, but then attained about 70% of control by one month. There was no significant difference in NE levels between ganglia which were reinnervated and those which were not.

Dopamine (DA) content underwent a normal rise during the first two postnatal weeks, and then fell to reach adult values by one month. In denervated ganglia, the early rise in DA content was abolished, and in the adult, there was no significant difference from controls. By contrast, epinephrine (E) underwent a normal rise during the first postnatal week, and then fell to an undetectable level by one month. In denervated ganglia, there was a temporary enhancement of E content (2-5 times control) at two weeks, but this was followed by a return to control by one month.

In the absence of preganglionic innervation, the content of NE reached 70% of control, while the contents of DA and E were not significantly different than controls. Thus, most of the postnatal increase in NE content in the rat SCG is not mediated trans-synaptically. However, NE content did not completely reach control, even in animals in which reinnervation began after a two week delay. Furthermore, there were temporary effects of denervation on both DA and E contents. Therefore, we conclude that trans-synaptic signals modulate development during the first two postnatal weeks, but that these signals are not essential for the attainment of adult (or nearly adult) levels of catecholamines in the SCG neurons.

(Sponsored in part by NIH Grant NS15952)

274.4 THE EFFECTS OF NEONATAL STRESS ON THE DEVELOPMENT AND INNERVATION OF THE RAT ADRENAL MEDULLA. L. L. Ross and A. Pylpiw*. Dept. Anatomy, The Med. Coll. Pennsylvania, Philadelphia, PA 19129.

The first 3 weeks of life is a critical period in the development of the rat adrenomedullary system. The adrenomedullary cells are proliferating and differentiating rapidly and there is a reorganization of their preganglionic innervation. These maturational events are regulated by central neural mechanisms as well as peripheral endocrine influences. Because the role of the neonatal adrenomedullary system in the response to stress is uncertain, the present experiments were undertaken.

From days 2 to 5, rat pups were subjected to immobilization stress daily for one hour. The animals were allowed to survive until 40 days of age. Controls consisted of littermates who either were isolated from the mother for the same periods without immobilization or were left undisturbed. All 3 groups were distributed according to sex and mother. At sacrifice, adrenal catecholamine levels were determined by HPLC with electrochemical detection. In addition, we assayed for one of the central neural influences regulating adrenomedullary maturation, spinal cord serotonin (5-HT) and its receptors. The former was determined by HPLC/EC and the latter by 5-HT binding.

Both the norepinephrine (NE) and the epinephrine (E) content of the adrenals of neonatally immobilization-stressed females were significantly lower than controls at 40 days of age. Stressed males showed no differences. Although 5-HT levels in the spinal cords of stressed animals were no different than controls, 5-HT receptors in the stressed-females were 20% lower than that of controls. Males showed no differences from controls in 5-HT receptor levels.

These data indicate that neonatal stress causes long-term changes in the catecholamine content of adrenal medullary cells as well as in spinal cord 5-HT receptors and, for the period administered, these stress effects are obtained only in the female.

274.5 MORPHOGENESIS OF CARDIAC GANGLION NEURONS. R. David Heathcote and Peter B. Sargent. Dept. of Structural Biology, Stanford University School of Medicine, Stanford, CA 94305.

The cardiac ganglion is a derivative of the embryonic neural crest. It is located in the atrium of the heart and is composed of parasympathetic neurons which receive synaptic input from the vagus nerve. In the frog, Xenopus laevis, cardiac ganglion cells undergo their final cell division as early as two days after fertilization and start differentiating soon thereafter. Ganglion cells continue to arise and differentiate well into larval life (Heathcote, Soc. Neurosci. Abstr. 8:258).

The morphogenesis of individual cardiac ganglion cells was examined following intrasomatic iontophoresis of horseradish peroxidase. Mature ganglion cells in adult hearts lack dendrites and have a single axon, which remains unbranched for a considerable distance from the cell body. While some neurons in Xenopus larvae have a similar morphology, many are multipolar and branch profusely. Their processes extend for long distances and can occupy the entire atrium. In addition, many of these larval neurons have fine, unbranched filopodia that emanate both from the cell body and along the length of its axons. These filopodia are as long as 20 microns in larval neurons but are not seen in mature neurons.

These results suggest that during differentiation, supernumerary processes sprout from the cell bodies and axons of immature cardiac ganglion cells which are subsequently "pruned". This transition eliminates primary processes (those that arise from the cell body) as well as secondary and tertiary branches of the axon. It also effectively reduces the percentage of the atrium innervated by any particular ganglion cell. Thus a striking change in morphology is one component of ganglion cell differentiation.

274.6 SOMATOSTATIN IMMUNOREACTIVITY IN EMBRYONIC SYMPATHETIC GANGLIA P.H. Chenard* and G.D. Maxwell (SPON: Y. Grimm-Jørgensen) Dept. of Anatomy, Univ. of Connecticut Health Center, Farmington, CT 06032

Some adult peripheral sympathetic neurons contain both catecholamines and somatostatin-like immunoreactivity (SLI) (Hokfelt et al., 1977 PNAS 74: 3587-3591). We have investigated the occurrence of SLI in developing embryonic avian sympathetic ganglia.

SLI was identified by immunohistochemical methods in paraformaldehyde fixed cryostat sections from the trunk region of quail embryos. At stage 18 (Zacchei 1961 Arch. Ital. Anat. Embr. 66: 36-62), which corresponds to embryonic day (E) 4, SLI was detected in cells of the primary sympathetic chain. These chains are the sites of initial aggregation of neural crest cells to form the sympathetic ganglia. The SLI in these cells was seen in the cytoplasm and is absent from the nucleus. At stage 23 (E7), when the lumbosacral paravertebral sympathetic ganglia have reached their definitive location some cells contained SLI and they were often located in the ventral portion of the ganglia. When the antiserum directed against somatostatin was pre-incubated with somatostatin 1-14 immunoreactivity was abolished.

At stage 23-24 lumbosacral paravertebral sympathetic ganglia can be dissected from the embryo and the SLI content determined by radioimmunoassay. These ganglia contained substantial SLI. When calculated on a per mg protein basis, the SLI content declined by 90% between stage 23-24 (E7-8) and stage 26-27 (E9-10) and remained at this low level until at least stage 31-32 (E13-14). When calculated on a per ganglion basis, SLI content declined 75% from stage 23-24 to stage 26-27, indicating that the reduction in SLI content is due to an absolute decrease per ganglion and not solely to growth of tissue that does not contain SLI. In embryonic chick lumbosacral paravertebral sympathetic ganglia, many developmental changes (such as the initiation of synapse formation within the ganglia) occur during the developmental stages equivalent to those at which we find that SLI content decreases in embryonic quail lumbosacral paravertebral sympathetic ganglia. Thus, changes in the expression of SLI may be linked to other key developmental events occurring during sympathetic ganglion maturation.

274.7 NEURAL INFLUENCES ON MUSCARINIC ACETYLCHOLINE RECEPTORS IN DEVELOPING CHICK HEART. Margaret L. Kirby and Robert S. Aronstam. Departments of Anatomy and Pharmacology, Medical College of Georgia, Augusta, GA 30912.

The development of muscarinic acetylcholine receptors in chick heart was studied from incubation days 5 through 20 using [^{3}H]3-quinuclidinyl benzilate as a probe. The influences of atropine-exposure and removal of postganglionic neurons on receptor numbers and binding properties were investigated.

There was a parallel increase in receptor density in atrium and ventricle until the last half of incubation, when the atrial, but not the ventricular, receptor density increased. This increase was blocked by exposure to atropine on incubation days 11 through 14, but not on days 16 through 19. This specific regional increase was coincident with the appearance of functional cholinergic innervation of the heart. During this same period there was an alteration in muscarinic receptor binding properties in both atrium and ventricle that was characterized by an increase in the proportion of receptors displaying high affinity agonist binding. This increase was blocked in the atrium, but not the ventricle, by atropine exposure on incubation days 11 through 14. Thus, there is a critical period in the development of atrial muscarinic receptors during which the receptors are susceptible to modulation by exposure to an antagonist.

Parasympathetic postganglionic neurons were removed by cauterization of the neural crest over occipital somites 1-3 at embryonic stage 9-10. (This area has been shown to seed the cardiac ganglia.) The number of ganglion cells in the bulbar region of the heart was determined histologically and correlated with the number of muscarinic receptors in the atrium and ventricle on incubation day 15. There was a 66% decrease in the number of bulbar ganglion cells and a 43% decrease in atrial receptor density (on a mg protein content basis). Ventricular receptor density was unchanged. Conotrunical abornormalities result from removal of neural crest over somite S1-3. Since this area provides both structural and neural components to the developing heart, it is possible that children with conotrunical malformations due to neural crest abnormalities may have altered responsiveness to cholinergic agents.

These results indicate a role for cholinergic innervation in the ultimate functional configuration of the cardiac muscarinic system.

274.8 PERTURBATION IN ZINC METABOLISM AFTER POSTNATAL LEAD EXPOSURE IN RATS. S. M. Sato*, J. M. Frazier* and A. M. Goldberg. The Johns Hopkins Univ., Dept. of Env. Health Sci., Baltimore, Md. 21205

Previous morphological studies showed that postnatal lead exposure can lead to disturbances in the development of the mossy fiber boutons in the hippocampus. We hypothesized that lead may exert its toxic effect by interfering with zinc found in this neuronal pathway. To test this hypothesis, rat pups were exposed indirectly to lead by adminstering 0.2% lead acetate to dams via the drinking water during lactation for 21 days, while control litters were maintained on tap water. In order to evaluate whether the effects of postnatal lead exposure were selective for hippocampal zinc pools, the hippocampus was compared with the cerebellum in rats 30 and 90 days of age. There were no significant differences noted in total zinc levels in either the hippocampus or the cerebellum after postnatal lead exposure. Furthermore, no differences in the subcellular distribution of zinc were observed between control and lead-treated animals. Since the effects on zinc levels may be more subtle, the amounts of cytosolic zinc-binding species, isolated using Ultrogel AcA 34 gel permeation chromatography, were measured in control and lead-treated animals. In a previous study, we established that cytosolic zinc in the hippocampus was bound to three zinc-binding species. In this study, we determined whether postnatal lead exposure would specifically alter any of these cytosolic zinc pools. A striking decrease was observed in the amount of zinc associated with one of the cytosolic zinc-binding species, a putative zinc-glutathione complex (1.04 $\pm$ .27 ug zinc/g tissue in controls v.s. .61 $\pm$ .13 ug zinc/g tissue in lead-treated animals, $p < .01$). This effect was observed only in the hippocampus of 30 day old lead-treated rats. By 90 days of age, the effect was no longer present. The specific zinc pool affected constituted only 10 to 15% of the total zinc found in the hippocampus. Therefore, by virtue of its small contribution to total hippocampal zinc, a large decrease in this specific pool resulted in undetectable changes in both total and cytosolic zinc levels. These data suggest that lead preferentially affects a zinc pool found in the hippocampus and supports our hypothesis that postnatal lead exposure results in an alteration in zinc metabolism.

274.9 CATECHOLAMINERGIC PROPERTIES OF NEURONS AND PREGANGLIONIC AXONS IN THE RAT CILIARY GANGLION. Story C. Landis, Patrick C. Jackson and John R. Fredieu*. Dept. of Neurobiology, Harvard Medical School, Boston, MA 02115.

Neurons in the ciliary ganglion provide cholinergic innervation to the intrinsic muscles of the eye and are in turn innervated by cholinergic preganglionic neurons. In the irides of rats sympathectomized at birth with multiple injections of 6-hydroxydopamine (6-OHDA), we observed an extensive plexus of fibers that were weakly immunoreactive for tyrosine hydroxylase. Since ciliary neurons represent one possible source of these fibers, we examined the ciliary ganglion of normal rats and of rats treated as neonates with 6-OHDA for certain catecholaminergic properties: tyrosine hydroxylase- and dopamine-B-hydroxylase-like immunoreactivity (TH-IR and DBH-IR) and catecholamine (CA) histofluorescence.

TH-IR was present in 10-50% ciliary neurons in normal adult rats. After acute surgical superior cervical ganglionectomy, TH-IR could be detected not only in ciliary ganglion perikarya but also in restricted axonal arbors in the iris. Ciliary neurons did not exhibit detectable DBH-IR or CA fluorescence. Parasympathetic neurons in the sphenopalatine, submandibular and cardiac ganglia of normal rats were not TH-IR. In animals that had been treated as neonates with 6-OHDA, there was an increase both in the number of neurons in the ciliary ganglion that were TH-IR (up to 75%) and in the intensity of the immunofluorescence in many cells.

In addition to the presence of TH-IR in the ciliary neuron perikarya, many cell bodies were surrounded by TH-IR fibers. The fibers were present in normal rats, in rats surgically sympathectomized and examined 4 days later and in rats chemically sympathectomized at birth and examined as adults. Ultrastructural examination of TH immunoperoxidase material disclosed labelling of many preganglionic synapses. The synaptic terminals in the ganglion possessed obvious CA fluorescence, but no detectable DBH-IR or small granular vesicles after permanganate fixation. The presence of prominent pericellular CA fluorescence made it difficult to determine unequivocally whether ciliary neuron perikarya possessed any CA fluorscence.

Our studies to date indicate that some ciliary neurons in normal adult rats have TH-IR while other parasympathetic neurons do not. Further, they suggest that the level of TH-IR can be influenced by sympathectomy. In addition, many preganglionic axons contain TH-IR and catecholamine, probably dopamine. Studies are in progress to examine further the developmental and functional significance of the presence of catecholaminergic properties in these parasympathetic neurons and their preganglionic input. Supported by NINCDS and the American Heart Association.

274.10 ^{3}H-NOREPINEPHRINE UPTAKE AND CATECHOLAMINE CONCENTRATIONS IN DEVELOPING CHICK HEART FOLLOWING 6-HYDROXYDOPAMINE TREATMENT. D.E. Stewart and M.L. Kirby. Department of Anatomy, Medical College of Georgia, Augusta, GA 30912.

Developing sympathetic nerves first reach the heart of the embryonic chick on incubation days (ID) 10-11. Sympathetic cardiac innervation is not complete until after hatching (ID 21). Previous work has revealed that 6-hydroxydopamine (6-OHDA) treatment is effective in reducing neuronal ^{3}H-norepinephrine (^{3}H-NE) uptake in chick atria as early as ID 12. Furthermore, ingrowth of new adrenergic fibers occurs rapidly (between 24-72 hours following 6-OHDA). Daily treatment with 6-OHDA during the latter part of embryonic development is necessary to produce a maximal lesion. To achieve a maximal lesion using 6-OHDA to destroy cardiac sympathetic terminals during development, we administered 6-OHDA (100 mg/kg daily, saline with 0.5 mg ascorbate/ml as vehicle) in ovo by injecting through the airspace onto the inner shell membrane on ID 13-19. ^{3}H-NE uptake assays on chick atria (in vitro) were performed on ID 20. Specific neuronal uptake of ^{3}H-NE was defined as total uptake minus uptake in the presence of desmethylimipramine, a specific uptake blocker. Treatment with 6-OHDA produced a 67% decrease in specific neuronal ^{3}H-NE uptake from saline-injected controls. To correlate cardiac catecholamine concentrations with ^{3}H-NE uptake data, the concentrations (pg/mg tissue) of norepinephrine (NE) and DOPA in whole hearts were determined by high performance liquid chromatography. 6-OHDA treatment produced a statistically significant (53%) decrease in NE concentration in whole hearts compared with saline-treated controls (90 $\pm$ 10 pg/mg versus 190 $\pm$ 10 pg/mg, mean $\pm$ SEM). These same hearts had a 33% increase (not significant) in DOPA concentration (40 $\pm$ 10 pg/mg versus 30 $\pm$ 10 pg/mg). This data indicates that a significant proportion of catecholamines remains in the heart despite 6-OHDA treatment. The source of these catecholamines is thought to be a combination of (1) the few sympathetic nerves remaining in the heart, (2) circulating catecholamines from the adrenal medulla and (3) possibly de novo synthesis within the heart. The inability to completely eliminate ^{3}H-NE uptake in 6-OHDA treated hearts may indicate a population of 6-OHDA-resistant sympathetic nerves or ^{3}H-NE uptake by desmethylimipramine-insensitive cells.

274.11 FORMATION OF PARAVERTEBRAL SYMPATHETIC CHAIN GANGLIA IN CHICK EMBRYOS. J.W. Yip. Dept. of Physiol., Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA 15261.

The formation of the paravertebral sympathetic chain ganglia was investigated using quail-chick chimera. Single segments of quail neural tube with overlying neural crest at stages 11-15 (40-55 hrs) were transplanted homotopically onto chick embryos at similar stages. Transplantations were made at both cervical and thoracic levels. Eighteen embryos were sacrificed at stages 33-38 (7 1/2-12 days), serially sectioned and examined for the presence of quail cells in the paravertebral sympathetic chain ganglia.

Neural crest cells originating from a single segment of transplanted quail neural tube populated several contiguous sympathetic ganglia. The extent of neural crest migration was similar whether the transplantation was performed at stage 11 or 15. Thus, at least within those stages, there does not appear to be any temporal factor which determines which rostrocaudal ganglia are populated by a given segment of the neural crest. There was also no difference in the extent of neural crest migration whether embryos were sacrificed at stage 33 or stage 38. Sympathoblast migration thus appears to be completed by stage 33.

In cervical and thoracic levels, sympathetic ganglia arise largely from neural crest cells of the corresponding levels. Neural crest cells at a particular segment, however, will migrate longitudinally along the neural axis. Neural crest cells originating from a single segmental level migrate on average 2 segments rostrally and 3 segments caudally. Individual sympathetic ganglia of the cervical and thoracic levels may therefore contain neural crest cells that originate from 6 different segments of the neural axis. Whereas the majority of neurons within a particular ganglion arise from the same segment of the neural crest, there are diminishing contributions from progressively more distant segmental levels.

Selective synaptic connections based on the positional attributes of pre- and postsynaptic elements has been suggested in the mammalian sympathetic system and in the innervation of transplanted intercostal muscles by axons of the cervical sympathetic trunk (Wigston, D.J. & Sanes, J.R., Nature, 299:464, 1982). The segmental origin of sympathetic ganglion cells in the neural crest may be a basis for their innervation by preganglionic axons arising from particular levels of the spinal cord.

274.12 CONTRIBUTION OF SYMPATHETIC CARDIAC INNERVATION AND ADRENAL CATECHOLAMINES TO BASAL HEART RATE IN NEONATAL RATS. D.C. Tucker. Preventive Med., Washington Univ. Sch. of Med., St. Louis, MO 63110

Controversy exists about maturation of autonomic controls over the heart in neonatal rodents. Because enhanced sympathetic influence on heart rate was identified in neonatal rats genetically predisposed to hypertension (i.e. SHR rats, Tucker & Johnson in press), tonic sympathetic and parasympathetic controls of the heart during the neonatal period were further investigated. Using a series of selective pharmacological treatments, the present study suggested tonic cardiac control by both sympathetic cardiac nerves and circulating adrenal catecholamines by two days of age.

Rat pups from 26 Sprague Dawley (SD) and 9 Charles River (CR) litters were implanted with subcutaneous silver wire electrodes the day prior to testing. Recordings of ECG were made from freely moving pups at either 2, 5 or 8 days of age. After obtaining a stable baseline heart rate, bretylium tosylate (25 mg/kg) was injected to block release of NE from sympathetic cardiac nerves; pups were then returned to the dam. At 2.5 hours post bretylium injection, heart rate was sampled and the muscarinic receptor blocker atropine methylnitrate (10 µg/kg) was injected. Ten minutes later, the ganglionic blocker hexamethonium bromide (30 mg/kg) was administered to block release of adrenal catecholamines. Finally, the cardioselective β-adrenergic receptor blocker atenolol (1 mg/kg) was injected to directly antagonize chronotropic stimulation of the heart. All pups received this sequence of subcutaneous drug injections.

Heart rate responses were similar in CR and SD pups ($p>.10$). As expected, both basal heart rate and heart rate after autonomic blockade increased with age. Profile analysis indicated a significant contribution of sympathetic cardiac neural stimulation to basal heart rate (i.e. -48 bpm post bretylium treatment; $F(1,25=22.2$ $p<.0001$); the bradycardia was similar at 2, 5 and 8 days. Adrenergic influences of adrenal origin also contributed significantly to basal heart rate at all ages ($F(1,24)=130$, $p<.0001$); the heart rate decrease after hexamethonium injection was greater at 5 days than at 2 days of age (i.e. -56 bpm vs -27 bpm; $F(2,24)=3.41$, $p<.05$). Subsequent direct blockade of β-adrenergic receptors with atenolol further reduced heart rate at all ages ($F(2,24)-3.41$, $p<.0001$). Parasympathetic control was not evident at any age tested ($p>.50$).

These data suggest substantial tonic adrenergic influence on basal heart rate in newborn rats which comprises control by both sympathetic cardiac nerves and adrenal catecholamines.

274.13 REORGANIZATION OF SYMPATHETIC EFFERENT AND SACRAL AFFERENT INPUTS TO PARASYMPATHETIC GANGLIA OF THE URINARY BLADDER IN RESPONSE TO PARTIAL DENERVATION PRODUCED BY INTERRUPTION OF THE SACRAL PREGANGLIONIC OUTFLOW. W.C.de Groat and M.Kawatani*, Dept. of Pharmacology, Univ.of Pittsburgh, Pittsburgh, PA 15261

The urinary bladder (UB) receives an excitatory input from sacral parasympathetic (PSYM) preganglionic axons in the pelvic nerve (PN) and a mixed input from sympathetic (SYMP) efferent pathways in the hypogastric nerve (HGN) including: (1) inhibition of the detrusor muscle via β-adrenoreceptors, (2) inhibition of transmission in bladder ganglia (BG) via α-adrenoreceptors and (3) excitation of the trigone. Both nerves also contain afferent pathways from the UB. Clinical studies have suggested that injury to the PSYM innervation can lead to the unmasking of excitatory SYMP inputs to the UB which contribute to the development of autonomous bladder activity. This possibility was explored in chloralose anesthetized cats subjected to unilateral transection of sacral ventral roots 2-36 weeks before the experiment.

In these cats stimulation (stim) of the normal PN, but not the denervated PN elicited bladder contractions (BC). Repetitive stimulation (10-30 Hz) of the HGN ipsilateral to the denervation (DEN) produced a bimodel BC consisting of a large early contraction (EC) and a small late contraction (LC). HGN-stim on the normal side produced only the EC. The LC, detected 4-30 weeks after denervation, was blocked by atropine (10-20 μg/kg i.a.) but was not changed by α-adrenergic blocking agents (phenoxybenzamine, 0.5 mg/kg or dihydroergotamine, DHE, 0.1-0.5 mg/kg). The EC was not affected by these drugs. HGN-stim on the DEN-side also elicited a discharge in ipsilateral bladder postganglionic nerves (B-PGN) (latencies of 20-30 msec and at thresholds of 1-1.5V). The discharge was blocked by hexamethonium (C_6, 1-10 mg/kg) indicating it was synaptically mediated. HGN-stim at high intensities (7-10 V) on the normal side elicited long latency (80-200 msec) C_6 resistant, axonal volleys in ipsilateral B-PGN. Spontaneous B-PGN firing occurred on the DEN-side only. Stim of DEN-PN (10-20 Hz, 15-20 V) elicited a prolonged (3-5 min) increase in the firing. HGN-stim (10-30 Hz) on the DEN-side depressed the firing. Administration of DHE blocked the HGN inhibition and unmasked an excitatory response. The excitatory effects produced by stimulation of the PN or HGN were not blocked by atropine or C_6. Substance P enhanced and GABA, norepinephrine and leucine-enkephalin inhibited the spontaneous firing.

In summary, interruption of the sacral preganglionic outflow to the UB led to the reorganization of synaptic connections in BG which was reflected in: (1) the appearance of spontaneous firing (2) the formation of sympathetic cholinergic excitatory inputs and (3) the formation of non-cholinergic, non-adrenergic excitatory inputs from afferent axons remaining in the pelvic nerve.

274.14 EXCITATORY EFFECT OF SUBSTANCE P (SP) ON PARASYMPATHETIC GANGLIA IN THE CAT URINARY BLADDER, A.M.Booth, M.Kawatani*, T. Whitney* and W.C.de Groat, Dept. of Pharmacology, Sch. of Med., Univ. of Pittsburgh, Pittsburgh, PA 15261

The urinary bladder receives an afferent and preganglionic efferent innervation from the sacral cord via the pelvic nerve. Several weeks after surgical interruption of the preganglionic outflow in the cat, electrical stimulation of the de-efferented pelvic nerve elicits a prolonged discharge in the bladder postganglionic fibers which is resistant to cholinergic blocking agents. One explanation for these observations is that afferent pathways in the pelvic nerve can excite denervated ganglion cells in the bladder. Since some pelvic afferents contain SP,the present experiments were undertaken to determine whether exogeneous SP would mimick the non-cholinergic excitatory ganglionic response.

In normal ganglia in situ, intraarterial injection of SP elicited bladder contractions (1-10 μg/kg), facilitated postganglionic potentials evoked by pelvic nerve stimulation (0.1-1 μg/kg) and elicited an asynchronous postganglionic discharge (1-10 μg/kg. The SP induced bladder contractions were blocked by the SP-antagonist, D-Pro^2, D-Phe^7, D-Trp^9 -SP (1-5 μg/kg), whereas the ganglionic excitatory effects of SP were blocked by D-Arg^1, D-Pro^2, D-$Trp^{7,9}$, D-Leu^{11}-SP (5-10 μg/kg). The SP antagonists did not alter the ganglionic responses to tetramethylammonium or acetylcholine. SP discharges were not blocked by hexamethonium, atropine, leucine-enkephalin (L-ENK) or norepinephrine (NE) but were blocked by GABA. In denervated ganglia which exhibited spontaneous firing, SP elicited a discharge in lower doses (0.001-0.1 μg/kg). L-ENK, NE and GABA blocked the spontaneous firing but only GABA blocked the responses to SP.

Normal bladder ganglia in vitro, perfused with Krebs-Ringer solution responded to exogenous SP (30-100 μg) injected into the 10 ml tissue bath. With intracellular recording responsive cells were depolarized in a dose dependent fashion 1 to 2 minutes following administration of the drug. The depolarization lasted 2-3 minutes. Microliter quantities of 100 μg/ml SP pressure ejected onto the ganglia produced similar effects. The amplitude of epsp's or intracellular depolarizing current injections necessary to fire the cells was lowered and some cells were sufficiently depolarized to fire repetitively in the absence of any apparent synaptic or intracellular stimulation.

In conclusion, exogenous SP produces non-cholinergic excitation in the normal and parasympathetically denervated bladder ganglia. The effect of SP is mediated by depolarization of the ganglion cells. Further experiments will be required to determine whether SP is the mediator of spontaneous and pelvic nerve evoked non-cholinergic firing in denervated ganglia.

DEVELOPMENTAL DISORDERS

275.1 COBALT FOCAL EPILEPSY IN INFANT RATS. G. T. Golden, R. G. Fariello, P. F. Reyes*. Dept. of Neurology and Research Jefferson Medical College, Philadelphia, PA 19107 and VA Medical Center, Coatesville, PA 19320.

The occurrence of severe epileptic seizures early in life can lead to neuronal loss and impairment of brain development. In this study we have attempted to produce a chronic model of focal epilepsy in infant rats. Subdural placement of a cobalt powder-agar plug was performed on infant Long Evans hooded rats at six days of age. The cobalt powder was mixed with agar and saline and the resulting plug (1.5 mm) was placed overlying sensorimotor or parital cortex. Regular electroencephalographic recordings through scalp needles were conducted on a weekly basis until the rats reached adulthood. At the first EEG recording session (14 days of age) electrographic abnormalities were observed. Electrographic activity was characterized by a paucity of interictal spikes. Eighty percent of the animals presented ictal discharges, in the form of burst of polyspikes or spike and wave complexes, not dissimilar in their morphology from the discharges that have been observed in naive rats and interpreted by some investigators as normal EEG variants of sleep activity. Ictal discharges were longer lasting and appeared more frequently in cobalt treated rats. Aside from facial myoclonus, no behavioral convulsive seizures were observed. In general the neonatal brain of the rat seems to be more refractory to the epileptogenic action of cobalt than the adult brain. Histopathological features of the cobalt lesions will be described and compared to lesions seen in adult rats.

275.2 PRENATAL METHYLAZOXYMETHANOL(MAM) TREATMENT PRODUCES SPONTANEOUS HYPERACTIVITY IN NEONATAL AND ADULT RATS. P.R. Sanberg, T.H. Moran*, K.L. Kubos*, P.G. Antuono* and J.T. Coyle. Depts. of Neuroscience and Psychiatry, Div. of Child Psychiatry, Johns Hopkins Univ. Sch. Med., Baltimore, MD 21205 and Dept. of Psychology, Ohio Univ., Athens, Ohio.

Administration of the antimitotic agent MAM to rats on day 15 of pregnancy produces a marked hypoplasia of the telencephalon in the offspring with a resulting hyperinnervation of ascending neurotransmitter systems to the forebrain (Johnston and Coyle, J. Neurochem. 34:1429,1980). The present study examined the pattern of spontaneous locomotion in these MAM lesioned rats.

Pregnant rats were injected i.p. with 20 mg/kg of MAM on day 15 of gestation; control rats were injected with saline. The offspring of both groups were subsequently placed at various ages into computerized Animal Activity Monitors (Omnitech Electronics) and tested over a 24-hour period. These monitors provided detailed information of the animals' pattern of locomotion using 21 different variables measuring activity in the horizontal and vertical planes. A repeated measures ANOVA was used to analyze the statistical significance of the data.

The results demonstrated that, compared to controls, the MAM-lesioned rats exibited significant increases in nocturnal locomotor behaviors beginning at 10 days old and continuing into adulthood. The pattern of this nocturnal hyperactivity in adults was demonstrated by significant increases in total distance traveled, excursions around the walls of the apparatus, stereotypic and vertical movements. The amount of time moving in the horizontal plane, however, did not differ between groups, reflecting that a significantly greater average speed was exhibited by the MAM lesioned animals.

These findings suggest that rats with forebrain microencephaly induced by prenatal treatment of MAM may provide a useful model for hyperkinesis in humans which is also correlated with a significantly higher rate of cerebral atrophy (Nostralla et al, Soc. Bio. Psychiat. Abstr.,42,1983). Furthermore, it is likely that the hyperinnervation of catecholaminergic terminals within the cortex of MAM lesioned rats may mediate this spontaneous hyperactivity. Supported by MH26654, the Pratt Family and Friends HD grant, and the Tourette Syndrome Association.

275.3 DEFICIENCY OF D-AMINOACID OXIDASE (DAAO) IN THE REELER MOUSE. J. Vamecq , A. Goffinet & F. Van Hoof (SPON: M. David-Remacle) Université catholique de Louvain and I.C.P., UCL 75.39, B-1200 Brussels Belgium.

The function and cellular localization of DAAO remains largely controversial. In mice, the only organs where this enzyme displays a significant activity are the cerebellum, brain stem, jejunum and kidney cortex. In the latter organ it has been located in the peroxisomes. In the cerebellum, DAAO is associated with sedimentable particles which lack the other peroxisomal oxidases (Gaunt, G.L. & de Duve, C., J. Neurochem., 26:749, 1976). In the cerebellum of 20 homozygote reeler mice (agranular mutants), DAAO activity assayed with 0.1 M D-proline represented 40.5 ± 6.7% (standard deviation) of matched control mice, and in the kidney, 54 ± 8. There was no overlapping value between normal and reeler mice. A similar deficiency of DAAO was found with D-alanine and D-valine as substrates. Control enzymes (ß-hexosaminidase, sulfatase C and cytochrome c oxidase) were normal in both organs from reeler mice. In the kidney and in the liver, catalase activity was also normal.

The probability that cerebellar DAAO belongs to the granule cells is stressed by experiments with methylazoxymethanol according to J. Slevin et al. (Dev. Neurosci. 5:3, 1982). When this alkylating agent is injected intraperitoneally to normal new-born mice it prevents multiplication of granule cells and affects drastically the appearance of DAAO activity (50-fold less than controls on day 21). Kidney DAAO and control enzymes in both organs are unaffected by this treatment.

In the mutant, deficiency of cerebellar DAAO probably reflects the scarcity of granule cells but this provides no explanation for the lesser activity of DAAO in kidney. The biochemical observations could be reconciled if two or more isoenzymes contributed to the DAAO activity; the reeler mutant could then be characterized by the absence of the major cerebellar isoenzyme.

This work was supported by NIH Grant 9235, the Belgián F.R.S.M. and F.N.R.S, Crédit au Chercheur 1.5.598.83F. J. Vamecq is ICP-fellow.

275.4 EARLIER IS WORSE: BEHAVIORAL, ANATOMICAL AND ELECTROPHYSIOLOGICAL DIFFERENCES BETWEEN EARLY AND LATE POSTERIOR PARIETAL INJURY IN RATS. B. Kolb, C. Holmes* and I.Q. Whishaw. Dept. of Psychology, University of Lethbridge, Lethbridge, Alberta,Canada, T1K 3M4

Rats with removal of the posterior parietal cortex (area 7) in adulthood were compared behaviorally, anatomically, and electrophysiologically to rats with similar removals at 1 or 5 days of age. Ablations in adulthood impaired foot placing on a narrow beam and retarded the learning of the position of a hidden target in the Morris water task. Use of the forepaws during feeding, puzzle latch opening, grooming, tongue use, food hoarding, and learning of a radial arm maze was normal. In contrast, infant operates were impaired at nearly every test administered. There was no evidence of any sparing of function and the youngest operates were worst of all on many tests.

Examination of cerebral weight, neocortical thickness, cross-sectional cortical area, barrel field and thalamic organization showed that although the neonatal operates had much smaller areas of cavity, they had significantly smaller brains, the posterior cortex was abnormally thin, the barrel fields were abnormally organized and the thalami were shrunken and abnormally formed. The extent of the abnormalities were far worse in the 1 day than in the 5 day operates, although both groups differed from the adults. Electrophysiological studies showed that cortical and hippocampal atropine-resistant and atropine-sensitive EEG in freely moving animals was normal in all groups in spite of the anatomical abnormalities. The results of stimulation of the motor cortex in acute preparation shall also be reported.

The results suggest that early brain damage may have greater effects upon the animal than similar injury in adulthood. Early injury appears to prevent the development of some behavioral capacities that an equally extensive injury at maturity would not have destroyed, behavioral effects that are correlated with abnormal cortical and subcortical morphogenesis. These results provide the evidence in support of Hebb's prediction in 1949 that early brain damage should have far more deleterious effects upon brain and behavior than similar injury at maturity.

275.5 THE EFFECTS OF PERINATAL CHLORPROMAZINE ADMINISTRATION ON CEREBELLAR MONOAMINES IN THE ADULT RAT. R.S. Hannah*, D. Parkinson , A.W. Spira and S.H. Roth. Depts. of Anatomy and Pharmacology and Therapeutics, University of Calgary, Calgary, Alberta, Canada. T2N 4N1.

Previous studies have established that perinatal chlorpromazine (CPZ) administration produces both a reduction in Purkinje cell number and chronic alterations in Purkinje cell dendritic architecture. Since the monoamine system in the cerebellum has been suggested to possess some inductive properties during development, an attempt was made to examine its status in perinately CPZ treated, mature animals. CPZ (15 mg/Kg) was administered intramuscularly to timed pregnant Long-Evans rats beginning on day 18 post coitus. Maternal CPZ or normal saline administration was continued on a once daily basis until day 21 postnatal.

Animals were allowed to eat and drink ad libitum. At birth, the litter size was culled to eight pups to negate any intra-litter nutritional variation based on unequal litter size. The animals were sacrificed at six months of age, and the cerebella removed. Two histochemical methods were utilized to examine the monoamine fiber distribution; these were the fluorescence histochemical formaldehyde method of Falck and Hillarp (J. Histochem. Cytochem. 10: 348-354, 1962) and the glyoxylic acid fluorescence histochemical method of Lindvall and Bjorklund (Histochem. 39: 97-127, 1974). High pressure liquid chromatography with electrochemical detection (HPLC) was used to measure cerebellar levels of noradrenaline, dopamine and serotonin.

Both histochemical fluorescence methods demonstrated the following alterations in the treated animals: a paucity of fluorescent axon terminals in the molecular layer, a concentration of fluorescent axon terminals in juxtaposition to the basal region of the Purkinje cell body and numerous fluorescent axon terminals in the granule cell layer. Monoamine levels as measured with HPLC demonstrated a statistically significant reduction in noradrenaline, dopamine and serotonin in the treated animals. The most severe reduction, approximately 35%, occurred with serotonin, with noradrenaline and dopamine reduced by approximately 20%. These results suggest that perinatal CPZ administration produces chronic alterations in the cerebellar monoamine system.

(Supported by MRC, Canada, and Alberta Mental Health).

275.6 ECTOPIC NEURONS IN THE BRAIN OF THE AUTOIMMUNE MOUSE: A NEUROPATHOLOGICAL MODEL OF DYSLEXIA? G.F. Sherman, A.M. Galaburda, and N. Geschwind. Department of Neurology, Beth Israel Hospital and Harvard Medical School, Boston, MA.

The brain in developmental dyslexia has been found to be structurally abnormal (Drake, J. Learn. Dis., 1:9, 1968); Galaburda and Kemper, Ann. Neurol., 6:94, 1979). Micropolygyria, abnormal cytoarchitecture (especially in the language regions), and ectopic neurons in cortical layer I were seen in the left hemisphere. Recently, Geschwind and Behan (PNAS, 79:5097, 1982) have found a relationship among developmental learning disabilities (including dyslexia), lefthandedness, and autoimmune disease. Since autoimmunity and dyslexia cluster in lefthanded individuals and their families, it was decided to examine an experimental animal that develops spontaneous autoimmune disease for the presence of brain abnormalities that might be similar to those seen in the human dyslexic brain.

We examined the brains of the New Zealand Black (NZB) mouse and its F1 hybrid (NZB/W). Six 30-day old NZB, six NZB/W, and six C57Bl/6J control brains were examined. An additional six NZB/W brains were examined at 90 days of age. The groups included both males and females. The animals were perfused with 10% formalin, the brains were removed, and after fixation were embedded in cellodin. They were then coronally sectioned at 30 micrometers and every fifth section was stained with cresylechtviolett for Nissl substance.

Ectopic collections of neurons were present in layer I of the cerebral cortex in four of the 30 day-old New Zealand mouse brains. The 90 day-old and control brains showed no abnormalities. Three of the abnormal brains had unilateral ectopic cells and one had a bilateral accumulation which was more severe on one side. There were also subtle distortions in the underlying cortical architecture. The abnormal brains were distributed equally over sex and three of the four brains were from the NZB strain. The two largest collections of ectopic neurons were present in the right hemisphere at the border between the primary and secondary somatosensory cortices.

We hypothesize that an immune-mediated process may be the cause of the abnormal neuronal migration that results in heterotopias in both the human dyslexic and NZB mouse. The NZB mouse provides an experimental model in which to explore this question. (Supported by NIH grants 14018 and 07211).

275.7 HYPERACTIVITY RESULTING FROM NEONATAL INFECTION WITH A HOST RANGE MUTANT HERPES SIMPLEX TYPE 1 VIRUS. L. S. Crnic, L. J. Yamamoto,* and L. I. Pizer*. Departments of Pediatrics, Psychiatry and Microbiology, University of Colorado School of Medicine, Denver, CO 80262.

Balb/c mice were injected subcutaneously with 10^6 plaque forming units of a host range mutant herpes simplex type 1 virus in the first day of life. The mutant had been selected to grow on primate but not mouse cells in vitro and so produced a mild infection in the neonatal mice. Control groups were either injected with the vehicle (media and cell fragments) or not manipulated. Mice were sacrificed at 3, 7, 14, 21, 28 and 60 days for determination of brain virus titers. At the latter 3 time points, open field activity was measured in an automated open field before sacrifice. Mice allowed to grow to adulthood were tested on step down passive avoidance learning and spatial discrimination learning in a radial arm maze.

Virus was evident in the brains by 3 days, reached peak titers of 2.9×10^3 plaque forming units per brain by 21 days, and viable virus was not detectable at 60 days in most brains. Small brain and body weight deficits were apparent throughout development in the virus-treated mice but were gone by adulthood. Hyperactivity in the virus-treated mice consisted of high activity levels throughout development and a failure to decline to adult levels by 60 days of age, even though no virus was detectable in most brains at that age. At 60 days of age, the infected mice crossed an average of 144 $\pm$ 34 squares while the vehicle group crossed 76 $\pm$ 26 and the controls 67 $\pm$ 37 squares in the open field. Prior studies have shown the hyperactivity to persist into adulthood in the absence of infectious virus. The adult mice also showed deficits in passive avoidance learning (7.25 $\pm$ 2.49 trials to criterion for infected versus 4 $\pm$ 0.35 for control), although their performance on a radial arm maze was not impaired, indicating that the passive avoidance learning deficit was probably not due to a learning deficit but rather difficulty in inhibiting behavior.

This sort of virus infection is a potential cause of the specific behavioral disorders of childhood. In addition, the selective destruction of brain areas by mild virus infections could be a useful tool for the study of brain function.

275.8 DEVELOPMENTAL DYSLEXIA: THIRD CONSECUTIVE CASE WITH CORTICAL ANOMALIES. A.M. Galaburda, G.F. Sherman and N. Geschwind. Department of Neurology, Beth Israel Hospital and Harvard Medical School.

Developmental dyslexia is a now widely recognized learning disability in which there is primarily a difficulty in the acquisition of reading and writing. Three consecutively-studied brains of dyslexics have shown cortical anomalies. The first, reported by Drake (J. Learn. Dis., 1:9, 1968), showed abnormal gyral folding and excessive numbers of ectopic white matter neurons. These were found in the parietal lobes bilaterally. Portions of the corpus callosum were thought to be thin. There was an associated cerebellar angioma that had bled. The second case, published by Galaburda and Kemper (Ann. Neurol., 6:94, 1979) exhibited cortical and subcortical heterotopias, micropolygyria, and abnormal cortical lamination in the left hemisphere. These anomalies were found in the cingulate gyrus and perisylvian cortex, and the micropolygyria occupied most of the left planum temporale. We report here the third case, that of a 14 year-old dyslexic boy with a positive family history of dyslexia. The brain weighed 1597 gm (large) after formalin fixation. It was embedded whole in cellodin and cut in gapless serial histological sections. Every 20th section was stained for Nissl and the adjacent section for myelin. The sylvian fissures and planum temporale were approximately symmetrical. There were a multitude of focal accumulations of ectopic neurons in layer I of the cortex of the left cerebral hemisphere only. They involved all lobes, but predominantly perisylvian regions. No micropolygyria was seen. The cortical architecture in neighboring areas showed laminar disorganization and primitive features. These consisted of poor delineation of laminae, relative curtailment of granular layer IV, paucity of neurons in layer III and large pyramids in layers V and VI showing random orientation.

Geschwind and Behan (PNAS, 79:5097, 1982) have found a relationship among developmental learning disabilities (including dyslexia), lefthandedness, and autoimmune disease. The NZB and NZB/W immune mice have shown mainly unilateral clusters of ectopic cells in layer I similar to those found in the two dyslexic brains studied by us. We postulate that the cortical abnormalities seen in the dyslexic brains and NZB mice may result from an alteration of the immune process during the late stages of neuronal migration.

275.9 PHYSIOLOGICAL AND BEHAVIORAL EFFECTS OF PREGESTATIONAL ADMINISTRATION OF MORPHINE TO MALE RATS Sarah C. Lantz* and Robert A. Jensen. Developmental Biopsychology Laboratory, Southern Illinois University, Carbondale, Illinois 62901.

In recent years an extensive body of information has been gathered on the consequences of female exposure to drugs and other agents both prior to and during gestation. Some literature also suggests similar consequences following male exposure to various agents. However, little systematic investigation of this finding has been carried out. Some chemical agents may affect aspects of male reproductive function and also the development of offspring.

Friedler (Fed. Proc., 1974, 33, 515) reported that morphine administered to male mice prior to mating produced offspring with lower birth weights than controls. In that study, male animals were withdrawn from the drug for five days prior to mating and females were drug free throughout the procedure. The present research was designed to determine whether pregestational administration of morphine to male animals produces teratogenic effects. In this research we investigated both physiological and behavioral parameters.

Twenty-seven male Long Evans rats (13 morphine, 14 saline) between 90 and 150 days of age were injected (s.c.) on a five-day schedule. On Day 1, each animal received a 10.0 mg/kg injection of morphine sulphate or saline control. On Days 2 through 5, each animal received both a morning and an evening injection with an increase of 2.5 mg/kg per injection. Following the last injection males were withdrawn for 5 days. They were then placed in mating cages with estrus females for 5 days. At birth, pups were culled to 6-8 per litter. Animals were weighed on Days 1, 4, 6, 8, 12, 16, 20, and post-weaning. Free-fall righting was tested on Day 1, negative geotaxis on Day 4, inhibitory avoidance on Days 24 and 25, active avoidance on Days 26 and 27, mother-pup interaction by a pup retrieval task and nest building. No significant differences in free-fall righting, visual placing, or in the mother-pup interactions were observed. Morphine-sired pups performed significantly poorer on the negative geotaxis test, an indication of delayed nervous system development. On Day 15, mophine-sired pups were significantly more active. Additionally, these animals performed significantly better in retention of an inhibitory avoidance task and in acquisition of an active avoidance task. In summary, lower weights, deficits in the negative geotaxis reflex, altered activity levels, and altered performance in two learning tasks indicate that pregestational administration of morphine to males may affect their offspring.

275.10 UNILATERAL CEREBRAL ANOXIC/ISCHEMIC DAMAGE IN NEWBORN RATS INCREASES HYPERTHERMIA-INDUCED SEIZURE SENSITIVITY. J. Olson and D. Holtzman. Dept. of Psych. and Neurol., Tulane University School of Medicine, New Orleans, LA 70112.

Unilateral ligation of the carotid artery combined with exposure to a hypoxic environment produces neuronal necrosis and gliosis ipsilateral to the ligation in adult (Levine S, Am J Pathol 36:1, 1960) and in seven-day-old rats (Rice et al., Ann Neurol 9:131, 1981). We have extended this model of hypoxic/ischemic brain damage to two-day-old animals in order to study the mechanism(s) responsible for the increased frequency of febrile seizures which often accompany the pathologic sequelae of neonatal cerebral ischemia.

Two day old Sprague-Dawley rat pups were anesthetized with Ketamine and immobilized on a 37°C heating pad. A partial thymectomy was performed followed by exposure of the common carotid artery between the sternohyoid and sternocleidomastoid muscles. A #8-0 silk suture was passed under the artery and tied tightly. Following recovery from anesthesia, the animals were placed in 100% humidified N_2 at 37°C for up to 40 min. The animals were allowed to recover before returning to the dam. Some pups were given sham operations or were exposed to anoxia without carotid ligation.

All of the ligated animals exposed to 40 min of anoxia died within 24 hrs while less that 25% of the animals exposed to 30 min of anoxia died during this period. No animals died following anoxia exposures of 15 min or less. At 5 and 10 days of age a seizure was induced by hyperthermia in ligated-anoxia-exposed animals and control litter mates. At 5 days of age the seizure temperature threshold (STT) was not significantly different in experimental compared to control animals (mean $\pm$ SEM = 42.8 $\pm$ 0.2°C for experimental animals, 42.8 $\pm$ 0.1°C for controls). At 10 days of age the STT was significantly lower for animals exposed to 30 min of anoxia after carotid ligtion (mean $\pm$ SEM = 43.5 $\pm$ 0.2°C for experimental animals, 44.5 $\pm$ 0.1°C for controls, $p<0.001$). The STTs of sham-operated animals and of animals exposed to anoxia alone were not different from controls.

The data indicate that brain damage produced by anoxic/ischemic exposure in neonatal rat pups produces increased sensitivity to hyperthermia-induced seizures in later life. This may provide a relevant model of febrile seizures in brain-damaged children.

This research was supported by grants to D. Holtzman from the NIH (NS16256) and the Cerebral Palsy Foundation.

275.11 BEHAVIORAL THERMOREGULATION IN THE DEVELOPING TWITCHER MOUSE. Charles E. Olmstead, UCLA, School of Medicine, Mental Retardation Research Center Group at Lanterman State Hosp., Pomona, CA 91769

The mutant twitcher mouse (B6.CE/twi) which was first described by Duchen et al. (Brain 106, 1980) is an enzymatically authentic (Kobayashi, et al. Biochem. Med. 27, 1982) model of the recessively transmitted Globoid cell (Krabbe's) leukodystrophy, a demyelinating disease of infantile onset. Clinical records of patients often show exaggerated swings in body temperature in the middle and late stages of this severe deymyelinating disease. Although we have no reason to suspect that a thermoregulatory defect plays a role in the pathogenesis of globoid cell leukodystrophy we were interested in determining the extent of the regulatory problem and whether it might be apparent prior to the other manifestations of the disease. The specific enzyme deficit in both the human and the twitcher mouse is galactosylceramidase and affected, carrier and normal individuals can be determined by enzyme assays done on clipped tail. The studies reported here were carried out to 1) develop a better understanding of the developmental pathophysiology of this demyelinating disease and 2) to develop non-invasive methods for evaluating treatment regimens as they are developed.

Thermal gradient. The thermal gradient, modeled after Ogilvie and Stinson (Canad. J. Zool. 44, 1966) and Satinoff et al. (Science 193, 1976), consisted of a 120 x 15cm aluminum plate with one end coupled tightly to a laboratory hotplate and the other immersed in ice. The gradient remained stable at between 15 and 40°C for up to 8 hours with only occassional replenishment of ice. Over the ages from 2 to 20 days of age mice in groups of 3 to 5 were placed randomly on either the warm or cold end of the gradient and their movements and postures noted for 3 hours. Usually the final position of individual mice on the gradient was stable for the last hour of observation.

Enzyme assays. Following the final trial, 0.5cm lengths of tail were clipped and galactosylceramidase was determined by an assay adapted from Suzuki (Meth. Enzymol. 50, 1978). Affected homozygous animals were readily identified prior to the onset of physical symptoms.

Mice from litters containing only heterozygotes and homozygously normal animals huddled together at progressively cooler portions of the gradient as a function of age. Mice from litters containing homozygously affected animals showed a much wider dispersion over the entire gradient and those with the lowest enzyme levels, who subsequently developed the disease, were concentrated at the colder extremes of the gradient. Although there was considerable between litter variability, at risk mice were easily distinguished from heterozygotes and normals within the litter as early as eight days of age on the basis of position. These data suggest that there may be an early thermoregulatory deficit in the twitcher mouse.

275.12 LOCOMOTOR DEVELOPMENT IN THE TWITCHER MOUSE. Richard Sugerman and Charles E. Olmstead. UCLA, School of Medicine, Mental Retardation Research Center Group at Lanterman State Hosp., Pomona, CA 91766.

The mutant twitcher mouse (B6.CE/twi) which was first described by Duchen et al. (Brain 106, 1980) is an enzymatically authentic (Kobayashi, et al. (Biochem. Med. 27, 1982) model of the recessively transmitted Globoid cell (Krabbe's) leukodystrophy. The specific enzyme deficit is galactosylceramidase, and affected and carrier individuals can be determined by enzyme assay done on clipped tail. The studies on the development of locomotor behavior reported here were carried out to 1) develop a better understanding of the functional pathophysiology of this demyelinating disease and 2) to develop non-invasive methods for evaluating treatment regimens.

Enzyme assays. At between 10 and 15 days of age, 0.5cm lengths of tail were clipped and galactosylceramidase was determined by an assay adapted from Suzuki (Methods Enzymology 50, 1978). Affected homozygous animals were readily identified prior to the onset of physical symptoms.

Gait development. Beginning at 12 days of age mice were placed twice daily onto a well-inked and brightly lit stamp pad and encouraged to run across an 8.5 x 11 inch sheet of paper to a darkened receptacle. The resultant footprints were analyzed on a digitizing tablet for step length and width and angles between fore and hind paws (Schallert et al. Science 199, 1978; Hruska et al. Life Sci. 25, 1979). All mice showed an increase in running speed and length and width of step across 15 to 30 days of age. Affected mice were not distinguishable from normals, on the basis of gait, until after 25 days of age at which time a broadening of the distance between the rear foot prints is seen. This initial symptom was followed by a blurring of discrete digit prints by 30 days of age through limb dragging to a cessation of locomotion by 35-40 days of age. In all cases the hind limbs were affected prior to the front. All animals died in the 7th or 8th week of life.

Open field. In a 50 x 25cm open field normal mice showed characteristic changes in behavior as a function of age and experience. Affected twitcher mice showed normal patterns of locomotion, exploration, rearing and grooming into the 4th week of life. As the locomotor changes occurred parallel changes were seen in the open field behavior, with rearing, exploration and locomotion disappearing in that order. Area grooming, which in normal mice developed in a rostral-caudal direction from face to body to tail, was arrested at the body stage in the 5th week and reduced to vestigal facial swipes by 35-40 days of age.

These data demonstrate that despite the enzyme defect the twitcher mouse shows normal functional development well into the 3rd and 4th weeks of life.

275.13 A BIOCHEMICAL STUDY OF THE EFFECT OF HYPOXIA ON CEREBELLAR DEVELOPMENT. M.C. Yu* (SPON: J. McArdle). Dept. of Anatomy, New Jersey Medical School, Newark, New Jersey 07103.

A study was made to determine the effect of hypoxia on the biochemical maturation of the rat cerebellum. Five-day old rats (Sprague-Dawley strain) were culled into 8 pups per dam, and placed into an hypoxic chamber where they were exposed for 7 consecutive days to a low oxygen environment of 10% O_2 and 90% N_2. During the period of hypoxia, the pups were taken out of the chamber twice daily at 9:00 AM and 4:00 PM for supplemental feedings with an enriched liquid diet in order to circumvent malnutritional factors due to decreased milk production by the dams. For control, another group of rats, also culled to 8 pups per litter, were exposed to ambient air only and nursed by their dams. On postnatal day 12, one week after the hypoxic exposure, all the rats were taken out of the chamber. One group of rats was killed immediately while the other groups were cross-fostered by other, normal lactating dams, and killed at postnatal days 17, 22, 40 and 90, respectively. At day 12, the cerebellar weight of the hypoxic rats was 45% of the control, and was 68, 77, 86 and 85% of the control group, at 17, 22, 40 and 90 days. The total contents of DNA, RNA, protein and cerebroside of the hypoxic rats at day 12 were 54, 50, 42 and 35% of the control, respectively. These values, with the exception of protein, lagged significantly behind the control throughout the experimental periods, so that at day 90, the contents of DNA, RNA, and cerebroside of the hypoxic rats were 83, 75 and 72% of the control. The protein contents of the hypoxic rats reached to 62, 90, 92 and 108% of the control at 17, 22, 40 and 90 days, respectively. These data suggested that hypoxia, imposed during the period of rapid neurogenesis (production of microneurons), caused a permanent cell deficit in the cerebellum as indicated by the reduction in DNA content. The process of myelination also appeared to be interfered with.

275.14 AGE AND MUTATION DEPENDENT CHANGES IN MYELIN MBPs. S. Greenfield#, E. L. Hogan, G. Gantt#, M. J. Weise#, S. W. Brostoff#. Dept. of Neurology, Med. Univ. So. Carolina, Charleston, SC 29425.

The immunoblot technique was used to identify myelin basic proteins (MBPs) in myelin and homogenates of sciatic nerve and brain from young and adult normal and mutant (qk, jp, msd) mice. Proteins were detected with anti-MBP serum following electrophoretic transfer from slab gels (modified from the system of Swank and Munkres). Using this gel system which resolves the 18.5K MBP into 18K and 18.5K components, we were able to detect differences in the basic protein composition of adult CNS and PNS myelin. A protein doublet was seen in the 21.5K region of PNS myelin which appeared as a single band in CNS myelin. An 18K basic protein was present in CNS myelin, which was absent in PNS myelin. The 17K basic protein in PNS myelin can be resolved into two distinct protein bands. Two basic protein bands migrating between 18.5K and 21.5K were seen in CNS homogenates of young qk mice but not in normal mice. The PNS basic protein compositions of qk, jp, and msd mice appeared qualitatively but not quantitatively similar to normal control mice. During development, the 18K CNS MBP appeared prominently during the active phase of myelinogenesis. At 10 and 15 days of age the 14K MBP in brain homogenates contains both 14.4K and 14.8K components while at later ages only the 14.4K MBP persists. Supported in part by NIH grants NS 12044 and NS 11867.

276.1 DEVELOPMENT OF GABAergic NEURONS IN PRIMARY CULTURES OF RAT RETINA: COMPARISON OF NEURONAL AND MIXED CULTURES. I. Pech* and P.V. Sarthy (Spon: T. Kennedy). Depts. of Physiol. & Biophys, & Ophthalmology, University of Washington, Seattle WA 98195.

In a previous report, we described conditions which allowed for survival of primary cultures of dissociated embryonic rat retinal neurons for 1 mo in culture in the virtual absence of glial (flat) cells [Soc. Neurosci. Abst. 8:49.4, 1982]. These cultures developed the ability to synthesize GABA from glutamate, to release GABA in a K^+-stimulated, Ca^{2+}-dependent manner, and to take up GABA via both high and low affinity uptake systems.

We now report that, by growing the cells in bicarbonate-containing medium in a 5% CO_2 atmosphere, one can obtain cultures containing both retinal neuronal and glial cells (mixed cultures). Under these conditions, the initial morphology is quite different than in the neuronal cultures. In the latter, the cells grow individually and begin to show some extension of neurites as early as 1 d.i.v. In the mixed cultures, the cells exist in undifferentiated clusters for the first week in culture. Towards the end of this time, one can begin to distinguish the flat cells from the neurons and, with increasing time thereafter, the cells acquire their mature appearance. The flat cells spread out as thin sheets on the surface of the dish, and the neurons grow on top of them. Although many more neurons attach and grow in the mixed cultures than in the neuronal cultures, the total survival time is similar in both conditions. Few neurons survive beyond 1 mo in culture, but the flat cells can be maintained for 2 mo or more.

The parameters of GABA function which were examined in the neuronal cultures were also examined in the mixed cultures. During the first week, when the cells existed in undifferentiated clusters, GABA synthesis, GAD activity and K^+-stimulated, Ca^{2+}-dependent GABA release remained low. Thereafter, they rose rapidly to reach a peak after 2 wk. GABA uptake, as measured biochemically, began to rise after 4 d.i.v. and peaked at 12 d.i.v. As in the neuronal cultures, uptake was seen to be energy-, temperature- and Na^+-dependent and to be blocked by 1 mM GABA, DABA and nipecotic acid. 1 mM β-alanine blocked uptake to a far greater extent in the mixed than in the neuronal cultures. Kinetic studies demonstrated the presence of both high and low affinity uptake systems for GABA uptake. With light microscopic autoradiography, little GABA uptake could be distinguished in the cell clusters which existed during the first week in culture. Thereafter, GABA uptake occurred in an increasing number of neurons with time. Virtually all neurons were labeled by 3 wk in culture. The glial cells demonstrated only low levels of labeling at all times in culture.

276.2 DIFFERENTIAL COMPATABILITY OF HYPER- AND HYPO-DOPAMINERGIC STATES WITH INFANTILE AND ADULT LOCOMOTOR PATTERNS OF MICE. M. J. Forster * and Z. M. Nagy. Bowling Green St. Univ., Bowling Green, OH 43403.

When removed from their home cage and tested in an open-field, infant mice aged 1-10 days typically pivot by turning with the forelimbs whereas older mice walk with both fore- and hindlimbs. While this age-related behavioral change is thought to reflect maturation of underlying neural substrates, few studies have attempted to identify those specifically involved. The present studies addressed the possible role of the dopamine (DA) neurons, as histochemical and biochemical studies suggest that DA systems undergo considerable postnatal development, and because the DA system appears to be involved in locomotor behavior of adults.

In initial studies, separate groups of mice aged 9, 11, or 13 days were injected with the DA antagonist, haloperidol (.2mg/kg), the agonist, apomorphine (.25mg/kg), or the appropriate vehicle and tested for open-field activity for 5 min, 0-, 30-, or 60-min postinjection. Pivoting and walking were measured in terms of the number of initiations, cumulative duration, and average duration per initiation. Control groups showed age-related change in locomotor patterns, with pivoting dominant at 9 days of age and walking dominant at 13 days. Comparisons among the age groups indicated that haloperidol completely attenuated the emergence of walking between 9 and 13 days whereas pivoting was not equivalently affected. Conversely, apomorphine promoted walking and greatly attenuated pivoting as early as 9 days of age.

In a second study, .1mg/kg haloperidol effectively reduced walking of 11- and 13-day-olds without affecting pivoting of 9-day-olds, while neither .2 nor .1mg/kg affected pivoting of 5-day-olds. Apomorphine (.25mg/kg) reduced pivoting of 5-day-olds but elicited behavior best described as crawling rather than walking.

The differential effects of hypo- and hyper-dopaminergic states upon walking and pivoting suggest that development of walking behavior may involve the DA system, while pivoting behavior may involve other neurotransmitter systems.

276.3 EFFECTS OF PRENATAL MATERNAL ADMINISTRATION OF CHLORPROMAZINE ON RAT OFFSPRING MOTOR FUNCTION AND MOTIVATED BEHAVIOR. J. Graefe* and M. Caplan. Dept. of Psychology, Adelph University, Garden City, NY 11530.

The use during pregnancy of psychopharmacological agents affecting the central nervous system (CNS) has markedly increased in recent years. Experimental studies indicate prenatal administration of CNS drugs to rats can lead to functional and behavioral changes in the offspring (Golub and Kornetsky, 1978; Coyle, Wayner and Singer, 1976). The present study examined behavioral changes of offspring of dams treated with chlorpromazine (CPZ) during gestation. CPZ was chosen because of its use by pregnant women and probable influence on developing dopaminergic (DA) systems in the brain resulting in possible alterations of motor function and motivated behavior.

Timed pregnant Sprague-Dawley rats were obtained from a breeder. Single daily injections of saline (SAL) or 4 mg/kg CPZ were administered s.c. on days 7-13 of gestation. At birth, litters were culled to 8 and pups were fostered to lactating dams until 21 days of age. Beginning on day 22, all offspring were tested for 3 consecutive days every 10 days on a different behavioral test each day (i.e. day 22- open-field for 5 mins., day 23- inverted screen, day 24- runway test for food). Subjects were food deprived 24 hrs. prior to the runway test. This sequence was repeated 4 times.

Both SAL and CPZ offspring showed increasing activity scores in the open-field over the 4 test occasions. The CPZ group consistently showed lower activity scores than did the SAL group except on day 22 when both groups were the same. Results of the runway test showed that the CPZ group had shorter latencies leaving the start box and faster run times (RTs) to the goal box than did the SAL group. Sex differences were found only in the runway test: females in both groups had shorter latencies and faster RTs than did males in their respective groups. The inverted screen test did not yield differences between treatment groups.

It appears that prenatal CPZ influences the development of central DA systems. Although the mechanisms mediating the effects of prenatal CPZ are largely unknown, the finding that CPZ offspring had lower activity scores in the open-field than did SAL offspring and shorter latencies and faster RTs in the runway suggests that prenatal CPZ treatment modifies the development of central DA systems that mediate locomotor activity and motivated behavior. Tonge (1973) has reported altered monoamine levels in rodents treated prenatally with CPZ. Whether the drug directly affected fetal DA-systems or induced maternal alterations of humoral influences on the fetal DA-CNS is not evident from these data, although CPZ has been shown to cross the placental barrier (Ghetti, Gliozzi and Cassano, 1969).

276.4 UNMASKING OF A NEONATAL SOMATOVESICAL REFLEX IN ADULT CATS BY ACTIVATION OF SEROTONIN AUTORECEPTORS WITH 5-METHOXY-N,N-DIMETHYLTRYPTAMINE (5-MeODMT). K.B.Thor, T.Hisamitsu*, W.C.deGroat, Dept.of Pharmacol.,Sch.of Med.,Univ. of Pittsburgh,Pgh.,PA 15261

In neonatal kittens micturition is induced by the mother cat licking the perigenital (PG) region. At about the time of weaning the perigenital-bladder (PG-B1) excitatory reflex disappears and throughout adult life tactile stimulation (stim.) of the PG region inhibits micturition. Transection of the spinal cord in adult animals causes the return of the PG-B1 excitatory reflex.

The present experiments explored the possibility that the serotonergic (5-HT) system may be involved in the switch from PG stim. induced BL excitation to inhibition during development. This hypothesis seemed reasonable since 1) 5-HT inhibits B1 activity and 2) spinal transection both eliminates 5-HT in the sacral spinal cord and results in the expression of the same reflex patterns seen in kittens where the 5-HT system has not matured. To see if the absence of 5-HT function in kittens and spinal cats can account for the presence of a PG-B1 excitatory reflex, we decided to suppress the 5-HT system in normal adult cats in an attempt to unmask the PG-B1 excitatory reflex. This was done by stimulation of presynaptic 5-HT autoreceptors with low doses of 5MeODMT to decrease 5-HT release. The response of the bladder (B1) to tactile stim. of the PG region and electrical stim. of the pelvic and pudendal (PUD) nerves was monitored by recording B1 pressure changes and B1 efferent neural activity in chloralose anesthetized cats.

During control periods, both large rhythmic B1 contractions and reflexes recorded from B1 postganglionic fibers in response to pelvic nerve stim. were abolished or greatly reduced by PG or PUD stim. Low doses (5-50 µg/kg i.v.) of 5MeODMT suppressed or eliminated the inhibition of the B1 by PG or PUD stim. in 7 of 7 cats and furthermore, in 4 of those 7 cats changed the inhibition to excitation. Rhythmic B1 activity was increased slightly or unchanged. The effect was maximal 3-5 min after injection and lasted 20-25 min. Larger doses (200-500 µg/kg i.v.) of 5MeODMT produced opposite effects: in those cases where a PG-B1 excitatory reflex was unmasked by low doses, larger doses suppressed the reflex by 50% and rhythmic B1 contractions were abolished, possibly via activation of postsynaptic 5-HT receptors.

In summary, 5MeODMT in normal adult cats produced somatovesical reflex patterns similar to those seen in kittens and chronic spinal cats. Reports that low doses of 5MeODMT depress 5-HT neurons suggests that in normal adult cats the 5-HT system suppresses the excitatory PG-B1 reflex and facilitates the inhibitory component of PG stim. Thus, during postnatal development the switch from PG induced B1 excitation to inhibition may reflect maturation of 5-HT bulbospinal control over spinal reflex mechanisms.

276.5 DEVELOPMENTAL CHANGES IN DOLICHOLS OF MAMMALIAN BRAIN. Y. Sakakihara*, W.C. Landesman*, R.I. Goldberg*, J.J. Volpe, Depts. Ped., Neurol., Biol. Chem., Washington Univ. Sch. Med., St. Louis, MO 63110

Dolichols are long-chain alcohols composed of five-carbon isoprene units derived from the cholesterol biosynthetic pathway. These compounds serve as carriers of saccharide moieties in the biosynthesis of glycoproteins. Because of this function and the importance of glycoproteins in differentiating systems, it is likely that dolichols play critical role(s) in one or more aspects of brain development. In this study, we define the content of free and esterified dolichols in developing rat brain.

Animals were studied from late fetal life to 13 postnatal months. Dolichols were isolated from brain by organic extraction, separated from other lipids by column chromatography, and identified and quantitated by HPLC. A striking increase in brain content of dolichols was defined. Thus, levels of total dolichol were extremely low in brain of the 17-day fetus (0.3 µg/g wet weight) and newborn (0.6 µg/g). Postnatally, a gradual increase in levels occurred until 15 days when a rapid rise to a peak level of 9.0 µg/g at 40 days was observed. (Thereafter little change was found until two to three months of age when a second rise in brain dolichol levels occurred, reaching the high levels (18 µg/g) previously reported in aging brain.) Approximately 65-70% of total brain dolichol was in the free form during the time of the early developmental increase.

In contrast to dolichols, cholesterol deposition exhibited a distinctly different developmental pattern. Thus, cholesterol content increased from relatively low levels in neonatal brain to nearly peak levels after approximately 21 days, when the rapid rise in dolichol levels was just beginning.

Coincident with the striking increase in brain dolichols with brain development, a distinct change in the distribution of the several molecular species that comprise the total dolichol fraction was demonstrated. Thus, with development the dolichols of shorter chain length (C80, C85) increased, whereas those of longer chain length (C95, C100) decreased.

The data thus define a striking increase in brain dolichols during the time period in the rat that corresponds to active myelination. The fact that the developmental increase in brain dolichols is independent of the increase in brain cholesterol suggests that the regulation of formation of dolichol is also an independent process. This is of particular interest because the precursor unit of dolichols is derived from the cholesterol biosynthetic pathway. The timing of the developmental increase in brain dolichols suggests that these compounds are involved in biosynthesis of glycoproteins critical for the progress of myelination. 276.6 PYRUVATE DEHYDROGENASE ACTIVITY IN REGIONS OF THE RAT BRAIN DURING POSTNATAL DEVELOPMENT. Roger F. Butterworth, Jean-François Giguère*, France Landreville* and Micheline Pelletier*. Lab. of Neurochemistry, Clinical Research Institute of Montreal (University of Montreal), Montreal, Quebec, Canada H2W 1R7.

The limited capacity of neonatal brain to oxidise glucose probably results from a maturational delay in the activity of the pyruvate dehydrogenase complex (PDHC). As part of a study to more fully elucidate the role of PDHC in brain development, the activity of the enzyme complex was measured in 7 brain regions of the male rat at different times during the postnatal period using an arylamine acetyltransferase coupled assay (Ksiezak-Reding et al., J. Neurochem., 38, 1627 (1982). 3 days after birth, PDHC activity was less than 15% of adult levels in all brain regions studied with the exception of hypothalamus and medulla-pons (30% of adult values in both cases). PDHC in these regions increased rapidly during the postnatal period to attain adult levels by 21 days postnatally, some 5-10 days ahead of those found in cerebral cortex, striatum and hippocampus. These differences in PDHC maturation likely reflect the greater degree of early maturity in these phylogenetically older brain structures.

Cerebellar PDHC developed significantly more slowly than in other regions of the brain, at all times after birth, to attain only 40% of adult levels by 21 days. Cerebellum, in contrast to other regions of brain, acquires most of its neuronal complement postnatally and the pattern of maturation of cerebellar PDHC found in the present study is paralleled by:-

(i) Increased incorporation of glucose into cerebral amino acids;

(ii) Development of parallel fibre synaptogenesis;

(iii) Development of specific cerebellar glutamate receptor binding sites.

These findings suggest that PDHC may play an important role in the development of metabolic compartmentation and maturation of cerebral function in the rat.

276.7 OPIOID-SENSITIVITY OF NEURONS IN ORGANOTYPIC CULTURES OF FETAL MOUSE DORSAL ROOT GANGLION (DRG) EXPLANTS GROWN EITHER ATTACHED TO SPINAL CORD OR IN ISOLATION. A. Chalazonitis and S.M.Crain, Dept of Neuroscience, Albert Einstein College of Medicine, Bronx, N.Y. 10461

Opiate agonists selectively decrease the Ca^{++} component of the action potential (AP) recorded from dissociated chick and mouse embryo DRG somas (Mudge et al, PNAS 76, '79; Werz and Macdonald, Br.Res.239 '82). In contrast, no significant alterations in the APs generated by adult mouse DRG neurons were detected during exposure of freshly isolated ganglia to opioids (Williams & Zieglgänsberger Neurosci.Lett.21, '81). To clarify this difference we compared the opiate sensitivity of sensory neurons in organotypic explants of DRGs attached to spinal cord cross-sections vs isolated DRG explants. Intracellular recordings were made with beveled micropipettes (40-80 MΩ) on DRG neuron somas (20-50 µm diam.) at 3-5 wks. in vitro. Opiate agonists were tested on DRG spikes evoked (at 0.1 Hz) in a balanced salt solution (BSS) containing 5 mM Ca^{++} and 5 mM Ba^{++} in order to enhance inward current through Ca^{++} channels and block delayed voltage-dependent K^{+} channels. A "hump" developed in the repolarizing phase of the spike under these conditions which was blocked by 5-10 mM Co^{++} (9 out of 9 tested neurons), confirming Ca^{++} mediation of this hump. Opiate agonists were bath-perfused (0.5 ml/min) for test periods up to 10 min. In 26 out of 50 DRG neurons (i.e.52%) in 47 DRG-cord explants, the duration of the Ca^{++} component of the AP was reduced in the presence of D-ala-D-leu enkephalin (DADLE) at 10 µM. On the other hand, in 26 isolated DRG explants, 27 out of 33 neurons (i.e.82%) were sensitive to DADLE (χ^2 test of significance: $p<0.005$). The decrease in duration of the Ca^{++} hump ranged from 20-100%, with means of $54\pm4\%$ for neurons in DRG-cord explants and $47 \pm 4\%$ in isolated DRG explants. These effects were reversed after return to Ca^{++}-Ba^{++}BSS and prevented by perfusion of the specific opiate antagonist, naloxone (3 µM), together with DADLE in all 12 neurons pre-tested for sensitivity to DADLE. In about 30% of the opiate-sensitive neurons (in both attached and isolated cultures) the shortening effect on the duration of the Ca^{++} hump "desensitized" within several min of exposure to the agonist; this opioid effect was stably maintained in the rest of the cells in 4-10 min tests. Also, although the duration of the Ca^{++} hump of the somatic DRG AP was significantly shorter in attached vs isolated cultures, some of the opiate-insensitive neurons still generated prominent Ca^{++} humps.

The data obtained thus far are consistent with the hypothesis that as the central terminals of fetal DRG neurites participate in the formation of opioid synaptic networks within the dorsal-horn region of DRG-cord explants (Crain et al, Br.Res. 133 '77, 157 '78) the opioid sensitivity of the perikaryal region of these DRG neurons may decrease.

276.8 ONTOGENETIC DEVELOPMENT OF THE SPECIFIC ^{3}H-NITRENDIPINE BINDING SITES IN THE RAT WHOLE BRAIN. H. Matsubayashi*, S. Kito, E. Itoga, M. Togo*, F. Ishizaki* and K. Mizuno*. Third Dept. of Int. Med. Hiroshima Univ. School of Med., Hiroshima, Japan 734.

The characteristics of Ca channel antagonist binding sites in the central nervous system with use of tritiated nitrendipine (^{3}H-NTD) as ligand have been investigated by several authors for the past two years. The authors studied ontogenetic development of ^{3}H-NTD binding sites in the rat brains. Materials were Wistar strain rat whole brains of 1 day, 3 day, 7 day, 14 day, 1 month and 2 month postnatal ages. In addition, brains of the prenatal stage were studied. The tissues were homogenized and washed repeatedly in 50mM Tris-HCl buffer (pH 7.4 at 25°C) and the final pellet was resuspended in Tris-HCl buffer of a tissue concentration of 50 mg original wet weight/ml. The authors performed saturation studies using tissue aliquots of 500ul at 25°C after 60 min incubation with various concentrations of ^{3}H-NTD. Specific binding was defined as the amount of ^{3}H-NTD displaceable by 1 uM nifedipine. Furthermore, autoradiography of ^{3}H-NTD binding sites of these brains of various ontogenetic stages using cryostat sections incubated with 0.6 nM ^{3}H-NTD for 2hrs at 0°C was done. As results, the mean Kd value of fetal, 1-day, 3-day, 7-day and 14-day-old rats was 868.6±236.7(s.d.)pM, whereas that of 1-month and 2-month-old rats was 467.0±25.4pM and binding affinities became higher after 1 month after birth. As for B max, it was 143.0±59.9 fmol/mg protein as the mean value of these various stages and there were no considerable changes in the course of ontogenetic development. Autoradiographic study revealed that ^{3}H-NTD binding sites were diffusely distributed in the gray matter, especially in the hippocampus, interpeduncular nucleus and olfactory bulb. Autoradiographic distribution of these binding sites was also studied ontogenetically.

These days, where ^{3}H-NTD binding sites are located, on the cell membrane or some of the intracellular organellas, has been discussed. It is known that the ionic dependence of the inward current of the action potential is changed from Ca ion to Na ion channels in the fetal development of the amphibian embryo and Ca ion channel is considered to be early developed. In our study, Kd values of Ca antagonist binding sites decreased after birth. This result was noteworthy, since in most of neurotransmitter receptor sites Bmax usually increased, while Kd values remained unchanged. This means that development of ^{3}H-NTD binding sites are not parallel to increase of synaptic sites in the developmental stages.

276.9 DEVELOPMENTAL REGULATION OF CELL SURFACE ANTIGENS IN CHICK NEURAL RETINA. G.J. Cole*, S.A. Dyer*, M.A. Derby* and L. Glaser* (SPON: W. Landau). Department of Biological Chemistry, Washington University School of Medicine, St. Louis, MO 63110

A previous study in our laboratory has described a fluorescent-activated cell sorter (FACS) method that permits the rapid screening of hybridomas that are secreting antibodies which react with surface antigens of retinal cell subpopulations (Dyer et al., Dev. Br. Res., in press). Using this method we have identified a number of monoclonal antibodies that bind distinct populations of embryonic neural retina cells. Two of our monoclonal antibodies react with surface antigens that are developmentally regulated and neural-specific. The monoclonal antibody C1H3 recognizes an antigen present on approximately 70% of the total cell population in dissociated cells from 9 day retina. This antigen is localized to cell bodies of the inner nuclear and ganglion cell layers, and to processes of the plexiform and nerve fiber layers. It has been identified by immunoblotting as a 140 kd polypeptide, which during development is diminished in concentration concomitant with the appearance of a 170 kd component.

A second monoclonal antibody, D1C4 reacts with a minor subpopulation of retina cells (5% of total cells). Immunohistochemical localization of the antigen recognized by D1C4 indicates that it may be present on ganglion cells. This conclusion is based on the presence of the antigen on processes of the inner plexiform and nerve fiber layers. The D1C4 monoclonal antibody recognizes two polypeptides: a major component with a MW of 260 and a minor species of 210 kd. Both antigens decrease as a percentage of total protein during development,and are only slightly detectable by immunoblotting at embryonic day 17.

The restriction of these antigens to distinct subpopulations of retina cells should prove invaluable in the isolation and molecular characterization of defined neural cell types. (Supported by Grants GM18405, GM28002, NSF PCM 80 11973, and 5 P01 GM28002-03.)

276.10 MOLECULAR EVENTS DURING CEREBELLAR DEVELOPMENT
W. Wille, H. Schaal*, and U.A.O. Heinlein*, Institute for Genetics, University of Cologne, Köln, West-Germany

During the histogenesis of the cerebellum (Cb) of wildtype (+/+) and staggerer (sg/sg) mice, regulation of some glycosidases has been demonstrated (Wille & Trenkner, J. Neurochem. 34:443, 1981; Wille et al. J.Neurochem. 40:235, 1983). In order to correlate the enzyme activities with their natural substrates, an attempt was made to describe more generally the alterations of glycolipid and protein patterns during the ontogeny of the Cb.

Gangliosides, which occur in relative high concentrations in the nervous system, are a natural substrate for the particulate neuraminidase, one of the glycosidases mentioned above. The developmental profiles of 6 major gangliosides show individual alterations during histogenesis. The most striking feature is a transient accumulation of GD3 with the highest molar percentage (23%) at P7. The rapid decrease during the second week after birth reduces the relative amount of GD3 to an adult level of 3.2%. Localization studies with the monoclonal Ab R24 (Pukel et al. J.Exp.Med. 155:1133, 1982) demonstrate that at P7 GD3 is only expressed in the external (and partly internal) granule cell layer, the site of postnatal neuron proliferation. In adult Cb only faint background staining is detectable. We interpret the neonatal dominance of GD3 as a consequence of massive de novo synthesis of membrane material rather than as a functional conversion of cell surfaces. The sg/sg Cb exhibits only in adult animals ganglioside differences to the +/+. The increase of GD3 and GM1 may be due to astrogliosis, and the decrease of GD1a and GT1b may be caused by degeneration of neurons.

The Purkinje cell specific protein P400 (Mikoshiba et al. Dev.Neurosci. 2:254, 1979) and the N-CAM protein (Edelman & Chuong, PNAS 79:7036, 1982) have been described during cerebellar development. By aid of one- and two-dimensional SDS-PAGE, sensitive silver staining, and labeling with radioactive sugars, amino acids, phosphate, and sulphate we characterized additional age- and genome-specific proteins: SP47 (IEP 6.4) appears only in the sg/sg Cb with an age-dependent increase corresponding to P400 in +/+; SD70 (IEP 8.4) increasing in postnatal +/+ Cb and not in sg/sg; SD28/SD29 doublet disappears in sg/sg Cb after P30; MP195/MP74 are two nuclear proteins occuring only in Cb older than P7; EP56 (IEP 6.0) increases between E11 and P0 and is absent in adult Cb; GP165, a glycoprotein specific for the molecular layer; EP45 (IEP 4.5), a phosphorylated protein with a kinetic similar to EP56; histones, which differ significantly in the sg/sg Cb. Data from in vitro translation of Cb poly(A)mRNA in reticulocyte lysate and Xenopus oocytes will be presented.

276.11 TECTAL REGULATION OF PROTEIN TRANSPORTS IN REGENERATING GOLDFISH OPTIC FIBERS. Myong G. Yoon+, Larry I. Benowitz++, Ellen R. Lewis++ and Frank A. Baker+. +Dept. of Psychology, Dalhousie University, Halifax, N.S. Canada, B3H 4J1, and ++Dept. of Psychiatry Harvard Medical School, McLean Hospital, Belmont, MA 02178.

Differential changes in the rapidly-transported proteins along the regenerating optic fibers were examined in the presence or absence of their main target, the optic tectum, to test its regulative effects in adult goldfish as follows: Both optic nerves were crushed in all experimental fish at the same time. In one half, the tectum was also ablated bilaterally so that the regenerating optic fibers were prevented from interacting with the tectum; (R-T) group. In the other half of the fish, the optic nerves were allowed to regenerate back to the tectum; (R+T) group. The complements of rapidly-transported proteins in the regenerating optic fibers were compared between these two groups, by differentially labeling with H^3- and C^{14}- proline, and 1 or 2 dimensional gel-electrophoretic separations of retinal proteins. At early post-operative periods (10, 15 and 20 days), no significant difference between the two groups was observed. Beginning on day 24, however, (R+T) group showed a prominent increase in 110-150K dalton species of retinal proteins relative to (R-T) group. Their differential increase in this protein species reached a peak on day 30, and subsided thereafter. In contrast, another species of the retinal proteins with molecular weights in 24-27K dalton range was found to label considerably more in (R-T) group than in (R+T) group, beginning on day 30, and persisting up to 5 months. These results indicate that the optic tectum exerts differential regulative effects on synthesis and/or transport of proteins in regenerating optic fibers; in particular, their interaction with the tectum enhances the 110-150K species, whereas it diminishes the 24-27K component. If the regenerating optic fibers are prevented from interacting with the tectum, the 24-27K component remains enhanced for several months.

276.12 FOOD DEPRIVATION INCREASES 5HT AND 5HIAA IN NEONATES BUT NOT OLDER RAT PUPS. F.M. Scalzo and L.P. Spear. Dept. of Psychology, State University of New York at Binghamton, Binghamton, NY 13901.

The serotonergic system has been implicated in the modulation of suckling behavior during development. While serotonergic antagonists markedly reduce suckling behavior in neonatal rat pups (Spear & Ristine, 1982), such antagonists conversely appear to induce suckling behavior in weanling rats (Williams et al., 1979; Ristine & Spear, 1982). The presence or absence of food has been shown to influence serotonin (5HT) synthesis in adult animals, presumably through influencing serum levels of the precursor amine tryptophan (e.g., Fernstrom & Wurtman, 1974) and its binding to serum albumin which is potently inhibited by serum nonesterified fatty acids (NEFA) (Yuwiler, 1977). It has been suggested that food deprivation may increase brain 5HT turnover to a greater extent in neonates than in older animals (Tissari, 1975; Tissari & Tikkanen, 1978). Such an increase in 5HT synthesis and release induced by food deprivation may be of functional significance in inducing suckling behavior in the neonate since there are ample postsynaptic substrates for 5HT even in the neonate.

The first experiment investigated the influence of 24 hour food and/or maternal deprivation and ambient temperature on levels of plasma NEFA and 5HT and its metabolite 5-hydroxyindole acetic acid (5HIAA) in various brain regions of 3, 9, 15 and 21 day old rat pups. Food deprivation at nest temperature increased 5HT and 5HIAA levels in 3 and 9 day, but not 15 or 21 day old animals. These increases were not related to alterations in serum NEFA's; NEFA's were decreased by deprivation in neonates and conversely increased in weanlings. The second experiment investigated the effects of 2, 4, 16 and 24 hours of food deprivation on 5HT and 5HIAA in various brain regions of 3 and 9 day old pups. By 16 hours of deprivation, increased levels of 5HT and 5HIAA were observed, an effect that was most dramatic at 3 days of age. These results suggest that the NEFA-independent deprivation-sensitive nature of the serotonergic system in neonates is not characteristic of older animals, evidence consistent with our hypothesis that 5HT may be important for stimulating suckling in neonates while inhibiting it in older rat pups.

276.13 **NORADRENALINE-DEPLETION DURING EARLY DEVELOPMENT INHIBITS CORTICAL RESPONSE TO ENVIRONMENTAL EXPERIENCE.** M.Mirmiran*, E.Brenner* and H.M.M.Uylings*, (SPON: European Neuroscience Association), Netherlands Institute for Brain Research, Amsterdam, Netherlands.

Post-weaning differential environmental experiences have been found to be effective in influencing the growth of the cerebral cortex in rats. Pre-weaning suppression of REM-sleep by means of chronic clonidine (an α-noradrenaline agonist) treatment was found to counteract the post-weaning enrichment effects on cortical growth *(1)*. The present study was undertaken in order to determine whether REM-sleep or central noradrenaline neurotransmission, both of which are being affected by clonidine, is the crucial factor in inhibiting the environmental effect on cerebral cortex.

Male Wistar rat pups were injected subcutaneously with either 100 mg/kg 6-OH-DA or saline on days 1,3,5, and 7 after birth. The drug regimen did not significantly influence the sleep-wake pattern of the developing rats. After weaning both saline and 6-OH-DA injected animals were reared under either 'enriched' or 'standard' environmental conditions. At 75 days of age the brains were dissected into 8 parts and weighed immediately. A specific increase was found in the weight of the cerebral cortex in 'saline-enriched' *vs.* 'saline-standard' groups. This environmental difference was absent between the two neonatally 6-OH-DA injected groups. Furthermore, a significant reduction in cortical growth was found in both 'standard' and 'enriched' 6-OH-DA treated animals.

These results, together with clonidine results *(1)* suggest that noradrenaline neurotransmission during early development is an important factor in mediating cerebral cortical growth.

(1) M.Mirmiran, H.B.M.Uylings and M.A.Corner: Pharmacological suppression of REM sleep prior to weaning counteracts the effectiveness of subsequent environmental enrichment on cortical growth in rats. Dev. Brain Res. *7* (1983) 102-105.

276.14 MODIFICATION OF RECEPTOR BINDING IN CAT VISUAL CORTEX DURING DEVELOPMENT: CORRELATION WITH FUTURE PLASTICITY. C. Shaw[1], C. Aoki[3], M. Wilkinson[2] and M. Cynader[1,2]. [1]Dept. of Psychology and [2]Dept. of Physiology and Biophysics, Dalhousie University, [3]Laboratory of Philip Siekevitz, Rockefeller University.

Receptor binding sites play a crucial role in neural signal transmission and modulation. Yet despite the wealth of information on normal neural properties and their modification by restricted visual experience, very little is known about the types or characteristics of receptor binding sites in cat visual cortex. We examined various receptor binding sites in cat visual cortex in terms of ontogenesis of receptor characteristics and the effects of dark rearing. Previous studies showed that the β-adrenoceptor antagonist, ^{3}H-dihydroalprendol labelled a single binding site (K_D = 0.54 ± 0.04 nM) at all ages (Wilkinson et al., 1983). The developmental curve showed a peak in the total number of receptor binding sites (B_{max}) by 3 mo. of age. Dark rearing had no effect on either K_D or B_{max}.

To examine benzodiazepine receptors, male colony cats were sacrificed at different ages. Benzodiazepine (BZD) receptor sites were examined in washed homogenates of visual cortex. BZD binding was assayed using ^{3}H-flunitrazepam (87.3 Ci/mmole), a BZD agonist, with clonazepam (3 x 10^{-6}M) used to measure non-specific binding. Incubations were performed at 0°C for 75 min., followed by filtration through Whatman GF/B filters and two washings with cold Tris buffer. All assays were run in triplicate. ^{3}H-flunitrazepam labelled different affinity binding sites at different ages in normal cats (3 day, K_D = 1.49 ± 0.18 nM; 57 day, 4.2 ± 0.48 nM; adults, 2.51 ± 0.40 nM). The B_{max} rose rapidly from birth, peaked at 2 mo. postnatal, and declined slightly thereafter. The nature of the BZD-GABA complex is not fully understood, but it appears that GABA can alter the characteristics of BZD binding. Addition of GABA (10^{-4}M) to homogenates of visual cortex in normal cats induced large increases in BZD affinity, but had little effect on B_{max}. The magnitude of the GABA effect on K_D varied with age (3d, 2.3x; 57d, 1.4x, adult, 2.8x). Dark rearing had no effect on B_{max}, but affinities were higher except in adult animals. GABA mediation of BZD binding was much lower in the adult dark-reared cats (1.7x) than normal adults. The latter observation may reflect alternations in the binding characteristics of GABA receptors (see Needler et al., 1983, this volume).

BZD receptor affinities thus changed with age, with addition of GABA, and following dark rearing. These data suggest that dark-reared cats retain greater plasticity (Cynader & Mitchell, 1980) than their normal counterparts by an alteration in the development of certain receptor binding characteristics.

276.15 ONTOGENY AND LAMINAR DISTRIBUTION OF GABA RECEPTOR SITES IN THE STRIATE CORTEX OF NORMAL AND DARK REARED CATS. M. C. Needler*, C. Shaw and M. Cynader (SPON: V. LoLordo). Dept of Psychology, Dalhousie Univ., Halifax, N.S.

Gamma-aminobutyric acid (GABA) is thought to be a major inhibitory neurotransmitter in the cat visual cortex. Little is known, however, about the ontogeny, total number, affinity or distribution of GABA receptor binding sites. We have used [^{3}H]-muscimol (29.4 Ci/mmole), a potent GABA agonist, to autoradiographically localize GABA receptor sites in slide-mounted sections (Young and Kuhar, 1979; Penney et. al., 1981) of the striate cortices of normal and dark reared cats. Animals were perfused with PBS, their brains rapidly removed and frozen. After three rinses in cold Tris citrate to remove endogenous GABA, selected sections were incubated with [^{3}H]-muscimol for 30 minutes at 4°C. In adjacent sections, non-specific binding was determined in the presence of 10^{-4}M GABA. Sections were rinsed in three five second washes in cold Tris citrate to remove unbound ligand. Sections were apposed to either dry emulsion-coated (Kodak NTB2) coverslips or LKB Ultrofilm.

Dense [^{3}H]-muscimol binding was observed in the striate cortices of all cats. The low (15%) nonspecific binding observed in sections which had been coincubated with GABA indicated that most of the [^{3}H]-muscimol binding involved specific receptor sites in the cortex. The number of these receptor sites was relatively low (60% of peak density) in a 3-day old kitten, increased with age until 1-2 months postnatally, and then declined to about 70% of this peak value in adulthood. A clear laminar distribution of receptor sites was observeable at all ages. [^{3}H]-muscimol binding increased gradually from layer I to layer III, peaked dramatically in layer IV, fell of sharply in layer V and increased again in layer VI. These laminar differences were least striking in very young kittens.

The ontogeny and laminar distribution of GABA receptor sites in dark reared cats mirrored our findings for normal animals. Dark reared cats, however, demonstrated consistently higher levels of labelling than did normal animals of comparable ages. Experiments now in progress will determine whether this difference reflects changes in total number (B_{max}) or in binding affinities of the receptor sites. These findings parallel those for benzodiazepine receptor sites (Shaw et. al., 1983, this volume). The results suggest that GABA receptor sites can be modified by visual experience, and may thus be involved with some of the physiologic alterations observed in the visual cortex of dark reared animals.

276.16 DEVELOPMENTAL AND NEURONAL REGULATION OF β-ADRENERGICALLY-ACTIVATED ADENYLATE CYCLASE ACTIVITY IN THE RAT PAROTID GLAND. Barbara R. Talamo , Neurosciences Labs, Dept. of Neurology, Tufts Medical School, Boston, MA 02111.

β-adrenergic activation of adenylate cyclase activity in the rat parotid gland increases sharply between 14 and 18 d postnatal. This increase does not correlate with changes in β-adrenergic receptor density [Ludford and Talamo, J. Biol. Chem. 255:4619 (1980)], but parallels an increase in nucleotide binding protein (G/F) detected in membranes by covalent labeling with ^{32}P-NAD in the presence of cholera toxin [Ludford and Talamo, J. Biol. Chem. 258:4831 (1983)]. The two proteins labeled by cholera toxin, of M_r 43,000 and 48,000, increase two-fold during this critical 4 day period while [^{125}I]-HYP binding and affinity remain unchanged. During this same period, large increases in fluoride activation also occur, supporting the hypothesis that the increased response is due, at least in part, to increases in G/F. In rats denervated neonatally with 6-hydroxydopamine, β-adrenergic receptor sites develop at a normal rate and increase only after maturation of the cells is normally completed. The 1.5 fold increase in receptor density is accompanied by a 1.7 fold decrease in K_{act} of isoproterenol for adenylate cyclase, but maximal stimulation of adenylate cyclase activity does not increase. There is no change in the amount of G/F. Another explanation for the developmental increase in hormone-activation of adenylate cyclase could be that the catalytic unit (C) of the cyclase itself is increasing. C was assayed by activation with forskolin, reported to activate C in S-49 lymphoma cells, which have no detectable G/F by cholera toxin labelling. Forskolin activation is not enhanced by addition of guanine nucleotides. Stimulation is 21-fold at maximal levels of 700 M forskolin and is greater in Mn^{++} than in Mg^{++}. Low concentrations of forskolin potentiate -adrenergic activation of cyclase in parotid membranes in the presence of Mn^{++}, which by itself gives only a 3-fold stimulation. This indicates some enhancement of the receptor-G/F unit interaction with C in the presence of forskolin. However, maximal NaF activation, which proceeds through G/F, is additive with maximal forskolin stimulation. This suggests that G/F-sensitive cyclase and forskolin-sensitive cyclase may comprise different populations. Preliminary results show that maximal levels of isoproterenol stimulation in mature animals increase 2.4-fold compared to membranes prepared from 10d animals , while NaF stimulation increases 2-fold and isoproterenol + limiting forskolin increases by 2.3-fold. Maximal forskolin stimulation increases only 1.5-fold, suggesting that increases in C are less than increases in G/F.

276.17 ONTOGENY OF α_1-RECEPTORS AND THE EFFECT OF CASTRATION ON α_1-RECEPTOR LEVELS IN MALE GUINEA PIGS. A.E. Johnson*, B. Nock*, H.I. Ryer*, and H.H. Feder* (SPON: E. Satinoff) Institute of Animal Behavior, Rutgers Univ., Newark, NJ 07102.

In order to describe the development of α_1-receptors in male guinea pig brain, four different brain regions known to contain a high concentration of α_1-receptors (cortex) or steroid receptors (preoptic area, hypothalamus, and amygdala) were assayed at various stages of prepubertal development (1, 7, 14, 21 days) and in adulthood (60 days) using 1.25nM (^{3}H)prazosin. We found that (^{3}H)prazosin binding in cortex remained low (66% adult levels) through postnatal day 14 then gradually increased to adult levels. Binding in POA and HYP decreased from day 1 (132% and 116% of adult) to adult levels by day 7 in HYP and day 21 in POA. No developmental changes were found in AMG. Because differences in (^{3}H)prazosin binding demonstrated above could be due to changes in apparent affinity (Kd) or receptor number (Bmax), α_1-receptors were assayed using a range of concentrations of (^{3}H)prazosin (.1 to 1.0nM). Analysis of Rosenthal plots showed that differences in binding between infants (1 to 3 days old) and adults were due to changes in receptor number rather than affinity.

Since gonadal activity appears to increase during development and steroids have been shown to influence receptor levels in other neurotransmitter systems we examined the effects of endogenous steroids on α_1-receptors. We tested the effects of neonatal or adult castration on α_1-receptor content in CTX, POA, HYP, and AMG of male guinea pigs. No differences were found between castrated (either neonatal or adult) and intact animals. These results agree with the failure to demonstrate an effect of estrogen and progesterone on α_1-receptor levels in the female guinea pig (Nock and Feder, 1983). However, since receptors were measured in relatively large brain areas, possible steroid effects on discrete nuclei might be obscured. Therefore, steroid regulation of α_1-receptors cannot be ruled out at this time.

DEVELOPMENT AND PLASTICITY: LIMBIC SYSTEM

277.1 BOTH TRANSITORY AND IRREVERSIBLE FIMBRIA/FORNIX "CONDITIONING" LESIONS FACILITATE RECOVERY FROM BILATERAL HIPPOCAMPAL LESIONS IN RATS. B.E. WILL and G. TONIOLO*. Lab. de Neurobiologie des comportements, Université Louis Pasteur, 67000 Strasbourg, France.

The aim of the present series of experiments was to evaluate whether a cerebral "conditioning" lesion could facilitate recovery of behavioral function following a second or "testing" lesion in rats. The "conditioning" lesions used were unilateral fimbria/fornix lesions, produced either by electrolytic or transitory chemical (colchicine 5µg, 10µg, 15µg) treatment . The "testing" lesions were one-stage electrolytic bilateral dorsal hippocampal lesions. One group of rats (H) sustained only hippocampal lesions without any "preconditioning" ; two groups of unlesioned rats served as controls (one injected with buffer and one with electrode intrusion). Hebb-Williams maze learning was conducted one month after hippocampal lesions and two months after "preconditioning". In comparison with controls, a significant increase in errors was observed with both the H and the "preconditioned" groups. However, in comparison to the H rats, those "preconditioned" by electrolytic as well as 5µg colchicine lesions performed at a higher level. The colchicine effects were dose dependent. The AChE and CAT activities were determined in the hippocampus. The biochemical results are discussed in relationship to the behavioral results emphasizing their importance for the understanding of the serial lesion effect.

277.2 HIPPOCAMPAL-CHOLINERGIC SYSTEM DEVELOPMENT AND PLASTICITY IN NORMAL AND EARLY LEAD EXPOSED RATS. D. P. Alfano, T. L. Petit and J. C. LeBoutillier*. Div. Life Sciences and Dept. Psychology, Univ. of Toronto, West Hill, Ont. M1C 1A4.

A review of previous evidence suggested the possibility of a functional association between the effects of early lead (Pb) exposure, hippocampal damage and cholinergic deficiency. To further assess this possibility, Long-Evans hooded rat pups were exposed to Pb for the first 25 postnatal days via the maternal milk. Dams were fed either 4.0% $PbCO_3$ or a Na_2CO_3 control diet throughout this period. At 30 and 115 days of age, the brains of Pb and control animals were processed for acetylcholinesterase histochemistry. Morphometric evaluation of the molecular layer of the hippocampal dentate gyrus indicated that while absolute increases in the dimensions of the afferent systems to the hippocampal dentate gyrus are observed between 30 and 115 days of age, no significant rearrangement in the pattern of lamination occurs during this time. No effects of Pb were seen on the development of the cholinergic innervation of this brain region at either of these ages. Unilateral perforant path transections performed on Pb and control animals at 100 days of age indicated reduced cholinergic plasticity in the molecular layer of the hippocampal dentate gyrus of Pb exposed animals, as indicated by AChE histochemistry. These findings indicate that a decrease in neuroanatomical plasticity may be a critical brain mechanism underlying the learning deficits observed following exposure to Pb.

277.3 MESOLIMBIC DOPAMINERGIC MODULATION OF THE EXCITATORY RESPONSES OF THE NUCLEUS ACCUMBENS NEURONS TO HIPPOCAMPAL STIMULATION. C. R. Yang* and G. J. Mogenson. Dept. of Physiology, Univ. of Western Ontario, London, Canada N6A 5C1.

The nucleus accumbens (NAc) of the ventral striatum receives converging inputs from many limbic regions, including afferents from the subiculum of the hippocampus (Hipp). This nucleus also receives a rich dopaminergic (DA) projection from the ventral tegmental area (VTA). In earlier experiments using extracellular single unit recording techniques, we observed that the excitatory responses of the NAc neurons to single pulse stimulation of the Hipp (subiculum) were attenuated by a conditioning train of stimulus pulses (10 Hz) delivered to the VTA (Yang and Mogenson, Can.Fed.Biol.Soc.abs.,1983). This attenuation did not occur in animals in which the VTA was treated two days earlier with 6-hydroxydopamine (with desipramine pretreatment). These observations suggest that the attenuation reaction might be mediated by the mesolimbic DA neurons. Thus, the present study was undertaken to obtain further evidence to show whether the attenuation, resulting from VTA conditioning stimulation, of the activation of NAc neurons to Hipp stimulation is dopamine-mediated.

Extracellular single unit recordings were obtained from the medial NAc of urethane-anaesthetized rats using glass micropipettes filled with 0.2% pontamine sky-blue in 0.5 M sodium acetate. In some experiments, a recording electrode filled with 3M NaCl and assembled in parallel with a five-barrelled micropipette was used for simultaneous recording and iontophoretic application of DA.

In the first series of experiments in 8 rats haloperidol, a DA antagonist, was injected intraperitoneally (0.3-0.5 mg/kg) to investigate the attenuation effect on the activation of the NAc neurons to Hipp stimulation resulting from VTA stimulation. Following haloperidol administration, the attenuation previously observed with VTA stimulation occurred in only 39% (23/59) of the NAc neurons tested ($\chi^2 = 35.9$, $p < 0.001$).

In a second series of experiments in 8 rats DA was administered by iontophoresis to NAc neurons activated by Hipp stimulation. The iontophoresis of DA(5-20 nA) significantly reduced the Hipp activation of 89% (25/28) of the NAc neurons tested. This effect is similar to the attenuation effect which resulted from VTA stimulation.

The observations suggest that the excitatory inputs of Hipp to NAc neurons are modulated by the mesolimbic dopaminergic system.

277.4 SEX DIFFERENCES IN THE DENDRITIC RESPONSE TO DIFFERENTIAL ENVIRONMENTS IN THE GRANULE CELLS OF THE DENTATE GYRUS. Janice M. Juraska, Jonathan Fitch*, Constance Henderson*, and Natalie Rivers*. Dept. of Psychology, Indiana Univ., Bloomington, IN 47405.

Males have often been described as the more vulnerable sex and, therefore, may be more susceptible to the effects of their rearing environment. We have previously found that male rats show greater dendritic differences than female rats in some cortical neuronal populations following rearing in complex (EC) and isolated (IC) environments.

The dentate gyrus of the hippocampus is a late developing structure that is likely to be susceptible to environmental effects. We reared male and female hooded rats in either EC or IC for a month after weaning in two separate replications. Granule neurons were sampled from the upper one-third and the lower two-thirds of the granule cell layer in Golgi-Cox stained coronal sections. A concentric ring analysis revealed that in both replications in both upper and lower layers neurons from females showed large differences due to the environment with EC females having more dendritic material in the middle to upper dendritic tree than IC females. Male differences in response to the environment were very small to nonexistent. An analysis of branch number and length in the first replication revealed that this female plasticity occurred in terminal branch length. Evidently the type of sex differences seen in dendritic response to environmental conditions varies with the area of the brain examined. In the dentate, females show much larger dendritic *differences than males.*

277.5 DEVELOPMENT OF THE GABA SYSTEM IN THE RAT HIPPOCAMPUS. D. L. Martin, and J. W. Swann. (SPON: A.T. Campagnoni). Center for Labs and Research, NYS Dept. of Health, Albany, NY 12201.

Previous studies in our laboratory have shown that the CA3 region of hippocampal slices from immature rats (9-19 days old) has a pronounced capacity to generate prolonged, self-sustained afterdischarges in response to brief repetitive orthodromic stimulation (Swann and Brady, Neurosci. Abst. (1982) 8, 1016). Since GABA-mediated inhibitory synaptic transmission is thought to play a central role in the prevention of epileptogenesis in mature hippocampus, we have examined the development of the hippocampal GABA system. Glutamate decarboxylase (GAD) activity in whole hippocampus and in the CA1, CA3, and area dentata (AD) subfields was measured as a function of age. Intracellular recording was also used to determine the presence of GABA-mediated ipsps in immature hippocampus.

Whole hippocampi were dissected, blotted, weighed and frozen at 3, 10, 13, 16, 20, 23, 30 and 112 days postnatal. The CA1, CA3 and AD regions were dissected, weighed and frozen from animals killed at 10, 16 and 30 days. GAD activity was determined in homogenates of the tissue samples by measuring the production of [^{14}C]GABA from uniformly labeled [^{14}C]glutamate. Total hippocampal GAD activities at 3 and 10 days were only about 2 and 14 percent of the activity in mature hippocampus (2.1 µmol GABA/h/hippocampus at 30 days). Thus about 86% of the GABA system developed after 10 days of age. The specific activity of GAD increased about 3 fold (from 1.6 to 4.7 nmol/h/mg tissue) from 3 to 10 days and approximately tripled again by 20 days (15.1) after which there was little further increase. This pattern is similar to that observed in other brain regions. The developmental patterns of GAD in CA1, CA3 and AD were parallel with small but significant differences in the specific activity of GAD among the subfields. The specific activity of GAD approximately tripled between 10 and 30 days in all three subfields. Intracellular recordings revealed that orthodromic stimulation of the CA3 region of day 10 hippocampal slices resulted in brief monosynaptic epsps followed by prolonged ipsps which were similar in appearance to those in mature CA3 pyramidal cells. Moreover, bath application of the GABA antagonists bicuculline or penicillin produced ipsp blockade and depolarizing shift generation in the immature pyramidal cells. Thus, inhibitory Gabergic synaptic transmission appears to be functional at an age when GAD activity is only about 14% of that in the mature hippocampus. Pre- or postsynaptic alterations in the efficacy of GABA synapses during repetitive stimulation may be responsible for the seizure sensitivity of the immature hippocampus.

277.6 VARIATIONS IN THE CYTOARCHITECTURE OF THE DENTATE GYRUS OF THE SPRAGUE-DAWLEY RAT. D.R. Pierce and J.R. West. Dept. of Anatomy, Univ. of Iowa, College of Medicine, Iowa City, IA 52242.

The relatively simple cytological organization of the hippocampal formation lends itself well for studying a variety of basic topics of neurobiology including development and neuronal plasticity. Although long thought to possess uniform organization throughout its length, it is now recognized that some variations exist along the septotemporal axis. There are cytological variations in the dentate gyrus of adult albino rats. Sprague-Dawley rats from two sources (King Labs, Oregon, WI and Harlan Sprague-Dawley, Indianapolis, IN) exhibit major distortions in the form of convoluted dentate gyri and a wider, flattened hilar region in the temporal one-third of the hippocampal formation. In horizontal sections the distortions appeared as an accessory dentate gyrus. In coronal sections the variations ranged from slight ripples in the molecular layer to convolutions (major distortions) of the medial (infrapyramidal) blade of the dentate gyrus. Major distortions occurred in approximately half of the animals that we examined. They occurred in both males and females, were found unilaterally on either side, and occasionally were bilateral. In spite of the sometimes rather dramatic alterations in the shape of the medial blade, the molecular layer retained its characteristic trilaminarity in Timm's-stained sections. The distortions were not artifacts due to perfusion or sectioning; they were found in brains that were not perfused and in those sectioned in a variety of planes. These variations in organization may prove to be useful in the future for investigating the normal development of convoluted cortical structures.

This study was funded in part by grant AA05523 to J.R.W.

277.7 PERINATAL GLUCOCORTICOIDS ALTER DENTATE GYRUS EVOKED POTENTIALS. J. Vicedomini*, A. Nonneman, S.W. Scheff, and S.T. DeKosky. Psychology, Anatomy, and Neurology Depts., Univ. Kentucky and Lexington V.A. Medical Center, Lexington, KY 40506.

Perinatal glucocorticoid administration in rats retards postnatal neurogenesis in populations of dentate gyrus granule cells. The current study examined extracellular evoked potential activity in the dentate gyrus of adult rats given a single injection of dexamethasone early in ontogeny.

Rats received either a high dose (100 mg/kg) or low dose (1 mg/kg) of dexamethasone hydrochloride on postnatal day 4. One group of control subjects received an injection of saline; another control group, a nutritional control group, received maternal deprivation (8 hrs. daily access to dam) intended to produce body and brain growth suppression comparable to that observed in drug treated subjects. In adulthood we assessed various electrophysiological measures: laminar depth profiles, input/output functions, and paired-pulse facilitation.

Control and nutritional control subjects did not differ significantly from each other on any measure. Laminar depth profile analyses revealed significant reductions (30%) in the spatial extent of the negative field potential evoked in high and low dose subjects. The location of the major synaptic sink, produced by monosynaptic perforant path activation in stratum moleculare, was also significantly changed in high and low dose subjects. Analyses of input/output functions revealed that high dose subjects required significantly higher inputs to generate population synaptic potentials (PSPs, 26%) and population spikes (PSs, 28%) than those found in low dose and control subjects. These group differences emerged in tests using high intensity stimuli, as no significant differences in threshold (stimulus required to first generate PSP or PS activity) were found. Paired-pulse stimulation tests also revealed significant effects of the perinatal dexamethasone treatment. Maximal PSP facilitation was observed in control subjects using a 35 ms interstimulus interval (ISI). High dose and low dose subjects exhibited significantly less PSP facilitation at 35 ms. Low dose subjects failed to show significant PSP facilitation at any ISIs tested, while high dose subjects exhibited maximal PSP facilitation at ISIs longer (60 ms) than those found to be most effective in controls. These electrophysiological findings may underly the behavioral impairments observed in tests of hippocampal function reported for rats treated with glucocorticoids. 277.8 BIRTHDATES OF NEURONS IN THE ENTORHINAL AND SUBICULAR CORTICES OF THE CAT. J. M. Wyss, B. Sripanidkulchai* and T. L. Hickey. Departments of Anatomy and Physiological Optics. Univ. of Alabama in Birmingham, Birmingham, AL 35294.

The [^{3}H] thymidine autoradiographic method was used to determine the birth dates of neurons in the cat parahippocampal gyrus. Cat fetuses were exposed to a single pulse of the radioactive marker between the 20th and 55th embryonic day. All animals were delivered normally and allowed to survive for 2-6 months postnatal. The resulting autoradiographs demonstrate three spatiotemporal gradients of cell birth in the entorhinal and subicular cortices. First, an inside-out gradient is apparent; i.e., neurons in the deeper layers are born earlier than those in the more superficial layers. Second, a rhino-to-dentate gradient exists. Accordingly, cells closer to the lateral entorhinal region tend to be generated earlier than those further away. Third, a temporal-to-septal gardient is present. Neurons close to the anterior pole of the temporal lobe are born earlier than those more caudally located. Whereas the first two gradients have been observed in other species, the latter gradient has not been reported consistently. Three exceptions to these overall gradients exist. First, neurons near the layer I/II border are born earlier than the majority of the layer II neurons. Second, neurons near the transition zone between two adjacent regions are born earlier than neurons located in the middle of each region. Third, the prosubiculum and subiculum do not exhibit a clear inside-out or temporal-to-septal gradient. These exceptions to the normal gradients may shed light on the processes underlying the normal alignment and migration of neurons.

277.9 STRAIN DIFFERENCES IN CELL NUMBERS IN THE RAT DENTATE GYRUS. Gary M. Peterson and Barbara D. Boss. The Salk Institute, and the Clayton Foundation for Research/California Division, P.O. Box 85800, San Diego, CA 92138.

In the past decade there have been several papers that have included estimates of the numbers of granule cells in the rat dentate gyrus. The published figures for the total number of granule neurons on each side varies from just over 600,000 to over 2 million. Although the highest estimate is clearly erroneous (being based on inappropriate methods for estimating cell density), it is not clear why there should be so much variability in the reports from different laboratories. Bayer (1982) has recently suggested that much of the variability is attributable to the study of animals of different ages and her own counts of the numbers of dentate granule cells in Wistar rats indicate a progressive increase in the number of granule cells during the first year from just under 900,000 to 1.28 million (an increase of 40%). Since postnatal neurogenesis is a striking feature in the rodent dentate gyrus, this hypothesis is both plausible and attractive, but it is only partially supported by our own data. We report here a strain difference between Sprague-Dawley and Wistar rats in: (1) the volume of the granule cell layer and in the total number of granule cells; and (2) the changes in these two measures with age.

Volume and cell number was estimated from a series of Sprague-Dawley rats 1, 4, and 14 months of age and Wistar rats 1, 4, and 12 months of age, using the method described by Schlessinger et al. (1975). In Sprague-Dawley rats we have found no evidence for an increase in granule cell number between 1 and 14 months of age; the total number of cells ranged from 1.15 to 1.24 million. The volume of the granule cell layer also remained relatively constant at 1.14 to 1.20 mm^3. Cell density ranged from 9.6 to 10.9 x 10^5 granule cells/mm^3. In our 1 month old Wistar brains the volume and total cell number were substantially less than in the Sprague-Dawley brains of the same age. During the first year the volume of the granule cell layer in the Wistar animals increased from .76 mm^3 to 1.13 mm^3 (49%) and the number of granule cells increased from 640,000 to 810,000 (26%). The cell density was less than in age-matched Sprague-Dawleys and decreased slightly over one year from 8.4 to 7.1x10^5 cells/mm^3 (15%).

Comparing our data with that from other laboratories it would appear that there are significant strain differences not only in the total number of granule cells and in the volume of the cell layer, but also in the pattern of postnatal development. Using the same methods for cell counting and for estimating the volume of the dentate gyrus our data suggest that there is an increase of about 25% in the number of granule cells during the first year in Wistar rats but not in Sprague Dawley rats and that, on average, the number of granule cells in the Sprague Dawley dentate gyrus is somewhat higher than in Wistar rats.

278.1 EFFECTS OF CHOLECYSTOKININ ON INTRACELLULAR RECORDING IN CAUDATE NEURONS. E. Andersen, C. Hull and N. Buchwald, Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

Heavy concentrations of cholecystokinin (CCK) cell bodies are found in the rat cerebral cortex. The caudate nucleus (Cd) has been shown to contain high levels of CCK receptors. The prepiriform cortex (Cx) in the cat has been demonstrated with both anatomical and electrophysiological techniques to have a direct projection to the Cd. This presents the questions of whether there is a CCK pathway from Cx to Cd, what effect CCK has in the cat, and how CCK can be tested and manipulated. Intracellular recordings in the Cd were made in response to electrical stimulation of Cx and to direct application of CCK. CCK effects were compared to those of GABA, glutamate, and the CCK vehicle. Finally, CCK antibody was used to manipulate the effects of CCK.

The micropressure technique was utilized to directly apply the test substances to the Cd in cats. This method eliminates possible alterations of the peptide and antibody caused by the electrical currents used in traditional microiontophoretic methods. The ejection pipettes were constructed with 2-5 barrels of capillary tubing. The recording electrode was attached so that it projected 80-120μ from the ejection barrels.

Intracellular recordings showed that micropressure application of CCK octapeptide (0.1mM) onto single Cd neurons caused a large membrane depolarization of 30-50mV in 38/45 neurons, a dramatic increase in the firing rate in 29/45 neurons, and a decrease in the amplitudes of the postsynaptic potentials (PSPs) evoked by Cx stimulation in 9/11 neurons. In comparison, pressure application of glutamate caused membrane depolarizations of 10-30mV and an increased firing rate without affecting the PSPs, whereas GABA hyperpolarized the membrane, decreased the firing rate and also decreased the amplitudes of the PSPs. The onset of the effects occurred 2-15 sec after 1 kg/cm^2 pressure was applied and the effects outlasted the application period by 15-120 sec. The CCK vehicle, Bovine Serum Albumin, had no effect on 9/12 Cd neurons. Direct application of the CCK antibody blocked the effects of subsequent CCK applications in 6/8 Cd neurons.

These results are in accord with other recent studies which indicate that CCK may be used as a neurotransmitter in the CNS. Components of the excitatory effects of CCK in the Cd seem to be comparable to response components of both glutamate and GABA. There may be CCK projections from the Cx to the Cd in addition to CCK inputs from local Cd neurons. Finally, this study shows that peptide antibodies may be used to manipulate the electrophysiological effects of this class of neurotransmitters.

278.2 RAT NEOSTRIATAL NEURONS IN IN VITRO SLICE PREPARATIONS: (II) THE IONIC NATURE OF REGENERATIVE POTENTIALS. H. Kita, T. Kita* and S. T. Kitai. Dept. of Anatomy, Michigan State University, East Lansing, MI 48824.

The ionic nature of regenerative potentials in rat neostriatal neurons was studied using in vitro slice preparations. The procedures used to prepare neostriatal slices and the methods used for intracellular recordings and intracellular labeling were the same as in the accompanying abstract. Direct stimulation of the neuron with outward current injections through the recording electrode generated fast spike potentials (FSPs). FSPs were completely blocked by the application of TTX (10^{-5} g/ml) in Ringer solution. After application of TEA (2-5 mM), outward current injections could generate FSPs and slow spike potentials (SSPs). The SSPs were characterized by slow depolarizations, long durations and slow repolarizations. Application of TTX in TEA-containing Ringer solution blocked generation of FSPs but not SSPs. These SSPs were not triggered after the substitution of Ca^{++} by Mg^{++} in the medium. The above data suggested both Na^- and Ca^{++} spikes could be generated in neostriatal neurons. Depolarizing postsynaptic potentials (DPSP) evoked by relatively strong local stimulation triggered both FSP and SSP in some neurons. SSPs were more easily triggered by short interval double stimulations or a local stimulation during artificial depolarization of the neuron by outward current injections. After application of TEA, all the neurons triggered SSPs on DPSPs. The SSP on DPSPs were not seen after reduction of Ca^{++} concentration. The results that outward current injection into neurons in normal Ringer solution never generated SSPs, but DPSPs evoked by local stimulation could trigger SSPs, suggested tha the threshold for Ca^{++} spikes was lower in dendrites (where most excitatory synapses are found) than somata. The SSPs may serve an important function in the integration of synaptic inputs onto neostriatal neurons and may trigger Ca^{++} dependent phenomena such as a Ca^{++} induced K^+ permeability increase.

278.3 RAT NEOSTRIATAL NEURONS IN IN VITRO SLICE PREPARATIONS: (I) ELECTRICAL MEMBRANE PROPERTIES AND LOCAL STIMULATION EVOKED RESPONSES. S. T. Kitai, H. Kita and T. Kita*, Dept. of Anatomy, Michigan State University, East Lansing, MI 48824.

Electrical membrane properties and responses to local stimulation were studied in in vitro slice preparations. Rats were decapitated, the brains were removed and blocks containing the neostriatum were sectioned on a Vibratome (250-400 μm) in the parasagittal plane. A slice was placed in a recording chamber and continuously superfused by oxygenated Ringer solution (concentration in mM: NaCl 124, KCl 5.0, $MgSO_4$ 2.0, KH_2PO_4 1.25, $CaCl_2$ 2.0, $NaHCO_3$ 26 and glucose 10, pH 7.2-7.4). Local stimulation was applied through a bipolar electrode placed on the surface of the slice. Glass pipettes filled with 2M K-methylsulfate or 3-4% HRP in 0.05 M tris buffer (pH 7.6) and 0.5M K-methylsulfate with the DC resistance between 30-70 MΩ were used for recordings.

The data reported here are only from neurons having stable resting membrane potentials of more than 50 mV which were to generate spike potentials of amplitude greater than 70 mV. All neurons (n = 52) showed nonlinearity of input resistance in the hyperpolarizing direction (i.e. anomalous rectification). The mean input resistance at the resting membrane potential was 16.6 MΩ. The mean membrane time constant (τ_o) was 5.3 ms and derived from the semilogarithmic plots of transmembrane potential shift produced by small hyperpolarizing current pulses. In some neurons, the equalizing term (τ_1) was also determined and it has a mean value of 1.0 ms. Measurement of τ_o using the strength-latency relation showed a similar value (5.0 ms) to that measured from voltage transients. Direct stimulation of the neuron by outward current injections triggered a single fast spike potential (FSP) or repetitive FSPs. Strong outward currents decreased the amplitude and increased the duration of repetitive FSPs. For their increases in current strength resulted in inactivation of FSPs. Local stimulation evoked only depolarizing postsynaptic responses (DPSPs). Potentiation of DPSPs for longer trains of repetitive stimulation caused post-tetanic potentiations lasting for a few min. DPSPs may be compounded EPSPs and IPSPs, since both Cl^- injection into the neurons and bicuculline or picrotoxine application into the medium resulted in an increase in amplitude in DPSPs. Antidromic spikes preceding DPSPs were observed in some neurons after local stimulation. Local stimulation failed to trigger initial segment and somatic spikes when it was applied during DPSPs which were evoked by a preceding stimulation or during artificial membrane hyperpolarization. Intracellular labeling of neurons indicate that recordings were made from medium spiny neurons.

(Supported by NIH Grant NS 14866 to S.T.K.).

278.4 RAT NEOSTRIATAL NEURONS IN IN VITRO SLICE PREPARATION: (III) THE EFFECTS OF 4-AMINOPYRIDINE ON THE NEOSTRIATAL NEURONS. T. Kita*, H. Kita and S. T. Kitai (SPON: A. Koestner), Dept. of Anatomy, Michigan State University, East Lansing, MI 48824.

4-Aminopyridine (4-AP) which is known to broaden presynaptic spikes by blocking the repolarizing potassium flux and potentiate transmitter release has been used to enhance IPSPs in some in vitro studies of the CNS.

In this study, we observed the effects of 4-AP (0.1 M-1 M) on either synaptically or directly activated responses of rat neostriatal neurones in slice preparations.

1) Effects of 4-AP on synaptic responses evoked by local stimulation. Local stimulation evoked depolarizing postsynaptic potentials (DPSPs) with spikes. 4-AP prolonged the decay phase of DPSPs resulting in a long plateau which accompanied a conductance increase. The amplitude and polarity of the plateau were dependent on the membrane potential. The potentiation of DPSPs, observed with a paired stimulation in control medium was not seen after application of 4-AP. The amplitude of the plateau depolarization was potentiated by an intracellular Cl^- injection or in the presence of the low Cl^- medium. This potentiated plateau depolarization was decreased or blocked by administration of bicuculline or picrotoxin. Repetitive stimulation decreased the amplitude and half-decay time of the plateau depolarization. 4-AP application at times induced spontaneous activities which were never observed in normal slice preparation. Spontaneous activities were more clearly visible when the neuron was either injected Cl^- or when Cl^- was added to the medium.

2) Effects of 4-AP on the direct activation. After application of 4-AP, intracellular stimulation of the neuron with outward current injections generated fast Na spikes and slow spike potentials (SSPs). SSPs were characterized by a slow depolarization, long duration and slow repolarization. Addition of TTX (10^{-5} g/ml) in 4-AP containing medium blocked generation of fast Na spikes, but not SSPs. These SSPs were abolished after the substitution of Ca^{++} by Mg^{++} in the medium and with 1 mM EGTA.

These data suggested that 4-AP enhances synaptic transmission by an increase of Cl^- permeability. The effects of bicuculline or picrotoxin on the potentiation phenomena indicate that GABAergic inputs may influence Cl^- permeability. SSP generation by outward current injections in the presence of 4-AP would suggest that 4-AP may affect not only the presynaptic, but also the postsynaptic sites.

(Supported by NIH Grant NS 14866 to S.T.K.).

278.5 DEVELOPMENT OF SOMATOSENSORY RESPONSIVENESS IN THE BASAL GANGLIA IN THE CAT. M.S. Levine, J.S. Schneider, C.D. Hull, and N.A. Buchwald. Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

Our laboratories have shown that many of the connections of the basal ganglia (BG) are in place and functional by the first few postnatal weeks in the cat. There are, however, a number of indices that remain immature during early postnatal periods. The present experiments sought to ascertain further functional development of BG neurons in awake kittens prepared for chronic recording by determining responses of these neurons to tactile stimulation of the face (punctate or brushing stimuli). Neuronal responses in the caudate nucleus (Cd), the globus pallidus (GP), or entopeduncular nucleus (Ento) were assessed in developing kittens and compared with similar data obtained from adult cats. 522 Cd units were recorded in 7 kittens and adult cats. In the youngest (13-20 days) no cells (0/110) responded to facial tactile stimulation. In kittens 30-35 days old, 1% (1/101) of Cd cells tested responded to facial stimulation. This cell had a large receptive field (i.e., entire face), responded to both touch and brushing stimuli, but was not directionally sensitive. 6% (5/79) of Cd cells in 60-64 day kittens responded to facial stimulation. Responses occurred to brushing and were mostly nondirectional. 9% (6/67) of Cd cells in 90-100 day old kittens responded. Units directionally sensitive to brushing stimuli began to appear at this age. In contrast, in adult cats there were more responsive cells (22%, 36/162), more punctate responses with small receptive fields, and more directionally sensitive cells. To date, 124 GP cells and 89 Ento cells have been recorded from 6 kittens. In 30-40 day kittens 2% (1/40) of GP cells responded to facial stimulation, while 6% (1/17) of Ento cells responded. Receptive fields were the entire face, and responses were only to brushing (no directional sensitivity). In 60-70 day kittens, 12% (7/60) of GP cells and 7% (2/30) of Ento cells responded. Receptive fields were mostly bilateral and moderate to large in size. These cells responded almost exclusively to brushing stimuli and showed virtually no directional sensitivity. 33% (8/24) of GP cells and 19% (8/42) of Ento cells in 90-100 day kittens responded. Units responsive to punctate stimuli and those directionally sensitive to brushing stimuli appear at this age. The results contrast with those found in adult cats, where there are more responsive cells, more discrete receptive fields, and more punctate responses. These findings demonstrate both quantitative and qualitative maturational changes in the ability of BG neurons to encode sensory information during postnatal development.

278.6 BASAL GANGLIA INFLUENCES ON BRAINSTEM NEURONS. N.A. Buchwald, J.S. Schneider, M.S. Levine, and C.D. Hull. Mental Retardation Research Center, UCLA, Los Angeles, CA 90024.

There is increasing evidence that basal ganglia (BG) neurons can interact with both sensory and motor neurons in the brainstem. The present experiment was designed to characterize the electrophysiological interactions of BG output neurons and neurons in the trigeminal nuclei and adjacent brainstem areas.

Extracellular unit recordings were obtained from 8 adult cats. Twenty-three cells were sampled from the trigeminal main sensory nucleus (Sens. V), 10 cells from the trigeminal motor nucleus (Mot. V), 25 cells from the pedunculopontine nucleus (PPN), and 10 cells from the reticular formation (RF). 55% of Sens. V cells responded to stimulation of the trigeminal sensory ganglion (V gang.) only (mean latency=3 msec, s.d.=.08). 23% of Sens. V cells responded to both ganglion and entopeduncular nucleus (Ento) stimulation (mean latency=20 msec, s.d.=5.2). 40% of these cells, when tested in a conditioning-test pulse (C-T) paradigm, showed Ento inhibition of trigeminal sensory responses (effective C-T intervals ranging between 20-100 msec). Similar findings were obtained for RF neurons.

Twenty-two percent of PPN cells tested responded to V ganglion stimulation only (mean latency=12 msec, s.d.=2.0) while 25% responded to Ento stimulation only (mean latency=8 msec, s.d.=3.0) and 16% responded to both V ganglion and Ento stimulation. 5 PPN cells tested in a C-T paradigm showed Ento inhibition of evoked trigeminal sensory responses, with effective C-T intervals ranging between 50-125 msec.

In contrast to the effects upon Sens. V, RF, and PPN cells, no BG influences have been observed to date on neurons in the trigeminal motor nucleus. Many of the motor neurons tested responded to stimulation of the V ganglion and/or stimulation of the trigeminal mesencephalic nucleus. None of these cells responded to BG stimulation nor could trigeminal sensory responses be modulated by BG stimulation. At present, only masseter motor neurons have been identified (by antidromic response to masseter nerve stimulation). BG effects on digastric motoneurons are presently under investigation.

The data indicate that interactions exist between the BG, trigeminal system, and other brainstem areas. Of particular interest is the finding that trigeminal sensory and PPN neurons can be affected by BG stimulation while trigeminal motoneurons are apparently unaffected. These results suggest that previously observed BG effects on the trigeminal motor system may be mediated indirectly via influences on trigeminal sensory and RF neurons.

278.7 THE EFFECTS OF CONTEXT AND STIMULUS SPECIFICITY ON CAUDATE UNIT ACTIVITY DURING HEAD MOVEMENT. C. Manetto* and T.I. Lidsky, SUNY, Stony Brook, NY 11794. Many of the motor problems experienced by humans and experimental animals with basal ganglia (BG) damage are "context dependent" (i.e., these symptoms are present only during certain circumstances). For example, rats with lesions in the globus pallidus have difficulty positioning their heads during ingestion but show normal head positioning during grooming, walking, and rearing. Context dependent problems such as these seem to be characteristic of BG damage in general as limb and trunk movements are similarly affected.

Previous electrophysiological studies have implicated the caudate in the control of head movements (1). To assess the context dependent role of the BG in head movement, units in the caudate were recorded extracellularly in awake cats restrained in a device designed to allow horizontal rotational head movements. Simultaneously, EMG was recorded from the several neck and trunk muscles.

It was possible to elicit specific types of head movements by presenting various stimuli to the animals. For example, cats would track stimuli they found pleasurable (e.g, cat food) and avoid or move away from stimuli they found aversive (e.g., cod liver oil). Movements made in the absence of a distinct stimulus were categorized as spontaneous movements.

Forty cells, established as head movement related, showed clear changes in firing rate with sensory triggered movements. However, units showing activity with movements elicited by one stimulus showed either no response or a different response with movements of similar topography evoked by another stimulus. It should be noted that these unit responses were not sensory responses: on trials where stimulus presentation resulted in no head movement, there was no change in unit firing rate. None of the units showing head movement related activity responded during spontaneous movements.

These data suggest that the BG is involved in sensory-controlled movements rather than movement in general. This involvement is analogous to the supplementary motor area's (SMA) involvement in movement. Tanji & Kurata (2) demonstrated that units in SMA, responsive to sensory triggered movement, show stimulus specificity as well. It is noteworthy that this area may influence movement by gating sensory input into motor areas (3). Similar suggestions have been made about the mechanism by which the BG influence motor functioning (4). The anatomical connections from the BG to the SMA via VA/VL lend further support to the notion of BG gating of sensory information into motor systems (supported by NS 16054).

278.8 REDUCTION OF CORTICALLY EVOKED UNIT ACTIVITY IN RAT STRIATUM DURING TREADMILL LOCOMOTION. D.J. Woodward, M.O. West and J.K. Chapin. Dept. Cell Biology, University of Texas Health Science Center, Dallas, Texas 75235.

One of the objectives in studying the structure and function of the striatum is to clarify how convergent sensory and motor information is processed. In order to consider this issue, we have examined the responses of striatal neurons to electrical stimulation of neocortical areas during different motor behaviors. Adult, female Long-Evans rats were prepared for chronic recording with a detachable microdrive that was located over the striatum, permitting stable unit recording over several hours. Stimulating electrodes were positioned in ipsilateral cortical white matter guided by recent studies of the anatomical organization of direct corticostriate projections (Knowles et al 1980 Soc. Neurosci. Abst. 6:270).

Post-stimulus histograms (PSH) were obtained for nine striatal units recorded from five animals using cortical stimulation consisting of single pulses, 0.15 ms and 200 to 1000μA. PSHs showed robust evoked unit responses that consisted of excitation-inhibition sequences, in agreement with results of numerous acute studies. Responses requiring the least stimulus current were obtained with the recording electrode positioned in striatum 0.3 to 0.9 mm posterior to Bregma (level skull) and 3 to 4 mm lateral to midline, and the stimulating electrode placed in the forepaw area of primary somatosensory cortex, at Bregma and 4 mm lateral to midline.

During awake, motionless behavior, excitatory responses showed an average latency to onset of 6.6 ms and a duration of 31 ms, followed by an inhibitory period that averaged 90 ms. In contrast, during slow-paced treadmill walking, the excitatory peak in histograms for all nine units was significantly reduced by an average of 57%. This reduction in excitatory response was not due to a generalized suppression of striatal unit activity, since over 70% of striatal units in these studies showed increased firing rates during movement.

These results indicate that mechanisms exist which regulate neuronal transmission from cortex to striatum as a function of behavior. Further tests are required to explore the possibilities that these effects are 1) due to altered monosynaptic transmission in striatum, 2) due to changes in the number of corticostriatal fibers activated or 3) dependent upon activity in other afferent systems such as the nigrostriatal dopamine input.

278.9 MOVEMENT RELATED NEURONS IN THE ENTOPEDUNCULAR NUCLEUS OF THE CAT
J.R. Morse and T.I. Lidsky (Sponsor: J. McLaughlin), SUNY at Stony Brook, Stony Brook, N.Y. 11794.

As part of an ongoing series of experiments investigating the sensory-motor functions of the basal ganglia, the responses of 165 entopeduncular nucleus cells to somatosensory stimuli were sampled in behaving cats. In most cases these neurons were also monitored during head movement. An acrylic plug containing the chronic recording chamber was fixed to the skull and also allowed the cat's head to be held painlessly in a holder which could rotate left or right. Movements were controlled by the investigator (passive) or the cat (active). A potentiometer mounted in the head restraint provided a record of these movements.

Approximately 15% of the sampled neurons changed firing rates in relation to head movement. Though firing changes did not precisely precede or follow the onset of movement in most cases, responsive units displayed a repeatable increase or decrease in activity accompanying movement. A number of cells responding during active movements did change firing rates prior to movement onset. In some cases there was a distinct difference in the responses to left vs. right movements. Approximately 54% of these movement related cells also responded to somatosensory stimulation. Of these, 50% had facial fields, 43% had fields involving back, neck, or shoulders, and 7% were responsive to visual stimuli.

Both clinical and experimental data indicate that the basal ganglia play a role in head positioning and oro-facial movement. The entopeduncular nucleus like other components of the basal ganglia processes sensory information from the face as well as information related to movement of the head. This kind of information could be important in the control of behavior relevant to prey capture and ingestion.

278.10 ACTIVITY OF NEURONS IN THE GLOBUS PALLIDUS IN RELATION TO DIRECTION OF MOVEMENT OR PATTERN OF MUSCULAR ACTIVITY.
S.J. Mitchell, R.T. Richardson, F.H. Baker, and M.R. DeLong. Depts. of Neurology and Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

The direction of limb movement has been shown to be an important determinant of neuronal discharge in the basal ganglia. In a recent study neural activity in the putamen (the receptive portion of the basal ganglia) was most often related to the direction of movement rather than to the pattern of muscular activity. The present study was undertaken in order to determine whether neural activity in the globus pallidus (GP), which receives input from the putamen and in turn gives rise to output from the basal ganglia, is also preferentially related to the direction of movement rather than the pattern of muscle activity.

Macaque monkeys were trained to perform an arm visuomotor tracking task similar to that employed in the earlier putamen study. Animals made flexion or extension movements of the elbow. After aligning the arm within a central window and holding for a variable period, a sustained 150g flexor or extensor load or a brief 75g perturbation in the flexor or extensor direction was applied to the arm via a torque motor. The animals had to reposition their arm within the center window, hold for a variable period, and then, in response to a target movement, make a rapid elbow flexion or extension movement with either an assisting or opposing load (or no load). The animals then held at the target for a variable period which was followed by a liquid reward. Neurons were studied in both the external (GPe) and internal (GPi) segments of the GP and in the ventral GP (GPv) which lies below the anterior commissure.

Of the movement related neurons in GP, 39%, 53%, and 13% in GPe, GPi, and GPv respectively were related to the direction of arm movement. None of the cells studied showed a pattern of activity similar to that of the muscles. Of the neurons responding to load application, 49%, 83%, and 46% in GPe, GPi, and GPv respectively showed directional responses. Also, 45%, 20%, and 22% of cells in GPe, Gpi, and GPv showed a relation to static load.

These findings indicate that neurons in the GP, as in the putamen, are related to the direction of movement irrespective of the pattern of muscular activity used to make the movement. This, together with the finding of earlier studies that GP neurons are related to the amplitude/velocity of movement indicates that the basal ganglia may play a role in the control of movement parameters (i.e. the direction, amplitude, and velocity of movement) rather than in the selection or control of specific muscles.

278.11 ACTIVITY OF NEURONS IN THE MACAQUE NUCLEUS BASALIS OF MEYNERT IN A VISUOMOTOR TRACKING TASK.
R. T. Richardson, S. J. Mitchell, F. H. Baker, and M. R. DeLong. Depts. of Neurology and Neuroscience, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205

Some neurons of the nucleus basalis of Meynert (nbM) have been shown to respond phasically with reaching movements and with juice delivery. To better characterize these correlations, nbM neurons were studied in macaques trained to perform a visuomotor tracking task for a juice reward.

During the task, the arm was restrained to allow only flexion or extension of the elbow. The animal first aligned his arm with a central target light and held it there for a variable time. A brief perturbation or a sustained load in either the flexor or extensor direction was applied to the arm via a torque motor. The animal had to recover his original position and hold again for a variable time before the target light moved either to the left or the right. The monkey made a rapid flexion or extension with assisting or opposing loads (or unloaded) in order to realign his arm with the target light. After a third variable hold time, juice was delivered to the monkey and simultaneously the lights were extinguished and the load removed.

Many neurons in the nbM proper (i.e. in the subpallidal region of the basal forebrain) and nbM border neurons (those nbM cells located in the medullary laminae of the pallidum and at the edges of the anterior commissure and the internal capsule) were active when the load was applied and/or during the movement segment of the task. Very few of the responding nbM proper neurons showed a directional preference; however, nbM border neurons did show a directional preference about as frequently as did pallidal neurons. In contrast to pallidal cells, only a few neurons in each nbM area had a tonic response to the sustained load. No nbM neuron had a dynamic load-related response during the movement segment. These results suggest that nbM neurons do not encode information about specific parameters of movement as do pallidal neurons, but rather that they encode some general feature about movement or its occurrence. Also, nbM border neurons seem to have properties more similar to pallidal neurons than do the nbM proper neurons.

Twice as many neurons in the nbM proper as in the pallidum or the nbM border areas responded to delivery of juice. The neurons which did respond to juice delivery frequently also responded to all movements. This suggests that these neurons may encode major events in the animal's behavior or environment rather than reward or drinking per se. Some nbM neurons showed stimulus-locked responses to target onset or offset and/or to light movement, indicating a possible response to visual input.

278.12 NEURAL CORRELATES OF ISOMETRIC FORCE IN "MOTOR" THALAMUS AND GLOBUS PALLIDUS.
M.-C. Hepp-Reymond, R. E. C. Anner-Baratti* and J. H. J. Allum. Brain Research Institute, Zurich University CH-8029 Zurich.

There is now convincing evidence that precentral cortical neurons are tightly involved in the control of fine-graded isometric contractions of finger muscles. The possible participation of the "motor" thalamus and the globus pallidus (GP) in this control was investigated in two alert monkeys trained to generate, between thumb and fore-finger, two successive step-and-hold increases in force, the first being lower (0 to 0.2 N) than the second (ca. 0.2 to 0.7 N). Neurons were recorded according to standard techniques and low current stimulation (5 - 30 µA) was applied through the recording microelectrode.

Following histological reconstruction, 115 neurons with stable relation to the motor task were retained for analysis. From those 55 were located in the "motor" thalamus (VL/VLo nuclei) and 60 within the GP (44 in GPi and 16 in GPe). The discharge patterns were classified into two basic types: One population which was rarely encountered in the finger region of Area 4 was called atypical and displayed sequences of phasic and tonic firing rate modulations without a simple relation to the force traces. The other neuronal group, called typical, had discharge patterns similar to those in Area 4, and represented 58% of the VL/VLo and GP neurons.

A large group of typical and atypical neurons (71% of the VLo/VPLo and 88% of the GP neurons) showed modulations of their tonic firing rate with static force. For the typical neurons monotonic increase of the firing frequency over two or more force levels was observed in 72% of the thalamic and only in 46% GP neurons. Mean rate-force slopes were 63 Hz/N for the thalamic and 62 Hz/N for the GP neurons, being similar to the cortical slopes (Hepp-Reymond and Diener, Exp. Brain Res., Suppl. 7, 1983). Among the neurons whose activity decreased with force only a small percentage in both subcortical regions showed a monotonic decrement. The onset of change in firing rate measured at the time of force increase from the low to the high level occurred later in the GP than in the thalamic or cortical neurons.

These data strongly suggest that neuronal subpopulations in the thalamus and the GP participate in the control of fine-graded force exerted by the fingers in a way similar to Area 4, the similarity being more evident for the thalamic than for the GP neurons.

278.13 EFFECTS OF APOMORPHINE IN SUBSTANTIA NIGRA PARS RETICULATA: VARIABLE RESPONSES IN NORMAL RATS AND INHIBITORY EFFECTS IN 6-HYDROXYDOPAMINE LESIONED RATS. E.K. Lee*, B.L. Waszczak, and J.R. Walters (SPON: D.A. Bergstrom). NINCDS, NIH, Bethesda, MD 20205.

The substantia nigra (SN) pars reticulata receives a major striatal input and transmits information to premotor nuclei outside the basal ganglia, including the ventromedial (VM) thalamus and superior colliculus (SC). Since neuronal activity in the pars reticulata can be considered to reflect net changes in striatal output function, it was of interest to determine how these neurons would respond to stimulation of striatal postsynaptic dopamine (DA) receptors. Previous studies in this laboratory revealed that, when given to awake, paralyzed rats, a single 320 µg/kg i.v. dose of the DA agonist apomorphine (APO) significantly increased the firing of neurons in the globus pallidus, a second nucleus which receives a major striatal input.

Extracellular, single unit responses of SN pars reticulata neurons to a 320 µg/kg i.v. dose of APO recorded in chloral hydrate anesthetized rats were extremely variable (n=29). To rule out concern that anesthesia was responsible for the variable responses, all further studies were carried out in paralyzed, locally anesthetized rats. However, reticulata responses to APO remained highly variable: 35% of cells excited by >25%; 24% inhibited by >25%; 41% of cells unaffected (± 25%) 5-10 min after injection (n=17). The average response for all cells tested was a moderate increase in firing by 39 ± 25%. Further studies were carried out on neurons which were identified as nigrothalamic or nigrotectal cells on the basis of antidromic activation from the VM thalamus or SC, respectively. Among nigrothalamic neurons, responses to 320 µg/kg APO were again highly variable: 32% of cells excited; 32% inhibited; 36% unchanged 5-10 min after APO. The average effect for all cells was an increase by 16 ± 5% (n=22). Nigrotectal cells tended to be either unaffected (57% of cells) or excited (36% of cells); only one cell was inhibited by >25%. The average response of nigrotectal neurons was an increase by 21 ± 11% (n=14).

In contrast to the variable responses observed in normal rats, APO caused a more consistent and often total inhibition of firing of both nigrothalamic and nigrotectal neurons in rats which received 6-hydroxydopamine (6-OHDA) lesions of the SN DA pathway 6-8 weeks previously. Of 17 nigrothalamic cells tested, 14 (82%) were inhibited by an average of 93 ± 19% of their baseline rates; only 2 cells were excited and 1 was unaffected. Similarly, of 21 nigrotectal cells recorded in lesioned rats, 17 (81%) were inhibited by an average of 82 ± 6% of their baseline rates; only 2 cells were excited and 2 were unaffected.

The variable response of pars reticulata neurons to i.v. APO in normal rats contrasts strikingly with the consistent excitatory responses to APO seen in the globus pallidus and suggests that complex or multiple indirect effects of the drug may contribute to the varied reticulata responses. However, in 6-OHDA lesioned rats, the existence of striatal DA receptor supersensitivity may specifically exaggerate an inhibitory DA-mediated striatal influence upon these neurons.

278.14 STUDY OF FIRING PATTERN OF NIGRAL DOPAMINERGIC NEURONS AFTER NEOSTRIATAL LESION IN RATS, EFFECT OF MUSCIMOL. D. Doudet*, C. Gross*, and B. Bioulac. Groupe Motricité, Lab. de Neurophysiologie, Univ. de Bordeaux II, 146 rue Léo Saignat, 33076 BORDEAUX CEDEX (FRANCE).

As shown by post-mortem analysis the major neuropathological trait of the Huntington's chorea is a degeneration of the intrinsic neurons of the neostriatum. The destruction of the neostriatum by kainic acid mimics that situation (Coyle, J.T., Biol. Psychiatry, 14 : 251, 1979). Nigral dopaminergic (DA) neurons in normal rats exhibit a regular pattern of discharge (Wilson, C., et al., Brain Res., 136 : 243, 1977). Their autocorrelogram show a pronounced rhytmicity. The neostriatal lesion induces, in most nigral DA-cells, the appearance of an electrophysiological syndrome characterized by a disorganized activity and a decrease in frequency (Doudet, D. et al., Neurosc. Letters, Suppl. 10, S154, 1982). We have examined in the present work the firing pattern of identified DA-neurons located in the pars compacta of the substantia nigra before and after a kainic acid neostriatal lesion. We have, then, tested the effect of muscimol, a GABAergic agonist, on this electrophysiological syndrome. *Methods* : Nigral DA-cells, which were recorded in normal and lesioned rats, were identified during recording period on the basis of location, electrophysiological and pharmacological characteristics. The baseline unit activity was recorded for at least 200 sec before muscimol injection. The drug has been intravenously administered (2.5 mg/kg). *Results* : In normal animals, muscimol was tested on 18 identified DA-neurons. All these neurons had a very regular autocorrelogram. Their mean frequency was low ($\bar{F}$: 3.60 spikes/sec). As previously described (Waszcak, B., et al., Brain Res. 188 : 135, 1980), the injection of muscimol induced an increase in frequency ($\bar{F}$: 5.46 spikes/sec), but did not alter the rhytmicity. In lesioned animals, muscimol was tested on 27 DA-neurons presenting the so-called electrophysiological syndrome. All these neurons had a very low frequency ($\bar{F}$: 2.62 spikes/sec) and an autocorrelogram without periodic fluctuations. Muscimol produced on 24 of these 27 neurons a frequency increase ($\bar{F}$: 4.07 spikes/sec). However, the main observation resides in the fact that 21 of these 24 DA-cells exhibited a reorganisation of their patterns of discharge. This reorganisation lasted over a mean period of 27 min. following the injection.

Conclusions : The abnormal activity of numerous nigral DA-cells, after neostriatal lesion, may finally impinge upon motoneurons via ascending and descending pathways and participate in the genesis of choreic movements. The present data suggest that : (1) the absence of GABAergic neostriato-nigral pathway may partly account for the DA-cell dysfunction ; (2) the GABA agonist could be of interest in choreic syndrome therapy.

278.15 GLUTAMATE'S ROLE IN THE SUBSTANTIA NIGRA (SN): EFFECTS OF (-)-BACLOFEN AND LESION OF THE CORTICONIGRAL PATHWAY ON ACTIVITY OF SN PARS COMPACTA AND PARS RETICULATA NEURONS. T.H. Lanthorn, M. Knight, L. Steardo* and J.R. Walters. NINCDS, Bethesda, MD 20205.

Several lines of evidence suggest there may be a glutamatergic pathway from prefrontal cortex to the substantia nigra (SN). This study initiates an examination of the influence of this pathway and glutamate on SN activity.

Single unit recordings of SN cell firing rates were made in chloral hydrate anesthetized rats to test the effects of systemically applied (-)-baclofen, a drug which blocks transmission at several glutamatergic synapses. (-)-Baclofen has been shown to slow dopamine (DA) cell activity (Grace & Bunney, Br Res Bull 5,S2:537, 1980). We confirmed this and found that pars reticulata neurons appear 2½ times less sensitive than DA neurons to the rate-reducing effect of (-)-baclofen. While 56% of the pars reticulata neurons (n=9) showed enhanced firing rates at lower doses of this drug, most (89%) were inhibited by increasing doses. The ED50 was 11.5 ± 3.7 mg/kg, iv.

To explore the role of a glutamatergic innervation of the SN from prefrontal cortex, unilateral transection of the frontal cortex was made in rats by a combination of knife cuts and aspirative lesion. Nine days later, glutamate content was determined in punches of SN by HPLC. The SN ipsilateral to the lesion contained significantly less glutamate than did the contralateral SN (37.6 ± 2.2 vs 57.2 ± 2.2 nmol/mg protein, n=5), supporting the idea of a glutamatergic projection from prefrontal cortex to the SN. Serine content was not significantly changed. Similarly lesioned rats were anesthetized with chloral hydrate for single unit recording studies 2-3 weeks after the lesion. All spontaneously active DA and all non-DA (reticulata) neurons for which a positive-negative spike could be found were recorded in 9 passes through the SN. DA cell activity was not significantly altered by the lesion; 0.89 ± 0.08 DA cells/pass fired 3.4 ± 0.33 spikes/sec in control rats (n=6), 0.77 ± 0.11 DA cells/pass fired 4.0 ± 0.40 spikes/sec in lesioned rats (n=15). Firing rate of reticulata cells was also unchanged; 18.2 ± 1.11 spikes/sec in controls and 16.1 ± 1.20 spikes/sec in lesioned rats. However, 1.62 ± 0.11 reticulata cells/pass were found in controls, while significantly fewer, 0.85 ± 0.14 cells/pass, ($p < .005$) were found in rats with frontal cortex lesions. Thus, while reticulata cells were less affected by (-)-baclofen than were DA cells, only in the reticulata was there a reduction in the number of spontaneously active cells after frontal cortex lesion. This change in the pars reticulata may result from the loss of glutamatergic input from prefrontal cortex to the SN or be mediated indirectly via effects of the lesion on other areas, e.g. striatum. The lack of effect of the lesion on DA cell activity suggests that DA cells are not tonically excited by corticonigral innervation.

278.16 THE BASAL GANGLIA AND THE CONTROL OF URINARY BLADDER MOTILITY IN THE RAT. A. Dray and R. Metsch*. Department of Pharmacology, University of Arizona, Medical School, Tucson, Arizona 85724.

The involvement of the central nervous system in the control of urinary bladder motility is poorly understood although it is apparent that both neurological lesions of the CNS and central drug action may produce bladder dysfunction. Presently, the role of the basal ganglia has been explored since both lesions (in Parkinson's disease) and stimulation (in cats) of the structures alter bladder motility. Experiments were made in adult rats (200-220 g) anesthetized with ketamine or urethane. Cystometry was performed routinely following cannulation of the bladder via the urethra. The bladder was filled in 0.1 ml increments until micturition contractions were initiated (overall 27-60 mm Hg). Micturition waves were constant for an individual animal as were the frequency of contractions. All manipulations in the brain were made using stereotaxic methods. Bipolar electrical stimulation (0.5-8 volts; 1-100 Hz; for 20 msec to 2 min) of the striatum inhibited micturition contractions. Repeated pulses of higher frequency were more effective than single shocks delivered at lower frequency. Bilateral stimulation was more effective than unilateral stimulation. Intrastriatal microinjections of dopamine (1-4 µg) or apomorphine (1-5 µg) either inhibited or stimulated micturition waves. Carbachol (1-5 µg) consistently reduced contraction frequency. These effects were reversed by haloperidol (1 µg) and atropine (1 µg), respectively. Chronic (14-20 day) lesions of the striatum made electrolytically or by kainic acid injections consistently produced "hyperactive" detrusor function revealed by cystometry, whereas 6-hydroxydopamine lesions of the substantia nigra produced a "hypoactive" bladder. These data suggest that the basal ganglia have a complex role in regulating urinary bladder motility and that the rat may be useful in evaluating the physiological and neurochemical basis for this regulation.

279.1 CORTICAL AND SUBCORTICAL EFFERENT PROJECTIONS OF THE MEDIAL GENICULATE NUCLEUS IN RAT. J.E. LeDoux, A. Sakaguchi, D.J. Reis. Lab of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021

We examined the efferent projections of the medial geniculate neucleus (MG) in rat, a species in which such projections have not been analyzed using axonal transport techniques.

Wheatgerm agglutinin-conjugated HRP (30-40nl) was microinjected into MG in male, Sprague-Dawley rats (n=8). The diffusion sphere of the injection typically included the principal and magnocellular divisions of MG, with the dorsal division and adjacent regions such as the suprageniculate and peripeduncular nuclei inconsistently involved. In all cases labeled cell bodies were seen in the ipsilateral inferior colliculus and nucleus of the lateral lemniscus, thus confirming the placement of the injection in MG.

Each injection resulted in the anterograde transport of HRP to the ipsilateral neocortex, where two terminal zones were observed. The posterior zone overlapped with the area identified by Krieg (J.Comp.Neurol. 84, 221-275, 1946) as the primary auditory cortex (area 41), but also included most of areas 39, 40, and 2a. The smaller anterior projection zone was located in the anteroventral portion of the somatosensory cortex (area 2). In both zones, terminals were densest in cortical lamina III and IV, but terminals were also observed amongst densely packed cell bodies in the deep lamina.

Subcortically, terminals were observed in the ventromedial hypothalamus (VMH), central and lateral amygdala (AMY), and the ventral aspects of the caudate-putamen (C-P). Fibers giving rise to these terminals could be traced from the internal capsule. In each area, a few retrogradely labeled cell bodies could be identified amongst the terminals.

These findings identify the neocortical distribution of MG efferents and in addition demonstrate that MG projects to several subcortical areas involved in autonomic and somatomotor control. These projections could conceivably play a role in the expression of autonomic and behavioral responses elicited by acoustic stimuli (see Sakaguchi, LeDoux, and Reis, Neurosci. Abs., 1983). Supported by PHS grant HL 18974.

279.2 NEURONS OF LAYER III IN CAT PRIMARY AUDITORY CORTEX (AI): VARIETIES OF PYRAMIDAL AND NON-PYRAMIDAL CELLS. Jeffery A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

The structure of layer III cells and axons was studied in Golgi, Nissl, fiber, and electron microscopic preparations in adult cats. Layer III lies from about 400 to 800 µm beneath the pial surface, and is distinct from layer II by its somewhat larger neurons and the vertical orientation of their dendrites and axons, the denser plexus of horizontally and vertically arranged fibers, and the participation of many layer III neurons in the commissural system interconnecting the primary auditory cortices (Code and Winer, 1983, this volume). The layer IV boundary is marked by large, deep-lying layer III pyramidal cells whose basilar dendritic arbors often encroach into layer IV, and whose axons pass laterally in AI for considerable distances. Besides the commissural component, certain layer III pyramidal cells project to the ipsilateral AII (Winguth and Winer, 1983, this volume). There are five types of layer III pyramidal cells. In all, eleven varieties of neurons are distinguished on dendritic, somatic, and axonal morphology. Layer IIIa is dominated by small and medium-sized pyramidal cells whose apical dendrites rarely enter the upper part of layer I; their axon divides in layer III, often passing laterally. Larger, layer IIIb pyramidal cell dendrites may extend to layer I, their apical dendrites forming prominent vertical arrays, and their axons may descend while emitting extensive branches. Two kinds of stellate pyramidal cells--smooth or sparsely spinous, also occur. Non-pyramidal cells lie throughout layer III. Their round, oval, or fusiform somata, limited dendritic fields, and slender local axonal branches distinguish them from pyramidal cells, and their collaterals may contribute to the fine local axonal plexus in electron micrographs of the neuropil (Larue and Winer, 1983, this volume). The six kinds of non-pyramidal neurons include tufted or bitufted cells with vertically polarized dendrites; sparsely spinous stellate neurons with more spherical dendritic fields; stellate cells with sparse, poorly radiating dendritic patterns; bipolar neurons with a few sparse dendritic branches; multipolar cells with spherical, radiating dendritic arbors; and tiny neurons with slender dendrites and limited dendritic domains. Non-pyramidal cell axons ramify locally, often forming vertical arcades in layers II, III, and IV. The distribution of pyramidal and non-pyramidal cell axons suggests at least five targets for layer III neurons: local projections restricted to the cell's immediate vicinity; vertical branches to superior and inferior cortical layers, but limited to the approximate width of the cell's dendritic fields; longer, horizontal pathways chiefly terminating in AI; ipsilateral cortico-cortical projections, e.g., to AII; and commissural pathways. The manifold forms of layer III cells and their diverse targets in the auditory cortex imply that they participate in different pathways. This research was supported by USPHS grant R01 NS16832.

279.3 LAYER III OF CAT PRIMARY AUDITORY CORTEX (AI): AN ULTRASTRUCTURAL STUDY. David T. Larue* and Jeffery A. Winer. (SPONSOR: T. Nakada). Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

We studied layer III somata and neuropil as part of an inquiry into the organization of AI. Neurons were classified in the light microscope as either pyramidal or non-pyramidal on the bases of size, dendritic branching pattern and appendages, and axonal morphology from Golgi, Nissl, and plastic-embedded, toluidine blue-stained sections (Winer, 1983, this volume). In the electron microscope pyramidal cells typically have large, triangular somata with a thick dendrite emerging from the apical and thinner dendrites from the basal poles, prominent Golgi apparatus at the origins of dendrites, a nucleus with a single modest invagination, a rather patchy, darkly colored and abundant cytoplasm, and a ventrally directed axon. Non-pyramidal cells, in contrast, usually have smaller, round somata with smooth contours, an axon and thin dendrites arising without polarity, modestly developed Golgi apparatus, an eccentric nucleus with multiple, lobular invaginations, and a sparse rim of uniform and granular perinuclear cytoplasm. In electron micrographs pyramidal cell somata are about 25% larger than non-pyramidal perikarya (see Table below). Both cell types receive an average of 4.5 synaptic endings in mid-nucleolar thin sections. However, the morphology of axo-somatic endings differed markedly: 80% of those on pyramidal cell somata have flattened synaptic vesicles, while non-pyramidal cells receive almost equal numbers of endings with flattened or round vesicles. The pattern of axo-spinous and axo-dendritic synapes in the neuropil differed markedly from that of axo-somatic endings. Axon terminals with round vesicles comprise 88% of these endings, while the remaining 12% have flattened vesicles. Dense cored vesicles occasionally appeared in somatic endings and in the neuropil but those on somata were found only in flattened vesicle terminals; those in the neuropil were usually found in round vesicle endings. This implies that the patterns of synaptic inputs are specific to different kinds of layer III cells, and that the innervation of the neuropil is different. Since several types of layer III pyramidal and non-pyramidal cells project commissurally in AI (Code and Winer, 1983, this volume), or have a role in the cortico-cortical pathways connecting subdivisions of auditory cortex (Winguth and Winer, 1983, this volume), different patterns of synaptic organization of pyramidal and non-pyramidal cells might have functional significance in the spatial segregation of auditory input to particular cells. We are now studying the origins of these axonal endings. This research was supported by USPHS grant R01 NS16832.

Summary of Axonal Endings in Layer III of Primary Auditory Cortex

	Pyramidal cells (N=13)	Non-pyramidal cells (N=9)	Neuropil
Mean somatic diameter (s.d.)	16.6 (2.2 µm)	12.8 (1.8 µm)	----
Number of synaptic endings	60	40	438
Number of endings with flattened vesicles	48 (80%)	19 (47.5%)	54 (12%)
Number of endings with round vesicles	12 (20%)	21 (52.5%)	384 (88%)

279.4 HETEROGENEOUS ORIGIN OF COMMISSURAL NEURONS IN CAT PRIMARY AUDITORY CORTEX (AI). Rebecca A. Code and Jeffery A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720

The cells of origin of the commissural system in cat primary auditory cortex were studied as part of an inquiry into the organization of AI. After injection of 1-6 µl of horseradish peroxidase conjugated to wheat germ agglutinin into the convexity of the middle ectosylvian gyrus, the contralateral AI was cut into serial, 60 µm thick frozen or Vibratome sections and processed using the DAB, Hanker-Yates, or TMB chromogens after a 48-72 hour survival. Retrogradely labeled commissural cells were found only in layers III, V, and VI of AI. Of the 7164 labeled cells studied in 4 cats, 71% (5086) were found in layer III and 29% (2078) were found in layers V-VI. Labeled cells often form clusters, columns, or strips within layer III; between these clusters few or no cells were labeled. The distribution of peroxidase-labeled cells is topographically organized in the contralateral AI. If the injection was primarily in the rostral part of AI, the maximum number of labeled cells was in the rostral part of the contralateral AI. If the injection included all of AI, then most labeled cells lay throughout AI on the contralateral side. The control for the localization of the injection in AI was the pattern of retrograde labeling in the ipsilateral ventral nucleus of the medial geniculate body, which also varied systematically with the position of the injection in AI. The area of the retrogradely labeled somata was measured with an electronic digitizer from drawings made with a camera lucida. About 80% of the labeled cells in layer III are small, medium-sized or large neurons (average somatic area: 294.8 sq. µm; see Table below; Nissl counterstain). Their triangular somata and thick primary dendrites suggest they may be pyramidal cells. Approximately 20% were classified as non-pyramidal cells; their average somatic area is 216.9 sq. µm, and their oval or fusiform somata are typical of non-pyramidal cells (Winer, 1983, this volume). A t-test revealed a significant difference ($p<.001$) between the average area of labeled pyramidal and non-pyramidal somata in layer III. We believe that they probably represent two morphologically distinct inputs arising from layer III, in addition to the contribution of cells in layers V and VI. The correlation of the types of labeled pyramidal and non-pyramidal cells with the neuronal populations and patterns of synaptic endings in layer III is the subject of current study. This research was supported by USPHS grant R01 NS16832.

Horseradish Peroxidase-Labeled Commissural Cells in Layer III of AI

Type of cell	Average somatic area (sq. µm)	Standard deviation (sq. µm)	Range (sq. µm)	Number of cells
pyramidal	294.8	93.2	149.9-681.8	325
non-pyramidal	216.9	55.8	117.4-446.4	83
pyramidal and non-pyramidal	278.9	92.3	117.4-681.8	408

279.5 ARCHITECTURE OF LAYER II IN CAT PRIMARY AUDITORY CORTEX (AI) AND SOME IPSILATERAL CORTICO-CORTICAL CONNECTIONS. Sandra D. Winguth and Jeffery A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

As part of an inquiry into AI we studied the structure and connections of layer II in adult cats with Golgi, Nissl, and axoplasmic transport methods. Layer II lies between 200-400 μm deep to the pial surface and is distinct from the cell-poor layer I, and from the larger neurons, especially pyramidal, of layer III. In layer II small and medium-sized pyramidal cells occur, their apical dendrites branching extensively. Their basilar dendritic arbors are rarely as robust as those of layer III pyramidal neurons, nor are their somata as large or angular. Their axon projects within layers II and III and may have side branches. Smooth multipolar stellate cells have limited, primarily vertical dendritic fields radiating irregularly from an oblate somata. The axon has many (30 or more) collaterals, some locally distributed, others projecting laterally and ventrally, but most confined to layer II. Chandelier cells have multiangular somata with well developed apical and sparsely branched basilar dendrites. The latter may turn and ascend to layer I, often entering it, while the axon forms extensive side branches and projects laterally within layer II, and toward layer III. Moderately spinous or spiny stellate cells have flask-shaped perikarya and 2-5 primary dendrites. These ramify in layer II but the extremities, often encrusted with appendages, may invade adjacent layers, and their axons branch locally. Sparsely spinous stellate cells have round somata but, in contrast to the chandelier cells their dendrites are thinner and have a radiate branching pattern irregularly filling a sphere. Their axon has many local branches directed toward layer III and fewer lateral ones. Bipolar and bitufted cells have long vertical dendritic arbors, often running to layers I-III, and with variable numbers of dendritic appendages. Their drumstick-like somata lie throughout layer II. Other types of cells may also occur. Small horseradish peroxidase injections in AII retrogradely label ipsilateral AI somata in layers I-VI. Labeled layer II somata have various, usually triangular shapes, and may form small clusters or strips remote from the AI-AII border. The locus of retrogradely labeled cells in the medial geniculate body was a control for the cortical locus of injection. Since layer II neurons are not retrogradely labeled except by ipsilateral cortical injections, we conclude that their connections differ from those of layer III cells (Winer, 1983, this volume; Code and Winer, 1983, this volume; Larue and Winer, 1983, this volume), and layer V cells (Games and Winer, 1983, this volume), each of which participates in the commissural system. In this sense layer II is more closely allied in its organization with layer IV. This research was supported by USPHS grant ROl NS16832.

279.6 PROJECTIONS OF LAYER V IN AUDITORY CORTEX TO THE RAT INFERIOR COLLICULUS: CELLS OF ORIGIN AND NEURONAL ARCHITECTURE. Kate D. Games and Jeffery A. Winer. Department of Physiology-Anatomy, University of California, Berkeley, California 94720.

We injected horseradish peroxidase into the inferior colliculus of adult rats to compare the retrogradely labeled layer V cells with neurons characterized in Golgi and Nissl preparations as part of a study of the organization of auditory cortex. Layer V lies between 700-875 μm deep to the pial surface and is distinct from the smaller, primarily non-pyramidal somata of layer IV, and the heterogeneous cells of layer VI. In Golgi preparations we commonly observed three varieties of layer V pyramidal cells. Many pyramidal cells have well developed basilar dendrites and a stout apical dendrite. Stellate pyramidal cells have more spherical dendritic fields and a pronounced radiate branching pattern. Inverted pyramidal cells are also present. Pyramidal cell somata are about 15-22 μm in diameter. Among the non-pyramidal cells are bipolar or bitufted neurons with fusiform somata and vertically polarized dendritic fields, and stellate cells with smaller, more radiate dendritic domains and oval or flask-shaped somata averaging 7-15 μm in diameter. Large horseradish peroxidase injections in the inferior colliculus labeled approximately half of the layer V cells in the auditory cortex above the rhinal sulcus. Many such cells have a triangular perikaryon and tend to be large. Smaller, fusiform somata were rarely labeled. In sections with many labeled neurons in layer V, groups of 5-10 labeled cells were interspersed among patches of unlabeled neurons, and single, labeled neurons were uncommon. Smaller horseradish peroxidase injections produced the same pattern of cortical retrograde transport, though on a lesser scale. The number and distribution of retrogradely labeled cells in the auditory cortex, contralateral inferior colliculus, and the subdivisions of the cochlear nucleus (and other nuclei of the auditory brain stem), were systematically related to the size and locus of the injection. In the cat some layer V auditory cortex cells project commissurally (Code and Winer, 1983, this volume) and ipsilaterally (Winguth and Winer, 1983, this volume). The possibility thus exists that layer V participates in three efferent pathways. This research was supported by USPHS grant ROl NS16832.

279.7 LAMINAR DISTRIBUTION AND DENDRITIC BRANCHING OF SPINE FREE NON-PYRAMIDAL NEURONS IN RABBIT AUDITORY CORTEX. N. T. McMullen, E. M. Glaser and M. Tagamets*. Dept. Physiology, Univ. of Maryland Sch. of Medicine, Baltimore, Maryland 21201.

A computer microscope study of the morphometry and laminar distribution of spine free nonpyramidal neurons in electrophysiologically verified primary auditory cortex was carried out in 3 adult rabbits. The laminar and tangential locations of all impregnated neurons in 300 um thick Golgi-Cox Nissl sections through primary auditory cortex were determined. These neurons were classified as pyramidal(P); spine free nonpyramidal(NP) and "other"(O, which included spiny, bipolar and small nonpyramidal cells). The three cortices were comparable in terms of density of impregnation(350 neurons/mm^3), relative proportion of cell types impregnated(87%, 9% and 4% for P, NP, and O respectively) and impregnation frequency(0.92%). The spine free NP variety constitutes 72% of all nonpyramidal cells present. They are found in a mid-cortical stratum approximately 800 um wide with peak concentrations at 450 to 750 um beneath the pia corresponding to lamina III and IV. A total of 60 spine free NP were studied with our image combining computer microscope (Glaser et al, J. Neurosci. Meth., '83) The average cell has a large soma(376 um^2), 7.9 dendrites and 44 branches. Total dendritic length averages 3087 um. 56% of the dendritic length and 52% of the branches are found in the 2nd and 3rd order segments. A combination of dendritic stick, Fourier and statistical analyses revealed a highly significant spatial orientation of their dendrites along a vertical(perpendicular to the pia) axis parallel to the apical dendrites of neighboring pyramids. NP cells in all three cortices also exhibited a significant tangential orientation of dendrites along a dorso-ventral axis. This appears to be normal to the isofrequency contours of rabbits mapped electrophysiologically. An examination of NP dendrite systems using a 3-D Sholl-type radial analysis showed that the pronounced vertical orientation is sculptured from an initially random distribution of dendrites as a result of: a) vertically directed dendritic growth and branching as dendrites grow centrifugally and b) decreased branching and rapid termination of dendrites growing tangentially. The longest dendrites are those directed toward the white matter. Supported by NIH Grants NS17861, GM27165 and a Bressler Research Award from the University of Maryland School of Medicine.

279.8 TERMINATION PATTERNS OF THALAMIC, CALLOSAL, AND ASSOCIATION AFFERENTS OF THE PRIMARY AUDITORY AREA IN THE RHESUS MONKEY. D. N. Pandya and D. L. Rosene, VA Medical Center Bedford, MA and Boston University School of Medicine.

Following radiolabelled amino acid injections of the medial geniculate body (MGB), supratemporal plane (STP) and superior temporal gyrus (STG) in the rhesus monkey, it is observed that the thalamic afferents to the primary auditory area were most prominent. These thalamic afferents were organized in the form of distinct bands, with most of the terminals being localized in layer IV with some extension of terminals in layer III. The callosal afferents by contrast were considerably less pronounced and occurred in spatially separated clusters, terminating in layer IV as well as layer III in the primary auditory area. The association afferents from the STG to the primary auditory area terminated in layer I in a continuous band.

In order to determine the extent to which callosal afferents overlap with the thalamic terminations, in one animal an isotope injection was placed in the MGB and the corpus callosum was sectioned. The thalamic terminations (labelled grains) and callosal afferents (fiber degeneration) were compared in adjacent sections prepared with the autoradiographic and silver impregnation (Fink-Heimer 1961) techniques respectively. The results showed both overlap and interdigitation patterns for these afferents within the primary auditory area.

Thus it seems that for the most part the thalamic, callosal and association inputs to the primary auditory area are conveyed in a topographic manner. There is, however, evidence for convergence of these inputs within the primary auditory area.

279.9 A GOLGI ANALYSIS OF THE AUDITORY CORTICES OF THE MONKEY. P. B. Cipolloni*, D.N. Pandya, and V.M. Knowlton,*(SPON: M.Malone) V.A.M.C., Bedford, MA and Boston University School of Medicine

The auditory cortical neuronal cell types of the monkey have been analyzed in adult rhesus monkeys using two Golgi impregnation techniques. (Braitenberg, V., Guglielmotti, V. and Sada, E., Stain Tech., 42: 277-282, 1967; Valverde, F., Contemporary Methods in Neuroanatomy, W.J.H. Nauta and S.O.E. Ebbesson (Eds). Springer-Verlag, New York,1970.)

The neuronal cell types can be divided into two classes based on the presence or absence of dendritic spines. The spinous neurons are segragated into typical pyramidal neurons,"star pyramids", spinous bipolar and spinous stellate neurons. The typical pyramidal neurons have their cell bodies in all cortical layers except layer I and vary in size. They all have a pyramidal or round cell body, and an apical dendrite coursing perpendicular to the cortex toward the pia, with varying numbers of tangential branches. The "star pyramid", usually found in layer IV, has a more symmetric dendritic array than the typical pyramidal neuron. At times one superficial dendrite may course into layer III. The cell bodies of spiny bipolars may be in layers III or V. They have a prominent apical shaft coursing directly toward the pia and an equally prominent basal shaft coursing either directly or obliquely toward the white matter. The axons of all the above neurons arise from the deeper portions of the somas and course to the white matter. Spinous stellate neurons are only occasionally seen and then only in layer IV. The dendrites of these cells have a symmetrical trajectory around the cell body. The axon of these cells may arise from the cell body or one of the dendrites.

The non-spinous neurons can be divided into stellate, bitufted, bipolar, and neuroglioform neurons. The smooth stellate neurons are found in layers II through VI, usually have spherical cell bodies and radially oriented dendrites appearing to occupy a spherical field of varying size. The bitufted cell has a spherical to elliptical cell body. Several dendrites arise from the superficial and deep poles of the soma and are arrayed in an hour-glass distribution. The smooth bipolar cell has a cigar-shaped cell body which is usually radially oriented in the cortex and has apical and basal main dendrites with each main dendrite having a few tangential branches. The axonal plexus of these three neuronal cell types vary markedly in terms of complexity. The neuroglioform neurons are observed in layers II, III,and V. These very small neurons have numerous short dendrites totally confined to one cortical layer with its axons tightly entwined within the dendrites.

279.10 RESPONSES OF SINGLE NEURONS IN CAT PRIMARY AUDITORY CORTEX TO TONE- AND NOISE-BURST STIMULI. D. P. Phillips*, A. D. Musicant*, S. S. Orman*, G. F. Wilson* and C.-M. Huang* (SPON: R. M. Benjamin). Dept. Neurophysiol. and Waisman Ctr., Univ. Wisconsin, Madison WI 53706.

Most cat primary auditory cortex (AI) neurons are sharply tuned to a best frequency (BF), and their spike counts are either a monotonic or a nonmonotonic function of the intensity of a BF tone. In the present study, we gathered detailed data on the frequency-intensity response areas of AI cells, and have obtained evidence for an association between the selectivity of a neuron to tone frequency and intensity on the one hand, and its ability to respond to broad-band noise on the other. All data were obtained from single neurons in barbiturate anesthetized cats to which tone- and noise-burst stimuli were presented through calibrated, sealed stimulating systems.

In general, neurons which responded to noise bursts showed spike counts which were monotonic in shape for most or all tone frequencies to which the neurons were sensitive. The spectrum level of a neuron's BF in a threshold noise stimulus was almost always lower than its pure tone threshold, suggesting that at threshold levels, the neuron was responding to energy in the noise stimulus summed over a relatively wide bandwidth. For those neurons whose noise spike count functions were also monotonic, intensity dynamic ranges were typically wider for noise than for tones. The fact that other neurons with monotonic tone spike count functions displayed nonmonotonic noise spike count functions suggests that the high intensity parts of their tone response areas may have been bordered by inhibitory regions.

The majority of neurons failing to respond to noise stimuli were those whose pure tone spike count functions were strongly nonmonotonic such that their spike counts fell to zero at high stimulus levels, regardless of tone frequency. These neurons had completely circumscribed frequency-intensity response areas, responding to tones only within narrow domains of frequency and intensity. These cells were less common than monotonic neurons, and appeared to be segregated into small cortical loci approximately 300 microns in diameter. The nonmonotonic shape of these cells' pure tone spike count functions must be produced by inhibitory processes because the cochlear output shows no such property. The insensitivity of these cells to noise stimuli of any intensity suggests that their excitatory tone response areas may be flanked by side-band inhibition.

279.11 STABILITY OF INTENSITY FUNCTIONS OF SINGLE NEURONS IN AUDITORY CORTICAL FIELD A-I. T. McKenna, D.M. Diamond*, and N.M. Weinberger. Dept. of Psychobiology, Univ. of Calif. Irvine, Irvine, CA 92717.

The sensory evoked discharges of auditory cortical neurons are modified during associative learning. We have assessed the reliability of sensory encoding of single neurons in a nonlearning situation by obtaining intensity functions in unanesthetized animals, with control of peripheral factors. Stability of stimulus encoding was measured by repeatedly determining intensity functions of single auditory cortical neurons across time and different states of arousal, in chronically prepared cats under neuromuscular blockade to insure stimulus constancy at the periphery. EEG and pupillary dilation were monitered continuously. A series of tones of 100 to 300 ms duration, at best frequency, were delivered at 10 different intensities (25 trials per intensity). This series was then repeated as many as 4 times, at 15 min. intervals. For some series, no stimuli were given during the 15 min. wait, nor between blocks of trials. During some of these series the animals exhibited slow wave activity and pupillary constriction. In other series the animal was aroused by single paw shocks delivered either before a series, or prior to each block of 25 trials. Over 70% of the neurons sampled exhibited no significant changes in the intensity function (plot of means of discharge rate for interval of peak response minus prestimulus rate) under all conditions examined. Some neurons exhibited stable intensity functions although background discharge rates had decreased over series which were accompanied by an increase in the level of arousal. Intensity functions were of 3 types: a) monotonic b) nonmonotonic and c) multipeaked, irregular. Intensity functions for the first 2 types of cells were predominately stable, whereas those for the 3rd category were not.

These results contrast with previous studies of the influence of state of arousal on the responsiveness of auditory cortical neurons in behaving monkeys, which reported that many or most neurons were strongly modulated by behavioral state. However, factors such as middle ear muscle activity, species differences, auditory areas sampled, or contextual and task related variables need to be considered in assessing the influence of arousal on the neuronal encoding of stimulus dimensions such as intensity.

279.12 FREQUENCY DISPARITY SELECTIVITY IN CAT PRIMARY AUDITORY CORTEX (AI). J.R. Mendelson and M.S. Cynader, Dept. of Psychology, Dalhousie University, Halifax, Nova Scotia, Canada.

The intensity and timing relationships of acoustic stimuli in the two ears are important cues for sound localization. When a sound source moves from left to right the stimulus amplitude increases in the right ear and decreases in the left. Because the head attenuates high sound frequencies more strongly than low frequencies, high frequency components will be diminished relative to low frequencies in the left ear. The overall peak of the frequency spectrum will thus be shifted toward higher frequencies in the right ear and lower frequencies in the left. The change in the shape and the peak of the frequency spectrum in the two ears will be a progressive function of the horizontal eccentricity of the stimulus. Little attention has been devoted to the neurophysiological investigation of this binaural frequency disparity as a possible cue to sound localization.

We examined the responses of cells to tones of different frequencies (delivered via ear speakers) in AI of anaesthetised, paralyzed cats. The characteristic frequency (cf) of each cell was determined and the cell classified as showing binaural facilitation (EE) or binaural inhibition (EI). Then, while the cf was presented to the contralateral ear, a series of pure tones of varied frequency were simultaneously presented to the other ear. Stimulus intensity was the same for the two ears.

Of the EE cells studied above, about 1/4 showed the greatest binaural facilitation when there was no difference in the frequency of the tones presented to the two ears. In contrast, nearly 3/4 of these cells gave their greatest binaural response when tones with different frequencies were presented. Approximately 1/3 of the EI cells showed their deepest inhibition with binaural presentation of the same frequency. The remaining EI cells showed their deepest inhibition when different frequencies were presented to the two ears. In both the EE and EI cells that responded to non-zero frequency disparities between the two ears, about 50% showed the greatest degree of facilitation (or inhibition) when the ipsilateral ear received higher frequencies than the contralatral ear, while the other 50% responded best (or showed greatest inhibition) when the ipsilateral ear received lower frequencies than the contralateral ear.

The results show that the responses of both EE and EI cells in AI are strongly dependent on the relative frequency content of stimuli in the two ears. The frequency disparity cue studied here appears to play a potentially important role in controlling the responses of both cortical cells and the behaving organism to sound sources of different eccentricities.

279.13 LAMINAR ANALYSIS OF SINGLE UNIT ACTIVITY IN AUDITORY CORTICAL FIELD AII OF CAT: STABILITY OF TUNING FUNCTIONS. D.M. Diamond*, N.M. Weinberger, Dept. of Psychobiology, UC Irvine, Irvine, CA.

Previously, we reported that every cell recorded in AII displayed discharge plasticity during associative learning (Neurosci. Abst. 8:317,1982). This investigation is the first in a series of studies designed to characterize the functional significance of such plasticity. Specifically, changes in auditory cortical activity during learning may represent alterations in receptive field characteristics. Preliminary to studying the possible effects of learning on receptive fields, this report is concerned with the degree to which tuning curves are stable in AII.

Single unit activity was recorded in chronically prepared cats under neuromuscular blockade to insure stimulus constancy at the periphery. The responses of single cells to tones of various frequencies were determined initially and again after a period of 15 to 30 minutes of silence.

There are two major findings related to an overall description of AII unit activity and of the stability of sensory evoked responses. First, the breadth of tuning and background rate of activity change as a function of the depth from the surface. Cells from 200-800u have background firing rates of 5.0 sp/sec., exhibit complex evoked responses consisting of periods of inhibition and excitation and can have narrow tuning functions. Cells from 800-1200u have high background rates (14.4 sp/sec), exhibit homogeneous evoked responses consisting of excitation at a latency of 12-18 msec and are very broadly tuned. Cells located from 1200-2100u have low background rates (1.9 sp/sec) and rarely respond to tonal stimuli. However, they usually discharge to complex sounds such as keys jangling. Previous reports have described only broadly tuned cells in AII, but this may be due to the fact that the studies used anesthetics which suppressed the activity of the upper and lower layers. The broadly tuned cells which are located from 800-1200u are likely to be in layer IV and receive direct thalamic input, thereby making them less susceptible to anesthetic agents.

The second finding is that the tuning functions of AII cells in each respective layer are largely stable. Moreover, components of evoked responses such as onsets, offsets and periods of inhibition are highly reproducible over time. Hence, the frequency response characterisitics of AII cells are relatively invariant in the absence of training.

279.14 EVIDENCE FOR CONNECTIONS BETWEEN AUDITORY CORTEX AND FRONTAL CORTEX OF THE BAT, PTERONOTUS PARNELLII. J.B. Kobler*, S.F. Isbey and J.H. Casseday. Neurobiology Program, U. of No. Carolina, Chapel Hill, N.C., 27514, and Depts. of Psychol. and Surgery (Otolaryngology), Duke Univ., Durham, N.C. 27710.

We present new anatomical evidence that reciprocal connections exist between auditory and frontal cortices and that cells in the frontal cortex respond readily to ultrasonic stimuli in this echolocating bat. We first noted prominent anterograde and retrograde labeling in dorsolateral frontal cortex after a large injection in auditory cortex of wheat germ-agglutinin conjugated to horseradish peroxidase (HRP). Further evidence that this frontal area is connected to the auditory pathway was obtained from HRP injections placed in physiologically defined parts of auditory cortex. These cortical areas, which respond to auditory stimuli and which receive input from the medial geniculate body, have reciprocal connections with frontal cortex. Electrophysiological methods were used in four experiments to place HRP injections in the area of frontal cortex that responds to acoustic stimuli. In all of these cases we found a similar pattern: cells were labeled in dorsal and anterior parts of the auditory cortex, and few labeled cells were found in the central part of the auditory field. This central part probably corresponds to primary auditory cortex, an area we defined previously by cytoarchitecture and the anterograde transport of ^{3}H-leucine from the ventral division of the medial geniculate body. Labeled cells were also found in the depths of the lateral sulcus, in cingulate cortex, and in areas dorsal and posterior to auditory cortex. The main thalamic input to the frontal area is from the mediodorsal nucleus. In addition, the frontal area receives a projection from cells in the suprageniculate nucleus, an area which we have found to project to the auditory cortical field.

Single units and evoked responses to tone pips were mapped with microelectrodes in the frontal region in bats lightly anesthetized with metofane. Most units responded broadly to frequencies between 10 and 120 kHz and often showed increased sensitivity and sharp tuning to frequencies around 60 kHz, which is the most intense harmonic of this bat's sonar pulse. Latencies ranged from as short as 10 msec to greater than 75 msec. Units habituated readily and frequently responded to tone pips with bursts of 2-8 spikes.

These observations that the frontal cortex of Pteronotus has well developed connections with the auditory system is significant in view of this animal's sophisticated biosonar behavior. The results are particularly intriguing in view of current hypotheses implicating frontal cortex in functions such as spatial orientation and vocalization. [Supported by NSF grant BNS 82-17357.]

279.15 THE EFFECTS OF AUDITORY CORTICAL LESIONS ON SEVEN CHOICE SOUND LOCALIZATIONS BY FERRETS. Gerard Kavanagh* and Jack B. Kelly. (SPON: E.W. Peterson) Department of Psychology, Carleton University, Ottawa, Ontario, Canada, K1S 5B6.

Auditory cortical lesions have failed to produce marked impairments in sound localization in rats tested under various stimulus conditions in either two or seven choice sound localization. In contrast, a number of reports have indicated that severe deficits occur in other mammalian species following equivalent lesions. The possibility has been suggested that differences exist among mammals in the degree of cortical dependency of sound localization. For purposes of further comparison, we have undertaken studies of the effects of auditory cortical lesions using ferrets as subjects. Ferrets were selected as a readily available laboratory species with a well developed neocortex and a likely compatibility with behavioral training and testing procedures already established for rats. Results have shown the ferret to be an excellent species for behavioral studies. Normal animals rapidly learn to execute spatial responses in a semicircular maze for water reinforcement. They are capable of localizing sounds in either a two choice or a seven choice test situation and exhibit highly reliable levels of performance. The effects of cortical lesions have been examined in two cases following bilateral lesions of auditory cortex. Lesions included both primary auditory cortex (AI) and surrounding areas receiving projections from the medial geniculate body. Both animals had severe postoperative impairments in seven choice sound localization even when the stimulus, a train of clicks repeated at two per second, was left on until a response was completed. Neither animal was capable of performance above the level expected by chance when tested with a single click presented at the beginning of each trial. A third animal, tested following unilateral ablation of auditory cortex was found to have reduced performance contralateral to the side of the lesion. Impairments were evident with both two per second and single clicks. Deficits persisted with repeated testing over a prolonged postoperative recovery period. We conclude that ferrets are severely impaired in the ability to localize sounds in space following lesions of auditory cortex.

279.16 THE EFFECTS OF AUDITORY CORTICAL LESIONS ON SEVEN CHOICE SOUND LOCALIZATION BY THE RAT. P.W. Judge* and J.B. Kelly. Dept. Psychology, Carleton University, Ottawa, Ontario, Canada, K1S 5B6

Previous studies of the effects of auditory cortical lesions in the rat have shown only minor impairments in two-choice sound localization following large bilateral lesions (Kelly, J. Neurophysiol., 44, 1161-1174, 1980). The following study was undertaken with the expectation that deficits would be more readily apparent in a localization task which required responses to multiple sound sources. Albino rats were trained to localize sounds in a seven-choice test apparatus. The effects of both bilateral and unilateral lesions were evaluated. The test procedure required that an animal approach clicks delivered from one of seven loudspeakers located at 30 degree intervals around the perimeter of a semicircular maze. A click was presented when a subject made contact with a spout located in the center of the maze equidistant from the seven loudspeakers. This ensured that an animal's head was aligned with the 0 degree azimuth speaker position at the beginning of each trial. Animals were first trained to localize clicks repeated at two per second, and were then tested with a single brief click presented at the onset of each trial. Normal rats were capable of high levels of performance with two per second click trains, but attained only intermediate levels of performance with single clicks. Following unilateral lesions of auditory cortex, performance levels remained essentially unchanged. Comparison of animals with left versus right hemisphere lesions revealed no evidence of contralateral impairments in sound localization. Bilateral lesions resulted in slight impairments in localization although some ability to localize remained even with complete bilateral destruction of auditory cortex. These results are consistent with previous reports that lesions of auditory cortex in the rat do not produce severe impairments in sound localization.

279.17 CONTRALATERAL DEFICITS IN HUMAN AUDITORY PERCEPTION AFTER UNILATERAL CEREBRAL LESIONS. T. Allard* and T.A. Zeffiro. Dept. Psychol., Mass. Inst. Tech., Cambridge, MA 02139 and Neurol. Serv., Mass. Gen. Hosp., Boston, MA 02114

Patients with unilateral cerebral lesions show subtle changes in the auditory perception of material presented to the contralateral ear. These changes have been described as defects in the perception of degraded speech sounds. This impairment is dissociable from disorders of language and could involve processing of nonverbal auditory stimuli. We present preliminary evidence that lesions of either hemisphere disrupt the perception of transients in both speech and nonspeech sounds.

Monaural detection thresholds for 1-ms and 500-ms bursts of white noise were obtained from 13 patients, aged 22 to 57, with left-hemisphere or right-hemisphere lesions. An adaptive $\hat{}$ estimation procedure was used in a computer-controlled, 2-interval, 2-alternative forced-choice paradigm with feedback. All subjects had normal and symmetrical thresholds for the 500-ms bursts. The normal group exhibited a symmetrical, 20-dB elevation in threshold for 1-ms bursts. In contrast, both patient groups showed a significantly greater contralateral increase in 1-ms thresholds when compared to performance with the ipsilateral ear ($p < .01$, matched-pair t-test).

This nonverbal perceptual impairment was associated with a deficit in the perception of a synthetic speech continuum varying voice-onset time (VOT). Speech sounds ranging from /da/ to /ta/ were presented to each ear at 90 dB SPL. Most patients labeled stimuli presented to the ear ipsilateral to the lesion in a stable and categorical fashion. In contrast, labeling of contralateral stimuli was erratic. Discrimination of VOT pairs was less accurate with the contralateral ear than the ipsilateral one. Three aphasic patients could not label stimuli presented to either ear. Two of these subjects showed normal ipsilateral discrimination but impaired contralateral performance demonstrating a clear dissociation between linguistic and auditory mechanisms. Speech and nonspeech perceptual deficits were uncorrelated.

Deficits in the perception of acoustic transients indicate that cerebral auditory areas play an important and specific role in the processing of certain classes of speech sounds. The contralateral nature of the impairment is consistent with a theory of hemifield organization in the human auditory system.

VISUAL CORTEX: EXTRASTRIATE VISUAL AREAS II

280.1 THE ORGANIZATION OF CORTICAL VISUAL AREAS IN A STREPSIRHINE PRIMATE, GALAGO SENEGALENSIS. John Allman and EveLynn McGuinness*, Division of Biology 216-76, California Institute of Technology, Pasadena, California 91125.

The order Primates is divided into two suborders: haplorhines (tarsiers, monkeys, apes, and man) and strepsirhines (galagos, lorises, and lemurs). In order to trace the evolutionary history of the cortical visual areas, we have sought to determine which areas are present in both suborders. We have mapped the representations of the visual field with microelectrode recordings in the visual cortex of a strepsirhine primate, Galago senegalensis. Our results indicate that the primary visual area (V-I), the second area (V-II), and the middle temporal (MT), the dorsolateral (DL), the medial (M), the ventral posterior (VP), the ventral anterior (VA) visual areas are all present in Galago. Previous data indicate that these areas are present in New World monkeys. There is also substantial evidence from other laboratories that most, if not all, of these areas also are present in Old World monkeys. Galago also possesses extensive, visually responsive inferotemporal and posterior parietal cortical regions, but, as in monkeys, receptive fields of neurons in these regions do not appear to be organized in obvious visuotopic maps.

Recently Horton and Hubel (Nature, V. 292, p. 762, 1981) have reported that the system of cytochrome oxidase stained patches in layers II and III of striate cortex are present in Galago as well as New and Old World monkeys but are not present in nonprimates such as cats and tree shrews. The results suggest that there exists a distinctive primate pattern in the functional organization of striate cortex.

Taken together these similiarities in the organization of striate and extrastriate visual cortex in strepsirhine and haplorhine primates suggest that these features were present in the common ancestor of these living forms, which would have been a primitive primate living during the Eocene period 36 to 55 million years ago. These early primates possessed large frontally directed eyes and an expanded posterior neocortex; they were small, probably nocturnal, visually predatory, insectivorous creatures that lived in the fine terminal branches of trees (Cartmill, Science, V. 184, p. 436, 1974; Simons, Primate Evolution, 1972; Radinsky, Am. J. Phys. Anthrop., V. 27, p. 385, 1967). The comparative neurobiological data suggest that many of the distinctive features of the primate visual system developed in these early primates. 280.2 SUPPRESSION FROM IPSILATERAL VISUAL FIELD IN AREA V4 OF THE MACAQUE. J. Moran*, R. Desimone, S.J. Schein#, and M. Mishkin (SPON: C. Gross). Laboratory of Neuropsychology, NIMH and #Section on Visual Processing, National Eye Institute, Bethesda, MD. 20205.

Like other prestriate areas, V4 contains a representation of the contralateral visual field. Within at least the central 5°, V4 excitatory receptive fields (RFs) rarely extend more than 1° across the vertical meridian (VM) into the ipsilateral visual field. Yet, V4 receives a heavy commissural projection not strictly limited to the representation of the VM (Van Essen and Zeki, J. Physiol., 1978). We have previously found that V4 RFs have silent suppressive surrounds: Stimuli placed outside the RF are without effect themselves yet are able to suppress the response to an RF stimulus. We report that the suppressive surrounds of V4's RFs extend far into the ipsilateral visual field.

We studied neurons within the representation of the central 5° of V4 in 3 anesthesized (N_2O), paralysed macaques using a semi-chronic preparation. We mapped the RF of each cell by hand and determined the optimal RF stimulus. All RF centers were in the contralateral field, and the mean overlap of the VM was only 0.6°. To test for a suppressive surround, we measured the response to the paired presentation of the RF stimulus and a large annulus (O.D. 21°, I.D. slightly larger than RF) and compared it to the response to the RF stimulus alone. The response of 74% of the cells was significantly suppressed by the annulus. The mean suppression across all cells was 75%. The surround stimulus alone elicited no response. These results were corroborated in one alert monkey, trained to fixate.

To determine if the suppressive surrounds extended into the ipsilateral field, we measured the response to an RF stimulus alone and compared it to the response to an RF stimulus paired with a bar (15° X 20° wide) confined to the ipsilateral visual field. The bar's medial edge was located at 0, 0.5, 1, 2, 4, 8, and 16 degrees into the ipsilateral field. Across all cells suppression was significant out to at least 16°, ranging from 58% at 0° to 18% at 16°.

To determine the contribution of the corpus callosum to the ipsilateral suppression, we sectioned the posterior 1/2 of the corpus callosum in one of the monkeys. Whereas the suppression by an annulus remained equal to that in normal animals, the suppressive effect of the bar confined to the ipsilateral field was significantly reduced. Across all cells suppression was significant only out to 4°; even at 4° the suppression was only half that seen in normal animals.

We conclude that the suppressive surrounds of V4 RFs extend far into the ipsilateral visual field and that the corpus callosum mediates at least part of the suppression.

280.3 DIRECTIONAL PROPERTIES OF PARIETAL VISUAL NEURONS IN MONKEY
M. A. Steinmetz*, C. J. Duffy, B. C. Motter*, and V.B.Mountcastle
The Bard Laboratories of Neurophysiology, Dept. Neuroscience,
The Johns Hopkins Un. Sch. of Med., Baltimore, Md., 21205

The majority of visual neurons in the inferior parietal lobule (area PG) have large, often bilateral receptive fields and respond more vigorously to moving than to flashed stationary stimuli. 90% of the movement sensitive cells respond differentially to stimuli moved in opposite directions through the same zone of their RF's. The "best" directions for 40% of these cells are opposed in the opposite halves of the visual field, pointing either inward or outward with respect to the point of fixation.

The aim of the experiments described here was to study the mechanisms determining the organization of directionalities. For these experiments Macaque monkeys viewing binocularly the central $100^0 x100^0$ of a tangent screen were trained to achieve and maintain fixation of a 0.3^0 target light, and to detect its dimming in order to receive liquid reward. Luminous test stimuli ($10^0 x10^0$) were back projected onto the screen and moved 10^0, 20^0, 40^0 or 100^0, during the fixation period, along the horizontal, vertical, or diagonal axes, at velocities of 30^0/sec to 120^0.sec.

The results indicate that for some parietal visual neurons, the directional-specific response is due to local directional properties within the RF. For other cells, the directionality is the result of the history of the stimulus movement, including movements outside the RF for that cell. For many neurons,both influence the radial organization of the directional responses.

Only rarely are these directional responses evoked by movements along a single axis. More commonly, responses are evoked by stimuli traversing several or even all 4 meridians (8 directions) tested. For many cells, the intensity of response varied with the radial direction of stimulus movement. We have used a sinusoidal regression analysis to estimate a radial directional preference for these cells. Our analyses indicate that all directions are represented in the population of neurons from each hemisphere, with some weighting toward preferred directions into the contralateral field.

These directional properties appear to be ideally suited for a system dealing with spatial relations, and the constancy of the image of the world during movements of head and eyes. In addition these neurons may provide signals for the perception of optic flow patterns associated with translational movements of the body through space, and for the attraction of gaze toward moving objects entering the periphery of the visual field during attention to foveal tasks. 280.4 CONNECTIONS OF VISUAL CORTEX ROSTRAL TO THE MIDDLE TEMPORAL AREA (MT) IN OWL MONKEYS: EVIDENCE FOR A VISUAL REGION IN SUPERIOR TEMPORAL CORTEX. R.E. Weller and J.H. Kaas, Depts. of Psychology and Anatomy, Vanderbilt Univeristy, Nashville, TN 37240.

The Middle Temporal Area (MT) of visual cortex has been identified in all primates investigated, and its projections have been described in prosimian galagos, New World marmoset monkeys, and most recently, Old World macaque monkeys. In macaque monkeys, MT projects, in addition to other areas, to bordering cortex adjacent to the representation of the peripheral visual field of MT. We found a similar projection from MT in owl monkeys. Single, restricted injections of ^{3}H-proline in MT of 6 owl monkeys demonstrated terminations in a region of cortex rostral to MT, in the caudal superior temporal gyrus and extending into the caudal end of the temporal sulcus. The projections from MT to this Superior Temporal Region (ST) were bilateral, strongest in granular and supragranular layers of cortex, patchy, and sometimes discontinuous dorsally and ventrally. We investigated the connections of this MT-receptive ST region by placing single, small injections of ^{3}H-proline into dorsal ST in 3 additional owl monkeys, and into ventral ST in 2 other owl monkeys. These injections were judged to be in ST and not in adjacent MT, the Dorsolateral Area (DL), or Inferior Temporal Cortex (IT), from architectonics and the known connections of MT, DL, and IT. While the ST region may project to some areas of visual cortex which also receive input from MT, DL, or IT, ST also projects uniquely to other regions of cortex: 1) a large region of parietal cortex in the caudal Sylvian fissure, extending slightly onto the surface of cortex below the fissure; 2) IT cortex of the ventro-medial surface; 3) cortex in other parts of the temporal sulcus; and 4) all parts of MT. The laminar pattern of projections from ST is different for different target areas, e.g., terminations in the rostral temporal sulcus are concentrated in layer IV, while terminations in MT and the Sylvian fissure are concentrated in layers above and below IV. Injections into dorsal ST result in discontinuous projections to ventral ST, and vice versa, and these interconnections suggest that separate dorsal and ventral subdivisions may exist in ST. However, due to the patchy nature of terminations in the ST area in general, and the many similar connections of dorsal and ventral parts of ST, this suggestion must remain tentative.

280.5 RESPONSE PROPERTIES AND DISTRIBUTION OF NEURONS WHICH RESPOND TO FACES IN THE MONKEY. C.M.Leonard, E.T.Rolls, G.C.Baylis*, F.A.W.Wilson*, G.V.Williams*, C.Griffiths* and E.Murzi*. Dept. Exptl. Psychol., Oxford Univ., Oxford, England.

Neurons which respond selectively to faces have been found in the cortex in the fundus of the superior temporal sulcus (STS) of the macaque monkey (Perrett, Rolls and Caan, 1982). We are now investigating whether neurons which respond to faces are also found in areas connected to the cortex in the STS, and if so how their responses may differ. In the ventrolateral part of the inferior temporal cortex (area TE) (which projects into the STS), only a small proportion (1% of our current sample) of neurons responded selectively to faces, compared with 20% in the fundus of the STS. The proportion of neurons which responded to faces increased (to 5%) as the recording sites moved into the ventral bank of the STS. In the STS, neurons which responded to faces were found to be distributed over a long anterior-posterior extent which included the anterior and middle thirds of the sulcus (approximately 4 to 16 mm anterior to ear bar zero in the 3-6 kg rhesus and cynomolgous monkeys). Some neurons which responded to faces were also found in the amygdala, which receives projections from temporal neocortical areas. A number of these neurons were found in and around the basal accessory nucleus of the amygdala. These neurons were more likely than those in the STS to differentiate between individuals. In some cases their responses occurred preferentially to categories of faces, such as those of infant monkeys. In the ventral striatum, which receives connections from the amygdala and the temporal lobe neocortex, neurons were found which could respond to faces, but often the emotional significance of the face was important, and some of these neurons also responded to other emotion-provoking visual stimuli.

An analysis of the response properties of face-selective neurons in the temporal neocortex is providing evidence that they respond to different parts of the spatial frequency spectrum present in faces, that responses can occur to a negative image of a face, that in some cases they can respond partly to simple representations of facial features such as two circles to represent the eyes, and that the distance of the face can be important.

These results are consistent with the hypothesis that the brain of the monkey contains a neuronal system in which processing first becomes specialized for parts of faces, then for particular faces or for some types of face, and then becomes appropriate for emotional responses made to such faces.
