366.8 INABILITY OF BRAIN MICROTUBULES IN ALZHEIMERS DISEASE TO COLD-DEPOLYMERIZE. S.R. Campbell*, S. Khatoon*, B.E. Haley* and J.T. Slevin (SPON: K. W. Barron). Depts. of Neurology, Biochemistry and Medicinal Chemistry, Sanders-Brown Center on Aging, Lucille Parker Markey Cancer Center, VA and Univ. Kentucky Med. Ctrs., Lexington, KY 40536-0084.

GTP is a requirement for tubulin polymerization. The nucleotide photoaffinity probe 8-azidoguanosine 5'-triphosphate (8N$_3$GTP) has been shown to be a biological mimic in this system and an effective active site probe of the exchangeable GTP binding site of β-tubulin. We have previously shown a decrease (>90%) of γ and α [^{32}P]8N$_3$GTP photoinsertion into a cytosolic protein (55 K Mr) of Alzheimer's (AD) brain, identified as the β-subunit of tubulin. Of 5 AD brains tested, total protein comigrating with tubulin protein was similar in AD and age-matched controls. Therefore, AD brain tubulin, while present, has its exchangeable GTP binding site blocked/modified such that it can not interact with [^{32}P]8N$_3$GTP.

Recent experiments in which AD and control brain homogenates were photolabeled at 4°C with γ[^{32}P]8N$_3$GTP and fractionated by centrifugation (100 xg for 30 minutes, 4° C) showed that essentially all of the protein corresponding to the α and β subunits of tubulin of AD homogenates was recovered in the pelleted fraction and was completely unlabeled. In contrast, control brains showed less than 50% of the tubulin protein in the pellet. Photolabeling of the β-subunit in the control supernatant was 6-fold higher than that seen in the corresponding pellet. These results indicate that, whereas microtubules cold depolymerize in control brains, microtubules in AD brain do not depolymerize at 4°C. We hypothesize that lack of photoinsertion of γ [^{32}P]8N$_3$GTP into the β-subunit of tubulin in AD brain is a consequence of AD tubulin protein being totally in the polymerized microtubular form. In this state, its exchangeable GTP site is unavailable to added 8N$_3$GTP.

366.9 EXPRESSION OF "NEURONAL" AND "ALZHEIMER" ANTIGENS IN CULTURED SKIN CELLS. A.C.Baker* and J.P.Blass.
Dementia Research, Burke Rehab. Center, Cornell University Medical College, White Plains, NY 10605.

Abnormalities in cultured skin "fibroblasts" from patients with Alzheimer's disease have been reported from several laboratories, but their relevance to the clinically important changes in neurons remains unsettled.

Skin cell lines from Alzheimer and matched control subjects were obtained from the Coriell Institute. When grown under a combination of conditions described by others to favor the differentiation of neurons, the morphology of skin cells from both Alzheimer and control subjects became less spindle shaped and more "neuron-like"- rounder cells with larger nuclei and some processes.

Antisera whose specificity has been established were kindly donated by the indicated individuals. Under "differentiation conditions", both six Alzheimer and six control cell lines stained with a polyclonal antibody to "neuron-specific enolase" (commercial) and a polyclonal antibody to neurofilaments (C. Marotta). Three Alzheimer, but not three control cell lines stained with a monoclonal antibody to paired helical filaments (I. Iqbal), with the Alz-50 monoclonal antibody to A-68 protein (P. Davies), and with a polyclonal antibody recognizing phosphorylated and nonphosphorylated tau (I. Iqbal). Preliminary experiments suggest that manipulations of cellular metabolism can accentuate or ameliorate the expression of the abnormalities.

These data suggest that cells cultured from skin can be useful models for studying cellular mechanisms associated with neurons in vivo in a neurological disease.

366.10 CYTOSKELETAL PROTEIN PHOSPHORYLATION IS ALTERED IN THE BRAINS OF ALUMINUM-TREATED RATS. G.V.W. Johnson and R.S. Jope. Dept. of Pharmacology and the Neuropsychiatry Program, University of Alabama at Birmingham, Birmingham, AL 35294.

Cytoskeletal abnormalities are a major pathological characteristic of several neurodegenerative diseases, including Alzheimer's disease. There is increasing evidence that an association exists between these abnormalities and protein phosphorylation. Also, brain Al^{3+} levels are elevated in Alzheimer's disease and Al^{3+} has been shown to be associated with NFTS. Previously we have demonstrated that cAMP levels are significantly elevated in the brains of rats maintained on 0.3% Al^{3+} for one month (Brain Res. 403:1, 1987). This and other evidence has led us to formulate the following hypothesis for the mechanism of Al^{3+} neurotoxicity. We postulate that when brain Al^{3+} levels are elevated there is increased activation of adenylate cyclase, possibly via interactions of Al^{3+} with G proteins, which leads to increased cAMP-dependent protein kinase activity, resulting in aberrant protein phosphorylation.

To examine the effects of Al^{3+} on protein phosphorylation we measured total in vivo protein phosphorylation and in vivo phosphorylation of 2 cytoskeletal proteins (NF 200kD & MAP2) using immunoprecipitation techniques with monoclonal antibodies in control or Al^{3+}-treated rats (maintained on 0.3% dietary Al^{3+} for 1 month). Four hours after 1mCi of ^{32}Pi was injected icv the rats were anesthesized and perfused with cold buffer. A homogenate was prepared from the cerebral cortex and total in vivo protein phosphorylation and phosphorylation of MAP2 and NF 200kD were determined. Overall ^{32}Pi incorporation into brain phosphoproteins was significantly elevated in the Al^{3+}-treated rats compared to controls, however, not all proteins showed an increase in phosphorylation with Al^{3+}. The phosphorylation of proteins with apparent molecular weights of 90kD, 200kD, and 300kD was significantly increased in the aluminum-treated rats, whereas that of a protein of an apparent molecular weight of 150,000kD was significantly decreased. To further examine the identity of the 200kD and 300kD phosphoproteins, MAP2 and NF200kd were immunoprecipitated with monoclonal antibodies and subjected to SDS-PAGE. Both MAP2 and NF200kD from the Al^{3+}-treated rats were phosphorylated to a significantly greater extent when compared to controls. These studies demonstrate that certain cytoskeletal proteins are abnormally phosphorylated in Al^{3+}-treated rats and since these proteins can be phosphorylated by cAMP-dependent protein kinases we hypothesize that the Al^{3+}-induced increases in cAMP may be responsible in part for this increased protein phosphorylation.

366.11 **DECREASED GROWTH FACTOR RESPONSE AND PROTEIN PHOSPHORYLATION IN FIBROBLASTS FROM AGED AND ALZHEIMER DONORS.** C. Peterson and C.W. Cotman, Dept. Psychobiology, University of California, Irvine, CA 92717

Cytosolic free calcium is depressed in cultured skin fibroblasts from aged and Alzheimer donors (PNAS **83**:7999). The present study was designed to determine whether calcium mediated processes, such as the response to growth factors and protein phosphorylation, are altered in these same cells.

Cultured skin fibroblasts from young (23±1 yr), aged (61±2 yr) and Alzheimer (62±1 yr) donors were obtained from the Camden Cell Repository. Alzheimer cell lines were age- and sex-matched and only donors with confirmed Alzheimer's disease or those that had first degree relatives with confirmed Alzheimer's disease were used in these studies. To avoid complications due to *in vitro* aging all cells were studied at early passages (5-10).

For the growth factor studies fibroblasts were plated on day 0 into 24 multiwell plates (10,000 cells/well) in Dulbecco's modified Eagles medium with 10% fetal calf serum. On day 3 the medium was removed and replaced with serum-free. On day 4 the cells were fed serum-free medium that contained ^{3}H-thymidine (0.5 uCi/well) and a growth factor (e.g., platelet derived growth factor, epidermal growth factor, fibroblast growth factor or serum) at concentrations that increase cytosolic free calcium (JBC **258**:8066). Twenty-four hours later the cells were harvested and thymidine incorporation was quantitated by liquid scintillation counting. Protein was determined in parallel non-radioactive cultures. Basal thymidine incorporation was depressed similarly by aging and Alzheimer's disease. Growth factor stimulated DNA synthesis was lower in cells from aged donors and even less in cells from Alzheimer's donors when compared to young donors.

For protein phosphorylation experiments fibroblasts were plated in 75 cm^2 flasks on day 0. Six days later the cells were harvested by scraping, sonicated in buffer and aliquots (100 ug protein) were incubated for 2 min in the presence of ^{32}P-ATP and either calcium, calcium+calmodulin or cyclic AMP+isobutyl-methylxanthine. Proteins (50 ug) were separated by electrophoresis on a 10% acrylamide gel and the phosphorylated proteins were visualized by autoradiography. Cyclic AMP dependent protein phosphorylation was depressed by aging and further reduced by Alzheimer's disease. In the presence of either calcium or calcium+calmodulin only high molecular weight protein phosphorylation declined in cells from aged donors and was reduced even further by cells from Alzheimer's donors.

Thus, growth factor stimulated DNA synthesis and protein phosphorylation are depressed in cultured skin fibroblasts from aged and Alzheimer's donors and these may be related to decreased cytosolic free calcium.

Supported in part by ADRDA, the French Foundation and AG00096

366.12 SHORT AND LONG SCRAPIE INCUBATION TIME MICE HAVE DISTINCT PRION PROTEIN GENE ALLELES. D. Westaway*, P. Goodman*, C. Mirenda*, G. Carlson* and S. B. Prusiner. Dept. of Neurology, University of California, San Francisco, CA 94143-0518; Jackson Laboratory, Bar Harbor, ME 04609.

Biochemical evidence implicates a protein, PrP^{Sc}, as the major and possibly sole component of the scrapie prion. PrP^{Sc} is related to a benign cellular protein, PrP^{C}; both PrP isoforms are encoded by the same cellular murine gene, *Prn-p*. Mendelian analysis of prototypic short (NZW: 113 days), and long incubation period mice (I/Ln: 200-385 days) has defined a single autosomal dominant gene, *Prn-i*, as a major determinant of the length of scrapie incubation periods. A *Prn-p* Xba 1 restriction fragment length polymorphism (RFLP) cosegregates with the incubation period phenotype, establishing linkage between *Prn-p* and *Prn-i* (Carlson et al., *Cell* 46:503, 1986). We have isolated molecular clones of chromosomal *Prn-p* genes from NZW and I/Ln mice, and have defined a restriction/modification phenomenon which has interfered with previous attempts to clone PrP genes in *E. coli*. Mapping of these clones reiterates that the gross structure of *Prn-p* genes is the same in NZW and I/Ln mice (Westaway and Prusiner, *Nucleic Acids Res.* 14:2035, 1986) consisting of a spliced 5' leader sequence separated from the coding sequences. However, the NZW and I/Ln alleles are distinguished by Eco Rl, Pst 1, Sst 1 and Taq 1 polymorphisms in addition to the Xba 1 polymorphism described above. Using these enzymes, inbred mouse strains can be divided into at least six *Prn-p* RFLP haplotypes. Interestingly, three long scrapie prion incubation period mice, I/Ln, P/J and IM, share a distinctive RFLP haplotype, emphasizing the linkage between *Prn-p* and *Prn-i* and implying that these mice carry the same allele of *Prn-p*. [IM mice are homozygous for the p7 allele of the *Sinc* gene (Bruce and Dickinson, in *Slow Transmissible Diseases of the Nervous System* 2:71-86, Academic Press, NY, 1979)]. We have sequenced the coding regions of the NZW and I/Ln *Prn-p* genomic clones. The I/Ln allele differs from the NZW sequence in at least two amino acid codons: one of the nucleotide variations corresponds to a replacement in a codon conserved in mouse, hamster and human PrP genes. These sequence variations have been assessed in other inbred mouse strains. Our findings suggest that changes in the properties of scrapie prions ("strain instability") passaged in long incubation period mice may be due, at least in part, to a novel PrP gene sequence. These data also contend that some instabilities of scrapie "strains" observed by other investigators (Bruce and Dickinson, op. cit.) may be epigenetic, rather than mutational in origin.

366.13 HYBRIDIZATION ANALYSES OF ALZHEIMER'S BRAINS FOR HERPESVIRUS DNA. D. Walker*, J. R. O'Kusky, P.L. McGeer and E.G. McGeer. Kinsmen Lab. of Neurol. Res., Dept. of Psychiatry, and Div. Medical Microbiology, Dept. of Pathology, University of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

The role of a neurotropic virus in Alzheimer's pathology (accumulation of neurofibrillary tangles, senile plaques and loss of cholinergic neurons) has been suggested. The association of Herpes simplex virus type 1 (HSV-1) with the pathogenesis of Senile dementia of the Alzheimer's type (SDAT) was examined using a sensitive in situ hybridization method, with negative results. Various sections of brains from SDAT cases, along with appropriate controls, were examined. In addition, to confirm that the analyses were sufficiently sensitive to detect latent HSV-1 DNA, positive sections of trigeminal ganglia from SDAT and normal cases were obtained.

Sections from paraffin embedded samples were processed for in situ hybridization using the procedure of Brigati et al. (Virology 126:32-50, 1983), with minor modifications. Two cloned HSV-1 DNA restriction enzyme fragments from HSV-1 strain F (Eco R1 fragments D and G), representing 22% of the complete virus genome, were used as probe. These fragments did not hybridize with normal human DNA under the conditions used. The cloned HSV-1 DNA was separated from the plasmid vector and labeled by random priming with ^{35}S dCTP to a specific activity of approximately 10^{9} cpm/ug. Slides were coated in Kodak liquid film emulsion and exposed for 4-8 weeks. Four sections from each sample of frontal cortex, temporal cortex, hippocampus and substantia innominata from SDAT cases were examined. In every sample, sections adjacent to those used for hybridization showed evidence of typical SDAT pathology. The presence of cells with numbers of grains above background levels was not detected in any of the Alzheimer's brain sections. Positive hybridization was also not detected in regions of brains from nondemented controls. However, the presence of HSV-1 DNA in trigeminal ganglia of normal and SDAT cases was detected, after 4 weeks exposure. The percentage of positive cells, calculated using computer-assisted grain counting, was less than 6%. The ability to detect HSV-1 DNA in trigeminal ganglia leads us to conclude that the methodology should have been sufficiently sensitive to detect Herpes simplex virus in brain tissue at levels capable of producing neuronal pathology.

366.14 UBIQUITIN RESPONSE IN CULTURED NERVOUS TISSUE AFTER HEAT SHOCK AND ALUMINUM INTOXICATION.
A. Morandi*, V. Fried*, H. Smith*, G. Perry and P. Gambetti. (SPON: PJ Whitehouse)
Institute of Pathology, Case Western University, Cleveland, OH 44106 and St. Jude Children's Research Hospital, Memphis, TN 38101.

Ubiquitin (Ub), a highly conserved protein, plays a central role in an ATP dependent non-lysosomal proteolytic system. In this system Ub-conjugated proteins are targeted for proteolysis and rapidly broken down by ATP dependent proteases. Recently, it has been shown that the Ub system becomes especially active during heat shock or stress conditions in which altered proteins accumulate in cells. Although studies on Ub-conjugates in heat shock have been carried out in various cell type, little is known about the role of Ub dependent proteolytic system in neurons. Interest in the Ub conjugates in the nervous system has been highlighted by the recent discoveries that they are increased in Alzheimer disease and in other degenerative diseases of the nervous system. We have investigated the presence and the distribution of Ub-conjugates in human and rabbit dorsal root ganglia explants exposed to stress and in normal conditions, using four monoclonal and two polyclonal antibodies to Ub conjugates. The cultures were let grown on polylysine coated plastic dishes and maintained in serum free defined medium. Two stress conditions were produced: 1) Heat shock at 45^{0} C for 20 or 5 minutes; 2) Intoxication with aluminum lactate for eight days. Two monoclonal and both polyclonal antibodies reacted with the cultures.

Both stress conditions result in a different distribution of Ub-conjugates and an overall increase in the intensity of the immunostaining compared to untreated cultures. In control cultures Ub-conjugates were demonstrated in the nuclei and perikaria with variable intensity according to the Ub-antibodies used, whereas immunostaining of neurites was weak or absent. Following both stress conditions, immunostaining of nucleus and perikarion remained variable although generally it increased in intensity. On the contrary, a marked increase of immunostaining was consistently observed in neurites.

These findings indicate that the ubiquitin system is present in human and animal neurons and that is activated under different types of stress conditions. The presence of a large amount of Ub-conjugates epitopes suggests that, under stress conditions, the Ub system is especially active in neurites where it may play a protective role.

366.15 EXPRESSION OF HLA-DR AND INTERLEUKIN-2 RECEPTOR ON REACTIVE MICROGLIA IN SENILE DEMENTIA OF THE ALZHEIMER TYPE. S. Itagaki*, P.L. McGeer, H. Tago* and E.G. McGeer (SPON: D. D. Greenwood). Kinsmen Lab. of Neurol. Res., Dept. of Psychiatry, Univ. of British Columbia, Vancouver, B.C., Canada, V6T 1W5.

HLA-DR is a class II cell surface glycoprotein of the human histocompatibility complex usually expressed on the surface of cells that are simultaneously presenting foreign antigen to T-lymphocytes. Interleukin-2 (IL-2) is a lymphokine with many functions including growth induction of certain T- and B-cell lines. Using immunohistochemical procedures with multiple specific monoclonal antibodies to HLA-DR and the IL-2 receptor, we have found microglia reactive to these membrane surface proteins throughout the cortical gray matter of postmortem brains of patients with senile dementia of the Alzheimer type (SDAT). They were particularly concentrated in areas of senile plaque formation and were also seen suurounding degenerating neurons. Double immunostaining with antibodies to glial fibrillary acidic protein (GFAP) showed that HLA-DR and IL-2 receptor positive cells were different from the reactive astrocytes which form scar tissue in brain following neuronal death. However, occasional positively staining giant astrocytes were seen. Small numbers of resting microglia were HLA-DR positive in white matter of both normal and SDAT brains. Double immunostaining for choline acetyltransferase (ChAT) and HLA-DR in the substantia innominata of SDAT cases demonstrated degenerating ChAT neurons being phagocytosed by HLA-DR positive reactive microglia. The SDAT cases all had reduced cortical choline acetyltransferase levels as measured biochemically. In the 11 brains studied, the number of hippocampal HLA-DR positive cells was positively correlated with the number of plaques and negatively correlated with average cortical ChAT. (Supported by grants from the Medical Research Council of Canada and the Alzheimer's Association of B.C.)

366.16 BRAIN GLIAL CELLS EXPRESS MARKERS OF IMMUNE COMPETENCE IN AGING AND DEMENTIA. J. Rogers and S. D. Styren* (SPON: Steven F. Zornetzer). Institute for Biogerontology Research, 13220 N. 105th Avenue, Sun City, AZ 85351.

Glial proliferation in aging and Alzheimer's Disease (AD) has been documented, but the context in which this occurs remains unclear. An immune or autoimmune context would explain numerous aspects of AD pathogenesis, as well as the age-related increase in neural autoimmune disorders. Unfortunately, the usual markers of immune function such as HLA-DR (an MHC antigen necessary for T-cell recognition and antigen presentation) have been difficult to detect in brain, leading to the concept of brain immunologic privilege.

Using micro- and ultrastructural immunohistochemical techniques, we have tested for HLA-DR, HLA-DQ, HLA-DP, IL-2, T4, and T8 and can now show profuse brain reactivity for several of these immune system antigens. The cells expressing such markers include microglia and macrophages. The presence of immune-related antigens on these cells strongly suggests that their normal phagocytic role may, in some cases, be carried out in the context of an immune response. To argue that these cells may be of hematologic origin is to miss the point: the point is that phagocytic cells expressing classic immune-related antigens can now be observed profusely in human elderly and AD brain, and that this finding provides a potential mechanism for immune involvement in age-related neurologic disorders.

366.17 RETINAL GANGLION CELL DEGENERATION IN ALZHEIMER'S DISEASE. C.J. Bassi*§, J.C. Blanks§, D.R. Hinton*†, A.A. Sadun§ and C.A. Miller*†. §Doheny Eye Foundation, Dept. of Ophthalmology and †Dept. of Pathology, USC School of Medicine, Los Angeles, CA 90033.

Our group had previously demonstrated degeneration of the optic nerves and retinal ganglion cell layer in patients with Alzheimer's disease (AD) (N. Engl. J. Med. 315:485-487, 1986). The present study further characterizes degeneration in AD retinas. Donor eyes from AD patients and age-matched controls were either prepared as whole-mounts or processed for routine transmission EM.

In retinal whole-mounts, loss of ganglion cells (ranging from 20 to 80%) was observed in AD patients relative to age-matched controls. The loss was not confined to any retinal area. Many of the remaining ganglion cells had evidence of degeneration, such as darkly stained or vacuolated cytoplasm.

Similar observations were found in radial sections. Damage to the retina was observed in the ganglion cell layer (GCL), while the outer and inner nuclear layers appeared normal. Affected cells in the GCL of AD cases were either swollen or shrunken, had a vacuolated appearance, and some had evidence of nuclear disintegration. At the ultrastructural level, swelling of the mitochondria and endoplasmic reticulum, pale cytoplasmic density, and dispersed nuclear chromatin were observed. There was no evidence of neurofibrillary tangles within the ganglion cells, and no neuritic plaques or amyloid angiopathy were found in the retina. Extensive glial processes were sometimes seen adjacent to the vacuolated ganglion cells.

These findings, together with our previous paper, provide compelling evidence for degeneration of the primary visual pathway in AD. This degeneration may be the anatomical substrate for visual deficits found in AD.

366.18 GLIAL NUMBERS CORRELATE POSITIVELY WITH DENDRITIC NEUROPIL IN NORMAL AGING HUMAN CORTEX AND IN ALZHEIMER'S DISEASE. P. D. Coleman and D. G. Flood. Depts. of Neurobiology and Anatomy and Neurology, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642.

Cerebral cortex was sampled from middle frontal gyrus and superior temporal gyrus of clinically, neuropsychiatrically, and neuropathologically defined normal and Alzheimer's disease (AD) human brains. The interval between death and obtaining the tissue averaged 6.4 hours with a minimum of 2.5 hours and a maximum of 10.5 hours. Blocks of tissue from homologous regions of each hemisphere were embedded in celloidin, sectioned at 200 or 30 μm and processed, respectively, for Golgi-Cox staining for quantitative study of dendritic extent of single neurons or for Nissl staining with cresyl violet for counting of numbers of neurons and glia. The data presented here were obtained by making computer-aided measurements of the dendritic extent of layer II pyramidal neurons in both regions and by computer-aided counts of layer II neurons and layer I/II glia. All cell profiles were entered into Apple II+ or IIe computers manually via a graphics tablet. Average dendritic extent per layer II pyramidal neuron was multiplied by the number of layer II neurons in a strip of cortex to obtain an estimate of dendritic neuropil.

Examination of the measure of estimated dendritic neuropil as a function of numbers of glia reveals a strong positive correlation of +0.87 for middle frontal gyrus and +0.75 for superior temporal gyrus. AD cases and normal cases appear to show a similar relationship between dendritic neuropil and glia, with the exception of one case of early onset (long duration of 15 years) AD with a large number of glia but low dendritic neuropil.

These data are consistent with an interpretation of glia as sources of neurotrophic factors. Furthermore, the data suggest that in AD the glia continue to be normal sources of trophic factors, with the possible exception of early onset, long duration AD, when glia may play a more traditional neuropathological role in formation of scar tissue.

Supported by the National Institute on Aging, grants AG 01121 and AG 03644.

366.19 EXPRESSION OF $pp60^{c-src}$ IN BRAIN OF AGING RAT. M. F. Matocha*, S. W. Fitzpatrick*, J. R. Atack*, and S. I. Rapoport. (SPON: C. Grady). Laboratory of Neurosciences, NIA, NIH, Bethesda, MD 20892.

There is considerable evidence that abnormal phosphorylation is associated with cytoskeletal disorders in the aging brain, and it has been suggested that phosphorylation of tyrosine residues is involved in the neuropathology. Of the several protein-tyrosine kinases that have been identified, the $pp60^{c-src}$ kinase has been extensively characterized and found to be highly expressed in brain relative to other organs. In the present study, we quantitated $pp60^{c-src}$ kinase activity and determined the relative levels of this protein in brains of rats of different ages as a first step in assessing whether it has a role in abnormal states.

A 100,000g supernatant and pellet fraction was prepared from whole brain of individual male Fischer-344 rats, aged 4 (n = 7), 14-16 (n = 7), and 22-23 (n = 8) mo. An immune complex kinase assay was carried out by reacting supernatant or pellet protein with a monoclonal antibody against RSV $pp60^{src}$, followed by incubation of the immunoprecipitated protein with [γ-^{32}P]ATP, unlabeled ATP, and casein as the exogenous substrate. The reaction mixture was subjected to polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate and the radiolabeled proteins were detected by autoradiography. Appropriate bands were excised from the gel and quantitated by liquid scintillation counting. Samples from individual animals and corresponding controls that had not been reacted with antibody were analyzed in triplicate.

Casein phosphorylation increased linearly with the amount of protein and time of incubation, and kinase activity was found exclusively in the supernatant fraction. The specific activities (mean ± SD, fmol phosphate transferred to casein / min X mg of protein) of brain $pp60^{c-src}$ detected in animals ages 4, 14-16, and 22-23 mo were 251 ± 37, 211 ± 31, and 214 ± 47, respectively, and did not differ significantly by 1-way ANOVA ($p > 0.05$). Brain $pp60^{c-src}$ also was immunoprecipitated from the same supernatant fractions and detected by immunoblot analysis. There was no substantial change in the level of $pp60^{c-src}$ protein among the various-aged rats.

These data correlate with our previous findings showing that levels of c-src-like mRNAs in rat brain are age-invariant (Matocha et al, J. Cell Biol., 103, 425A (1986). The persistence of activity and protein levels of the $pp60^{c-src}$ kinase in the mature brain provides further support for its role in maintaining normal brain structure and function.

HIPPOCAMPUS

367.1 RECIPROCAL CONNECTIONS BETWEEN THE INTERPEDUNCULAR NUCLEUS AND THE HIPPOCAMPAL FORMATION. B. Fass[1] and G.S. Hamill[2] (SPON: R.B. Hamilton). [1]Dept. of Anatomy, Univ. Louisville Med. Sch., Louisville, KY 40292; [2]Dept. of Anatomy, M.S. Hershey Med. Sch., Hershey, PA 17033

The interpeduncular nucleus (IPN) is a brainstem component of the limbic system. Recent studies have shown that the IPN is directly connected to basal forebrain structures; e.g., the medial septum and diagonal band nucleus (Hamill & Fass, 1984; Groenewegen et al., 1986). It also has been shown that the IPN projects to the hippocampus (HPC) (Groenewegen et al., 1986; Wyss et al., 1979). The cells-of-origin of the IPN's projection to the HPC are concentrated within a specific subnucleus; i.e., apical. We now report that there is a reciprocal pathway from the HPC to the IPN which terminates primarily in the central subnucleus.

Adult male albino rats were injected with WGA-HRP (10% in DMSO) and allowed to survive 48 hrs. The injection was placed in the anterodorsal (n=6) or posteroventral (n=5) HPC. Frozen sections were processed using tetramethylbenzidine as the chromogen (after Gibson et al., 1984).

The anterodorsal injection-site included CA3 and the dentate gyrus of the HPC's septal pole. The posteroventral injection-site included CA1 and CA3 of the HPC's temporal pole, plus the subiculum. WGA-HRP did not spread into the habenula, and there was no anterograde labeling in fasciculus retroflexus.

Numerous retrogradely-labeled cells were present in the apical subnucleus. There were qualitatively more of these labeled cells after posteroventral HPC injections than after anterodorsal HPC injections. In addition, retrogradely-labeled cells were observed in the lateral subnucleus bilaterally. No labeled cells were found in the central or rostral subnuclei. These observations are consistent with previous reports (Groenewegen et al., 1986; Wyss et al., 1979).

An unexpected finding was the presence of anterograde labeling in the IPN. The densest labeling was in the central subnucleus. Qualitatively, the density of this labeling was comparable to that in the molecular layer of the contralateral dentate gyrus. There was little or no anterograde labeling in the apical subnucleus.

The present findings indicate that the IPN shares reciprocal connections with the HPC. These connections appear to be highly organized; a specific subnucleus of the IPN (apical) projects to the HPC, while a different subnucleus (central) receives inputs from the HPC. Studies are in progress to identify the cells-of-origin of the HPC's projection to the IPN.

Supported by a grant from the Medical Research Committee, University of Louisville Medical School (B.F.).

367.2 SEROTONERGIC AND NONSEROTONERGIC PROJECTIONS FROM THE RAT INTERPEDUNCULAR NUCLEUS TO THE SEPTUM, HIPPOCAMPAL FORMATION AND RAPHE: A COMBINED IMMUNOCYTOCHEMICAL AND FLUORESCENT RETROGRADE LABELLING STUDY OF NEURONS IN THE APICAL SUBNUCLEUS. K.T.Montone*,B.Fass[1] and G.S.Hamill[2].Departments of Anatomy, Penn State University College of Medicine, Hershey, PA 17033, and [1]University of Louisville, Louisville, KY 40292.

The apical subnucleus can be clearly identified in the caudal end of the interpeduncular nucleus in rats by its population of large, multipolar neurons containing serotonin. In this study, the subnuclear distribution and immunocytochemistry of apical neurons projecting to the diagonal band/septum, hippocampal formation and/or raphe was determined using a technique combining retrograde fluorescent labelling and immunocytochemistry on the same tissue section.

Sprague-Dawley adult rats were anesthetized with Nembutal (40mg/kg), and 100-500 nl of both (0.05%) fast blue and (50%) rhodamine-conjugated microspheres stereotaxically injected into either the diagonal band or dorsal hippocampal formation respectively, or into the raphe. Following 4-8 days survival and an intraventricular injection of colchicine to inhibit axoplasmic transport (200ug/25ul H2O; 24 hours prior to perfusion), the rats were perfused through the heart with 10% buffered formalin. Frozen sections were cut coronally through the injection sites and IPN, coverslipped (n-propyl gallate) or processed for 5HT immunocytochemistry.

After injection of fast blue into the diagonal band/septum and rhodamine into the dorsal hippocampal formation, or vice versa, retrogradely-labelled cells were found throughout apical subnucleus. Analysis of sections incubated with 5HT antiserum showed a small number of labelled cells contained serotonin. Occasional apical cells contained both fast blue and rhodamine, indicating a dual projection to each area. Injection of rhodamine into the raphe also labelled apical cells that did not contain serotonin.

This study revealed that some apical neurons containing serotonin, and others an unidentified transmitter/s innervated the diagonal band/septum, dorsal hippocampal formation and raphe through ascending and descending projections. Occasional apical cells were found that projected to both septum and dorsal hippocampal formation via collaterals. Since the IPN receives reciprocal projections from each of these regions, one of its functions may be the integration of subcortical limbic activity.

367.3 MODULATION OF PERFORANT PATH-DENTATE FUNCTIONAL PROPERTIES BY COMMISSURAL SYSTEM: ACUTE EFFECTS OF CONTRALATERAL HIPPOCAMPAL ABLATION. R.L. Port, R.J. Sclabassi and T.W. Berger, Departments of Behavioral Neuroscience, Psychiatry and Neurological Surgery, University of Pittsburgh, Pittsburgh, PA 15260.

We have previously described long-term changes in the functional properties of the perforant path-dentate (PP-DG) synapse in unilaterally hippocampectomized rabbits (Port, et al, Soc Neurosci Abstr, 12, 1986). The system response to a pair of impulses was profoundly altered. At four weeks post-lesion, peak facilitation was reduced from a control mean of 47.5% to 9.3%; the duration of inhibition increased from 62.5 ms to 175 ms. The present experiment quantifies the immediate effect of commissural denervation on DG reactivity to perforant path input.

Adult, male albino rabbits were acutely prepared under halothane anesthesia. Bipolar stimulating electrodes were placed in the PP and a recording electrode positioned in the granule cell layer of the DG. Random impulse trains (1004 impulses, Poisson distribution with a mean frequency of 2.0 Hz) of electrical stimulation were delivered to the PP and evoked field potentials were recorded from the DG. Stimulation intensity was adjusted to elicit a population spike of 10-20% maximum amplitude to a single impulse. The contralateral dorsal hippocampus was aspirated and a second impulse train delivered. Kernels were computed by cross-correlating interval duration with population spike amplitude.

Pre-lesion data revealed significant second order nonlinearity at intervals less than 250 ms. Short intervals (<50 ms) resulted in a suppression of population spike amplitude whereas longer (60-250 ms) intervals produced facilitation. Peak facilitation (90-160%) occurred around 100 ms. Ablation of the contralateral hippocampus produced a modest decrease in response amplitudes at short intervals and a robust increase in the degree of facilitation found at longer intervals. These data characterize the manner in which commissural input influences the functional characteristics of the DG. It is possible that the decreased responsivity to short intervals reflects a loss of direct excitatory input and the increased responsivity to longer intervals may be due to the loss of indirect input via inhibitory interneurons (Douglas, et al, J Comp Neurol, 219, 1983). Supported by The Whitaker Foundation, Office of Naval Research, and NIMH (09433).

367.4 DIFFERENCES IN NONLINEAR PROPERTIES OF THE MEDIAL AND LATERAL PERFORANT PATH. T.W. Berger, C.L. Weikart* and R.J. Sclabassi. Departments of Behavioral Neuroscience and Neurological Surgery, Univ. of Pittsburgh, Pgh., PA 15260.

We have been applying nonlinear systems analytic methods to investigate functional properties of the perforant path-dentate system in the rabbit. For this analysis, trains of 4064 electrical impulses were applied to the perforant path. Intervals between impulses varied randomly according to a Poisson distribution having a mean interval of 500 ms, with intervals ranging from 1 ms to 5000 ms. Amplitude of the population spike evoked by each impulse was measured, and cross-correlation techniques were used to compute first, second, and third order kernels of a power series expansion. First order kernels reflect the average population spike amplitude to all impulses in the train. Second order kernels represent the modulatory influence of the preceding impulse on the system response to the present impulse. Third order kernels represent the modulatory influence of the two preceding impulses.

We previously have reported that second order nonlinear properties of the medial perforant path include almost complete inhibition of the population spike to inter-impulse intervals of 10-20 ms, and facilitation of approximately 100% to intervals in the range of 50-300 ms. For intervals longer than 300 ms, the system functions linearly. Significant third order interactions that are primarily inhibitory occur in response to a wide range of stimulus combinations.

In the present experiments, we examined the nonlinear properties of the lateral perforant path and found them to be markedly different. Second order kernels for the lateral perforant path reveal inhibition for almost all inter-impulse intervals within the range of 10-1000 ms. In some preparations, a slight facilitation (10-20%) of population spike amplitude is seen in response to intervals of 50-100 ms. In further contrast to the medial perforant path, third order kernel values are almost exlusively positive, indicating facilitative interactions.

These data provide further evidence that the perforant path-dentate projection is not homogeneous, and incorporates at least two functionally distinct subsystems.

367.5 NONLINEAR RESPONSE CHARACTERISTICS OF THE PERFORANT PATH-DENTATE GYRUS SYSTEM IN THE IN VITRO RABBIT HIPPOCAMPUS. T.P. Harty, T.W. Berger, R.J. Sclabassi and G. Barrionuevo. Departments of Behavioral Neuroscience, Neurological Surgery and Psychiatry, University of Pittsburgh, Pittsburgh, PA 15260.

Nonlinear systems analytic procedures were used to study network properties of the in vitro rabbit hippocampus. The procedures involve stimulation of the perforant path using trains of 4064 impulses with randomly distributed inter-impulse intervals (mean frequency = 2.0 Hz). A cross-correlational analysis determined the relationship between inter-impulse interval and amplitude of the evoked population spike recorded from the dentate granule cell layer.

We previously have shown that second order kernels of granule cell responses from in vivo preparations are characterized by almost complete (80-90%) inhibition of spike amplitude in response to inter-impulse intervals of 10-20 ms, which returns to baseline (no interaction) at 65 ms. Inhibition is followed by spike facilitation which reaches a maximum of 70-80% at about 100 ms and returns to baseline at intervals of 250-350 ms. In the present studies, we examined granule cell response in the in vitro hippocampal slice. Initial results from slices at a recording temperature of 34° C are characterized by maximum facilitation of 300-400% at the shortest intervals, which decays to baseline at intervals of 100-200 ms. When the recording temperature is 37° C, second order kernels are similar to kernels at 34° C, but with greater facilitation at the shortest intervals. At 31° C, trains tend to show less facilitation than 37° or 34° at the shortest intervals, which falls to baseline more quickly (100-150 ms). Facilitation is followed immediately by 20-30% inhibition for a period of 200-600 ms.

In general, in vitro second order kernels do not exhibit the inhibition at short intervals characteristic of in vivo second order kernels. Instead, the early inhibition is replaced by a peak of facilitation that is 80-90 ms earlier and 4-5 times greater than the facilitory peak of the in vivo preparation. In addition, the in vitro facilitatory peak decays to baseline 100-200 ms earlier than the in vivo peak. One potential basis for these differences in nonlinearities is that several feed-forward and feedback connections of the dentate gyrus and hippocampus are reduced (inhibitory basket cells) or eliminated (commissural fibers and return fibers to entorhinal cortex) in the slice preparation. Supported by The Whitaker Foundation; NIMH (MH 30915); NIH (NS 24288); Office of Naval Research; BRSG (RR 07084); and an RCDA (NS 01196) to G.B.

367.6 STATIONARY CURRENTS LOCALIZED TO CA1 STRATUM RADIATUM IN ADDITION TO SYNAPTIC CURRENT IN S. LACUNOSUM-MOLECULARE FOLLOWING ANGULAR BUNDLE STIMULATION IN THE RAT: CURRENT SOURCE-DENSITY EVIDENCE. M. A. King. Laboratory for Systems Neurodynamics, Department of Neurosurgery, University of Virginia, Charlottesville, VA, 22908.

The current source-density (CSD) method was used to calculate the position, relative magnitude, and time course of currents generated in hippocampal region CA1 following electrical stimulation of entorhinal-hippocampal afferents in the angular bundle. Averaged (4-8) extracellular recordings of population evoked potentials were obtained at 30-50 micron intervals across the apical dendrites, in urethane-anesthetized adult male albino rats. High and low intensity stimulation was alternately delivered at 1/30 sec.

In addition to a reliable current sink in the stratum lacunosum-moleculare (SLM) synaptic terminal field, one or more regions of inward current flow were observed in stratum radiatum (SR). Twenty-six CSDs from 14 rats showed an SR sink between 208 + 16 and 274 + 17 (s.e.m.) microns dorsal to the hippocampal fissure, corresponding to 36.3 + 2.5 - 48.6 + 3.2 % of the distance from the fissure to stratum pyramidale. A second, more proximal sink was observed in 13 CSDs (343 + 23 - 413 + 30 microns, 58.8 + 3.9 -61.2 + 6.6 %), and a third observed in 4 CSDs (366 + 25 - 425 + 38 microns, 62.7 + 5.2 - 69.8 + 8.4 %). These sinks were virtually constant in width (65 + 5, 58 + 8, and 59 + 14 microns, 11.8 + 1.1, 9.7 + 1.5, and 9.8 + 2.1 %, respectively), and magnitude (112 + 27, 99 + 22, and 41 + 20 % of SLM, respectively), over the time course of the synaptic current in SLM. They were not present prior to the onset of pEPSPs, indicating that they do not represent regions of passive conductivity differences, (i.e., artifactual sinks or sources). There are at least 3 possible explanations for these standing sinks: they may be related to dendritic "spikes", they may represent a hitherto unrecognized synaptic input (feed-forward excitation) from a population of afferents relayed through the angular bundle, or they may in fact be current sources for (feed-forward) inhibitory synapses. A videotape exhibiting these currents over time will be presented.

367.7 PHASES OF FIRING OF MEDIAL AND LATERAL SEPTAL NEURONS AND THE IMPORTANCE OF HIPPOCAMPAL FEEDBACK. M. Stewart and S. E. Fox, Department of Physiology, SUNY Health Science Center, Brooklyn, New York 11203.

The septal nuclei are intimately connected with the hippocampus. In fact, it has been suggested that the theta rhythm is the result of oscillations in a loop consisting of connections from the medial septal nuclei (MSN) to hippocampus to lateral septal nuclei to MSN. Rhythmically bursting neurons of the MSN, and hippocampal pyramidal cells and interneurons all fire phasically with the theta rhythm. The firing of lateral septal neurons relative to the theta rhythm has not been studied previously, so the significance of a septo-hippocampal loop remains unclear.

Systemic atropine, sufficient to eliminate the urethane theta rhythm, eliminates the phase-locked firing of hippocampal pyramidal and interneurons as well as the rhythmic firing of one group of MSN cells. These atropine-sensitive MSN cells may derive their rhythmicity from a septo-hippocampal loop or from another input such as a local interaction with atropine-resistant MSN cells.

Single cells were recorded extracellularly from medial and lateral septum of urethanized rats. EEG was recorded near the hippocampal fissure (dentate) and above the alveus (CA1). A cooling probe was placed in the ventral hippo-campal commissure (VHC) to reversibly eliminate the theta rhythm.

The distribution of mean firing phases of rhythmic MSN neurons (n=73) is extremely broad. The population mean is near the positive peak of the dentate theta rhythm (negative peak of the CA1 theta rhythm), but every phase is well represented. The distributions for confirmed atropine-resistant (n=11) and atropine-sensitive (n=7) cells are equally broad. Of the lateral septal neurons analysed, 11/20 were significantly phase-locked. The distribution of these cells is much less broad, with most cells firing a single action potential on the positive-going phase of the dentate theta cycle.

Cooling the VHC produced no effect in 18/20 rhythmic medial septal neurons. (The two that were apparently cooling-sensitive were atropine-resistant.) Cooling eliminated the phasic firing of lateral septal cells by suppressing their spontaneous firing altogether.

We conclude that the rhythmic neurons of the medial septum do not in general require hippocampal feedback for their rhythmic behavior, while those lateral septal cells which are phasic seem to depend upon an extremely powerful input from the hippocampus for their firing during the theta rhythm.

367.8 CURRENT SOURCES FOR THE ALTERNATING AND SUSTAINED POTENTIALS OF THE HIPPOCAMPAL THETA RHYTHMS OF THE RAT. J. Brankačk* and S.E. Fox. Dept. Physiol., SUNY Health Sci. Ctr. Brooklyn, NY 11203.

The neuronal circuitry underlying the generation of the extracellularly recorded hippocampal theta rhythm is poorly understood despite thirty years of research. Current source density (CSD) analysis is a powerful method for location of sources and sinks of transmembrane current, and in combination with other data can identify active synaptic sites. Since hippocampal inputs are highly laminated, this leads to straightforward predictions of the anatomical projections involved in theta rhythm generation.

Rats were prepared with a fixed electrode above CA1, a reference electrode on the skull and a microdrive for advancing an electrode through the hippocampus. Stimulating electrodes were implanted in the ventral commissure and in entorhinal cortex. The rats were trained to run in a wheel for water reward to generate periods of hippocampal theta separated by non-theta EEG. Profiles of EEG and evoked potentials were recorded from the fixed and moveable electrodes at 80 um intervals. CSD profiles were computed by taking a weighted second derivative of the voltage profiles as a function of depth. Recordings from the fixed electrode provided a control for consistency, and a phase reference for averaging theta cycles. CSD profiles of the evoked potentials provided precise depth data for unknown EEG sources.

Amplifier time constants were greater than 6 s to allow recording of the sustained shift in potential associated with the presence of theta rhythm. For the EEG recordings the average non-theta voltage at each depth was taken as a baseline for the average theta wave. Measurement of sustained components is necessary for CSD analysis of the EEG, since it is not simply a transient event. Failure to do so will cause a sustained source or sink to be missed completely, or worse, a diminution in a sink to appear as a source (or vice versa).

The most prominent phasic generator of theta rhythm is a sink near the hippocampal fissure whose peak occurs at the phase of the peak negativity at that site (positive peak of CA1 theta). This may represent a phasic excitatory input from the entorhinal cortex. A weaker phasic sink appears in stratum radiatum of CA1, peaking on the positive-going phase of the CA1 theta. Other CA1 sources and sinks are relatively small. A large phasic sink at the level of the basal dendrites of CA1 pyramids in urethanized rats (peaking on the CA1 negativity) was conspicuously absent during walking. The most prominent sustained generator is a sink in the inner one-third of the dentate molecular layer that is flanked above and below by sustained sources. This dentate pattern was identical to that found in urethanized rats, and may reflect tonically increased activity in septal afferents.

367.9 IMMUNOHISTOCHEMICAL AND ELECTROPHYSIOLOGICAL EVIDENCE FOR DISTINCT POPULATIONS OF RAT HIPPOCAMPAL CA1 PYRAMIDAL CELLS. K.G. Baimbridge, H.McLennan*, J.J.Miller and M.J.Peet*. Dept. of Physiology, University of British Columbia, Vancouver, B.C. Canada V6T 1W5

The observations of Cajal and Lorente de Nó suggested that CA1 pyramidal cells could be classified into two subtypes, referred to as "large deep" and "small superficial" and that the relative proportion of these cells was somewhat species dependent. Bayer has also noted a clear difference in the neurogenesis of the deep and superficial cells in the rat. Recent reports have for the most part simply referred to "pyramidal cells" and have not suggested that there may in fact be more than one population perhaps with different biochemical and physiological characteristics.

Using immunohistochemical methods to study the distribution of two calcium binding proteins, calbindin D28K (CaBP) and parvalbumin (PV), it became apparent that CaBP immunoreactivity was restricted to the closely packed superficial layer of rat CA1 pyramidal cells. Furthermore, PV immunoreactivity, which is localized within the somata and axonal arborizations of a subpopulation of GABAergic interneurons in the CA1 region, forms an intense band of staining around the deep (non-CaBP) pyramidal cells which would suggest, according to Lorente de Nó, that the interneurons are of the polygonal basket cell type. Thus, on the basis of PV and CaBP-immunoreactivity, the two distinct layers of cells are clearly distinguishable. Of additional interest is our previous observation that the CA1 pyramidal cells of the guinea pig (alone among the many species examined) are completely devoid of CaBP immunoreactivity and are anatomically arranged in an almost completely uniform layer some 3-4 cells in width.

We are presently combining electrophysiological recording from rat hippocampal slices maintained in vitro with lucifer yellow (LY) injection and subsequent CaBP immunohistochemistry. Preliminary results have confirmed two populations of LY injected CA1 pyramidal cells by the presence or absence of CaBP immunoreactivity. Our results also suggest a difference in their electrophysiological responses to depolarizing current pulses. The identified cells were not interneurons on the basis of their lack of axonal arborization in the pyramidal cell layer, the absence of PV-immunoreactivity and their electrophysiological properties. We suggest that the clear distinction of two populations of pyramidal cells of the rat hippocampus should be considered when interpreting the functions of the CA1 region.

367.10 HIPPOCAMPAL AND ENTORHINAL PLACE CELLS: WHAT HAPPENED WHEN THE LIGHTS WENT OUT. G.J. Quirk, R.U. Muller*, J.L. Kubie, and J.B. Ranck, Jr., Dept. of Physiology, SUNY Health Sciences Center at Brooklyn, N.Y. 11203.

The location-specific firing of hippocampal place cells is controlled by enviromental cues. Physical rotation of the cue set produces a similar rotation of the firing fields of place cells. Cue removal studies have shown that the location-specific firing is not dependent on any single cue modality (O'Keefe and Conway, Exp. Brain Res., 31:573, 1978). O'Keefe, in his early characterization of place cells (Exp. Neurol., 51:78, 1976), observed that spatial firing persisted in the dark for the majority of cells. This study was qualitative in nature, and did not take into account possible changes in firing rate, field size, field shape, etc. We have reexamined the question of place cell firing in the dark using infrared tracking, and a high resolution mapping system for describing location-specific firing (Muller, Kubie, and Ranck, J. Neurosci., 1987).

Experiments were performed in a cylindrical enviroment (76 cm in diameter and 51 cm high) uniformly gray in color except for a white card affixed to the wall. The rat chases food pellets in the cylinder while spike data and the rat's position are sampled by computer. An infrared emitter was attached to the rat's headstage and a video camera, sensitive in the infrared range, was used. The spectral sensitivity of the rat's visual system falls off sharply at 620 nm (Birch and Jacobs, Vision Res., 15:687, 1975), which is well below the infared range. Lights were turned off midway into a 16 minute session and the spatial firing patterns in the two 8 minute halves were compared.

For hippocampal place cells, spatial firing persisted in the dark, confirming the findings of O'Keefe. The location of the firing fields in the two halves of the session were identical. In some instances, the in-field firing rates were higher in the lighted half. Thus, turning out the lights had only a small effect, even though the white card exerts stimulus control over place cell firing (Muller and Kubie, J. Neurosci., 1987). The persistence of spatial firing in the absence of visual cues may be due to the use of non-visual cues and/or a mnemonic representation of the enviroment. In this context, it is interesting to ask if the recently reported location-specific firing of cells in the entorhinal cortex persists in the dark (Quirk and Ranck, Soc. Neurosci. Abst., 12:1524, 1986).

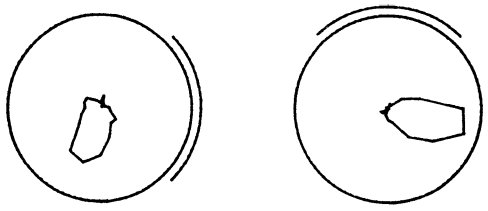
Supported by NIH grants NS14497, NS07117, and NS20686.

367.11 A QUANTITATIVE ANALYSIS OF HEAD-DIRECTION CELLS IN THE POSTSUBICULUM. J.S. Taube, R.U. Muller*, J.B. Ranck, Jr. Dept. of Physiology, SUNY Health Sciences Center, Brooklyn, NY 11203.

Many neurons in the deep cell layer of the postsubiculum discharge as a function of a rat's head direction in the horizontal plane, independent of the rat's behavior and place in the environment (Ranck, Neurosci. Abstr. 10:599). We report here results from using a quantitative method for analyzing the firing rate of "head-direction" cells as the rats move freely in a simple environment.

Single cell recordings were made from head-direction cells in the post-subiculum while rats moved freely throughout a 76 cm diameter, 51 cm high cylinder. The cylinder was gray except for a large white cue card taped to the inside wall; a curtain surrounded the cylinder. Two light-emitting diodes (LEDs), spaced 8 cm apart, were secured horizontally 2 cm above the rat's head; a red LED was positioned above the rat's nose and a green LED positioned over the rat's back. An automatic video/computer system digitized the position of each LED at 60 Hz. Horizontal head direction was calculated from the relative positions of the two LEDs and sorted into twenty 18° bins. The number of spikes fired during each 1/60th sec was counted, so that firing rate as a function of head-direction could be computed.

An angular firing specificity score was computed by taking the ratio of the firing rate in the bin with maximal firing, to the average firing rate in the three diametrically opposite bins. The mean ratio for 8 cells was 31.9 (range: 4.65-83.8). Following a standard session, the cue card was rotated 90° and another session was performed. In 5 cells, the head direction of maximal firing rotated with rotation of the cue card; this result was reversible upon returning the cue card to its original position. Below are the results from one cell.



Standard 90° Counter-clockwise Rotation

The vector from the center of the circle to a point on the polygon indicates the cell firing rate as a function of the rat's head direction. The arcs outside the 15 spikes/sec circle represent the cue card position.

These results indicate that some postsubicular cells encode information concerning the animal's head direction and that selective visual cues in the environment can exert control over the firing rate of head-directional cells.

367.12 SOME PROPERTIES OF EARLY-FIRING CELLS IN THE RAT DENTATE GYRUS. E. W. Kairiss and G. V. Goddard. Department of Psychology and The Neuroscience Centre, University of Otago, Dunedin, New Zealand.

The dentate gyrus of the rat contains a diversity of neuronal morphologies including granule cells and numerous non-granule cell types. The latter may influence the response of granule cells to synaptic excitation from the perforant pathway (PP) by feed-forward inhibition. In this study, we have used extra-cellular unit recording techniques to examine the responses of cells which may be involved in feed-forward inhibition.

Experiments were performed on urethane-anesthetized Sprague-Dawley rats. The ipsilateral PP and the contralateral hilus (CH) were stimulated using monopolar electrodes. Field and unit potentials were recorded with glass micropipettes, positioned near the cell body layer. Since we were interested in the particular class of neurones which may mediate feed-forward inhibition, cells were selected for study which discharged before the onset of the population spike.

A total of 10 units from 38 experiments met our acceptance criteria. The unfiltered spike width at base ranged from 0.2-0.5 ms, and the spontaneous activity of these cells never exceeded 5/s. The responses to PP stimulation at low intensities generally consisted of single action potentials, but higher stimulus strengths could elicit 2 or 3 spikes. The latency of discharge decreased rapidly with increasing stimulus strength, and often reached asymptote at stimulus levels subthreshold for the generation of a population spike. Cells were not strongly influenced by recurrent inhibition as measured by paired-pulse tests. Stimuli applied to the CH, effective in inhibiting the PP-evoked population spike, had variable effects on unit firing. CH stimulation alone fired units in only 3/10 cases (latencies from 3.6-11.9ms). Unit responses to PP stimulation were also affected by preceding CH stimulation, displaying either a change in the latent period, or complete inhibition.

The effects of high frequency stimulation (four 100 Hz trains, each 30ms long, separated by 1s) applied to the PP were studied in 4 cases. Potentiation of the population spike was seen to persist for up to several hours following the trains. Although the general pattern of unit discharge remained unaltered, the apparent threshold for activation was decreased in all 4 cells.

These observations (1) support the existence of a heterogenous subpopulation of low-threshold neurones, with properties distinct from granule cells, and which may be involved in local-circuit interactions; and (2) underscore the need for a more extensive examination of the electrophysiology of these cells coupled with morphological identification.

(Supported by Canadian MRC and New Zealand MRC)

367.13 PHYSIOLOGY OF STRATUM LACUNOSUM-MOLECULARE INTERNEURONS IN CA1 REGION OF GUINEA PIG HIPPOCAMPUS. J.-C. Lacaille and P.A. Schwartzkroin. Dept. Neurological Surgery, Univ. of Wash., Seattle, WA 98195.

To further elucidate the role of local circuit neurons (interneurons) in hippocampal CA1 circuitry, we have characterized with intracellular recordings 1) the membrane properties, 2) the synaptic responses and 3) the synaptic interactions with other hippocampal cells, of interneurons in str. lacunosum-moleculare (L-M) in CA1 region of hippocampal slices.

The intracellular response characteristics of L-M interneurons (n=43) were distinctly different from responses of pyramidal cells and of other interneurons (basket cells and oriens-alveus interneurons). L-M interneurons had a high RMP (-58 mV), a high R_{in} (64 megohms), a time constant of 8.6 ms and a large amplitude (60 mV), relatively long duration (2 ms) action potential. A large afterhyperpolarization (11 mV, 34 ms) followed a single action potential. A late afterhyperpolarization (5.4 mV, 242 ms) usually developed after a train of action potentials (31/43 cells). Most L-M interneurons did not display any spontaneous firing.

Excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs) were evoked in L-M interneurons from stimulation of major hippocampal pathways. EPSPs were most effectively elicited by stimulation of fiber pathways in transverse slices. The efficacy of major pathways in eliciting EPSPs was (in descending order): str. L-M > rad. > oriens > alveus > dentate str. mol. > CA3 str. lucidum. In contrast when major pathways were stimulated in longitudinal slices, IPSPs were predominantly evoked. These IPSPs were followed by depolarization-hyperpolarization oscillations of the membrane.

Local synaptic interactions were examined with simultaneous intracellular recordings between L-M interneurons and a) intrasomatically impaled (49 pairs), or b) intradendritically impaled (46 pairs) pyramidal cells, and c) str. pyramidale interneurons (4 pairs). In 9 of 42 (21%) intrasomatic recordings from pyramidal cells, a hyperpolarization developed (mean peak amplitude 0.91 mV, peak latency 86 ms, time to decay 93 ms) during L-M interneuron current-evoked (0.5 nA, 100 ms) firing. In 11 of 46 (24%) intradendritic recordings from pyramidal cells, a hyperpolarization was also produced (mean peak amplitude 0.67 mV, peak latency 74 ms, time to decay 76 ms) during current-evoked firing of L-M interneurons. Following intrasomatic (49 pairs) or intradendritic (46 pairs) stimulation-induced (0.5 nA, 100 ms) firing of pyramidal cells, correlated changes in membrane potential were not observed in L-M interneurons. In 2 of 4 str. pyramidale interneurons, hyperpolarizing potentials (mean peak amplitude 0.74 mV, peak latency 58 ms, time to decay 70 ms) were seen during current-evoked firing of L-M interneurons.

These physiological results show that L-M interneurons have neuronal and synaptic properties distinct from other hippocampal cell types. Functionally, L-M interneurons may mediate feedforward, but probably not feedback, inhibition of pyramidal cells.

Supported by NIH, NINCDS grants NS 15317 and NS 18897, by NSERC of Canada, and by FRSQ of Quebec.

367.14 MORPHOLOGY OF STRATUM LACUNOSUM-MOLECULARE INTERNEURONS IN THE CA1 REGION OF GUINEA PIG HIPPOCAMPUS. D.D. Kunkel, J.-C. Lacaille and P.A. Schwartzkroin. Department of Neurological Surgery, Univ. of Washington, Seattle, WA 98195.

Previous morphological and physiological studies have shown numerous types of nonpyramidal neurons (interneurons) in the hippocampus. We have physiologically identified an interneuron type in the CA1 region of lacunosum-moleculare (L-M) in guinea pig hippocampus (Lacaille and Schwartzkroin, accompanying abstract). These interneurons were intracellularly injected with Lucifer Yellow or HRP and examined morphologically using light and electron microscopic techniques.

This interneuron population was clearly nonpyramidal, and forms a relatively homogeneous group. The somata were situated in str. L-M near the str. radiatum border. Most of the identified cells were fusiform and multipolar, with cell bodies approximately 20 x 25 um in size. At the EM level, the somata were similar to other interneurons with a small convoluted nucleus and a high density of cytoplasmic organelles. Dendrites of these interneurons radiated from the soma along str. L-M; after running a short distance, the dendrites turned primarily into str. radiatum where they branched. In a few instances, dendrites crossed the pyramidal cell layer and continued into str. oriens. Some dendritic branches could be observed ascending in str. L-M, crossing the hippocampal fissure, and projecting into the dentate gyrus molecular layer. Dendrites were smooth and somewhat varicose, especially distally. Numerous synaptic contacts were seen onto these aspinous dendrites.

The axon usually originated from a primary dendrite in str. L-M. It projected along str. L-M toward the CA1/CA3 border and/or toward the subicular regions. The axon branched shortly after emerging from the dendrite and the collaterals continued into strata radiatum and pyramidale, occasionally entering str. oriens. In some cases collateral branches ascended toward the hippocampal fissure and crossed into the outer molecular layer of the dentate gyrus.

Axonal processes formed synaptic contacts with spiny dendrites of CA1 (presumably pyramidal cells) in both strata L-M and radiatum. Synaptic contacts were made onto dendrites of granule cells in the outer molecular layer of the dentate gyrus. Occasional synaptic contacts were seen on other interneuron-like dendrites in strata L-M/radiatum and in the outer molecular layer of the dentate gyrus. Serial section analysis of these synaptic contacts showed them to be of the symmetric type.

Afferent pathways have been lesioned to determine afferent synaptic input onto these str. L-M interneurons.

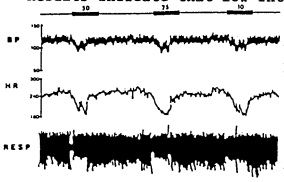
Supported by NIH, NINCDS NS-18897 and NS-15317, by NSERC of Canada, and FRSQ of Quebec.

367.15 CARDIOVASCULAR RESPONSES TO ELECTRICAL STIMULATION OF HIPPOCAMPUS IN RAT. K.G. Ruit and E.J. Neafsey. Department of Anatomy, Loyola University Medical Center, Maywood, IL 60153.

Our laboratory has previously reported a projection from the infralimbic and prelimbic regions of the rat medial frontal cortex (MFC) to the vagal solitary nucleus (NTS) (Terreberry and Neafsey, 1983), and electrical stimulation of these regions of the MFC elicits changes in heart rate (HR), blood pressure (BP), respiration (RESP), and gastric motility. A major afferent projection to these regions of the MFC arises in the CA1 and subicular regions of the hippocampal formation (Swanson, 1981). The present study examined the effects of electrical stimulation of the hippocampus on HR, BP, and RESP.

Rats were anesthetized with Ketamine HCl (100mg/kg, IP), a tracheal cannula inserted for artificial ventilation and to monitor RESP, the femoral artery cannulated for recording BP, and EKG leads placed in the chest and back to monitor HR. The hippocampus was stimulated using a glass insulated tungsten microelectrode (tip exposure 100 microns). Stimulation parameters were 60sec trains of negative 0.25msec pulses at 25Hz beginning at a current intensity of 50uamps and gradually lowering the intensity until a threshold current was determined for a physiological response. Physiological effects were recorded on a physiograph and small marking lesions were made along each electrode track for histological reconstruction. In some experiments, methyl atropine (0.4mg/kg) was administered in order to determine if the response was vagally mediated. In other experiments, a lesion was placed in the ipsilateral MFC in order to determine the pathway underlying the response since it is possible that the hippocampus may exert its cardiovascular effects via a HIPP=>MFC=>NTS circuit.

Results indicate that low intensity (<50uamps) electrical stimulation of all fields of the hippocampus produces marked decreases in HR, BP, and slower, more regular RESP (see figure). The decreases in HR and BP are also seen in artificially ventilated animals indicating that these effects are not due to respiratory changes. Administration of methyl atropine blocks the bradycardia completely, indicating that these responses are largely mediated by the vagus. Ablation of the MFC by aspiration markedly attenuates responses to stimulation of the ventral but not the dorsal hippocampus. This observation is consistent with the fact that it is only the ventral CA1 and subicular regions which project to the MFC (Swanson, 1981). In conclusion, MacLean's concept of the hippocampus as part of the limbic "visceral brain" appears to be valid. (Support: Loyola Pott's Fund)



367.16 RADIATION-INDUCED HIPPOCAMPAL DAMAGE PRODUCES LOCOMOTOR HYPERACTIVITY AND SPONTANEOUS PERSEVERATIVE TURNING BUT NOT ENHANCED TURNING SPEED.
J.L. Ferguson*, M.A. Mulvihill, T.J. Nemeth and G.A. Mickley*. Behavioral Sciences Department, Armed Forces Radiobiology Research Institute, Bethesda, MD 20814-5145.

X irradiation of the neonatal rat hippocampus causes a selective reduction in the population of granular cells of the dentate gyrus. This brain damage is correlated with locomotor hyperactivity that can be measured by square crossings in an open field (Bayer, S.A. et al., Nature New Biol. 242: 222-224, 1973) as well as infrared beam breaks (Mickley, et al., Soc. Neurosci. Abstr. 12/2: 1531, 1986). Radiation-induced hippocampal damage also causes perseverative spontaneous turning in an isolated bowl (Mickley, et al., Soc. Neurosci. Abstr.12/2: 1531, 1986). Previous measures of stimulated activity have relied predominantly on metrics of distance traversed rather than speed of motion. In the present experiment we measured the rate of spontaneous bowl turning in rats with radiogenic hippocampal damage.

Neonatal rat's cerebral hemispheres received fractionated exposure to 1300 rads of X rays during the first 15 days post partum (Bayer, S.A. and Peters, P.J., Brain Res. Bull. 2:153-156, 1977). This procedure depleted 86% of the hippocampal granular cells while sparing other brain areas. Control animals were sham irradiated. Ten- to 25-week-old subjects were placed in large bowls and spontaneous turning was recorded over 5 or more 30-minute sessions. We measured the length of turning bouts as well as the duration of individual quarter turns. Through the use of the Omnitech Digiscan system we also recorded locomotor activity by counting infrared beam breaks.

In the brain-damaged rats we observed statistically significant ($p<0.05$, ANOVA) enhancement of locomotion as measured by infrared beam breaks in the horizontal plane. Further, irradiated rats exhibited significantly longer bouts of bowl turning ($p< 0.05$, ANOVA) than did sham-irradiated animals. The speed of turning was not enhanced, however, in the rats with hippocampal damage. Speed of movements during the long bouts of irradiated animals was not different from the rate of turning observed during the shorter bouts of the sham-irradiated rats.

These data highlight the need for further specificity in the reporting of locomotor hyperactivity. Metrics that reveal both area traversed as well as speed of motion are relevant. As was observed in the case of rats with depleted hippocampal granular cell populations, these two measures of hyperactivity are not necessarily positively correlated.

367.17 A VASOPRESSIN-LIKE SUBSTANCE (VP-LS) IS RELEASED FROM THE RAT DORSAL HIPPOCAMPUS (DH): IN VITRO EFFECT OF NOREPINEPHRINE (NE). A. D. Ramirez* and V. D. Ramirez. Department of Physiology and Biophysics, University of Illinois, Urbana, IL 61801.

We report for the first time the release of a VP-LS from the DH using in vitro superfusion and in vivo push-pull perfusion methods.

Bilateral DH slices from four decapitated rats were randomly distributed into four superfusion chambers ($\bar{X}$=54.61 mg DH wet weight/chamber). In a control chamber superfused for 4.2 h (starting about 11:00 h) the mean release rate of VP-LS from the DH as measured by RIA with a 2% cross-reactivity with oxytocin was 0.352±.08 pg/min with 5 distinct episodic pulses. At interval 27, 30 mM K^+ was infused for 10 min. A marked mean increase in VP-LS of 6.97±4.7 pg/min (7 intervals) was noticed. In two chambers with low spontaneous mean release of VP-LS (0.56±.32; 6 intervals) a first infusion of 10^{-5} M NE increased the mean release rate of VP-LS close to 3 fold whereas a second infusion using an identical dose of NE increased the release of VP-LS over 15.6 fold over control values. Lastly, a depolarizing dose of 30 mM K^+ further augmented the release of VP-LS to 15.2±5.4 (7 intervals). In 4 other chambers in which the spontaneous mean release rate of VP-LS was 3.57±0.4 (6 intervals) NE 10^{-5} M slightly increased its release to 4.04±0.82 (6 intervals); however, the second dose of 10^{-5} M NE was clearly effective since the mean release rate rose to 6.03±.78 (7 intervals); the K^+ challenge rose even further the release rate of VP-LS to 7±0.96 (4 intervals). In three chambers in which the mean control release rate was very high (15.05±1.6; 9 intervals) a slight increase to the first (18.6±1.4; 6 intervals) but a significant increase to the second infusion of NE (22.5±3.3; 7 intervals) was observed. A robust response was seen after K (47.8±4.0; 4 intervals).

In three rats bearing PPC in the DH and perfused for as long as 3 h, clear pulses of VP-LS were detected in the 10 min perfusate collections (5 pulses/rat) with a mean release rate of 1.7±.41, 2.8±.51, and 3.3±.76 pg/min, respectively.

The data indicate that the DH of freely behaving rats releases a putative peptide similar to vasopressin in a pulsatile manner with a remarkable consistency among these rats. In addition, in vitro slices of the DH release a similar VP-LS though a marked variation in its release was noticed under these conditions. Notably, all preparations responded with a consistent significant increase in VP-LS release to a second dose of 10^{-5} M NE but not to a first identical dose of NE, indicating clearly that this neurotransmitter can potentiate the release of this substance under in vitro conditions.

367.18 EFFECTS OF FORNIX TRANSECTION ON MATERNAL BEHAVIOR IN THE RAT. B. Osborne, B.C. Woodside* and J.E. Jans*. Dept. of Psychology, Concordia University, Montreal, Quebec, Canada H4B 1R6.

Previous investigators have reported that dorsal hippocampal lesions result in gross deficits in maternal behavior (Kimble, Rogers & Hendrickson, J. Comp. Physiol. Psychol., 63, 401-407, 1965) while fimbria damage although resulting in some deficits in retrieval and nest building did not affect survival rate of the offspring (Terlecki & Sainsbury, 1978). In this study the effects of fornix transection performed prior to mating on the subsequent performance of maternal behavior was investigated.

Fornix transections were performed on nulliparous female rats under sodium pentobarbital anaesthesia. A second group of females were sham-operated. Fornix transction which also caused extensive fimbria damage did not apparently affect the probability of females becoming impregnated, the progress of pregnancy or of parturition.

On both Days 2 and 7 postpartum lesioned animals showed marked deficits in retrieval and nestbuilding. A difference in the pattern of mother-litter contact between the groups was also observed. Lesioned animals had more frequent contacts with their offspring throughout the observation period. Typically these contacts were very short and resulted in an overall increase in nest time only during the light phase in the second week postpartum.

These data suggest that fornix transection produces deficits in maternal behavior similar to effects seen in other species-typic behaviors; that is a disruption in the frequency and sequencing of behavioral components.

367.19 CALCIUM BINDING PROTEIN (CALBINDIN) IMMUNOCYTOCHEMISTRY IN NORMAL RAT HIPPOCAMPAL GRANULE CELLS: HIGHEST DENDRITIC CONCENTRATION PRECISELY WHERE HILAR MOSSY CELLS INNERVATE R.S. Sloviter Neurology Res. Ctr., Helen Hayes Hospital, NY State Dept. Hlth., W. Haverstraw, NY 10993

Calbindin-D28K (Calcium Binding Protein; CaBP) is widely distributed in brain and has been suggested to influence calcium dependent processes (1). Like others (1-3), we have mapped CaBP in the rat hippocampus immunocytochemically using DAB as a chromagen, with similar results. CaBP is present in many, but not all, hippocampal interneurons, dentate granule cells, CA2 and CA1 pyramidal cells. CA3 pyramidal cells and nearly all hilar neurons, cells highly susceptible to seizure-induced damage (4), are CaBP-negative. Using benzidine dihydrochloride (BDHC) as the chromagen, a previously unreported finding was made. Use of BDHC gives discrete stain particles with little background, allowing differentiation between lightly and darkly stained elements. This characteristic of BDHC made visible a darkly stained lamina in the exact region innervated by the hilar mossy cells that form the ipsilateral associational/commissural (IA/C) input to the inner dentate molecular layer. This stained lamina could be the CaBP-positive terminals of this pathway or an increased concentration of CaBP in granule cell dendrites exactly where this pathway innervates. To address the question of localization, rats received bilateral perforant path stimulation that selectively destroys hilar mossy cells and somatostatin-positive cells (4). 3 days later, silver staining showed degeneration of the dentate IA/C input. CaBP staining at 3 to 14 days survival showed that removal of this pathway did not affect the dense CaBP staining in the inner molecular layer. These data suggest that CaBP is concentrated in the exact portion of the granule cell dendrite where the IA/C pathway, which apparently activates kainate-displaceable glutamate binding sites (5), innervates area dentata. The possibility exists that the presence of CaBP in granule cells may protect them from kainate receptor-mediated seizure-induced damage (4) and that the vulnerability of CA3 and hilar neurons to kainate receptor-mediated mossy fiber discharge may, in some way, be related to the absence of CaBP in these cells.

CATECHOLAMINES: MPTP

368.1 DESTRUCTION OF DOPAMINE (DA) NEURONS WITH MPTP DECREASES DA AUTORECEPTOR SENSITIVITY IN MICE, L.M. Hryhorczuk* and M.P. Galloway, (SPON: R. Lisak), Lafayette Clinic and Wayne State Univ. Sch. Med., DETROIT, MI 48207

Although Parkinson's Disease (PD) is marked by a substantial loss of DA-containing neurons, a subset of DA neurons remains intact and is presumably implicated in the conversion of l-DOPA to DA and the subsequent release of DA. As such, adaptations of the regulatory mechanisms of the remaining DA neurons takes on added significance. We have utilized the GBL model for studying synthesis modulating DA autoreceptors (ARs) in vivo in C57/BL mice pretreated with the neurotoxin MPTP.

Mice treated with MPTP (51 mg/kg, ip, x 6 days) and sacrificed 10 days later had a 90% depletion of striatal DA. Enhanced activity of the remaining DA neurons was evidenced by increases in the DOPAC/DA, HVA/DA, and DOPA/DA ratios of 2.3, 5.3, and 2.5 fold, respectively. Administration of GBL to mice pretreated with MPTP increased striatal DA synthesis (i.e., DOPA accumulation after NSD-1015) suggesting that terminal ARs exert tonic inhibition of DA synthesis in remaining neurons. Reversal of the GBL induced increase in DOPA synthesis was measured after administration of different doses of apomorphine (30, 100, 500 ug/kg,sc) and the results expressed as percent of the GBL control. Under these conditions, there was a decreased responsiveness to a given dose of apomorphine in mice lesioned with MPTP. Similar, but less robust results were obtained in animals with a less severe DA depletion suggesting that the degree of AR desensitization may be related to the extent of DA cell loss.

Overall, the results suggest that compensation of DA neurons that remain after generalized DA cell death may arise as a consequence of decreased functional sensitivity of inhibitory terminal DA AR's. Chronic treatment with a DA agonist, such as in PD, would be predicted to accelerate AR desensitization and lead to an unpredictable, relatively unregulated release of DA. Alternatively, use of an AR-selective agonist as an adjunct to l-DOPA therapy in PD, as suggested originally by Carlsson, may achieve proper DA tone by manipulating AR function. Support (MPG) from the United Parkinson Foundation, DA-04120, MH-41227, and the State of Michigan-DMH

368.2 MPTP AND 6-HYDROXYDOPAMINE EFFECTS ON TETRAHYDROBIOPTERIN (BH_4) AND BIOGENIC AMINE METABOLISM IN RAT AND MOUSE BRAIN. Robert A. Levine, Sandy K. Demetriou*, Sandy Tait*, and [1]Sheldon Milstien*, Laboratory of Molecular Neurobiology, Lafayette Clinic and Wayne State Univ. Sch. of Med., Detroit, MI 48207, and [1]Laboratory of Neurochemistry, NIH, Bethesda, MD, 20892

l-methyl-4-phenyl-l,2,3,6-tetrahydropyridine (MPTP) was used in mice and 6-hydroxydopamine (6-OHDA) in rats to lesion nigrostriatal dopamine neurons and investigate the cellular localization in striatum of enzymes involved in the synthesis of BH_4. BH_4, the cofactor which is rate-limiting for the activity of tyrosine (TH) and tryptophan hydroxylases, is an important regulator of dopamine and serotonin synthesis. BH_4 levels in CSF and postmortem brain are decreased in several neurological diseases. In BH_4 biosynthesis, GTP cyclohydrolase (CH) converts GTP to dihydroneopterin triphosphate (NH_2P_3); NH_2P_3 is converted to 6-pyruvoyltetrahydropterin (6-PPH_4) by 6-PPH_4 synthase; 6-PPH_4 is converted by one or two enzymes to BH_4, the last enzyme being sepiapterin reductase (SR). MPTP (10 mg/kg i.p., once each day for 5 days; sacrifice on day 17) was administered to male C57/Bl mice and 6-OHDA (8 ug in left nigra) to rats (sacrifice on day 30). MPTP decreased TH by 50% and DA and metabolites by greater than 70%; decreased BH_4 and CH by 50%, and did not alter 6-PPH_4 synthase or SR activity. These same parameters are being currently being measured in rat striata after 6-OHDA. The preliminary results with MPTP suggest that 6-PPH_4 synthase and SR are not predominantly located in nigrostriatal dopamine neurons. In contrast, there is significant localization of TH, CH, and BH_4 in striatal dopamine terminals. It is unclear whether BH_4 biosynthesis occurs in other non-aminergic cells in striatum, however, the large decrease in CH and BH_4 after MPTP suggests that BH_4 synthesis occurs largely in striatal dopamine terminals. 6-OHDA is being utilized to confirm these findings in the rat. It is possible that 6-PPH_4 synthase and SR are necessary for metabolic pathways not related to BH_4 biosynthesis, although other functions have yet to be described.

368.3 STUDIES ON THE MITOCHONDRIAL UPTAKE OF THE 1-METHYL-4-PHENYL-PYRIDINIUM SPECIES. D.M. Placenti*, J.B. Hwang*, R.E. Heikkila and W.J. Nicklas (SPON: R.C. Duvoisin). Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

It is generally accepted that 1-methyl-4-phenylpyridine (MPP^+), the metabolite of the neurotoxicant, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), is the actual toxic agent which causes degeneration of the dopaminergic nigrostriatal pathway. The ultimate mechanism by which MPP^+ causes cell death is not clearly established. It has previously been determined that MPP^+ inhibits NADH-linked oxidation at Site 1 of the mitochondrial electron transport chain. This inhibition requires a concentrative uptake of MPP^+ into mitochondria which is driven by the membrane potential. To study this uptake process further, we have examined ^3H-MPP^+ uptake and MPP^+-inhibited mitochondrial metabolism using analogs of MPP^+, non-related organic cations such as acetylcarnitine (AcCn) and methionyllysine (MetLys), and pyridine-containing compounds such as nicotine (NC), chloroquine (CQ) and related compounds. Dopamine (DA) and specific DA uptake blockers had no effect on the mitochondrial uptake of ^3H-MPP^+. As expected, analogs of MPP^+ did inhibit this process; even analogs such as 1-methyl-4-t-butylpyridinium, which itself is a poor inhibitor of NADH-linked oxidation, inhibited MPP^+ uptake. Cations such as AcCn and MetLys (at concentrations up to 1 mM) did not decrease the metabolic toxicity of MPP^+ or its uptake. NC did inhibit the uptake of ^3H-MPP^+; however, at concentrations used (1-2 mM) it partially uncoupled the mitochondria, thereby collapsing the membrane potential. Since uptake of MPP^+ is dependent upon maintenance of the membrane potential, this may explain the effects of NC. CQ, on the other hand, decreased both the uptake of ^3H-MPP^+ and the MPP^+-induced inhibition of NADH-linked oxidation without uncoupling oxidative phosphorylation. The effective range for CQ action was between 0.5-5 mM. Studies using alternate sequential additions of CQ or MPP^+ indicated that the decrease in the MPP^+-induced inhibition of Site I activity was due to the inhibition by CQ of MPP^+ uptake into the mitochondria. Analogs of CQ (quinacrine and quinidine) did not behave similarly. It is not yet known whether this CQ effect has any role in the reported protection by CQ of MPTP toxicity in primates [D'Amato et al., Life Sci. 40:705, 1987]. However, the above data on substances which affect ^3H-MPP^+ uptake indicates that compounds such as CQ or uncoupling agents, in general, might be useful in testing the hypothesis that inhibition of NADH-linked mitochondrial respiration is an important mechanism in mediating MPTP neurotoxicity.

368.4 MONOAMINE OXIDASE-A (MAO-A) AND THE NEUROTOXICITY OF 1-METHYL-4-PHENYL-1,2,3,6-TETRAHYDROPYRIDINE (MPTP). A. Giovanni*, P.K. Sonsalla, B.A. Sieber*, L. Manzino*, D. Placenti*, and R.E. Heikkila (SPON: J.R. Ravens). Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

MPTP is neurotoxic to nigrostriatal dopaminergic neurons in experimental animals including primates, dogs and mice. It has been shown, both in vitro and in vivo, that MPTP is metabolized by monoamine oxidase-B to a dihydropyridinium intermediate ($MPDP^+$) which in turn spontaneously oxidizes to form the 1-methyl-4-phenylpyridinium species (MPP^+). It has also been shown that pretreatment of mice with a dose of deprenyl which selectively and extensively inhibits MAO-B, but which does not affect MAO-A (i.e., 2.5 mg/kg), completely protects mice from the neurotoxic actions of MPTP. In contrast, pretreatment of mice with a dose of clorgyline which selectively and extensively inhibits MAO-A, but which has no significant effect on MAO-B activity (i.e., 2.5 mg/kg), is not protective. This has led to the conclusion that MAO-B, but not MAO-A, plays an important role in the bioactivation of MPTP.

However, based on experiments in vitro with pure MAO-A and MAO-B and with mouse whole brain tissue preparations, it is clear that MPTP can be oxidized by both MAO-A and MAO-B. For example, the K_m value for MPTP oxidation by pure MAO-A is slightly but significantly lower than its K_m value for oxidation by pure MAO-B. In contrast, the V_{max} value for MPTP oxidation by pure MAO-B is much higher than its V_{max} value for oxidation by pure MAO-A. Similar results are obtained in mouse brain tissue preparations. Thus, based on K_m values, MPTP is a better substrate for MAO-A, and based on V_{max} values, it is a better substrate for MAO-B. It is reasonable to speculate that MAO-A might play a role in MPTP bioactivation in vivo when the MPTP concentration is low (at or below the K_m value for oxidation by MAO-A). In support of this concept, we have found that although deprenyl pretreatment of mice (2.5 mg/kg) greatly inhibits the formation of ^3H-MPP^+ from ^3H-MPTP, the pretreatment of mice with a combination of deprenyl and clorgyline (each at 2.5 mg/kg) appears to inhibit ^3H-MPP^+ formation to a greater extent. Moreover, clorgyline alone appears to inhibit ^3H-MPP^+ formation slightly. These observations suggest that some MPP^+ formation is being mediated in vivo by MAO-A. It follows that there might be some circumstances when the bioactivation of MPTP by MAO-A would conceivably play a significant role in the neurotoxic process.

368.5 RELATIONSHIPS BETWEEN MPTP-INDUCED NEUROTOXICITY AND THE LEVELS OF MPTP METABOLITES IN THE BRAINS OF SEVERAL STRAINS OF MICE. P.K. Sonsalla, D.M. Placenti*, L. Manzino* and R.E. Heikkila, Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

It has been shown that 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is neurotoxic to nigrostriatal dopaminergic neurons in several species of animals including mice. We have recently reported that there are marked strain differences in the susceptibility of mice to MPTP. For example, C57 black mice were very sensitive to MPTP, whereas CF-W mice were moderately affected and CD-1 mice were relatively unaffected by MPTP treatment (4 injections, 20 mg/kg/injection, at 2 h intervals; Sonsalla and Heikkila, 1986). The present experiments were conducted to determine possible reasons for this differential sensitivity. MPTP neurotoxicity depends on 1) the monoamine oxidase-B (MAO-B)-catalyzed oxidation of MPTP and the formation of the 1-methyl-4-phenylpyridinium species (MPP^+) and 2) the active uptake of MPP^+ into nigrostriatal dopaminergic neurons. Thus, we measured brain MAO-B activity, the in vitro oxidation of MPTP by MAO, and neostriatal MPP^+ transport in several strains of mice (C57 black, CF-W and CD-1). In addition, brain levels of MPTP and MPP^+ were determined in these strains of mice following the systemic administration of radioactive MPTP.

Neostriatal MAO-B activity (using C^{14}-benzylamine as substrate) was only slightly less in CF-W and CD-1 mice than in C57 black mice. In addition, the in vitro oxidation of MPTP by MAO-B in whole brain mitochondrial preparations from CF-W or CD-1 mice was only slightly less than that observed in preparations from C57 black mice. However, after MPTP treatment (20 mg/kg, s.c.) whole brain levels of MPP^+ were 28% and 41% less in CF-W and CD-1 mice, respectively, than were levels in the brains of C57 black mice. It seems unlikely that the small differences in brain MAO-B activity among the various strains alone could account for the observed differences in brain levels of MPP^+ or in the neurotoxicity of MPTP. This is particularly apparent with CF-W and CD-1 mice, which have similar levels of MAO-B but are differentially affected by MPTP treatment. There were no differences in ^3H-MPP^+ transport into neostriatal synaptosomes from C57 black, CF-W or CD-1 mice, indicating that differential MPP^+ transport into dopaminergic neurons is not a factor associated with sensitivity differences. In conclusion, the sensitivity of different strains of mice to MPTP appears to correlate with brain levels of MPP^+. Additional data regarding the biodistribution and pharmacokinetics of MPTP and MPP^+ in the brains of these mice will be presented.

368.6 THE ROLE OF MONOAMINE OXIDASE-A IN THE BIOACTIVATION OF SEVERAL MPTP ANALOGS. R.E. Heikkila, S.K. Youngster*, B.A. Sieber*, P.K. Sonsalla, K. McKeown* and T.P. Singer*, Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854 and VA Medical Center, San Francisco, CA 94109.

It has been shown that MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) administration results in a destruction of the dopaminergic nigrostriatal pathway in experimental animals including mice, dogs and monkeys. MPTP itself is a protoxin which is metabolized by monoamine oxidase-B (MAO-B) to a dihydropyridinium intermediate which spontaneously oxidizes to the pyridinium species 1-methyl-4-phenylpyridinium (MPP^+). MPP^+ formation can be significantly attenuated and MPTP-induced neurotoxicity can be prevented by pretreatment of mice with inhibitors of MAO-B (e.g. deprenyl) prior to MPTP administration. In contrast, pretreatment of mice with MAO-A inhibitors (e.g. clorgyline) affords no protection against MPTP-induced neurotoxicity and has only a slight inhibitory effect on MPP^+ formation. It follows that the oxidation of MPTP by MAO-B plays a major role in the neurotoxic process. In the present study we have determined the relative roles of MAO-A and MAO-B in the bioactivation of several MPTP analogs, including 2'methyl-MPTP and 2'ethyl-MPTP. We have also determined kinetic constants for the oxidation of the same MPTP analogs by pure MAO-A and MAO-B in vitro.

In contrast to the results obtained with MPTP, the dopaminergic toxicity of 2'methyl-MPTP was unaffected by pretreatment with deprenyl alone and was also unaffected by pretreatment with clorgyline alone (each 2.5 mg/kg). However, a combination of the two was fully protective against the neurotoxicity. In parallel experiments, deprenyl alone inhibited partially, clorgyline alone did not inhibit but the combination was very effective in inhibiting 2'methyl-MPP^+ formation from 2'methyl-MPTP. Pretreatment with deprenyl alone was ineffective whereas pretreatment with clorgyline alone afforded almost full protection against 2'ethyl-MPTP-induced neurotoxicity. Moreover, 2'ethyl-MPP^+ formation was markedly inhibited by clorgyline alone, but not by deprenyl alone. The neurotoxicity of other analogs of MPTP including 2'chloro-MPTP also was not prevented by deprenyl alone but was prevented by a combination of deprenyl and clorgyline. In vitro, all of these MPTP analogs are good substrates for MAO-A. These data demonstrate that not only MAO-B, but also MAO-A, can play a significant role in the bioactivation of MPTP-like neurotoxins and lend further support to the concept that pyridinium formation from the MPTP analogs is an important feature of the neurotoxic process.

369.1 CORTICAL EPINEPHRINE PROJECTIONS DEMONSTRATED BY RETROGRADE TRACING COMBINED WITH TYROSINE HYDROXYLASE AND PHENYLETHANOLAMINE N-METHYLTRANSFERASE IMMUNOCYTOCHEMISTRY. D.K. Beato*, W.J. Burke, T.H. Joh and J.H. Haring (SPON: P.A. Young). Depts. of Anatomy and Neurobiology and Neurology, St. Louis Univ. Sch. of Med., St. Louis, MO 63104 and Dept. of Neurology, Cornell Univ. Med. Coll., New York, NY 10021.

Phenylethanolamine N-methyltransferase (PNMT) is the terminal enzyme in epinephrine (Epi) biosynthesis and is therefore a useful marker for Epi-containing neurons and their processes. Using a sensitive assay for PNMT, we have shown PNMT to be present in both rat and human cortex. PNMT immunocytochemistry has demonstrated an extremely sparse PNMT-containing plexus in the cerebral cortex, as well as a more prominent plexus of PNMT-positive fibers in the central amygdaloid nucleus of the rat brain. Since PNMT is known to be present in some neurons in the absence of the other enzymes required for Epi production, we have used a combination of retrograde tracing with immunocytochemistry for PNMT and tyrosine hydroxylase (TH) to determine whether the cortical PNMT-containing plexus could be using Epi as a transmitter.

Adult, male Sprague-Dawley rats anesthetized with sodium pentobarbital received either focal WGA-HRP injections of the amygdaloid complex or large WGA-HRP injections of the frontal cortex. Brainstem sections were reacted for the presence of HRP using TMB as the chromagen, and the resulting TMB reaction product was stabilized. Sections were flat embedded in Araldite, and HRP-labeled neurons in the Epi-containing cell groups were selected for study. Serial sections 1µm thick were cut and adjacent sections were stained for PNMT and TH immunoreactivity, respectively, using a postembedding immunocytochemistry protocol. Injections of the cerebral cortex resulted in the labeling of neurons in the C_1 Epi cell group bilaterally. Only a few (10-20) lightly labeled neurons were seen in each case, consistent with our previous observations of a very sparse PNMT plexus. Although neurons containing PNMT or TH immunoreactivity or HRP alone were seen, a subset of C_1 neurons was shown to contain all three markers, suggesting the presence of an Epi projection to the frontal cortex arising from the C_1 cell group. The amygdala injections resulted in neurons being labeled in C_1 and C_2. A number of these neurons also contained HRP, TH, and PNMT and were therefore classified as Epi neurons. Thus, the present study has provided direct anatomical evidence for the presence of an Epi-containing projection to cortical structures in the rat brain.
Supported by NIH grant AG00302.

369.2 **TYROSINE HYDROXYLASE-IMMUNOREACTIVE NEURONS IN THE PRIMATE SUBFORNICAL ORGAN: SPECIES SPECIFICITY.** J. Lory*, J.H. Kordower, G. Bing*, J.R. Sladek Jr. and D.M. Gash (Spon: R. Mangano) Dept. of Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester N.Y. 14642, USA.

The advent of Falck-Hillarp and subsequently glyoxylic acid histoflourescence procedures allowed for the localization of catecholamine cell groups within the diencephalon and brain stem of the central nervous system. Studies in a variety of vertebrate species have discerned a general mammalian pattern of catecholaminergic nuclei. Using immunocytochemical localization for tyrosine hydroxylase, the rate limiting enzyme for catecholamine synthesis, we now report a species specific group of tyrosine hydroxylase-immunoreactive neurons contained within the subfornical organ.

Five new world Capuchin (Cebus apella) monkeys, three old world African Green (Cercopithicus aethiops) monkeys, and six rats were used in this study. The Capuchin monkeys and the rats were perfused with a PBS solution containing 4% paraformaldehyde and 0.1% glutaraldehyde. The African Green monkeys were perfused with a PBS solution containing 4% paraformaldehyde. Coronal frozen sections (30-40 µ) were incubated in the tyrosine hydroxylase primary antiserum (Eugene Tech.) at a dilution of 1:1000 at 4°C. Forty eight hours later the sections were processed with the unlabeled peroxidase method or via an immunoflourescence procedure utilizing Texas Red (Amersham; 1:800). Sections obtained from the Capuchin monkeys and the rats were processed simultaneously while the African Green tissue was processed separately.

In both species of monkeys, numerous tyrosine hydroxylase-immunoreactive perikarya were observed in the subfornical organ. These cells measured 20-30 um in diameter and possessed long beaded varicose fibers. In the Capuchin monkey, and to a lesser extent the African Green monkey, tyrosine hydroxylase-containing cell bodies tended to be localized in the lateral aspects of the subfornical organ with fewer cells in the central core. There appeared to be more cells in the Capuchin monkey as compared to the African Green primate. However, we are cautioned in this interpretation since perfusion protocols were different for these two monkeys and staining occurred at different times. In contrast, rats who were perfused and stained in an identical fashion as the Capuchin monkeys never displayed tyrosine hydroxylase-immunoreactive cell bodies in the subfornical organ. Immunoreactive fibers were commonly observed. However, these appear to be derived from an extrinsic source. When normal serum was substituted for either the primary or secondary antiserum, immunoreactivity was not observed.

This experiment documents a previously undescribed catecholamine cell group that appears to be species specific. Additonal monkeys are currently being processed for histoflourescence and for the secondary and tertiary enzymes of catecholamine biosynthesis to determine whether these cells contain dopamine, norepinephrine, or epinephrine.

369.3 TYROSINE HYDROXYLASE (TH)-IMMUNOREACTIVE NEURONS OCCUR WITHIN THE SPINAL CORD OF THE CHICKEN FROM HATCHING THROUGH ADULTHOOD. J.A. Wallace, T.C. Hoffman*, R.M. Mondragon*, R.R. Maez* and P.C. Allgood*. Department of Anatomy, University of New Mexico School of Medicine, Albuquerque, NM 87131.

Catecholaminergic (CA) neurons exist within the spinal cord of many lower vertebrate species, and have also recently been observed within the spinal cord of the adult rat. While CA neurons have not been detected by histofluorescence methods within the spinal cord of the adult chicken, we previously reported that TH-positive neurons are found throughout the spinal cord of late embryonic chicks (Anat. Rec. 214:140A, 1986). In the present study, we examined whether these TH-immunoreactive cells occur only transiently during embryonic development, or if they are present within the spinal cord of chickens throughout the period of maturation. The spinal cords of chickens were examined on the day of hatching, and at 1,3 and 6 months of age. At each age, the occurrence of the cells was determined at mid-cervical and upper lumbar cord levels. The cells were demonstrated by anti-TH immunocytochemistry on paraffin sections, employing the ABC peroxidase staining technique. Similar to the pattern found during embryogenesis, at hatching two populations of TH-positive cells were observed in cervical and lumbar cord segments. One group of cells was located beneath the central canal, and the other was situated within the dorsal horn of the spinal cord along the border between the gray matter and the lateral funiculus. Both populations of TH-immunostained cells were demonstrated at all post-hatching periods examined. With increasing age, no differences were seen in the general location of the cells nor in their staining intensity. On the other hand, the frequency of appearance of these cells decreased with the increasing age of the animals. However, this observation is most likely due to the dilution of the number of the TH-positive cells within the rapidly increasing mass of the cord as the chickens grow. Overall, it appears that the spinal cord TH-immunoreactive neurons persist in the chicken from embryonic periods to adulthood. We have also reported that developing TH-positive spinal cord cells cannot be visualized by CA histofluorescence methods unless the animals are pre-treated with monoamine oxidase inhibitors or loaded with L-DOPA (Anat. Rec. 218:144A, 1987). However, it remains to be determined whether these same cells, once they are mature, can be visualized immunocytochemically, utilizing antibodies against dopamine or norepinephrine.

369.4 **LUMBAR CORD DENSELY INNERVATES A SPECIFIC SUBREGION OF THE PERIAQUEDUCTAL GRAY WHICH PROJECTS TO PARAGIGANTOCELLULARIS AND PREPOSITUS HYPOGLOSSI, THE MAJOR AFFERENTS TO LOCUS COERULEUS (LC): POSSIBLE CONNECTIONS BETWEEN THE PERIPHERY AND LC.** G. Aston-Jones, M. Behbehani[1] and M. T. Shipley[2], Dept. Biol., New York University, NY 10003, and [1]Dept. Physiol. & [2]Dept. Anat. Cell Biol., U. Cincinnati School Med., OH 45627.

We have recently identified paragigantocellularis (PGi) in the rostral ventrolateral medulla as a major input to LC. PGi is predominantly excitatory on LC neurons (Ennis and Aston-Jones, this volume) and many PGi neurons projecting to LC are excited by noxious stimuli. Similar stimuli potently excite LC neurons, and these along with other results led us to propose that LC sensory responses may be mediated through PGi.

To test this hypothesis, the anesthetic lidocaine was microinjected into PGi and responses of single LC neurons to subcutaneous rear footpad stimulation (FS) were recorded. In all 5 LC neurons tested, the response to FS was abolished within 1 min after lidocaine injection (20-200 nl); recovery was obtained for 4 of these neurons, with responses returning within 10 min.

These results indicate that PGi may be a crucial component of LC responses to FS. However, we and others have found only sparse afferents to PGi from lumbar spinal cord, indicating that direct spinal projections to PGi may not mediate this response. We now report that: (i) injections of wheat germ agglutinin-conjugated horseradish peroxidase (WGA-HRP) into lumbar spinal cord produced dense anterograde labeling in a restricted portion of the midbrain periaqueductal gray (PAG), corresponding to the medial and dorsal ventrolateral PAG of Beitz and Shepard (1985). (ii) WGA-HRP injections in this subregion of PAG revealed strong reciprocal connections with the PGi area (primarily ipsilaterally) that contains LC afferent neurons. (iii) These PAG injections also reciprocally labeled the prepositus hypoglossi (PrH) area, the other major afferent to LC. (iv) Injections of WGA-HRP into PGi that produced anterograde labeling in LC also demonstrated specific reciprocal connections with this same subregion of PAG, and with the dorsal PAG. (v) Stimulation of the medial/ventrolateral PAG synaptically activates neurons in PGi.

These anatomic results indicate that specific areas of PAG project to the two main afferents to LC, suggesting that PAG could play a key role in controlling LC activity, perhaps coordinating LC and other PAG functions (e.g., analgesia). Our findings also suggest a possible circuit for responses of LC neurons to footpad stimuli, proceeding from the lumbar spinal cord to PAG and from there to PGi and PrH which in turn project to LC. Additional studies are in progress to test this possibility.

369.5 SOURCES OF THE NORADRENERGIC INNERVATION OF THE BED NUCLEUS OF THE STRIA TERMINALIS IN THE RAT. T. Duong, R.S. Fisher, C.R. Houser and A.B. Scheibel. UCLA Departments of Anatomy and Psychiatry, Mental Retardation Research Center and Brain Research Institute, Los Angeles, CA 90024.

The bed nucleus of the stria terminalis (BNST) in the albino rat is characterized by a dense noradrenergic (NA) innervation. The sources of this innervation have not been directly demonstrated. Using a combined retrograde tracer-immunocytochemical technique, we have found that the NA innervation of the BNST arises principally from the medullary groups (A1, A2) and locus coeruleus (A4, A6). Other noradrenergic groups (A5, A7) appear to make few if any contributions.

The right BNST of adult male Sprague-Dawley rats was injected with deactivated horseradish peroxidase conjugated to wheat germ agglutinin and colloidal gold (HRP-WGA-CG). After a 48-hour survival period, the animals were transcardially perfused with fixative, and the brains were cut in the sagittal or coronal plane. Sections were processed for the retrograde tracer by a silver enhancement method and further processed for DBH immunocytochemistry using a peroxidase-antiperoxidase method. This allowed us to view the HRP-WGA-CG retrograde tracer as black granules within DBH-positive neurons which were stained brown. The injection site was confined to the BNST which receives a dense plexus of DBH-positive varicose fibers in the ventrolateral portion and a light to moderate plexus throughout the rest of the nucleus.

Retrogradely-labeled DBH-positive neurons in the brainstem were found predominantly ipsilateral to the injection although a few were observed contralaterally.

Within the main portion of the locus coeruleus (A6), double-labeled neurons were distributed throughout the antero-posterior extent of the nucleus. These double-labeled cells were observed both in the dorsal and ventral divisions of the nucleus. They were mainly fusiform or bipolar in shape with their long axis running in the rostro-caudal direction of the nucleus. Some cells were also multipolar with no obvious direction of orientation. The dorso-caudal extension of the locus coeruleus (A4), which is located in the lateral corner of the anterior medullary velum, also contained double-labeled cells. These were mainly fusiform in shape. Ventral to this nucleus, double-labeled cells were observed in the subcoeruleus.

In the medulla, A1 is formed by a group of DBH-positive cells, lying dorsal to the lateral reticular nucleus. Double labeled cells were observed scattered throughout this NA nucleus. They were multipolar and their dendrites were oriented randomly. The A2 cell group consists of DBH-positive neurons mainly in and around the nucleus solitarius with a small number in the dorsal motor nucleus of the vagus. It extends from the level of the area postrema caudally past the obex. Medium-sized, double-labeled cells were observed in this nucleus. These neurons were multipolar with their dendrites oriented in a dorsomedial direction. Most were located within the nucleus solitarius portion of A2. A few were observed in the dorsal motor nucleus of the vagus. In the remaining two NA nuclei (A5, A7), double-labeled cells were rarely observed.

The BNST in the rat is thus characterized by a dense, convergent innervation originating from multiple NA brainstem nuclei. Supported by the David H. Murdock Foundation for Advanced Brain Studies.

369.6 ULTRASTRUCTURE OF NORADRENERGIC NEURONS IN THE CAUDAL VENTROLATERAL MEDULLA (A1 CELL GROUP) OF THE RAT. B. Nathan*, C. Gonzales*, M. Kalia (SPON. N. Moskowitz). Dept. Pharm., Thomas Jefferson Univ., Philadelphia, PA 19107

The A1 cell group in the caudal ventrolateral medulla comprises a compact population of noradrenergic (NA) neurons (Dahlstrom and Fuxe, '64) that show immunoreactivity with tyrosine hydroxylase (TH) and dopamine beta-hydroxylase (DBH). Light microscopic details of the rostrocaudal extent of this cell group and its relationship to cytoarchitecture of the medulla oblongata has been described (Kalia et al, '85). Since this cell group is located in a region of the detailed brainstem that is also occupied by numerous bulbospinal and visceral efferent neurons, analysis of the ultrastructural details of this region is necessary to understand the functional importance of these NA cells. We examined the ultrastructure of the A1 cell group in the rat, at a level 0.8 mm caudal to the obex, following fixation with acrolein (3.75%) in 2% paraformaldehyde in phosphate buffer (Pickel, '85). We analyzed tissue immunoreacted with an antibody directed against the more soluble enzyme-TH. No colchicine pretreatment nor the addition of Triton X-100 to increase the immunoreactivity and penetration of the antibody, respectively, was used.

Perikarya of the A1 cell group are medium sized with multiple spiny processes. The nucleus is large, centrally placed, with one to two shallow invaginations and a prominent nucleolus. The average nuclear-cytoplasmic ratio was 1:2. The most characteristic feature of the cytoplasm of A1 neurons was the presence of prominent, well-organized stacks of rough endoplasmic reticulum. A well-developed Golgi apparatus, free ribosomes, lysosomes, multivesicular bodies and large numbers of granular and agranular vesicles of different sizes were found. The soma was frequently associated with a glial cell that invested the A1 neuron over approximately 50% of its plasma membrane. The rest of the somatic surface was occupied by large axon terminals of which 2 to 3 made synaptic contact with the A1 cell in a single ultrathin section. **Dendrites** of A1 cells could be followed from the labeled neuron and were scattered in the neuropil in the immediate vicinity of the labeled cell. Most synaptic contacts with A1 dendrites were located on small dendrites or dendritic spines with a characteristic rosette arrangement (see drawing below) where 2 to 3, large unlabeled axon terminals, containing pleomorphic vesicles were seen simultaneously contacting the small A1 dendrite or dendritic spine. No dendro-dendritic synapses were seen. Dahlstrom and Fuxe ('64) had postulated the existence of NA axon terminals contacting NA dendrites in this region. We were able to demonstrate one to two examples of this arrangement. Labeled axons in the A1 cell group were invariably small (0.5-1 µm in diameter) and myelinated. A number of the ultrastructural features of the noradrenergic A6 cell group described by Pickel et al ('86) are similar to those seen in this study of A1 cells. Dual labeling techniques in the A2 cell group have revealed the existence of serotonergic (Pickel et al, '84a), peptidergic (Pickel et al, '79) and GABAergic (Pickel et al, '84b) nerve terminals contacting NA dendrites. The findings that NA dendrites in the A1 cell receive such a dense collection of synaptic inputs is new and needs to be evaluated in the context of the origin of their inputs and their neurochemical identity. The A1 region of the medulla oblongata does not receive afferents from the X and the IX nerves and therefore implicating centrally originating axons as sources of these, which by terminating in the A1 NA cell group provide the morphologic basis for the central role this region must play in central regulatory function. 369.7 INCERTOHYPOTHALAMIC A13 DOPAMINE SYSTEM. M.K. Sanghera, S. Grady*, W. Smith and D. Woodward. Depts, of Psychiat. and Cell Biol., Univ. of Texas Health Sci. Cntr., Dallas, TX. 75235.

The incertohypothalamic or nucleus A13 dopamine (DA) system has been implicated in the regulation of Luteinizing Hormone. Since gonadotrophin secretion is a sexually dimorphic function, the possibility that this nucleus may exhibit sexual dimorphism was investigated. A computer graphic system interfaced to a microscope was used to count, and measure the diameters of DA neurons labelled with antibodies raised to tyrosine hydroxylase (TH) and, display data in the 3-dimensional space of the nucleus. Four adult male, and female rats (in estrus), were deeply anesthetized with an interperitoneal injection of Nembutal. The brains were fixed via cardiac perfusion of saline and formalin, removed and then placed placed in formalin for 3-4 days. Frozen serial sections (50um) of the hypothalamus were taken throughout the caudal and rostral extent of the A13 and stained for TH (a gift from Dr J. Porter, UTHSCD). Data from every section containing A13 DA neurons were entered into the computer. The total number (± SEM) of TH-labelled cells in the nucleus in the male were 1296 ± 69 vs. 1252 ± 48 in the female (corrected for spurious counts, by the method of Abercrombie). The vast majority of cells in the A13 nucleus were of the large diameter, darkly stained, fusiform type. There was no differences in the diameters of these large cells (15.12 um ± 0.69 vs 15.8 um ± 0.32 in males and females respectively), nor in the smaller, rounded and lightly staining cells (8.82 um ± 0.30 vs. 7.00 um ± 0.23, male and female respectively). In addition to these two known populations of TH labelled cells in the A13 region, we found a hitherto third population of cells which were intermingled throughout the nucleus with the large fusiform type. These cells were somewhat more darkly stained than the small rounded cells, had little or no dendritic arborization and were of intermediate diameter in both sexes; (10.59 um vs. 0.44 in the male compared to 11.00 um ± 0.40 in the female). The data from this study indicate that (1) from numberical estimation of DA cell number there is no sexual dimorphism in the A13 DA system and (2) there is be an hitherto undescribed third population of TH labelled cells. Supported by Grant NS-24290-01.

369.8 THE DISTRIBUTION AND POSSIBLE CELLULAR ORIGINS OF VASOACTIVE INTESTINAL PEPTIDE (VIP) AND PEPTIDE HISTIDINE ISOLEUCINE AMIDE (PHI) IN THE RAT SUPERIOR CERVICAL GANGLION (SCG). C.A. Sasek, S. Landis and R.E. Zigmond. Depts. of Pharmacol., Harvard Med. School, Boston, MA 02115 and Case Western Reserve School of Med., Cleveland, OH 44106.

Studies on the acute effects of stimulation of the preganglionic cervical sympathetic trunk (CST) on tyrosine hydroxylase (TH) activity in the rat SCG have suggested the involvement of a noncholinergic preganglionic neurotransmitter in the stimulation of TH activity (TINS 8: 63, 1985). Secretin, VIP and PHI, all members of the secretin family of peptides, have been shown to increase TH activity in the SCG, suggesting that one or more of these peptides may be involved in the transsynaptic regulation of TH. A small number of neural processes containing VIP immunoreactivity (IR) has been reported to exist in the rat SCG. The purpose of the present study was to: 1) examine the distribution of these fibers in the SCG; 2) determine whether IR for other peptides of this family is also present; and 3) determine whether any such peptidergic fibers originate from preganglionic neurons of the intermediolateral cell column (IML). IR for VIP and PHI, but not for secretin, was found in the SCG. The distribution of VIP and PHI IR appeared identical in all respects. Large numbers of immunoreactive fibers and varicosities were present throughout the ganglion and its pre- and postganglionic nerve trunks. Dense clusters of immunoreactive fibers were also occasionally seen, as were labeled principal neurons. Examination of serial sections stained alternately for VIP or PHI IR revealed that at least some principal neurons contained both PHI and VIP IR. To determine if any of the immunoreactive fibers in the SCG originate from preganglionic cells in the IML, the CST was ligated. This resulted in a build up of VIP and PHI IR on the side of the ligature proximal to the spinal cord. Furthermore, when sections through thoracic spinal cord segments 1-3 of colchicine-treated rats were examined, both VIP and PHI immunoreactive cells and fibers were found in the IML. Tract tracing studies are in progress to determine if these peptide-containing cells do indeed innervate the SCG. These results demonstrate that two members of the secretin family of peptides are present in the SCG and that there is both an intrinsic and an extrinsic source for the peptide IR, with the latter possibly being the preganglionic sympathetic cells of the IML. These studies provide an anatomical basis for the hypothesis that VIP- and PHI-like peptides are released by preganglionic neurons and participate in the regulation of TH activity. (NS12651)

369.9 SECRETIN AND VASOACTIVE INTESTINAL PEPTIDE (VIP) STIMULATE TYROSINE HYDROXYLASE (TH) ACTIVITY IN SYMPATHETIC NERVE ENDINGS. M.A. Schwarzschild and R.E. Zigmond. Department of Pharmacology, Harvard Medical School, Boston, MA 02115.

Secretin and VIP stimulate TH activity in the rat superior cervical ganglion (SCG) (Ip et al., PNAS 79: 7566, 1982). TH activity in this ganglion is located primarily in the cell bodies and dendrites of sympathetic neurons. The purpose of the present study was to determine whether these peptides also increase TH activity in the terminals of these neurons, their primary sites for norepinephrine release. Rat irides and slices of rat submaxillary gland were incubated in the presence of the dopa decarboxylase inhibitor brocresine (30 μM). Control rates of dopa synthesis were 400 and 40 fmol/mg protein/min in the tissues, respectively. Dopa synthesis was reduced by more than 97% in tissues taken from animals that had had both SCG removed two days previously. Dopa synthesis was also blocked completely in submaxillary slices when α-methyl-p-tyrosine (0.2 mM), an inhibitor of TH activity, was included in the incubation medium. These results indicate that dopa accumulation in these end organs reflects the activity of TH in sympathetic nerve endings. In certain experiments, following incubation of tissues with secretin or VIP, TH activity was measured in tissue homogenates at pH 7.0, in the presence of a subsaturating concentration of the cofactor 6-methyl-tetrahydropterin (30 μM).

Both secretin and VIP stimulated dopa accumulation 4-fold in the intact iris. The EC_{50}'s of the two peptides were 30nM and 1 μM, respectively. Incubation of irides with either secretin or VIP (10 μM) also led to a 3-fold increase in TH activity measured in iris homogenates. In submaxillary slices, 10 μM VIP stimulated dopa acummulation (1.5-fold, $p<0.05$) only if the kallikrein-protease inhibitor, aprotinin (500 KIU/ml) was included. 1 μM VIP had no effect. Secretin produced a 4-fold maximal stimulation with an EC_{50} of 100 nM in these slices in the presence of aprotinin. Preliminary data suggest that secretin and VIP (10 μM) also stimulate dopa synthesis measured in situ and TH activity measured in homogenates in a third end organ of the SCG, namely the pineal gland. In submaxillary gland slices, the peptidergic stimulation of TH activity was not affected when Ca^{++} was excluded from the incubation medium, suggesting that secretin and VIP produce their effects on TH activity by acting directly on sympathetic neural processes, rather than by releasing substances from nearby neurons. Potential sources of peptides that might be involved in such a regulatory mechanism in vivo include (1) nearby parasympathetic or sensory nerve endings or (2) the general circulation. VIP-like immunoreactivity has been reported to be present in the rat submaxillary gland and iris, probably in postganglionic parasympathetic neurons. (Supported by NS12651)

369.10 ANTAGONISTS OF VOLTAGE-SENSITIVE CA^{++} CHANNELS BLOCK THE ACUTE INCREASE IN TYROSINE HYDROXYLASE ACTIVITY PRODUCED BY K^+ DEPOLARIZATION IN BOTH THE SUPERIOR CERVICAL GANGLION AND THE IRIS. A.R. Rittenhouse and R.E. Zigmond. Department of Pharmacology, Harvard Medical School, Boston, MA.

Tyrosine hydroxylase (TH) activity in the rat superior cervical ganglion (SCG) increases acutely following antidromic stimulation or depolarization with high K^+ (55 mM). In both cases, the increase is blocked by lowering Ca^{++} and raising Mg^{++} concentrations in the medium. Here we report that activation of TH in sympathetic neurons in the SCG by K^+ depolarization is dependent on Ca^{++} influx through voltage-sensitive Ca^{++} channels and that a similar mechanism is present in the terminals of these neurons located in autonomic end organs.

Ganglia were decentralized to remove preganglionic nerve terminals and were depolarized in vitro 4 days later with 55 mM K^+. Depolarization increased the rate of dopa synthesis in situ 3.1-fold. This increase was blocked by 69% and 61% by the addition of nimodipine (10 μM) or nitrendipine (10 μM) respectively, two blockers of voltage-sensitive Ca^{++} channels. Further studies indicated that a lower concentration of nimodipine (3 μM) was as effective as 10 μM.

To determine whether increased neural activity also increases TH activity in sympathetic nerve terminals, the preganglionic trunks of the SCG were stimulated unilaterally or bilaterally in vivo at 10 Hz for 15 min, using supramaximal depolarizing current. At the end of the stimulation period, the SCG and specific end organs containing terminals of neurons of the SCG were quickly removed, frozen, and stored at -80°C. TH activity, measured in tissue homogenates, increased an average of 4-fold in the SCG and 4 to 6-fold in the three end organs examined, the iris, pineal gland, and submaxillary gland. To determine whether the increase in TH activity in nerve terminals was dependent on Ca^{++} influx through voltage-sensitive Ca^{++} channels, irides were incubated for 15 min in high K^+. Hexamethonium (3 mM), atropine (6 μM), and phentolamine (10 μM) were present in the medium to block possible indirect effects on TH activity mediated by acetylcholine or norepinephrine release and subsequent stimulation of presynaptic receptors. High K^+ stimulated dopa synthesis in situ 3-fold, and this effect was maximal at 30 sec. The increase in enzyme activity was totally blocked in low Ca^{++} medium and was blocked by 75% in the presence of nimodipine (10 μM). The results suggest that the increase in TH activity produced by K^+ depolarization of both cell bodies and terminals of sympathetic neurons is mediated by an influx of Ca^{++} through voltage-sensitive Ca^{++} channels. (Supported by NS12651)

369.11 COLLIDINE (2-4-6 TRIMETHYL PYRIDINE) RELEASES TRITIATED NORADRENALINE (3H-NA) TAKEN UP BY RAT PINEAL AND VAS DEFERENS. J.L.Tomsig* and A.Pellegrino de Iraldi. Instituto de Biología Celular, Facultad de Medicina de Buenos Aires, Paraguay 2155, 1121 Buenos Aires, República Argentina.

Previous work in our laboratory demonstrated that collidine(2-4-6 trimethyl pyridine) used as a buffer in fixation procedures, abolishes the core osmiophilia and chromaffin reaction of granular synaptic vesicles in rat pineal and vas deferens nerves. This same effect was observed when tissues were briefly incubated with collidine and fixed thereafter. Those findings strongly suggested that the absence of core reactivity was due to a depletion of monoamines present in the synaptic vesicles by collidine.The results obtained with the use of collidine buffer, in conjunction with the well established histochemical procedures, could be also explained by assuming a higher rate of penetration for collidine than for glutaraldehyde or osmium tetroxide fixatives. In the present study we further investigated the effect produced by collidine in rat pineal and vas deferens previously incubated with 3H-NA. We found that collidine rapidly releases the exogenously added neurotransmitter from those tissues. The pineal gland bisected and the vas deferens trimmed in pieces of about 5 mg, were incubated separately in a Krebs modified solution containing 0.1 μM 3H-NA and gassed with 95% O_2:5% CO_2. The composition of the Krebs solution was (g/l) NaCl 6.9; KCl 0.35; $CaCl_2$ 0.28; $MgCl_2$ 0.11; NaH_2PO_4 0.12; $NaHCO_3$ 2.1; glucose 2; ascorbic acid 0.002; EDTA 0.0015; pH 7.4. After washing in the Krebs solution for 75 min, at 37°C, to allow the release of unspecific retained 3H-NA tissues were incubated in the following solutions:1)80 mM collidine buffer pH 7.4; 2) 80 mM cacodylate buffer pH 7.4; 3) modified Krebs solution; 4) 2.5% glutaraldehyde in 80 mM collidine buffer pH 7.4; 5)2.5% glutaraldehyde in 80 mM cacodylate buffer pH 7.4 and 6) 2.5% glutaraldehyde in 80 mM phosphate buffer pH 7.4. Samples of 0.5 ml were taken each 5 min for 30 min. Radioactivity of the samples was monitored in 15 ml of a solution 60/40 of toluene and methoxyethanol plus 3% 2,5-diphenyl oxazol (PPO).The tissues were homogenized in 10 volumes of 0.4N perchloric acid containind 1 mg/ml EDTA and 1.25 mg/ml Na_2SO_3. Collidine increased 3H-NA release 100 fold related to the initial value while the release elicited by cacodylate buffer or Krebs solution was almost negligible. Glutaraldehyde in collidine increaed the release 20 fold whereas by using cacodylate buffer or Krebs solution it is only increased two fold. Summarizing, collidine has a striking release-effect on stored 3H-NA which is greater when used alone than when mixed with glutaraldehyde. These studies are in agreement with histochemical studies previously reported and support the conclusion that collidine has a releasing effect on stored monoamines. This work was supported by a grant from the Cancejo Nacional de Investigaciones Científicas y Técnicas, R.Argentina.

369.12 **QUANTITATIVE AUTORADIOGRAPHIC ANALYSIS OF α_1- AND β-ADRENERGIC RECEPTORS IN INTRAOCULAR RAT CEREBELLAR GRAFTS.** N.R. Zahniser, P. Curella*, D.M. Burnett*, J.A. Miller*, M. Eriksdotter-Nilsson* and A.-C. Granholm*. Dept. Pharmacology, Univ. Colorado Hlth. Sci. Ctr., Denver, CO 80262 and Dept. Histology, Karolinska Institute, Stockholm, Sweden.

Electrophysiological responsiveness of cerebellar Purkinje cells to norepinephrine is diminished in aged rats. In order to determine whether intrinsic or extrinsic factors are responsible for this diminished responsiveness, we have begun studies of noradrenergic receptors in grafts of fetal rat cerebellum maintained in oculo. In the present experiments, α_1- and β-adrenergic receptors were studied in cerebellar grafts prepared from 15-day-old fetal rats (crown-rump length 12-14 mm) after 2 months in the anterior chamber of the eye of adult recipients. The cerebellar anlage continued their growth and development in oculo and had a final approximate diameter of 3 mm and weight of 2-5 mg. Routine histological analysis showed that these grafts possessed the typical trilaminar cortical microfolia and white matter areas previously described in such transplants. 2-[β(4-hydroxyphenyl)-ethylaminomethyl]-tetralone (BE 2254 or HEAT) was radioiodinated to [^{125}I]BE 2254 (IBE) and used to measure α_1-adrenergic receptors in 10μm sections with quantitative autoradiography (QAR). Specific binding of IBE was defined with 1μM prazosin, while β-adrenergic receptors were measured using specific binding of [^{125}I]-pindolol (IPIN) as defined with 1μM l-propranolol. Protein levels were measured in the same tissue sections using a densitometric assay and the QAR system. The α_1-adrenergic receptors were uniformly distributed throughout the grafts. In contrast, in the same grafts, the β-adrenergic receptors showed a more patchy or punctate distribution. At a concentration of IBE (200 pM) four-fold higher than its Kd value, the density of α_1-adrenergic receptors was 20 fmol/mg protein; a similar density of β-adrenergic receptors (30 fmol/mg protein) was observed at a concentration of IPIN (200 pM) equal to twice its Kd value. Similar experiments in intact cerebellum of young rats showed two-to-three-fold higher overall densities of both types of receptors. These results demonstrate that by using QAR, α_1- and β-adrenergic receptors can be localized and measured in intraocular grafts of rat cerebellum. Alterations in receptor properties may explain changes in electrophysiological responsiveness that occur with aging, and these can now be explored with this model. (Supported by USPHS AG 04418.)

370.1 ANTIAGGRESSIVE EFFECTS OF 5HT-1a AGONISTS. R.M. Carelli*, J.M. Liebman and G.C. Wagner. Psychology Dept., Rutgers Univ., New Brunswick, NJ and Pharmaceuticals Division, CIBA-GEIGY Corp., Summit, NJ

The serotonergic agonists 8-OH-DPAT, gepirone and buspirone have all been shown to displace serotonin from 5HT-1a receptors and, in addition, are all effective at increasing behavior in conflict paradigms and at reducing the aggressive behavior of mice. The following studies were conducted in an effort to determine the degree to which these compounds exert a differential effect on two measures of aggression, the resident-intruder and target biting paradigms.

In the resident-intruder paradigm, adult male Rockland-Swiss resident mice were housed individually in pan cages and exposed to standard, bulbectomized mice of the same sex, age and strain for 10-min test sessions. 8-OH-DPAT, gepirone and buspirone were administered IP in a corn-starch vehicle (pretreatment times = 20 min for 8-OH-DPAT and 30 min for gepirone and buspirone). A full dose-response curve for each compound was obtained using a repeated measures design with drug administration occurring no more often than twice/week. The vehicle was occasionally substituted for a drug dose. Intruder mice were drawn from a large population and the brief test session resulted in no injury to the subjects.

It was observed that 8-OH-DPAT, gepirone and buspirone all decreased the frequency of attack behavior (ED50 = 0.5, 3.2 and 5.0 mg/kg, respectively) and increased the latency to the first attack (ED50 = 0.6, 3.8 and 6.0 mg/kg, respectively). The drug vehicle had no effect on the aggressive behavior, which remained stable through the course of the study.

In the target biting paradigm, mice were placed in a small plastic cylinder and administered a mild 0.15 msec, 2.0 mA tail shock on a fixed-time 2-min schedule for 20-min daily sessions 5 days/week. These shock parameters were chosen as the minimal required to engender stable rates of behavior. Under baseline conditions, mice bit an inanimate target at three distinguishable rates: a high target biting rate immediately after the shock; an intermediate target biting rate during the intershock interval; and a low target biting rate during a 15-sec tone which signalled the impending shock. 8-OH-DPAT, gepirone and buspirone were injected IP as described no more often than twice/week.

It was observed that the administration of 8-OH-DPAT, gepirone and buspirone did not alter target biting behavior at doses as high as 1.6, 16.0 or 8.0 mg/kg, respectively.

These observations indicate that 5HT-1a agonists do exert a differential effect on aggressive behavior as assessed by these two paradigms and that the resident-intruder paradigm may be a sensitive procedure for assessing 5HT-1a agonist activity.

370.2 1-(2,5-DIMETHOXY-4-IODOPHENYL)-2-AMINOPROPANE HCL (DOI), A SELECTIVE 5-HT_2 AGONIST, EXERTS AN ANOREXIC ACTION IN RATS THAT IS PREVENTED BY LY53857, A SELECTIVE 5-HT_2 ANTAGONIST. L.E. Schechter and K.J. Simansky. Dept. Pharmacology, Medical College of Pennsylvania, Philadelphia, PA. 19129

Peripheral and central administration of serotonergic agonists can inhibit feeding in rats. Although the receptor subtypes responsible for serotonergic anorexia have not been studied systematically, some workers have suggested a role for central 5-HT_{1b} receptors(Dourish et al., Appetite, 7(suppl):127,1986). Recent data, however, indicate that the anorexic effect of peripherally administered 5HT is sensitive to 5-HT_2 receptor blockade (Fletcher and Burton, Psychopharmacol., 89:216,1986;Massi, Pharm.Biochem. Beh.,1987,in press; Simansky et al., this meeting). The present study therefore tested the effects of a selective 5-HT_2 agonist, DOI (Shannon,et al., Eur.J.Pharmacol., 102:23,1984) on milk intake in food-deprived rats.

Male Sprague Dawley rats(350-450 g) were housed individually with free access to fresh tapwater and maintained on a sweetened milk diet which was presented for 6 hrs. (1100-1700). The amount of milk consumed was measured for 30 min beginning 6 min following the ip administration of DOI or its vehicle. Controls ingested 21.4±1.6 ml during this test interval. DOI (0.1,1,2,4,8,10 uMol/kg;n=6-7/group) inhibited food intake in a dose-related fashion($p<.01$). For example, 2 uMol/kg reduced food intake by 46%($p<.01$) whereas 10 uMol/kg decreased intake by 81%($p<.01$). The ID_{50} estimated by regression was 3 uMol/kg.

Consistent with a role for 5-HT_2 mechanisms in DOI-induced anorexia, 60 min pretreatment with 6 uMol/kg of the selective 5-HT_2 antagonist, LY53857(Cohen et al.,JPET,235:319,1985), prevented the inhibition of food intake by an equimolar dose of DOI(VEH/DOI,-67%;LY53857/DOI,-11%,$p<.01$). A more extensive study showed that this antagonism by LY53857 (6uMol/kg, ip;n=7/group) was dose related($p<.01$). A dose as small as .26 uMol/kg of LY53857 markedly antagonized the anorexic action of 6 uMol/kg DOI(VEH/DOI,3.3±1.1ml; LY/DOI,13.3±3ml;$p<.01$). By comparison, 60 min pretreatment with 6 uMol/kg of xylamidine tosylate, a peripheral 5-HT_2 antagonist, did not prevent the anorexic action of an equimolar dose of DOI(VEH/VEH,21.3±1.4ml; XYL/VEH,20.3±2.0ml; VEH/DOI,6.3±1.4ml; XYL/DOI,5.0±1.5ml). This outcome contrasts with the potent antagonism by xylamidine of anorexia produced by peripheral 5HT and 4HT(Simansky,et al.,this meeting). Thus, the present study appears to implicate central 5HT-2 mechanisms in the anorexic actions of DOI. Further studies are investigating the behavioral and pharmacological specificity of this effect of DOI.(Supported by USPHS Grant MH41987-01 to KJS)

370.3 FENFLURAMINE AS A DISCRIMINATIVE STIMULUS: EFFECTS OF SEROTONIN (5-HT) AGONISTS AND ANTAGONISTS J. D. Smith* and R. Young* (SPON:J.H.Jonhson) Dept of Medicinal Chemistry, Sch of Pharmacy, MCV/VCU, Richmond, VA 23298.

The anorectic fenfluramine (FEN) exerts CNS effects predominantly through the release of endogenous 5-HT. Released 5-HT should interact at 5-HT receptors in a nonselective manner. The existence of at least two major populations of central 5-HT receptors, 5-HT1 and 5-HT2, is well established, and the possible existence of other populations (e.g. 5-HT3) and/or subtypes (e.g. 5-HT1A, 5-HT1B) of 5-HT binding sites have been proposed. Several site-selective and nonselective 5-HT agents have been identified; these agents include 8-OH DPAT (5-HT1A selective), TFMPP and mCPP (5-HT1B), MK 212 and 5-OMe DMT (5-HT nonselective), and quipazine (5-HT2).

In the present study, a drug discrimination procedure was used to examine the relationships between FEN and the above agents. Rats were trained to discriminate 1.5 mg/kg of FEN from saline in a two-lever operant choice task. The ability of the FEN-stimulus to substitute (i.e., generalize) to these agents was then examined. The FEN-stimulus (ED50 0.34 mg/kg) generalized to mCPP (ED50 0.56 mg/kg), MK 212 (ED50 0.69 mg/kg), 5-OMe DMT (ED50 7.19 mg/kg), and quipazine (ED50 1.31 mg/kg), and partially generalized to TFMPP (2.0 mg/kg=72% FEN-appropriate responding); a higher dose of TFMPP resulted in disruption of behavior (i.e., no responding). FEN-stimulus generalization did not occur to 8-OH DPAT (saline-like responding between 0.10 and 0.75 mg/kg).

In a series of antagonism tests, the FEN-trained rats were injected with various doses of ketanserin (KET, 0.05-10.0 mg/kg), a selective 5-HT2 antagonist, or 8-OH DPAT (0.01-0.50 mg/kg) prior to FEN (1.5 mg/kg) administration. Neither compound, over the dose range tested, completely attenuated the stimulus effects of FEN. Partial antagonism (i.e., ca. 50%) was observed however with 1.0 mg/kg of KET or 0.20 mg/kg of 8-OH DPAT. Interestingly, the administration of a combination of each dose of these drugs prior to FEN injection resulted in complete attenuation of the FEN-stimulus. The results suggest that (1) FEN probably produces a 5-HT nonselective stimulus effect and (2) in FEN-trained animals 8-OH DPAT appears to act as a 5-HT antagonist.

370.4 BEHAVIORAL ASSESSMENT OF 8-HYDROXY-2-(DI-N-PROPYLAMINO) TETRALIN(8-OH DPAT) IN TESTS FOR ANXIOLYTIC ACTIVITY. R. YOUNG* (SPON: G. METCALF). Dept of Medicinal Chemistry, Sch of Pharmacy, MCV/VCU, Richmond, VA 23298.

The behavioral effects of 8-OH DPAT, a site selective serotonin (5-HT1A) agent, were evaluated in two tests sensitive for anxiolytic activity. In the first test, rats were trained to lever-respond for sweetened milk on a multiple variable interval-fixed ratio (VI-FR) schedule of reinforcement. In the FR component a brief electric shock accompanied the presentation of reward (i.e., conflict procedure). The introduction of the punishment contingency markedly reduced rates of responding during the FR portions of the schedule. Treatment of these rats with diazepam (DZP) or 8-OH DPAT, administered intraperitoneally, significantly increased responding that was suppressed by shock over a five-fold (i.e., 1.0-5.0 mg/kg) and three-fold (i.e., 0.25-0.75 mg/kg) range of doses, respectively. In comparison, orally administered DZP or 8-OH DPAT significantly increased rates of punished responding across a 14-fold (i.e., 2.5-35.0 mg/kg) and 25-fold (i.e., 1.5-40.0 mg/kg) range of doses, respectively. By either route of administration, 8-OH DPAT produced maximum increases in punished responding that were smaller (400%) than those produced by DZP (600%).

In a second series of tests, rats were trained to discriminate either 2.0 mg/kg of DZP, 0.75 mg/kg of S(+)-amphetamine, or 3.0 mg/kg of ipsapirone (TVX Q 7821) from saline using a two-lever operant task. In tests of stimulus generalization, neither the DZP-stimulus nor the amphetamine-stimulus generalized to 8-OH DPAT or buspirone. In contrast, the ipsapirone-stimulus (ED50 = 0.87 mg/kg) generalized to 8-OH DPAT (ED50 = 0.09 mg/kg), buspirone (ED50 = 0.39 mg/kg), and gepirone (ED50 = 2.86 mg/kg) but not to diazepam. The results suggest (1) that 8-OH DPAT may possess anxiolytic properties which differ qualitatively from those produced by benzodiazepines and (2) the possible involvement of serotonergic systems in mediating the effects of 8-OH DPAT.

370.5 STIMULUS EFFECTS OF SECOND GENERATION ANXIOLYTICS: THE ROLE OF SEROTONIN. M.E.Pierson,* R.Young,* and R.A. Glennon* (SPON: G. King) Dept of Medicinal Chemistry, Sch of Pharmacy, MCV/VCU, Richmond, VA 23298

Unlike benzodiazepine (BDZ) anxiolytic agents, second generation anxiolytics such as buspirone (BUS), gepirone (GEP), and ipsapirone (IPSAP) display a low affinity for central BDZ receptors. In contrast, preliminary binding, drug discrimination, and other pharmacological data suggest that they may act via interaction at a particular population of serotonin receptors (i.e. 5-HT1 sites). The purpose of the present investigation was to further examine the role of 5-HT in the stimulus effects produced by BUS, GEP, IPSAP, a common metabolite (1-PP), and the BDZ diazepam. To this extent, male Sprague-Dawley rats were trained to discriminate ip administration of either the 5-HT1A agonist 8-OH DPAT (0.4 mg/kg), the 5-HT1B agonist TFMPP (0.5 mg/kg), or the non-selective serotonergic agent fenfluramine (1.5 mg/kg) from saline using standard two-lever operant techniques. The 8-OH DPAT stimulus generalized to BUS (ED50 1.5 mg/kg), GEP (ED50 2.1 mg/kg), and IPSAP (ED50 2.6 mg/kg) but all three agents were significantly less potent than 8-OH DPAT itself (ED50 0.17 mg/kg). The 8-OH DPAT stimulus did not generalize to 1-PP or diazepam (which produced saline-appropriate responding at doses of up to 1.0 and 2.5 mg/kg, respectively, and disruption of behavior at slightly higher doses). The TFMPP-stimulus (TFMPP ED50 0.2 mg/kg) did not generalize to any of the agents; all agents produced disruption of behavior at the highest doses evaluated. Each of the agents examined in fenfluramine-trained animals (fenfluramine ED50 0.34 mg/kg) resulted in partial generalization; (agent, maximal drug-appropriate responding and mg/kg dose): BUS (51%, 7.25), IPSAP (48%, 11), 1-PP (52%, 40). Higher doses produced disruption of behavior.

Additionally, TFMPP was administered (po) to rats trained to respond on a multiple VI-FR schedule of reinforcement. During the FR portion, a mild electric shock coincided with the presentation of reward (conflict procedure). In contrast to results with 8-OH DPAT and diazepam (these proceedings), TFMPP had no effect on punished responding.

The results of the present study support the idea that the mechanism of action of the BDZs may differ from that of the second generation anxiolytics and that the latter may involve a 5-HT, and in particular a 5-HT1A, mechanism. (Supported in part by VCU GIA #86/046)

370.6 FAWN-HOODED RAT STRAIN IS FUNCTIONALLY SUBSENSITIVE TO SEROTONIN AGONISTS RELATIVE TO SPRAGUE-DAWLEY AND WISTAR STRAINS. C.S. Aulakh*, P. Wang*, K.M. Wozniak* and D.L. Murphy. (Spon: S.N. Pradhan). Lab. of Clinical Science, National Institute of Mental Health. N.I.H. Clinical Center, 10/3D41, Bethesda, MD 20892

Fawn-Hooded (FH) rats possess a platelet storage pool deficiency analogous to that in the Chediak Higashi syndrome of humans (Meyers et al., Am. J. Pathol., 106:364,1982). Their blood platelets contain decreased numbers and contents of dense granules, decreased concentrations of serotonin (Tschopp and Weiss, Thomb. Haemorrh., 32:670, 1974) and possibly diminished uptake of serotonin (Stewart et al., Neurology, 33:176, 1983). The present study was undertaken to examine the possibility that FH rats may have altered CNS serotonergic function.

The food intake suppressant effects of three serotonin agonists, m-chlorophenylpiperazine (m-CPP, a selective 5-HT_{1B} agonist), 8-hydroxy-2-(di-n-propylamino)tetralin (8-OHDPAT, a selective 5-HT_{1A} agonist) and fenfluramine (a 5-HT releasing agent) were compared in three different rat strains: Wistar, Sprague-Dawley (SD) and FH rats. The animals were housed individually and had free access to water. The animals were trained to take their daily food from 10 a.m. to 2 p.m. At the end of the first hour of food access the remaining food was weighed, and the difference from the original amount constituted one measure of food intake. Administration of all three serotonin agonists produced dose-dependent decreases in one hour food intake in all three strains. FH animals were significantly less sensitive to the food intake suppressant effects of all three serotonin agonists than either Wistar or SD rats. Body weight gain over the nine week course of the study was also significantly less in FH animals than either Wistar or SD animals. We will also present the data comparing the effects of various doses of m-CPP on body temperature, neuroendocrine changes (prolactin, corticosterone and growth hormone) and brain levels of m-CPP in these three rat strains.

In summary, this study supports some other data that FH rats, a strain with a peripheral platelet serotonin storage pool disorder, also possesses altered central nervous system serotonergic function. Further analysis will seek to identify other altered behavioral and neuroendocrine responses to serotonergic agents in the FH strain and clarify the biochemical nature of these defects. Finally, the comparable anorexic responses of Wistar and SD strains to serotonin agonists in the present study suggests that conclusions about serotonergic function made from one of these strains can be extrapolated to the other.

370.7 TEMPERATURE EFFECTS OF m-CHLOROPHENYLPIPERAZINE (m-CPP) AND 8-HYDROXY-2-(Di-n-PROPYLAMINO)TETRALIN (8-OHDPAT) IN THE RAT AND THEIR MODIFICATION BY ANTIDEPRESSANT TREATMENTS. K.M. Wozniak*, C.S. Aulakh*, J.L. Hill* and D.L. Murphy (SPON: N.A.Garrick). Lab of Clin. Science, NIMH, NIH, 10/3D41, Bethesda, MD 20892

The putative 5HT_{1A} agonist 8-OHDPAT and 5HT_{1B} agonist m-CPP produce hypo- and hyperthermia in the rat, respectively. We attempted to analyze the neuropharmacological components of these physiologically opposite effects on temperature with various receptor antagonists. These included clonidine, propanolol, naloxone, pindolol, haloperidol, ritanserin, methiotepin, metergoline and phenoxybenzamine.

Groups of 6 or more male Wistar rats (250 g) were pretreated with one of the above antagonists and challenged 15 min later with a dose of 8-OHDPAT (0.25 mg/kg s.c.) or m-CPP (2.5 mg/kg i.p.), which was chosen from a prior dose-response evaluation. Rectal temperature measurements were recorded at time periods up to 120 min after agonist injection. Pretreatment with methiotepin abolished the hypothermic response to 8-OHDPAT but was ineffective on the hyperthermia induced by m-CPP. Haloperidol, propranolol and pindolol partially attenuated the 8-OHDPAT induced hypothermia but also were inactive against m-CPP induced temperature changes. Metergoline was found to be the only antagonist of those tested that abolished m-CPP induced hyperthermia. These findings demonstrate that different response systems are involved in the opposing effects of 8-OHDPAT and m-CPP on rat body temperature.

Further groups of 5-6 animals were implanted with osmotic minipumps that delivered clorgyline (1 mg/kg/day), imipramine (5 mg/kg/day), chlorimipramine (5 mg/kg/day) or saline and challenged with the test dose of 8-OHDPAT or m-CPP after 21 days of treatment. Rectal temperature measurements were likewise recorded at time periods up to 120 min after agonist or saline injection. Chronic clorgyline administration attenuated both the hypo- and hyperthermic responses to 8-OHDPAT and m-CPP challenge, respectively, whereas the chronic administration of the tricyclics, chlorimipramine and imipramine, attenuated only the m-CPP induced changes in temperature.

These data demonstrate that changes in rat rectal temperature can be useful in the assessment of (1) the specificity of allegedly selective receptor agonists, and (2) the adaptational changes in serotonergic mechanisms during long-term antidepresant treatment.

370.8 EFFECTS OF OLFACTORY BULBECTOMY ON SEROTONIN RECEPTOR MECHANISMS INVOLVED IN NEUROENDOCRINE AND THERMAL REGULATION IN THE RAT. J.F. Nash*, C.A. Stockmeier, M.T. Lowy, G.A. Gudelsky and H.Y. Meltzer (SPON: E. Nemeth), Department of Psychiatry. Case Western Reserve University, Cleveland, Ohio 44106

Olfactory bulbectomy (BULB-X) has been suggested to be an animal model of depression. Removal of or lesioning the olfactory bulbs produces several behavioral changes including hyperactivity, irritability, elevated basal serum levels of corticosterone (CST) and a deficiency in passive avoidance learning in group-housed rats. These behavioral effects of BULB-X can be normalized by the repeated administration of antidepressants such as amitriptyline, imipramine and mianserin. Furthermore, acute injection of the specific serotonin (5-HT) uptake blockers, fluoxetine or zimelidine, reversed the deficit in passive avoidance learning. BULB-X may alter 5-HT mechanisms resulting in physiological changes similar to those observed in depression and therefore may be a valid animal model of human depression. These studies were designed to examine the effect of BULB-X on serotonergic-mediated neuroendocrine and temperature responses. In addition, serotonin-2 (^{3}H-ketanserin) and beta-adrenergic (^{3}H-dihydroaprenolol) receptor binding was determined in the frontal cortex and hippocampus in an attempt to correlate changes in ligand-binding with physiological changes.

Male, Sprague-Dawley rats were placed in a sterotaxic apparatus and olfactory BULB-X or Sham-BULB-X was performed. The rats were individually housed for at least 21 days. No differences were seen in basal (0900 hr) serum CST levels between BULB-X and control (SHAM) groups. The rat dexamethasone (DEX) suppression test (DST) was conducted in which 2 ug/kg of DEX was administered at 0900 and serum CST measured at 1300 hr. Although DEX suppressed CST, neither BULB-X nor SHAM animals "escaped" the suppressant effect of DEX. Administration MK-212, a 5-HT agonist, elevated serum CST to the same extent in both treatment groups. Similarly no difference in serum CST was observed between BULB-X and SHAM groups following administration of the 5-HT_{1A} agonist, 8-OH-DPAT. Furthermore, BULB-X did not alter temperature changes following administration of either MK-212 or 8-OH-DPAT. BULB-X did not affect ^{3}H-Ket or ^{3}H-DHA binding in the frontal cortex. However, BULB-X significantly decreased ^{3}H-DHA binding in the hippocampus by 20% as compared to SHAM animals. These data suggest that BULB-X does not significantly alter these measures of 5-HT neuronal function but may affect neurotransmission via the beta-adrenergic receptor. Further characterization is necessary to validate the use of this animal paradigm of human depression.

370.9 5-HYDROXYTRYPTAMINE MODULATES LIGHT RESPONSE IN CRAYFISH RETINAL PHOTORECEPTORS. A. Picones* and H. Arechiga (SPON: J. Villarreal). Depto. de Fisiología, Biofísica y Neurociencias, CINVESTAV, México, D.F.

Various roles have been proposed for 5-hydroxytryptamine (5HT) in the crustacean nervous system (Kravitz et al. 1985, in Model Neural Networks and Behavior, A.I. Selverston, Ed. Plenum Press, p. 339). 5HT containing neurons have been identified in the crustacean optic ganglia (Elofsson, R. 1983. Cell Tissue Res. 232: 221). Preliminary observations have indicated that 5HT may influence the response to light of retinal photoreceptors (Arechiga et al, unpublished). In the present work we report evidences suggesting that 5HT has a facilitatory role of light response on crayfish retinal photoreceptors.

The experiments were conducted in adult crayfish Procambarus clarki, of either sex and in intermolt. Light responses, intracellularly measured in dark adapted isolated retinas, were enhanced in a reversible manner by topical application of 5HT (10^{-4} M). Both the initial rapid phase and the late slow phase of the receptor potential were similarly facilitated by 5HT. This effect lasted more than 30 min. Membrane conductance during the light response increased under 5HT in proportion with the enhancement of the receptor potential. With test light pulses of intensity at 50% values in the dynamic range of the V-log I curve, both potential and conductance changes attained values of about 40% higher than controls. There were no effects of 5HT on either resting membrane potential or membrane conductance in darkness.

An immunocytochemical survey was made of the lamina ganglionaris with rabbit anti-5HT as primary antiserum using whole mount tissue preparations and histological sections (16-18 μm). Immunoreactive perikarya and fibres were identified in the lamina. Fibres were distributed in a columnar arrangement between two more densely packed layers in the distal and the proximal margins of the neuropile. This pattern was more conspicuous when dissection and fixation of the eyestalk was done at night time.

The electron microscopy analysis of the preparations using a peroxidase-antiperoxidase method revealed immunoreactive fibres running parallel and in close apposition to photoreceptor axons.

These results support the notion of a physiological facilitatory role of 5HT in the crayfish retina.

370.10 ACTIVATION OF TRYPTOPHAN HYDROXYLASE FROM CORTEX AND MIDBRAIN BY ACUTE SOUND STRESS. M. C. Boadle-Biber, T-H. Phan* and K.C. Corley. Dept. of Physiol., Medical College of Virginia, Virginia Commonwealth Univ., Richmond, VA 23298.

Acute stress increases the turnover of 5-hydroxytryptamine (5-HT) in rat CNS. This effect has been observed with immobilization, footshock, fear and exposure to ether (see Weil-Fugazza et al., Brain Res. 297:247 1984). One important contributing factor to the enhanced 5-HT turnover observed in response to stress may be the activation of tryptophan hydroxylase (TrpH), the enzyme that is rate limiting in 5-HT synthesis and hence determines the overall rate of 5-HT formation. The enzyme from cortex is activated in response to electrical stimulation of the dorsal raphe nucleus in which the 5-HT cell bodies of origin are located (Boadle-Biber et al., Neurochem. Intl. 8:83 1986). We recently reported that sound stress (2 sec, 110 dB sound pulses, VI-1 min for 120 min) increases cortical TrpH activity, measured in vitro, by 50 % compared with sham stressed control male Fischer 344 rats (Boadle-Biber et al., Fed. Proc. 46:3780 1987). This increase in enzyme activity may result from enhanced serotonergic neuronal firing to phasic auditory stimuli (Heym et al., Brain Res. 1 232:29 1982). We now report that the increase in enzyme activity to sound stress is also observed with enzyme extracts from midbrain, which contains the 5-HT cell bodies of origin of cortical projections. This increase, like that of cortical enzyme, is reversed by incubation with alkaline phosphatase and is nonadditive with the increase in enzyme activity obtained under phosphorylating conditions. Further studies have shown that enzyme activity remains elevated when the rats are killed 30 min after termination of the sound stress, but returns to control levels by 1 hr. Graded increases in in vitro enzyme activity are obtained over a range of sound intensities (90 - 120 dB). Enzyme activity also becomes elevated when the duration of the stress is shortened from 120 to 60 or 30 min (110 dB) and when the length of sound stimulus is reduced to 100 msec instead of 2 sec (110 dB, 1 hr). Thus phasic auditory stimuli enhance TrpH activity from rostrally projecting 5-HT neurons in a manner that is indistinguishable from the increase in activity obtained with electrical stimulation. These observations together provide the first instance of a noninvasive stimulus that induces a rapid and reversible alteration in TrpH activity.

BIOGENIC AMINES AND RECEPTOR REGULATION

371.1 ADDITIVITY OF NEURAL ADAPTATION OF BETA-ADRENERGIC AND $5HT_2$ RECEPTORS TO IMIPRAMINE AND ELECTROCONVULSIVE SHOCK IN RATS: Regional Selectivity and Time Dependency. I.A. Paul*, G.E. Duncan*, R.A. Mueller, J.S. Hong and G.R. Breese. BSRC, UNC Sch. Med. and LBNT, NIEHS, Chapel Hill and Res. Tri. Pk., NC. 27514.

In previous work, we have demonstrated that electroconvulsive shock (ECS) selectively alters neuropeptide levels in brain regions whereas imipramine (IMI) does not, suggesting that the two antidepressant treatments are mechanistically separate (Paul et al., Soc. Neurosci. Abst. 12:416, 1986). In light of this data, we have examined the hypothesis that IMI and ECS may also affect beta-adrenergic (B-AR) and $5HT_2$ receptors ($5HT_2$-R) via independent mechanisms. Male rats were treated once daily for 1, 2, 4, or 14 d. with IMI (20 mg/kg, i.p.), ECS, or both. Controls received saline or electrode placement without current. The rats were decapitated 16 h. after the last treatment, and the brains dissected. Tissues were assayed for B-ARs or $5HT_2$-Rs using 1 nM ^{3}H-dihydroalprenolol (DHA) and 0.5 nM ^{3}H-ketanserin (KET) respectively. Non-specific binding was determined in the presence of excess isoproterenol for DHA or methysergide for KET.

IMI alone rapidly decreased cortical DHA binding, producing a 15% decrease by day 2 and a 23% decrease by day 4. In hippocampus, the effects of IMI were not evident until day 4 (-22%). Conversely, ECS alone produced significant effects on DHA binding in hippocampus by day 2 (-21%) but did not affect cortex until day 4 (-17%).

KET binding was not significantly affected by either IMI or ECS alone until day 4, at which time both cortex and hippocampus showed similar binding changes in response to IMI (-15% to -20%). In contrast, by day 4, ECS elevated KET binding by 11% in cortex but, was without effect in hippocampus.

When IMI and ECS were combined, cortical DHA binding changes were additive and apparent by day 2 (-30%). The additivity continued through day 15, finally producing a 50% reduction in binding. Significantly, B-AR changes of this magnitude are not produced in this rat strain by either treatment alone. In hippocampus, additivity was not evident until the 14th day of treatment. Cortical KET binding also displayed an additive response to IMI and ECS by day 4, being nearly the sum of the 11% increase due to ECS and the 15% decrease due to IMI (i.e. -8%).

These studies demonstrate that the effects of IMI and ECS on both B-ARs and $5HT_2$-Rs are additive. Further, the effects of ECS and IMI differ as to onset as well as to region of greatest sensitivity. These data, coupled with our previous work, support the hypothesis that ECS and IMI induce neural adaptation by separate mechanisms. Supported by USPHS grants HD-03110, MH-33127 and MH-39144.

371.2 ELECTROCONVULSIVE SHOCK INCREASES ALPHA-1 ADRENERGIC RECEPTOR BINDING IN RAT CORTEX AND AMYGDALA, BUT NOT IN OTHER BRAIN REGIONS. L.J. Grimm[1], D.C. Perry[1], J.A. Blendy[2], C.A. Stockmeier[2] and K.J. Kellar[2]. Depts. of Pharmacology, [1]George Washington Univ. Washington D.C. 20037, and [2]Georgetown Univ. Schools of Medicine and Dentistry, Washington, D.C. 20007.

Repeated administration of electroconvulsive shock (ECS) increases the density of alpha-1 adrenergic receptors labeled by [^{3}H]prazosin ([^{3}H]PZ) in rat cerebral cortex (Vetulani et al., Brain Res. 275:392, 1983; McLeskey et al., Soc. Neurosci. Abstr. 12:414, 1986), but not in hippocampus or hypothalamus (McLeskey et al., 1986). We have now employed quantitative in vitro autoradiography to measure [^{3}H]PZ binding with greater anatomical precision after ECS. Male Sprague-Dawley rats received ECS (150 mA, 60Hz, 300 ms duration) once daily for 10 days. Control animals were handled similarly, but no current was delivered. One day after the last treatment rats were decapitated and brains removed. Frozen 10 μ sections were incubated for 60 min at room temp containing 1 nM [^{3}H]PZ (13.8 Ci/mmol), then rinsed 2 X 5 min in ice-cold buffer, dried and apposed to Hyperfilm (Amersham). Alternate serial sections had 10 μM phentolamine added to the incubation to assess non-specific binding. Quantitation was done with a Loats computerized densitometer.

In agreement with previous results in membrane preparations, cortical [^{3}H]PZ binding was increased in ECS treated animals (22% higher in frontal/parietal cortex and 26% higher in parietal/striate cortex; both increases significant at $p<0.001$, t-test). The increase appeared to be most pronounced in the outermost laminae. Of all other regions surveyed, only the amygdala (but not the lateral amygdaloid nucleus) showed a significant change with ECS (22% increase; $p=0.002$). Hippocampus, hypothalamus, thalamus, geniculate nuclei, caudate putamen, central gray and cerebellum showed no significant differences. Earlier studies which used [^{3}H]WB-4101 to label alpha-1 receptors did not find changes after ECS (e.g. Bergstrom and Kellar, Nature 278:464, 1979). This could have been due to the fact that, under conditions employed, [^{3}H]WB-4101 labels serotonin-1a receptors as well as alpha-1 receptors (Norman et al., Mol. Pharmacol 28:487, 1985). Or, it might be due to the existence of subtypes of alpha-1 receptors (alpha-1a and alpha-1b) that can be discriminated by [^{3}H]WB-4101 but not [^{3}H]PZ (Morrow and Creese, Mol. Pharmacol. 29:321, 1986). If the latter is true, then ECS might affect these alpha-1 subtypes differentially. Current studies are comparing the effects of ECS on [^{3}H]PZ and [^{3}H]WB-4101 on brain binding sites in parallel.

371.3 EFFECTS OF ELECTROCONVULSIVE SHOCK ON [^{3}H]PRAZOSIN AND [^{3}H]WB-4101 BINDING TO ALPHA-1-ADRENERGIC RECEPTORS IN RAT CEREBRAL CORTEX. J.A. Blendy*, C.D. Rossiter*, and K.J. Kellar. Department of Pharmacology, Georgetown University Schools of Medicine and Dentistry, Washington, DC 20007.

Repeated administration of electroconvulsive shock (ECS) increases alpha-1-adrenergic receptors labeled by [^{3}H]prazosin in rat cerebral cortex (Vetulani et al., Brain Res. 275:392, 1983; McLeskey et al., Soc. Neurosci. Abst. 12:414, 1986). This contrasts with previous studies that found that ECS did not alter alpha-1 receptors labeled by [^{3}H]WB-4101 (Bergstrom and Kellar, Nature 278:464, 1979; Deakin et al., Psychopharmacology 73:345, 1981). Two potential explanations for this difference in results with the two ligands are that, under the conditions that it was used, specific binding of [^{3}H]WB-4101, labels serotonin-1A receptors as well as alpha-1 receptors (Norman et al., Mol. Pharmacol. 28:487, 1985); and that [^{3}H]prazosin appears to label two subtypes of alpha-1 receptors, alpha-1A and alpha-1B, while [^{3}H]WB-4101 labels primarily the alpha-1A subtype (Morrow and Creese, Mol. Pharmacol. 29:321, 1986). To determine whether ECS alters one or both alpha-1 receptor subtypes, we compared the effects of repeated ECS (once daily; 12 days) on the specific binding of [^{3}H]prazosin (nonspecific binding defined with 10 uM phentolamine) in the absence and presence of 1 nM WB-4101, which should occupy most of the alpha-1A sites. In addition, we measured [^{3}H]WB-4101 binding to alpha-1 receptors exclusive of serotonin-1A receptors by using the presence of 60 nM prazosin to define nonspecific binding.

Repeated ECS increased total specific [^{3}H]prazosin binding in the frontal-parietal cortex by 28% ($p<0.001$). In the presence of 1 nM WB-4101, [^{3}H]prazosin binding was increased by 30% ($p<0.001$). In the same tissues, [^{3}H]WB-4101 binding was increased to a lesser (14%) but statistically significant extent ($p<0.02$). These studies suggest that both alpha-1A and alpha-1B receptor subtypes might be increased by ECS, but that the alpha-1B subtype may be more affected.

371.4 EFFECT OF ALTERATIONS IN CIRCULATING GLUCOSE LEVELS ON α_2-NORADRENERGIC RECEPTOR BINDING SITES IN DISCRETE HYPOTHALAMIC AREAS. M. Jhanwar-Uniyal* and S.F. Leibowitz (SPON: W.R. Shapiro). The Rockefeller University, New York, N.Y. 10021.

Noradrenergic (NE) stimulation, specifically of the paraventricular nucleus (PVN), elicits eating and induces release of circulating glucose. Previous evidence indicates that this NE response is mediated via α_2-receptors and is greatest at the onset of the active (dark) cycle, when PVN α_2-receptor density reaches its peak. Moreover, deprivation of food (as little as 1 hr), specifically in the early dark period, decreases blood glucose levels and PVN α_2-receptor density, while deprivation in the late dark period actually enhances α_2-receptor concentration. The potent hypoglycemic agent tolbutamide, like food deprivation, also down-regulates medial hypothalamic α_2 receptors in close association with the decline in blood glucose. The present biochemical study investigates this effect of tolbutamide, and subsequent glucose injections, both at the start and end of the dark cycle, on α_2-receptor activity in discrete hypothalamic sites.

Male albino rats were administered vehicle (propylene glycol), tolbutamide (i.p. 50 mg/kg) or tolbutamide + D-glucose (25%) at 5 min or 15 min prior to sacrifice, at the start of the dark or light cycles. The brains were quickly removed and four hypothalamic sites, namely, the PVN, dorsomedial nucleus, medial preoptic nucleus and perifornical lateral hypothalamus, were micropunched. Standard radioligand technique was employed, using the α_2-agonist ^{3}H-p-aminoclonidine (^{3}H-PAC; 2.0 nM for high affinity binding site). Non-specific binding was determined in the presence of phentolamine (50 µM). Serum glucose levels were estimated using a YSI glucose analyzer.

The results demonstrate the following: 1) Tolbutamide treatment, within 5 and 15 min after injection at dark onset, caused respectively a 27% ($p < 0.05$) and 42% ($p < 0.05$) drop in serum glucose and a 48% ($p < 0.01$) and 63% ($p < 0.01$) decline in ^{3}H-PAC binding in the PVN but not other hypothalamic sites. 2) Tolbutamide treatment at the start of the light cycle produced a 49% ($p < 0.05$) decline in circulating glucose levels and a 40% down-regulation of α_2-receptor density only in the PVN. 3) Administration of D-glucose to tolbutamide-injected rats restored circulating glucose and significantly increased PVN binding (+28%) towards baseline, at dark onset but not at light onset. 4) In contrast to the PVN, the perifornical lateral hypothalamus exhibited an increase in ^{3}H-PAC binding 15 min after tolbutamide at dark onset. This effect was unresponsive to glucose administration. These findings suggest a close interaction between circulating glucose and PVN α_2-receptors, which depends upon the specific time within the diurnal cycle.

371.5 **REGIONALLY SELECTIVE REDUCTIONS IN THE DENSITY OF CENTRAL BETA ADRENOCEPTORS AFTER CHRONIC INTRACEREBROVENTRICULAR INFUSION OF ISOPROTERENOL IN RATS.** **G.A. Ordway*, C. Gambarana* and A. Frazer. Depts. of Pharmacology and Psychiatry, Univ. of Pennsylvania School of Med. and VA Medical Center, Philadelphia, PA 19104.**

Repeated treatment of rats with antidepressant drugs or electroconvulsive shock causes a marked reduction in the density of beta adrenoceptors in various regions of the brain, particularly in areas like the cerebral cortex where beta-1 adrenoceptors predominate. Chronic administration of centrally active beta agonists might similarly "down-regulate" central beta adrenoceptors and, therefore, might have potential antidepressant action. The beta adrenoceptor agonist, l-isoproterenol (ISO) activates brain beta-1 and beta-2 adrenoceptors in vitro, but does not penetrate the brain after systemic administration. Consequently, in this study the effect of chronic infusion of ISO into the lateral ventricles of rats on the density of central beta adrenoceptors was examined. Stainless steel cannulas were implanted in the right lateral ventricle of rats. Cannulas were connected via polyvinyl tubing to Alzet^R osmotic minipumps implanted subcutaneously. Pumps delivered drug or Ringer's solution at a rate of 1.05 ul/hr for 7 days. Rats were decapitated 10 to 12 hours after infusions were terminated and the brains were removed. Brain regions were selected for analyses based on their relative densities of beta-1 and beta-2 adrenoceptors: frontal cortex (FC, beta-1:beta-2 = 80:20), cerebellum (CB, beta-1:beta-2 = 10:90) and hypothalamus (HY, beta-1:beta-2 = 50:50). Beta adrenoceptors were measured in homogenates of these areas using the beta antagonist, ^{125}I-iodopindolol (IPIN). Infusions of ISO (5 ug/hr for 7 days) resulted in significant decreases in the Bmax of the binding of IPIN in CB (vehicle, 37±1 fmol/mg protein; ISO, 23±3 fmol/mg protein; $p<.001$) and HY (vehicle, 21±2 fmol/mg protein; ISO 9±1 fmol/mg protein; $p<.001$), but not in the FC (vehicle, 64±3 fmol/mg protein; ISO, 66±3 fmol/mg protein). In rats infused with ISO, the K_D of IPIN was unchanged in the FC (vehicle, 124±10 pM; ISO, 141±14 pM) and in the CB (vehicle, 48±1 pM; ISO, 47±2 pM), but was significantly increased in the HY (vehicle, 82±7 pM; ISO, 148±15 pM; $p<0.001$). Previous studies have shown that IPIN has a K_D for beta-1 adrenoceptors of about 150 pM and for beta-2 adrenoceptors of about 50 pM. Given this, one interpretation of these data is that repeated infusion of ISO is causing a preferential reduction in the density of beta-2 adrenoceptors in the brain. As ISO is a potent and full agonist at both beta-1 and beta-2 adrenoceptors, our results may indicate that central beta-2 adrenoceptors are more susceptible to down-regulation by beta agonists in vivo than are beta-1 adrenoceptors. **(Supported by research funds from the Veterans Administration and USPHS grants MH29094, MH14654 and MH09497).**

371.6 IMIPRAMINE TRANSPORT IN CULTURED MAMMALIAN CELLS INDUCES DOWN REGULATION OF BETA-ADRENERGIC RECEPTORS BY AN AUTONOMOUS MECHANISM. P.G. Lysko* and R.C. Henneberry* (SPON: P.R. Lowenstein). Molecular Neurobiology Section, Laboratory of Molecular Biology, National Institute of Neurological and Communicative Disorders and Stroke, National Institutes of Health, Bethesda, MD 20892.

Long-term treatment of laboratory animals with tricyclic antidepressants (TCAs) has long been known to lead to down-regulation of cell-surface receptors, including beta-adrenergic receptors. We have reproduced in primary cultured granule cell neurons from rat cerebellum and in cultured rat C6 glioma cells grown for 24 hr in the presence of 10 µM imipramine the TCA-induced down-regulation of beta-adrenergic receptors seen in brains of experimental animals. By measuring a decrease in [^{3}H]CGP-12177 binding to beta-receptors, we have found that amines such as chloroquine, NH_4Cl, (+)-propranolol, and trifluoperazine will down-regulate beta$_1$ receptors as well as does imipramine. This is seen in both C6 glioma cells and in the granule cell neurons. However, this apparent down-regulation is neither homologous nor heterologous, but is independent of the receptor. Rather, this autonomous down-regulation appears to occur as a consequence of imipramine transport and/or uptake into dense lysosomal and light endosomal fractions, where we have measured imipramine, propranolol, and dihydroalprenolol uptake after separation of the acidic organelles on Percoll density gradients. Therefore, the apparent down-regulation of beta-adrenergic receptors seen here for imipramine and other amines may be effected through a receptor-autonomous mechanism in common with the well known inhibitors of receptor recycling, chloroquine and NH_4Cl, which alkalize acidic organelles to interfere with receptor recycling and intracellular trafficking.

371.7 D-1 DOPAMINE RECEPTOR CHANGES AFTER CHRONIC TREATMENT WITH SCH 23390 AND/OR HALOPERIDOL. S.A. Parashos*, P. Barone*, I. Tucci*, and T.N. Chase. Experimental Therapeutics Branch, National Institutes of Neurological and Communicative Disorders and Stroke, Bethesda, MD 20892.

Recent experimental evidence supports the existence of interactions between D-1 and D-2 dopamine (DA) receptor subtypes. In order to study the possible impact of these effects on the chronic blockade induced D-1 DA receptor upregulation, four groups of five male Sprague-Dawley rats were treated for three weeks with the selective D-1 antagonist SCH 23390 (0.1 mg/kg sc), the predominantly D-2 antagonist haloperidol (1 mg/kg sc), the combination of the two drugs at the same doses, and the combination of their vehicles (control group). Four days after the final administration of the drugs the animals were sacrificed and D-1 DA receptor binding was studied in the striatum and nucleus accumbens by means of quantitative receptor autoradiography using ^{125}I-SCH 23982. Optical densities were evaluated by computer-assisted densitometry. SCH 23390 treatment significantly increased Bmax by 33% in both areas ($p < 0.01$). Haloperidol did not alter D-1 DA receptor numbers; however after combined administration of SCH 23390 and haloperidol, the D-1 DA receptor Bmax was 15% lower than the one obtained after chronic administration of SCH 23390 alone in the striatum ($p < 0.05$) but not in the accumbens. Receptor affinity remained unaffected by any of the treatments. Taken together with recent behavioral findings, these results imply that D-1/D-2 DA receptor interactions occuring in the striatum but not in the accumbens may be involved in chronic blockade induced D-1 DA receptor upregulation and corresponding behavioral effects, an observation with potential implications in the prevention and pharmacotherapy of drug-induced extrapyramidal disorders.

371.8 QUANTITATIVE AUTORADIOGRAPHIC DEMONSTRATION OF INCREASED D1 RECEPTOR BINDING IN RAT BRAIN AFTER REPEATED ELECTROCONVULSIVE SHOCK L.J. Fochtmann, M. Aiso*, R. Cruciani*, J.M. Saavedra, W.Z. Potter*. Section on Clinical Pharmacology, Laboratory of Clinical Science, National Institute of Mental Health, Bethesda, MD 20892.

Repeated electroconvulsive shock (ECS) has been shown to increase a variety of dopamine mediated behaviors in rats. However, corresponding changes in binding to dopamine receptors remain to be demonstrated. Previous work in our group and other has shown the utility of quantitative autoradiography using the ligand ^{125}I-SCH 23982, a highly selective D1 receptor antagonist, to precisely localize D1 receptor binding in the rat brain with greater sensitivity than that afforded by conventional membrane binding techniques. The present study examined the effect of chronic ECS on binding to dopamine D1 receptors using ^{125}I-SCH 23892 for in vitro quantitative autoradiography.

Male Sprague-Dawley rats weighing 200 - 250 g. received ECS (80 mA for .5 sec via ear clip electrodes) or sham ECS (handled and ear clips applied only) every other morning for a total of 8 treatments. One day after the final treatment animals were sacrificed between 9 AM and 11 AM. Brains were immediately frozen in isopentane and 16 micron sections were subsequently incubated with 250 pM ^{125}I-SCH 23892. Sections were opposed against ^{3}H-Ultrofilm and autoradiographs analyzed by computerize microdensitometry with comparison to ^{125}I standards.

Our previous work using ^{125}I-SCH 23892 for in vitro autoradiographic assessment of D1 receptor binding reveals a single class of high affinity binding sites in the caudate-putamen (B_{max} 174 ± 7 fmol/mg protein), nucleus accumbens (B_{max} 175 ± 8 fmol/mg protein) and substantia nigra pars reticulata (B_{max} 329 ± 47 fmol/mg protein). Chronic ECS produced a significant (45%) increase over these control values in D1 receptor binding in substantia nigra pars reticulata. A similar trend was present in caudate and nucleus accumbens with increase in D1 receptor binding of 35% and 30% respectively.

Although the exact function of the D1 receptor system is continuing to be elucidated, it has been postulated to have a modulatory effect on the D2 receptor system. If this is correct the changes we observe in the D1 receptor binding with chronic ECS may relate to clinical observations on the efficacy of electroconvulsive therapy (ECT) in treating psychotic sympotoms of depression as well as mania. It may also explain the improvements in Parkinsonian symptoms seen after chronic ECT is given to patients with the "On-Off" Syndrome as well as in patients receiving ECT for concommitant Parkinson's disease and affective disorder.

371.9 METHIONINE ADMINISTRATION INCREASES THE NUMBER OF SEROTONIN (5-HT) AND DOPAMINE (DA) BINDING SITES IN RAT'S BRAIN. C.E. Greenwood and M.T. Silvestre-Lontok*. Dept. Nutritional Sciences, Fac. Medicine, Univ. of Toronto, Toronto, Ontario, Canada. M5S 1A8.

We previously reported a 10-15% increase in Bmax, but no change in Kd, of striatal D_2-DA (spiperone) binding sites following methionine (MET) administration (500 mg/kg, i.p., twice daily for 5 days) to rats. Preliminary studies indicate that cortical 5-HT receptor number is also affected by MET administration (7.6±.4 vs 9.9±.8 pmol/g, mean±SEM for saline vs MET, $p<0.05$). The hypothesized mechanism of action is that MET, via increased methylation of membrane phospholipids, increases membrane fluidity thereby allowing cryptic receptors to become available for ligand binding. Direct confirmation of this hypothesis is unavailable however, and it is possible that MET is mediating its effect on receptor availability by an alternate mechanism. For example, MET administration also reduced by approximately 30% brain levels of tryptophan (TRP) and tyrosine (TYR), precursors for 5-HT and DA, respectively, due to increased competition for brain amino acid uptake. Thus MET may be mediating its effect on monoamine receptors indirectly by diminishing monoamine synthesis and inducing 'upregulation' of the receptors. Therefore to determine whether this effect of MET administration on monoamine receptor availability was due to decreased monoamine synthesis, the effect of administering MET or an equimolar dose of valine (VAL) to reduce brain TRP and TYR to an equivalent extent, on monoamine levels and receptor binding was measured. VAL and MET reduced brain TRP levels similarly (4.5 ±.1^a, 2.7±.2^b and 3.3±.2^b µg/g for saline, MET and VAL, $p<0.01$) However, this reduction in brain TRP levels did not influence steady-state levels of either 5-HT or its metabolite 5-HIAA. While similar neurochemical changes were observed with MET and VAL treatments, the changes in 5-HT binding were specific to MET treatment. That is, Bmax, but not Kd, of cortical 5-HT binding sites was increased by 13% in MET (7.7±.9) but not VAL (6.3±.6) treated animals, compared to controls (6.8±.5, $p<0.05$). A similar trend in 5-HT receptor number was observed in striatum. DA metabolism was influenced by both MET and VAL injections. Striatal DA levels were reduced by 26% (5.7±.7^a, 4.2±1.0^b, 4.1±1.0^b µg/g for saline, MET and VAL, $p<0.05$). This decrease in DA levels was reflected in lower levels of the DA metabolite DOPAC (1.9±.6^a, 1.3±.3^b and 1.6±.4^a, $p<0.05$), however this only reached significance in the MET treated animals. The other major DA metabolite HVA was unaffected by either amino acid. VAL injections did not produce similar changes in D_2-DA receptor number previously observed with MET. Thus the results of these experiments suggest that MET is mediating its effect on receptor availability independently of its effect on monoamine metabolism and hence indirectly support our hypothesis that the mechanism of action of MET is at the membrane level. (Ontario Mental Health Foundation).

371.10 SEROTONERGIC AND NORADRENERGIC INFLUENCES ON SEROTONIN TYPE 2 RECEPTOR REGULATION IN THE RAT: BEHAVIORAL AND BIOCHEMICAL STUDIES. A.S. Eison and G. Gianutsos. Section of Pharmacology and Toxicology, School of Pharmacy, University of Connecticut, Storrs, CT. 06268.

Chronic treatment of rats with a variety of clinically-proven antidepressants reduces the density of cortical serotonin type 2 (5-HT-2) receptors as well as the head shake response to 5-HT agonists. Similar effects are observed following chronic treatment with 5-HT-2 antagonists. While the down-regulation of 5-HT-2 receptors is associated with chronic antidepressant treatment, it is unclear whether this effect requires presynaptic 5-HT innervation or postsynaptic interaction with the 5-HT-2 receptor. Recent evidence suggests that enhancements of noradrenergic (NE) transmission may also play a role in antidepressant-induced changes in 5-HT-2 sensitivity.

The present studies have examined the effects of serotonergic and noradrenergic denervation in rats on the 5-HT-2 mediated head shake response. The behavioral effects of chronic (14 day) administration of a 5-HT-2 agonist (quipazine) and an antagonist (ketanserin) in unlesioned rats were also studied. Three days following the 5-HT-lesion, head shakes were unaltered while they were significantly above control 7 days post-lesion and below control 14 days post-lesion. No changes in head shakes were observed 3 days following NE-lesion despite a reduction of NE levels to 26% of controls. However, head shakes were significantly enhanced 10 days after lesion in the presence of an 87% depletion of NE. This suggests that disruption of presynaptic NE input by itself cannot account for the observed facilitation of 5-HT-2 mediated behavior. Chronic administration of quipazine and ketanserin both resulted in significant reductions in the head shake response comparable to those produced after 14 days of treatment with imipramine. Further, to complement all behavioral studies saturation binding parameters for beta-adrenergic and 5-HT-2 receptors will be presented. These studies demonstrate that noradrenergic as well as serotonergic influences may serve to modify 5-HT-2 receptor sensitivity.

371.11 DECREASED [^{3}H]SCH23390 LABELING OF STRIATAL D-1 SITES AFTER NIGROSTRIATAL INJURY. J.F. Marshall, R. Navarrete* and J.N. Joyce. Dept. of Psychobiology, University of California, Irvine, CA, 92717.

The up-regulation of striatal dopamine D_2 receptors following removal of the dopamine (DA) innervation has been a much studied phenomenon, because of its function significance in clinical and animal studies and because it has facilitated an understanding of CNS receptor regulation. Autoradiographic studies from this laboratory reveal that denervation-induced D_2 up regulation occurs predominantly in the lateral caudate-putamen (CP) of rats and monkeys. The current project extends this investigation to an analysis of the denervation-induced changes in D_1 sites, using both quantitative autoradiography and homogenate binding.

Male rats (200 g) were injected with 6-hydroxydopamine (6-OHDA, 8 ug in 4 ul) in the left rostral ventral tegmental area. The uninjected side served as control. Animals survived 4 d, 2 wk, 2 mo, 4 mo, or 11 mo postoperatively. Incubations were performed in 50 mM TRIS buffer plus ions containing 1 nM [^{3}H]SCH23390. Non-specific binding was defined using 5 uM (+)butaclamol. Adjacent sections were used for D_2 binding ([^{3}H]spiroperidol) or for labeling of high-affinity DA transport sites ([^{3}H]mazindol).

Eleven months postoperatively, rats showed dramatic (30-60%) losses of [^{3}H]SCH23390 binding in the CP ipsilateral to the 6-OHDA injection. The same rats showed the expected 15-50% elevations of specific [^{3}H]spiroperidol binding. Quantifying the autoradiographs revealed that the lesion-induced D_1 decrease was greatest dorsomedially; the D_2 elevation was greatest laterally. Autoradiographic studies of D_2 binding done on animals killed 4 mo or 2 wk postoperatively confirm this finding. At 2 wk, however, the ipsilateral CP decline in D_1 sites was more modest (10-20%, depending on CP region) that seen at the much later time points.

Scatchard analysis of the [^{3}H]SCH23390 (0.05-2.50 nM) or [^{3}H]spiroperidol (0.03-1.5 nM) binding was performed to CP sections of rats killed 8 weeks postoperatively. The B_{max} values of [^{3}H]SCH23390 binding ipsilateral to the lesion was less (1027 fmol/mg P) than in the control CP (1562 fmol/mg P) without a change in K_D (1.1 nM). [^{3}H]spiroperidol showed higher ipsilateral B_{max} (736 fmol/mg P) than in the control CP (653 fmol/mg P) without change in K_D (0.47 vs 0.49 nM).

No 6-OHDA-induced change in D_1 binding was apparent in autoradiographs through CP of rats killed 4 d postoperatively, even though DA loss is complete by that time.

Finally, preliminary studies of the [^{3}H]SCH23390 (1.0 nM) binding to ipsilateral and contralateral CP homogenates (P_2 fraction) reveal a similar effect: a 21% ipsilateral loss of CP binding 2 wk after 6-OHDA injection.

371.12 PHYSIOLOGICAL AND PHARMACOLOGICAL HORMONAL MODULATION OF THE RAT STRIATAL D1 DOPAMINE RECEPTOR. D. Lévesque* and T. Di Paolo, (SPON.: C. Harnois) Department of Molecular Endocrinology, Laval University Medical Center, Ste-Foy, Québec, G1V 4G2 and School of Pharmacy, Laval University, Québec, G1K 7P4, Canada,

It is well known that striatal D2 dopamine receptors are modulated by estrogens. After ovariectomy, their is no change in [^{3}H]spiperone striatal binding sites to D2 dopamine receptors. In female rats, hypophysectomy decreases by 20-30% [^{3}H]spiperone binding to striatal D2 dopamine receptors. In the present study we have observed that ovariectomy decreases (20 %, $p<0.01$ vs intact female rat) [^{3}H]SCH 23390 density of D1 dopamine receptor to striatal tissue with no change of affinity. No difference in [^{3}H]SCH 23390 binding affinity and density to striatal D1 dopamine receptors was seen between intact male and female rats. The density of striatal D1 dopamine receptor labelled with [^{3}H]SCH 23390 of hypophysectomized male rats are significantly higher (15 %, $p < 0.01$) compared to those in the intact female, while the affinity remains unchanged. A chronic treatment with 17β- estradiol (E_2, 10 ug b.i.d. for two weeks) of ovariectomized rats increases the density of striatal [^{3}H]SCH 23390 binding sites (Table I). NaCl significantly increases the affinity of [^{3}H]SCH 23390 to striatal tissue in both the control and treated groups.

TABLE I [^{3}H]SCH 23390 binding to rat striata

Groups	Assay buffer	Kd (nM)	Bmax (fmole/mg of protein)
Control	0 NaCl	0.363 ± 0.029	409 ± 17
	+ NaCl	0.244 ± 0.017 **	556 ± 48 **
E_2	0 NaCl	0.321 ± 0.033	590 ± 20 **
	+ NaCl	0.207 ± 0.012 ##	677 ± 38 &

** $p < 0.01$ vs cont. 0 NaCl; & $p < 0.05$ vs cont. + NaCl;
$p < 0.01$ vs E_2 0 NaCl.

Chronic treatment with E_2 increases the density of striatal D1 dopamine receptors by 22% an increase similar to the one observed previously for the D2 dopamine receptor (20-30%). In contrast, ovariectomy affects D1 dopamine receptors while D2 dopamine receptors remain unchanged. In spite of their co-localization in striatal tissues, the interaction of these two types of dopamine receptors is still not well understood. Our results show, as for D2 dopamine receptors, that D1 dopamine receptors are modulated by hormones under physiological and pharmalogical conditions. However, the regulation of these two dopamine receptors seems to be different. Supported by the MRC.

371.13 THE STRIATAL AGONIST BINDING SITE OF THE D-2 DOPAMINE RECEPTOR FLUCTUATES DURING THE RAT OESTROUS CYCLE. P. Falardeau, M. Morrissette* and T. Di Paolo. Department of Molecular Endocrinology, Laval University Medical Center, Quebec G1V 4G2, and School of Pharmacy, Laval University, Quebec G1K 7P4, Canada.

Behavioral and biochemical observations indicate that estradiol, progesterone and prolactin can influence the function of the nigro-striatal dopaminergic system. Striatal D-2 dopamine antagonist and agonist binding sites were measured during the rat oestrus cycle and compared to ovariectomized rats. Adult Sprague- Dawley female rats demonstrating at least two consecutive 4-day estrous cycles were included in the experiment. Animals were sacrificed either in the morning for ovariectomized rats and for rats in oestrus (E), diestrus I (DI), diestrus II (DII), proestrus A.M. (PAM) and in late afternoon for rats in proestrus P.M. (PPM). As previously reported, we observe a surge of plasma prolactin concentrations in the afternoon of PPM while estradiol levels increase gradually to reach a peak on the day of proestrus. Progesterone concentrations are more phasic with one peak the day of D1 and one on PPM. While no variation of the antagonist binding site of the D-2 dopamine receptor labelled with [^{3}H]spiperone was observed during the rat oestrus cycle, we observe here fluctuations of the agonist sites measured with the competition for [^{3}H]spiperone binding by apomorphine. In DII, 35% of the dopamine agonist binding sites are in a high affinity state and this proportion corresponds to that observed in ovariectomized rats. In PAM, PPM, E and DI, we observe a large conversion ($p < 0.01$) of the dopamine agonist high affinity sites into the low affinity (high affinity site: 15%). No significant change in the sum of high + low dopaminergic agonist binding densities and in the inhibition constants (Ki) for either the high or low affinity site of the D-2 dopamine receptor was observed during the rat oestrus cycle. Thus, physiological fluctuations of hormones as occur during the oestrus cycle can modulate extrahypothalamic biogenic amine activity, namely striatal dopamine systems which are not involved in the control of hormone secretion. This may be post-synaptically through an interaction with guanine nucleotide binding proteins. Supported by the MRC.

371.14 HORMONAL MODULATION OF GROWTH AND DOPAMINE RECEPTORS IN 7315a PITUITARY TUMORS. M.A. Bernier* and T. Di Paolo (SPON: S. Radouco-Thomas), Department of Molecular Endocrinology, Laval University Medical Center, Ste-Foy, Québec G1V 4G2 and School of Pharmacy, Laval University, Quebec G1K 7P4, Canada.

The hormonal modulation of growth and D-2 dopamine antagonist and agonist binding sites was studied in 7315a pituitary tumors. The agonist high- and low-affinity states of the dopamine receptor were investigated with apomorphine competition for [^{3}H]spiperone binding to dopamine receptors in 7315a tumors grown in intact female rats while the antagonist site of the receptor was investigated with saturation of [^{3}H]spiperone binding. The affinity and density of the antagonist state and of the high- and low-affinity agonist states are observed to be similar in 7315a tumors as for intact pituitary tissue and are similarly modulated by sodium (NaCl) and guanine nucleotide (Gpp(NH)p). 7315a tumor growth is slower in ovariectomized compared to intact female rats while 17β-estradiol (20 μg, b.i.d.) treatment for 2 weeks and discontinued for 1 week or treatment for 3 weeks inhibits growth of these tumors. Prolactin concentration and density of dopamine receptors are higher in tumors grown in ovariectomized compared to intact female rats while both are decreased after 23 days of 17β-estradiol treatment. Estradiol treatment decreases the affinity of the high- and the low-apomorphine binding sites while their proportions remain unchanged. In another series of experiments, we have compared growth of 7315a tumors and their dopamine receptors in male and female rats. Tumors inoculated in female rats grew faster than those inoculated in male rats. Plasma prolactin concentration is higher in tumor bearing female rats compared to male rats with these tumors. By contrast, tumor prolactin concentrations are lower in tumors from female rats compared to tumors carried by male rats. Dopamine antagonist and agonist binding sites have more affinity and a higher density in tumors grown in male compared to female rats. The proportion of the high- and low-agonist affinity states of the dopamine receptor remains unchanged whether the 7315a tumor was grown in male or female rats. These results confirm the hormono-dependence of these tumors. In addition, they show a relationship between tumor growth and dopamine receptors in 7315a tumors. Supported by the National Cancer Institute of Canada.

371.15 RELATIONSHIP BETWEEN BRAIN DOPAMINE LOSS AND D2 DOPAMINE RECEPTOR SUPERSENSITIVITY IN MPTP-INDUCED PARKINSONIAN MONKEYS. T. Di Paolo[1], P. Falardeau[1] and P.J. Bédard[2]. [1]School of Pharmacy, Laval Univ., Quebec, QC G1K 7P4 and Dept of Molecular Endocrinology, Laval Univ. Medical Center, Ste-Foy, QC G1V 4G2; [2] Dept. of Anatomy, Fac. Med., Laval Univ., Quebec, QC, G1K 7P4, Canada.

There is now much evidence that MPTP produces a severe parkinsonian syndrome. It is well known that this neurotoxin induces a loss of dopamine (DA) and its metabolites dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) concentrations in the caudate nucleus and putamen. However, data on brain DA receptors in MPTP-lesioned animals is still scarce. The present study seeks the relationship between DA, DOPAC or HVA concentrations and [^{3}H]spiperone binding sites in caudate nucleus, putamen and nucleus accumbens following DAergic lesion with MPTP in monkeys. Four ovariectomized monkeys (Macaca fascicularis) received intravenously MPTP in doses of 0.66 to 1.5 mg/kg whereas 3 were kept as controls. The animals were sacrificed one to five months after the injection of MPTP by an overdose of pentobarbital. The brains were immediately taken out, dissected and frozen. DA, DOPAC and HVA levels and [^{3}H]spiperone binding site densities (Bmax) and affinities (K_D) were determined. DA depletion varied from 37% to 100%. A mean elevation in [^{3}H]spiperone binding density of 114.81 ± 4.66% of control ($p < 0.01$) was observed when DA depletion was at least 90% of control values. No change in [^{3}H]spiperone binding dissociation constant was observed after MPTP treatment. We examined the correlation between DA, DOPAC and HVA concentrations and [^{3}H]spiperone binding. The best fit was a logarithmic correlation ($y = -7.185 \ln x + 111.148$; $R = -0.538$, $p < 0.001$) between DA concentrations (x) and the number of spiperone binding sites (y) in all structures. The correlation remained significant when structures were analysed separately (caudate nucleus: $R = -0.500$, $p < 0.025$; putamen: $R = -0.452$, $p < 0.05$; nucleus accumbens: $R = -0.856$, $p < 0.005$). The correlation between DOPAC or HVA concentrations (x) and [^{3}H]spiperone binding (y) were best represented by linear (DOPAC: $y = -0.734 x + 117.675$, $R = -0.607$, $p < 0.001$; HVA: $y = -0.531 x + 121.372$, $R = -0.540$, $p < 0.001$) rather than logarithmic equations (DOPAC: $y = -4.384 \ln x + 106.283$, $R = -0.333$, $p < 0.05$; HVA: $y = -0.601 \ln x + 133.940$, $R = -0.310$, $p < 0.05$). DA concentrations were found to be decreased more than HVA levels which may represent an increase neuronal activity and DA turnover of the remaining neurons after MPTP. The appearance of receptor supersensitivity after MPTP lesion where maximal decrease in DA is observed may reflect a second stage of compensation which becomes operative only when the number of remaining nerve fibers becomes too small to insure transmission. Supported by the Parkinson Foundation of Canada.

371.16 REGIONAL SENSITIVITY OF MESOLIMBIC AND STRIATAL D-2 RECEPTORS TO CHRONIC NEUROLEPTIC TREATMENT. A.M. Szczepanik*, C.A. Wilmot and D.B. Ellis*. (SPON: S.K. Puri). Dept. Biological Research, Hoechst-Roussel Pharmaceuticals Inc., Somerville, NJ 08876.

Many recent studies have shown that the striatum is a heterogeneous structure in terms of function, innervation and distribution of dopamine (D_2) receptors. In the present study, quantitative autoradiography was used to determine the effect of chronic neuroleptic treatment on the number and affinity of D_2 receptors in several regions of the striatum and the n. accumbens. Male Wistar rats (150-200 g) were treated daily with 1 mg/kg haloperidol, 20 mg/kg clozapine or vehicle for 21 days, n=6 per treatment group, and decapitated after a 24-hour washout period. Brain sections (20 microns, freeze-dried) were incubated with 0.2 - 1.4 nM [3]H-spiroperidol (77-85 Ci/mmole) in the presence or absence of 10 µM sulpiride, and subsequently apposed to tritium-sensitive film for 10-12 days. The autoradiograms were analyzed with a video camera-based image analysis system (RAS-R1000). Changes in receptor number or affinity in the n. accumbens and four regions of the striatum, i.e., rostral, medial, lateral and caudal portions, were determined by Scatchard analysis. Readings from the n. accumbens indicated a marked rostrocaudal gradient of D_2 specific binding, from 60% to <20% specific binding; therefore, readings from the rostral half with the higher density of D_2 receptors were used for Scatchard analysis. Results indicate differences in the sensitivity of striatal regions to D_2 receptor up-regulation following chronic dopamine antagonist treatment. Increases in receptor number occurred in the caudal (peripallidal) and lateral regions of the striatum and the n. accumbens, whereas no changes occurred in the rostral portion of the striatum.

371.17 DIFFERENTIAL EFFECT OF HIGH VS LOW DOSES OF CYCLO (LEU-GLY) ON DOPAMINE FUNCTION. N. Lee*, F. DeLeon-Jones*, C. Melchior, J. Fields, J. Lee* and R.F. Ritzmann. Olive View Medical Center, Sepulveda VAMC, UCLA, Los Angeles, Ca. 91342-1495., Univ of Il, Chicago 60612, Hines VAMC, Hines, Il 60141.

Pro-Leu-Gly-NH2(MIF), and its structural analogue cyclo (Leu-Gly) (cLG) alter both dopamine (DA) mediated behaviors and physiological responses. CLG also alters the specific binding of high affinity D-2 DA receptors in striatal tissue. One unusual property of cLG, MIF and related peptides is a bell shaped dose response curve. To date, however, no data exists relating to the mechanism of this phenomena. The purpose of this study was to examine the ability of both low and high doses of cLG to alter the DA system in the striatum by investigating the peptide's effect on a stereotypic response to apomorphine (APO) and on DA receptor binding after 3 different post-injection time intervals. Male, Sprague Dawley rats were divided into three groups: control, low and high doses. These groups received s.c. injection of water, 8mg/kg cLG, and 24mg/kg cLG respectively. Stereotypic behavior was rated at 1, 5 and 14 days after a single dose of cLG. Behaviors were elicited by administration of APO (0.5mg/kg i.p.) and observed between 10-12 a.m. Stereotypic responses were monitored every 5 minutes for 30 minutes after APO. A positive score was given for an amimal exhibiting continuous sniffing. Parallel groups of rats were used for DA binding. Animals were sacrificed and striata removed at 1, 5, and 14 days after cLG. Data from our stereotypy study suggest that after the low dose of cLG, animals showed increased stereotypic responses to APO at 1 and 5 days with this effect disappearing by 14 days. In the high dose group cLG produced a desensitization to APO induced behavior at 1 day but no changes in behavior at 5 or 14 days. Antagonist binding studies at 1 day showed no significant difference among Bmax values of the three groups (28, 34 & 38 fmol/mg). However cLG increased Bmax in the high dose group at 5 days compared to low dose and control groups. At 14 days the Bmax was increased for both low and high dose groups. The mean affinity values (29-57 pM) did not change as a result of cLG treatment.

These results suggest that: 1) at low doses cLG is a positive modulator of DA response whereas at the high dose this same peptide acts a negative modulator. Exact mechanism is unknown, however, one could speculate that cLG at the high dose acts as an antagonist at the same receptor or has an effect on another system other than DA which counterbalances the DA effect. 2) our study of D-2 DA receptors in the striatum shows that there is no correlation between antagonist binding and behavioral changes. Thus further studies of this receptor and behavior should be attempted with agonist binding.

371.18 CHRONIC AGONIST AND ANTAGONIST TREATMENT ALTERS DOPAMINE RECEPTOR LINKED ADENYLATE CYCLASE IN ANTERIOR AND NEUROINTERMEDIATE PITUITARY. B. Borgundvaag and S.R. George, Departments of Medicine and Pharmacology, Univ. of Toronto, Toronto, Ontario, M5S 1A8 Canada.

A number of cellular responses have been documented following chronic exposure of receptor systems to agonists and antagonists. Prolonged exposure to receptor stimulating agents has been reported to result in decreased numbers of receptors or down-regulation. Similarily, chronic exposure to antagonists has been reported to result in increased receptor numbers or up-regulation. Up- and down-regulation of receptor systems is not limited to changes in receptor numbers and include cellular responses with functional changes in post-receptor effector systems. In the present study we report the effect of chronic D2 dopamine receptor stimulation and blockade on the receptor-linked adenylate cyclase system in pituitary. Adult female Sprague-Dawley rats were injected with either bromocriptine (5 mg/kg/day, s.c.), haloperidol (2.5 mg/kg/day, s.c.) or vehicle, for 2, 9 or 14 days. Following treatment, animals were sacrificed by cervical dislocation, neurointermediate lobe (NIL) and anterior pituitary (AP) dissected and frozen at -70°C until use. Adenylate cyclase activity was determined by measuring the rate of conversion of [^{3}H]-ATP to [^{3}H]-cAMP. In both NIL and AP, treatment with bromocriptine resulted in a decreased ability of forskolin and guanine nucleotides to stimulate cAMP production. The Vmax for stimulation of adenylate cyclase activity at 10 uM forskolin was decreased following agonist treatment, and positively correlated with treatment duration. This effect was more pronounced at higher concentrations of forskolin, so that adenylate cyclase stimulation by maximal concentrations of forskolin was reduced by 30%. Guanine nucleotide activation of adenylate cyclase was also attenuated by bromocriptine treatment, with a 20% reduction of maximal stimulation. In anterior pituitary and neurointermediate lobe of vehicle-treated animals, n-propylnorapomorphine (NPA 50 nM) produced an average 18% inhibition of forskolin stimulated enzyme activity. Following bromocriptine administration, this was reduced to 5%, a reduction of 60%. Bromocriptine treatment did not affect the affinity of the enzyme for ATP with a Km of approximately 0.25 mM. Treatment with haloperidol resulted in slightly increased Vmax values for forskolin stimulated enzyme activity with no change in Km. The effect of NPA (50 nM) to inhibit forskolin-stimulated adenylate cyclase was enhanced in both AP and NIL following haloperidol treatment. These results suggest that chronic dopamine receptor activation or blockade result in alteration of the post-receptor mechanisms linked to both stimulation and attenuation of adenylate cyclase activity in AP and NIL.

372.1 EFFECT OF CHRONIC CAFFEINE ADMINISTRATION ON ADENOSINE A1, ADENOSINE A2 AND BENZODIAZEPINE RECEPTORS IN SPECIFIC AREAS OF THE RAT BRAIN. M. Dugich*, M. Hawkins*, N. Porter, and M. Radulovacki (SPON: R. M. Virus). Dept. of Pharmacology, Univ. of Illinois College of Medicine, Chicago, IL 60612.

Caffeine competitively inhibits agonist binding to both adenosine (Ado) A1 and A2 receptors in the rat CNS. In addition, caffeine may also inhibit the binding of benzodiazepines (BDZ) and, to some extent, the behavioral effects associated with these compounds. Chronic treatment with Ado antagonists, such as caffeine, can alter the sensitivity of Ado receptors in the CNS, and various regions of the brain are differentially affected. Since caffeine may also affect Ado A2 and BDZ receptors, we examined the effects of chronic treatment with caffeine on these receptor populations in different regions of the rat brain.

Male Sprague-Dawley rats were treated with caffeine (75 mg/kg/day, i.p.) or saline (.9%) for 12 days. Twenty-four hr after the last injection rats were sacrificed by decapitation and the brains were removed. Scatchard analysis of [^{3}H]-R phenylisopropyl Ado ([^{3}H-R-PIA) and [^{3}H] flunitrazepam were performed in cortical, cerebellar, and hippocampal membranes. Estimates of Ado A1 and A2 receptor number in striatal membranes were obtained by examining the difference between saturating concentrations of 5'-N ethylcarboxamide Ado ([^{3}H]-NECA) and [^{3}H]-R-PIA binding (Yeung and Green, Naunyn-Schmiedebergs Arch. Pharmacol. 325:218, 1984). Ado A1 receptor binding was significantly increased in cortical membranes from rats treated with caffeine (14%, $p<.02$, Student's t-test) with no change in Kd (1.2 nM). No significant changes in ligand binding to Ado A2 or BDZ receptors were observed.

These results suggest that the chronic administration of high doses of caffeine to rats selectively affects only Ado A1 receptors without producing changes in Ado A2 or BDZ receptors. It appears, therefore, that Ado A1 receptors are susceptible to the antagonistic action of caffeine suggesting that blockade of these receptors serves as a biochemical substrate for the stimulant effects of caffeine. (Supported by FED-AFOSR grant 85-0349)

372.2 DESENSITIZATION OF FUNCTIONAL ADENOSINE RECEPTORS FOLLOWING CHRONIC ADMINISTRATION OF DIAZEPAM. M. Hawkins*, W. Pan*, P. Stefanovich* and M. Radulovacki. Dept. of Pharmacology, Univ. of Illinois College of Medicine, Chicago, IL 60612.

Benzodiazepines (BZD) have been reported to inhibit the reuptake of adenosine (ADO) in the brain (Phillis et al., Brit. J. Pharmacol. 70:341, 1980). We have previously shown that chronic administration of diazepam decreases agonist radioligand binding to ADO A_1 and A_2 receptors in hippocampal and striatal membranes, respectively (Hawkins et al., Soc. Neurosci. Abstr., Vol. 12, Part 2, p 800, 1986). These effects are presumably due to an increase in synaptic ADO levels caused by diazepam. The aim of the present study was to determine if functional ADO receptors are affected by treatment with diazepam. For this purpose, we examined ADO-mediated adenylate cyclase activity and agonist radioligand binding following diazepam treatment. In addition, as ADO may modulate the sleep-wake cycle (Radulovacki et al., J. Pharm. Exp. Ther. 228:268, 1984), we also examined the effects of diazepam on sleep in rats.

Male Sprague-Dawley rats (300-350 gm) were implanted with subcutaneous ALZET mini-osmotic pumps containing diazepam (10 mg/kg for 7 days) and cortical electrodes for recording of the electroencephalogram (EEG). Polygraphic recordings were carried out during diazepam treatment and for the first 24h of withdrawal, following which the animals were sacrificed. ADO A_1 receptor binding was determined from Scatchard analysis of [^{3}H] R-PIA binding, while A_2 receptor binding was estimated by the method of Yeung and Green (Naunyn-Schmiedeberg's Arch. Pharmacol. 325:218, 1984) and by Scatchard analysis of [^{3}H] NECA and [^{3}H] R-PIA binding. BZD receptor binding was performed with [^{3}H]-flunitrazepam (Medina et al., Eur. J. Pharmacol. 90:125, 1983). Adenylate cyclase activity was determined by the conversion of [α-^{32}P] d-ATP to [^{32}P] d-cAMP as described by Cooper and Londos (J. Cyc. Nuc. Res. 5:289, 1979). Diazepam produced significant alterations in the EEG on the four stages of the sleep-wake cycle only during the first 12h of drug withdrawal. Agonist binding to ADO A_2 receptors was reduced by 25% as measured by Scatchard analysis and by 18% as measured by the [^{3}H] NECA minus [^{3}H] R-PIA assay (Yeung and Green, ibid). In addition, ADO stimulation of adenylate cyclase activity was significantly attenuated in striatal membranes from diazepam-treated rats. No changes in ADO A_1 or BZD receptor binding were observed in cortical or hippocampal membranes.

The present studies suggest that functional ADO receptors are desensitized following chronic treatment with diazepam. This conclusion is based on the observation that decreased agonist binding to A_2 receptors is associated with an attenuation in the ADO-stimulation of adenylate cyclase activity, an effect mediated for the A_2 receptor. (Supported by FED-AFOSR grant 85-0349)

372.3 OPPOSING ROLE FOR D-1 AND D-2 DOPAMINE RECEPTORS IN THE NEOSTRIATAL CONTENT OF CYCLIC GMP. W. C. Boyar, H. S. Kim, and C. A. Altar. Neuroscience Res., Pharmaceuticals Div., CIBA-GEIGY Corp., Summit, NJ 07901.

D-1 and D-2 receptors in striatal slices have been differentiated by their opposing effects on the production of cyclic AMP (Kebabian and Calne, Nature 77:93,1979) and the activity of adenylate cyclase (Onali et al., Eur. J. Pharmacol. 99:127,1984). D-1 and D-2 receptors have been differentiated in vivo by their actions on dopamine release (Boyar and Altar, J. Neurochem. 48:824,1987) and behaviorally by their effects on grooming (Molloy and Waddington, Psychopharm. 69:409,1984). We studied whether i.p. administration (mg/kg) of a D-1 (SKF 38393, 10-50) or D-2 (LY 171555, 0.25-1) agonist or a D-1 (SCH 23390, 0.02-2) or D-2 (sulpiride, 20-100; haloperidol, 0.3-0.5) antagonist could be distinguished by changes in the striatal content of cyclic GMP.

Male mice (Tac:SW) were injected with either the 0.9% saline vehicle (10 ml/kg) or a drug and killed by microwave irradiation at 30 min (or 2 hr for sulpiride and its vehicle). cGMP levels were measured in the striatum by radioimmunoassay (DuPont-NEN Corporation).

The D-1 antagonist SCH 23390 produced dose-dependent decreases in cGMP levels. Maximal suppressions of 28% were obtained with the 2 mg/kg dose. Conversely, the D-2 antagonists sulpiride and haloperidol increased striatal cGMP by up to 63% and 111%, respectively.

The D-1 agonist SKF 38393 produced dose-dependent increases in cGMP up to 90% at the 50 mg/kg dose. The D-2 agonist LY 171555 did not change cGMP levels.

In D1-D2 interaction studies, the 82% stimulation of cGMP by SKF 38393 (40 mg/kg) was blocked by SCH 23390 (0.3 mg/kg) and potentiated to 276% of control values by haloperidol (0.3 mg/kg).

To summarize, neostriatal cGMP levels are modulated in a manner similar to that for cAMP: D-1 receptor agonists stimulate production of cGMP, whereas D-2 receptors are inhibitory (antagonists increase cGMP) or inactive (agonists) for cGMP production. GTP (1 μM) stimulates adenylate cyclase (Nomura et al, Eur. J. Pharm. 106:437, 1984) and decreases the binding affinity of D-1 (Schulz et al, J. Neurochem. 45:1601, 1985) and D-2 (Creese et al, Mol. Pharm. 16:69, 1979) agonists. Thus, the changes in cGMP content reported here might contribute to functional interactions between D-1 and D-2 receptors via changes in GTP or cGMP-mediated responses.

372.4 α_2-ADRENERGIC RECEPTORS MEDIATE THE INHIBITION OF ISOPROTERENOL-STIMULATED CYCLIC AMP PRODUCTION IN STRIATAL AND CORTICAL NEURONS IN PRIMARY CULTURE. D.E. Kemp*, R.H. Lenox, J. Ellis and S. Weiss. Neuroscience Research Unit, Department of Psychiatry, University of Vermont College of Medicine, Burlington, VT 05405.

In slices of cerebral cortex, α_2-adrenergic agonists inhibit forskolin-stimulated cyclic AMP production. However, the same agonists lead to augmentation of the β-adrenergic stimulation of cyclic AMP production, a response that is not observed in other tissues. In this study, the actions of adrenergic agents on the intracellular production of cyclic AMP was examined in another CNS preparation, cortical and striatal neurons in primary culture, generated from the fetal mouse brain. We have previously demonstrated that these neuronal cultures display most of the properties of mature CNS neurons. Exposure of striatal neurons to increasing doses of the β-adrenergic agonist isoproterenol (ISO) resulted in a five-fold increase in intraneuronal cyclic AMP; half-maximal activation (EC_{50}) was achieved with 10nM ISO. Norepinephrine (NE; EC_{50}, 160nM) produced only a 3-fold increase in cyclic AMP levels. When cyclic AMP production was maximally activated with 10μM ISO, co-incubation with increasing concentrations of NE resulted in a dose-dependent attenuation of ISO-stimulated cyclic AMP levels. At 100μM NE, ISO-stimulated cyclic AMP production was inhibited by 40%; half-maximal inhibition was obtained with 56 nM NE. In the presence of the α_2-adrenergic antagonist yohimbine (10μM), cyclic AMP productions due to NE (100μM) or ISO (10μM) plus NE (100μM) were identical to ISO alone. The islet activating protein from Bordetella pertussis selectively ADP-ribosylates and inactivates N_i, the inhibitory guanine nucleotide regulatory protein of adenylate cyclase. When striatal or cortical neurons were exposed to pertussis toxin (100ng/ml) overnight, there was no detectable difference between ISO- and NE-stimulated cyclic AMP production. In fact, both agonists were able to stimulate cyclic AMP productions up to 8-fold; basal levels were unaffected. These data suggest that α_2-adrenergic receptors mediate the attenuation of β-adrenergic-stimulated cyclic AMP production in striatal and cortical neurons in primary culture, and do so via the inhibitory guanine nucleotide regulatory protein of adenylate cyclase.

S.W. and J.E. are recipients of a Medical Research Council of Canada Fellowship and a New Investigator Research Award (PHS R23 20740), respectively.

372.5 **INTERACTIONS BETWEEN DOPAMINE D1 AND OPIOID RECEPTORS IN THE RAT STRIATUM.** M. Parenti, L. Rusconi*, V. Cappabianca* and A. Groppetti*. Department of Pharmacology, University of Milan, Sch. of Medicine, Milan, Italy.

Presynaptic interactions between opioid and dopamine (DA) neurons are well documented. A close functional link between the two systems has been suggested to exist also postsinaptically in the rat striatum where opioid and DA-D1 receptors seem to modulate in a negative and a positive manner respectively the activity of a common enzyme, i.e. adenylate cyclase (AC). There are evidences suggesting that opiates and DA may regulate the same AC mojety by a receptor-receptor interaction. In this respect we have found that while the degeneration of striatal cell bodies by kainic acid totally abolishes both opioid-and DA-D1 receptor modulation of AC, the intrastriatal injection of a selective cholinotoxin, ethylcholine mustard aziridinium ion (AF64A) does not significantly alter both receptor activities excluding their presence on acetylcholine neurons. Moreover experimentally-induced changes in one receptor activity often results in compensatory alteration of the other. Intrastriatal pertussis toxin injection leads to a functional impairment of opioid receptor inhibition of AC through ADP-ribosylation of the inhibitory guanine nucleotide regulatory protein Gi and causes an increased stimulation of striatal AC by DA. A similar effect is induced by prolonged in vivo treatment of rats with morphine. Moreover the post-natal development of DA-and opioid-induced regulation of AC provides further support to the functional interdependence between the two receptor systems: AC is very sensitive to DA activation at birth and progressively decreases to about one third at adult age while opioid inhibition shows an opposite behaviour being almost absent at birth and maximal at adult age.

The above results therefore suggest that a reciprocal functional interaction between striatal DA-D1 and opioid receptors can serve as a mechanism to properly control AC activity. Disfunction of this system can be important in the etiopathogenesis of extrapyramidal diseases.

372.6 CYCLIC AMP ACCUMULATION SUPERSENSITIVITY TO THE ALPHA-1 AGONIST PHENYLEPHRINE (PHE) IN RAT HIPPOCAMPUS FOLLOWING LESION OF THE SEROTONERGIC MEDIAN RAPHE NUCLEUS (MRN). H. Ladinsky°, R. Vinci*, M. Parenti+, P. Cicioni* and S. Consolo*. Istituto di Ricerche Farmacologiche "Mario Negri", +Dipartimento di Farmacologia, Università di Milano and °Istituto De Angeli, Milan, Italy.

Serotonergic raphe deafferentation elicits an up regulation of a nM (^{3}H)WB-4101 binding site in rat hippocampus for which NE displays high affinity and prazosin low affinity. Guanine nucleotides affect the nM binding of hippocampus alpha-1 adrenergic receptors suggesting that these sites are agonist in nature. In the present study we determined whether the Gpp(NH)p-reduced "agonist binding" of (^{3}H)WB-4101 implicates a receptor-adenylate cyclase interaction in the rat hippocampus. Thus, the effect of specific alpha-1 agonist PHE on cAMP production in hippocampal slices of sham-operated and MRN-lesioned rats was examined. The concentration-response curve of PHE-induced cAMP accumulation in hippocampal slices on the MRN lesioned group was shifted strongly to the left with the peak increase being reached at the concentration 200 times lower (0.5 uM) than that required to raise cAMP formation to the same extent in slices of the sham-operated group. cAMP accumulation supersensitivity began 8 days (35%) and reached a plateau (50%) at 21 days postlesion. This effect was direct as it was found also in crude homogenate preparations. In addition, the increase, and the decrease, in cAMP generated by isoproterenol and acetylcholine was not affected by MRN lesion. The alpha-1 antagonist WB-4101 was the most potent inhibitor of the PHE-induced increase in cAMP formation (IC_{50} = 1.2 x 10^{-7} M), 100-fold lower than that of prazosin, (IC_{50} = 1.4 x 1^{-5} M); yohimbine and propranolol, alpha-2 and ß-antagonists, respectively, inhibited only at high doses. 5-HT (10 uM) induced a marked rightward shift of the concentration-response of PHE-induced accumulation without exerting any effect of its own on the cAMP basal level of MRN lesioned rats. It is concluded that alpha-1 receptor activation affects hippocampal adenylate cyclase activity either directly or indirectly and this interaction is negatively modulated by the 5-HT system.

372.7 NORADRENERGIC POTENTIATION OF CEREBELLAR PURKINJE CELL RESPONSES TO GABA: EVIDENCE FOR MEDIATION BY AN INTRACELLULAR SECOND MESSENGER SYSTEM. B.D. Waterhouse, F.M. Sessler, J.-T. Cheng and H.H. Yeh. Dept. of Physiol. and Biophys., Hahnemann Univ. Phila. PA 19102 and Dept. of Neurobiol. and Anat., Univ. of Rochester Med. Ctr., Rochester, NY 14642.

Previous in vivo studies from our laboratory have consistently shown that iontophoretically applied norepinephrine (NE) can potentiate GABA-induced depressant responses of cerebrocortical, cerebellar and hypothalamic neurons. Additional experiments employing amino acid analogs and a variety of adrenergic agonists and antagonists have further suggested that this noradrenergic facilitating action is specific for GABA and results from the activation of a beta type adrenoceptor. The goal of the present studies was to determine if the cyclic AMP second messenger system might also be a component of the mechanism responsible for this NE modulatory action on GABA responses. In one set of in vivo studies, extracellularly recorded responses of individual cerebellar Purkinje (P) cells to iontophoretic pulses (5-55nA, 10 sec duration) of GABA or beta-alanine were examined before, during and after 8-bromo- 3', 5' cyclic AMP (Brom-cAMP) microiontophoresis. A second group of in vitro experiments examined P-cell responses to GABA (5-50 nA.) before, during and after NE iontophoresis or bath application of forskolin (10-30µM). Peri-event histograms which summed unit activity during amino acid applications were quantitatively evaluated to assess the effect of NE, cyclic AMP and forskolin on GABA-induced inhibition. In the intact rat brain, iontophoretic administration of Brom-cAMP caused a marked NE-like augmentation of P-cell responses to GABA in 13 of 17 (76%) cells tested. As with NE, Brom-cAMP was ineffective in enhancing P-cell inhibitory responses to beta-alanine, an agent which like GABA causes hyperpolarization, by increasing Cl^- conductance. In 11 of 17 (65%) neurons tested in vitro, iontophoretically applied NE markedly enhanced P-cell responses to GABA in a manner similar to that observed previously in vivo. Bath application of forskolin was also capable of potentiating GABA-induced inhibition in each of 3 cases tested. In summary, these results indicate that a membrane permeable analog of cyclic AMP and an agent which directly activates adenyl cyclase can mimic the previously observed GABA-potentiating actions of NE. Thus, these findings provide further support for the contention that noradrenergic enhancement of GABA inhibition results from a cascade of transmembrane events which includes beta receptor activation, adenyl cyclase stimulation and increased intracellular production of cAMP. (Supported by AFOSR-85-0155 and NS 18081 to B.D.W.)

372.8 CYCLIC GMP ANALOGUES INCREASE THE EXCITABILITY OF CEREBELLAR PURKINJE NEURONS IN CULTURE. T. Jacquin*, C.P. Crimi* and D.L. Gruol, Div. Preclin. Neurosci., Scripps Clinic and Res. Foundation, La Jolla, CA 92037.

Cerebellar Purkinje neurons (PNs) express high concentrations of cGMP dependent protein kinase which is thought to play an important role in neuronal physiology (Schlichter et al, PNAS, 1980). As a first step toward defining the functional role of this cyclic nucleotide in the PN, we have tested the effect of membrane permeable analogues (50-500 µM) on the spontaneous activity and membrane properties of PNs in a model system: modified organotypic cultures derived from rat cerebellar cortex. The culture system and the morphological and physiological properties of the cultured neurons have been described (Gruol, Brain Res. 263, 1983). In the first series of experiments, extracellular recording techniques were used so that the intracellular environment was not disturbed. Firing rate and pattern were quantitated by computer. In the majority of PNs studied with this technique (N=22), cGMP analogues applied to the recording medium (several analogues tested) increased the spontaneous firing rate and regularized the patterns of activity. Mean firing rates were 10.8±1.1 (±SEM) under control conditions and 12.3±1.2 in the presence of cGMP, which were significantly different at the $P<0.0005$ level (Paired-sample t-test). In five cells, the bursting component of the control activity patterns was enhanced. Mean values for % burst were 17±6 for control and 40±3 in the presence of cGMP. Similar results were observed in intracellular recordings using whole cell methods. The main effect of cGMP on the spontaneous activity recorded intracellularly was an increase in the frequency of burst discharges and synaptic events. The most pronounced effect of cGMP on membrane properties was an enhancement of excitability, as demonstrated by an increase in the number of spikes evoked by depolarizing current pulses or synaptic events. In TTX treated preparations (n=4) the anode break Ca++ spike was prolonged by cGMP. The effect of cGMP analogues on resting membrane potential and the voltage response evoked by hyperpolarizing current pulses was variable. Resting membrane potential was hyperpolarized (3-15mV) in 5 cells, depolarized (5mV) in 1 cell and unchanged in 8 cells. Input resistance measured with hyperpolarizing current pulses was decreased in 5 cells, increased in 2 cells and unchanged in 7 cells. These data demonstrate that the excitability of PNs can be altered by cGMP analogues and support a physiological role for cGMP and its kinase in the PN. The fact that several actions of the cGMP analogues were observed suggests that cGMP may have more than one site of action in the PNs. (Supported by NINCDS Grant NS21777 to DLG and a grant from the Fondation de l'Industrie Pharmaceutique pour la Recherche to T.J.)

372.9 FORSKOLIN INCREASES THE EFFICIENCY OF ELECTRICAL STIMULATION OF VASOPRESSIN RELEASE FROM RAT NEUROHYPOPHYSIS IN VITRO

K. Allesøe & M. Treiman Inst. Medical Physiol. C, Panum Institute, Blegdamsvej 3C, DK-2200 N, Copenhagen

Electrical stimulation of rat neurointermediate lobe (NIL) in vitro characteristically results in an abrupt increase in the rate of vasopressin release above the pre-stimulation level, followed by a decline despite continuing stimulation. We have studied the rate of decline of vasopressin release during 40 min electrical stimulation as a function of the length of silent intervals between pulse trains. Pulses (0.2 msec/pulse, 16 Hz) were delivered as 20 sec trains with silent intervals varied from 10-60 sec between individual NILs. The perifusing medium was collected in fractions every 5 min and its vasopressin content measured by RIA. Release in the fractions following the peak was expressed relative to the peak value. Fig.1. shows that the decline in the rate of release was steepest with 10 sec silent intervals. Forskolin 10 uM added throughout the stimulation period increased the content of cAMP from 0.2 to 8.1±0.5 (SEM, N=4) pmoles/NIL. In the presence of forskolin the decline in the rate of vasopressin release was slower with silent intervals of 10 sec, but not of 20, 40 or 60 sec. Fig.2 shows the cumulative release (% of the peak) for different lengths of silent intervals, in the presence (×···×) or absence (●——●) of forskolin 10 uM. Thus, the efficiency of electrical stimulation (vasopressin released/single pulse) with 10 sec intervals was increased by 32 % in the presence of forskolin. In rats in vivo, during dehydration an increasing number of vasopressin neurons in supraoptic nucleus fire in bursts with inter-burst periods from 4 to 200 sec and the frequency of shorter periods increasing with the severity of osmotic stress. Increase in the efficiency of electrical stimulation with short silent intervals in vitro due to forskolin might reflect the presence of a cAMP-dependent mechanism in vivo counteracting the diminished efficiency of firing with shorter silent intervals under the conditions of high demand on the release of vasopressin.

(Fig 2.)

372.10 **INTRAHIPPOCAMPAL DISTRIBUTION OF FORSKOLIN AND CALMODULIN SENSITIVE ADENYLATE CYCLASE ACTIVITY IN MALE RATS.**

M. N. Gannon* and B. S. McEwen (SPON: A. Eden).
Laboratory of Neuroendocrinology, Rockefeller Univ., NY 10021.

We investigated the intrahippocampal distribution of basal, forskolin (F) and calmodulin-sensitive (CaM) adenylate cyclase (AC) activity in membrane preparations to determine the relationship of these biochemical measures to the localization of F-binding site(s) (Worley, P.S. et al. Proc.Natl.Acad.Sci. 83:4053, 1986). AC activity was measured, in membranes prepared in either sucrose (SB, 300 mM) or imidazole (IB, 10 mM) buffers containing 2 mM EGTA and 5 mM EDTA, pH 7.4, by the conversion of ^{32}P-ATP to ^{32}P-cAMP (Salomon, Y. et al. Anal.Biochem.58:511, 1974).

Both basal and F-stimulated (10 uM) AC activity were higher in dentate gyrus (DG) than in either ammon's horn (AH) or whole hippocampal (H) membranes prepared in SB (basal = 157±30, 68±15 and 89±23; 10 uM F = 712±80, 429±99 and 295±58 pmoles cAMP/mg/min^{-1} respectively, n ⩾ 4). The difference between the response to F in DG and AH was due to an increased V_{max}(898±135 vs. 659±132 pmoles cAMP/mg/min^{-1}, n = 4, $p < 0.05$, paired t-test), and not a difference in the EC_{50} (2.26±0.35 vs. 4.92±2.66 uM, n = 4). The differential response to F (10 uM) was maintained along the dorsal-ventral axis of the hippocampus. No dorsal-ventral differences were noted in the F (10 uM) response in either DG or AH. Omission of GTP (10 uM) from the incubation medium had no effect on either basal or F concentration-response curves in DG or AH, although GTP increased hippocampal F-binding sites.

Addition of both Ca^{2+} (250 uM) and CaM (50 U/125 ul) was required to stimulate AC activity in H membranes prepared in IB (basal = 77±15 Ca^{2+}/CaM = 176±16 pmoles cAMP/mg/min^{-1}, n = 4). Ca^{2+}/CaM AC activity was significantly higher in DG than AH (248±50 vs. 106±21 pmoles cAMP/mg/min^{-1} respectively, n = 3, $p < 0.05$ paired t-test). A similar difference in basal activity was also noted (92±9 vs. 57±7 pmoles cAMP/mg/min^{-1} respectively, n = 3). In preliminary experiments (n = 2), addition of F (10 uM) had no effect on the AC response to Ca^{2+}/CaM in DG and less than additive effects in AH, suggesting that part of the AC response to Ca^{2+}/CaM and F may occur through a common limiting mechanism.

In general, our biochemical measurements of F-sensitive AC activity parallel the intrahippocampal distribution of F-binding sites, but the relationship(s) between GTP, Ca^{2+} and CaM effects on F-binding and AC response remain to be clarified. Stimulation of AC in DG granule cells has been implicated in long term potentiation, thus in vitro measurements of AC activity may add to our understanding of cAMP involvement in memory processes.

372.11 NEURAL REGULATION OF ADENYLATE CYCLASE IN RAT BROWN ADIPOSE TISSUE. J.G. Granneman, Center for Cell Biology, Sinai Research Institute, Detroit, Mi 48235.

Many tissues decrease their responsiveness after exposure to increased levels of neural stimulation. In contrast, we have reported that cold exposure, which increased sympathetic nerve stimulation of brown adipose tissue (BAT) in rats, increased the responsiveness of adenylate cyclase to norepinephrine and fluoride. Furthermore, the sensitization of adenylate cyclase is prevented by surgical denervation, indicating this effect is in fact produced by neural stimulation.

We are examining the molecular basis of the increase in adenylate cyclase responsiveness and have found that exposing rats to 4°C for 3 days increased by 2-3 times the maximum velocity of adenylate cyclase activity to stimulation by guanylyl-5'-imidodiphosphate without altering the apparent affinity of the enzyme for the nucleotide. In addition, cold exposure increased maximal extent of cholera toxin-catalyzed [32]P-ADP ribosylation of the alpha subunit of the stimulatory regulatory protein of adenylate cyclase (G_s) in BAT membranes by 2-3 times but did not alter pertussis toxin labelling of the inhibitory regulatory protein. These results suggest that membranes of cold-exposed rats contain more functional G_s protein. However, direct immunological detection of G_s by Western blotting demonstrated that the total amount of G_s present in control and sensitized membranes is similar. Taken together, these results indicate that although control and sensitized membranes contain similar amounts of G_s, only a fraction of the total G_s present in control membranes is functional. Neural stimulation of BAT appears to increase by 2-3 times the fraction of existing G_s molecules that can stimulate cyclic AMP formation and serve as a substrate for cholera toxin. The exact mechanism by which neural stimulation increases the function of existing G_s molecules is not currently known, but may involve the interaction of G_s with membrane components that are unique to sensitized membranes. (Supported by NIH grant AM 37006).

372.12 NEUROMODULATION OF TYPE II CYCLIC AMP-DEPENDENT PROTEIN KINASE.

I. Held, H. Yeoh* and J. McLane. VA Hospital, Hines, IL 60141

The type II regulatory subunit of cyclic AMP-dependent protein kinase (R-II) is autophosphorylated through an intramolecular reaction with the catalytic subunit, but the physiological significance of this reaction is not fully understood. We have reported that the in vitro ^{32}P-autophosphorylation of R-II is increased in cytosolic fractions from denervated (DEN) solei compared to contralateral, control (CON) muscles of the rat. Also, the early onset (3 hr) and progression of this phosphorylative modulation was directly related to the denervation period and the length of the distal nerve stump. Therefore, this alteration is not solely due to the cessation of the impulse-directed release of acetylcholine with transection of the sciatic nerve.

Now, we show that the ratio of (+P)R-II (phosphorylated R-II) to (-P)R-II (dephosphorylated R-II) in vivo is markedly higher in DEN compared to CON solei. A rapid and direct experimental approach with precautions to prevent alterations during sample preparations is used to assess the relative content of (+P)R-II and (-P)R-II in vivo.. Solei are clamp-frozen in situ and put in liquid nitrogen upon removal, DEN (by cutting the nerve) and CON solei are kept paired during sample preparation, the muscles are rapidly homogenized with 10 mM potassium phosphate buffer pH 6.8, 1 mM EDTA, 1 mM 2-mercaptoethanol and 20 mM benzamidine to inhibit protein kinase, protein phosphatase and protease activities, and muscle cytosol (105,000g supernatant) is immediately treated in 2% sodium dodecyl sulfate (SDS) and 5% mercaptoethanol in a boiling water bath for 2 minutes. These samples are kept frozen until resolution of cytosol proteins by SDS-gel (7.5%) electrophoresis (SDS-PAGE) in the Laemmli system.

Afer SDS-PAGE and electrotransfer of the separated proteins to nitrocellulose sheets, (+P)R-II and (-P)R-II are visualized by autoradiography after immunodetection with rabbit anti-rat skeletal muscle R-II serum as the primary probe and either radioiodinated goat-anti-rabbit IgG or protein A as the secondary probes. The relative content of R-II isoforms is evaluated by soft laser densitometry of the autoradiographs.

The electrophoretic mobility of rat solei (+P)R-II is less than that of (-P)R-II to yield a difference of about 2,000 in their apparent molecular weights. When muscle cytosols are incubated with 1 mM ATP and 15 mM Mg or with 10 mM cyclic AMP before SDS-PAGE, then the mobility shift upon phosphorylation and dephosphorylation of R-II can be seen. Tissue and species differences in the occurrence of this phenomenon are well-recognized. The phosphorylation shift of rat solei R-II provides a direct experimental approach for evaluation of denervation-induced changes in the relative content of (+P)R-II and (-P)R-II.

372.13 cGMP PRODUCING NEURONAL NETWORKS IN THE HIPPOCAMPUS: A COMPARISON OF THE EFFECTS OF NITROPRUSSIDE AND POTASSIUM ON THE PRODUCTION OF cGMP IN RAT HIPPOCAMPAL SLICES INCUBATED IN VITRO AS REVEALED BY IMMUNOCYTOCHEMISTRY. J. de Vente±, J. Schipper±, L.Hudson,± and H.W.M. Steinbusch (SPON: W.J. Smeets). Dept. of Pharmacology, Vrije Universiteit, Medical Faculty, 1081 BT AMSTERDAM, The Netherlands.

Biochemical determination of cGMP revealed the presence of this cyclic nucleotide throughout the mammalian brain. The exact regional localization together with the differences between cellular concentrations in various cell types and the subcellular distribution of cGMP is, with a few exceptions, not known. Recently we described the use of a new cGMP antibody especially designed for application in immunocytochemistry (De Vente et al., Neuroscience, in press, 1987). This antibody was used in an in vitro study on the distribution of cGMP in rat hippocampal slices.

In this study male rats (180-220 g) were decapitated and the brains quickly removed. Hippocampal slices of either 100 or 300 um were prepared at 0°C in a normal isotonic salt solution. Slices were incubated for 30-60 min at 37°C and pH 7.4 in an atmosphere of 5%CO_2/95%O_2, and subsequently incubated in the presence of several pharmacological agents. The incubation was terminated either by adding fixative for immunocytochemical processing or by the addition of TCA for biochemical assay. cGMP was visualized in the 100 um slices using the newly developed antibody by a peroxidase-antiperoxidase procedure with a DAB/Ni intensification. The 300 slices were frozen and 10 um cryostat sections were collected on slides and processed for cGMP-immunoreactivity using a FITC procedure. Both immunocytochemical methods gave identical results. The staining was specific for cGMP as judged by conventional immunocytochemical controls.
At basal levels a weak cGMP staining was associated with blood vessels and cell bodies in the pyramidal layer of the hippocampus. In the presence of IBMX, (0.1-1.0 mM) cGMP immunostaining increased in blood vessels and cell bodies, whereas an occasional nerve fiber was observed. Sodium nitroprusside (10 uM) alone did not appreciable increase cGMP, but in combination with IBMX, theophylline or zaprinast (M&B 22.948) an intense staining of the blood vessel walls and a dense neuronal network throughout the hippocampus was observed. Treatment with K^+ (20 mM, isotonic replacement of Na^+) showed a circumscribed cGMP-immunoreactive neuronal network, principally located in or around the stratum lacunosum moleculare; this K^+ induced cGMP elevation was absolutely dependent on extracellular Ca^{2+}, whereas the cGMP response induced by the phosphodiesterase inhibitors or sodium nitroprusside was not. At an overall level the biochemical determination of cGMP in the hippocampal slices confirmed the immunocytochemical results. In conclusion, we found a widely distributed cGMP producing neuronal network which is regulated by at least two independent mechanisms.

372.14 TEMPORAL SPECIFICITY IN THE RESPONSE OF BRAIN ADENYLATE CYCLASE TO TRANSIENT STIMULI. Y. Yovell* and Y. Dudai. (SPON: V. Teichberg). Department of Neurobiology, Weizmann Institute, Rehovot 76100, Israel.

Studies in Aplysia and Drosophila have implicated adenylate cyclase in learning and short-term memory. One suggestion is that adenylate cyclase may serve as a molecular convergence locus for signals mediating conditioned stimuli (CS) and unconditioned stimuli (US) during associative learning (Eliot et al., Soc. Neur. Abs. 12: 400, 1986). This suggestion raises the hypothesis that adenylate cyclase may display temporally specific responses to converging stimuli, e.g., transmitter, G-activators or ions; and that such responses may underlie some elementary behavioral constraints of classical conditioning, e.g., the necessity for temporal pairing of CS and US. Until recently, direct probing of adenylate cyclase responses to transient and interacting stimuli was not feasible. We have recently developed a novel in vitro perfusion methodology for this purpose (Y. Yovell, Y. Dudai, E. Kandel and T. Abrams, in preparation). In this system, a synaptosomal membrane preparation is embedded on a filter in a small reaction chamber. The chamber is connected via a rotary valve to reservoirs containing assay solutions, from which it is continuously perfused. The perfusate is sequentially aliquoted and assayed for production of radiolabeled cAMP. A programmable pulse generator controls valve positions. Switching between reservoirs containing cyclase activators enables presentation of stimuli in a paired/unpaired manner. We have now employed this methodology to probe some temporal integrative properties of adenylate cyclase in a synaptosomal preparation from rat cerebral cortex. The response of adenylate cyclase to combinations of transients of Mg^{2+} and the GTP analog GTPγS, or to GTPγS and isoproterenol transients, revealed a temporally specific pattern: Paired presentations of GTPγS and Mg^{2+} transients resulted in greater cyclase activation then unpaired presentation. Conversely, paired presentation of isoproterenol and GTPγS transients yielded lower activation then their unpaired presentation. Latent "memory" of previous exposure to GTPγS was revealed by subsequent brief exposures to Mg^{2+} and transmitter analog; the latter, when following a GTPγS transient, caused additional persistent activation. Latent "memory" of previous exposure to transmitter analog was also revealed. In contrast, the cyclase complex did not exhibit "memory" of previous Mg^{2+} exposures. Although two of the stimuli used in these studies are non-physiological, they partially simulate properties of receptor and G-unit activation. We propose that asymmetric temporal integration of transient stimuli by the cyclase complex may play a role in modulation of synaptic plasticity, e.g. during elementary associative learning. (Supported in part by the US-Israel Binational Science Foundation, Jerusalem).

PRESYNAPTIC MECHANISMS IV

373.1 NON-QUANTAL RELEASE OF TRANSMITTER AT DEVELOPING NEUROMUSCULAR JUNCTIONS OF XENOPUS IN CULTURE. A.D. Grinnell, and S.H. Young. Jerry Lewis Neuromuscular Research Center, UCLA School of Medicine, Los Angeles, CA 90024.

Non-quantal, or 'leak' release of transmitter at the neuromuscular junction has been described in frog (Katz and Miledi, Proc.R.Soc.Lond. 196:59, 1977), mouse (Vyskocil and Illes, Pflugers Arch. 370:295, 1977), and Xenopus cells in culture (Sun and Poo, J.Neurosci. 5:64, 1985). In these studies, the presence of 'leak' release was assayed by slight hyperpolarizations of the muscle membrane potential after application of acetylcholine (ACh) receptor channel blockers to the junctions. Since the time course of the control-block-recovery cycles were long, detailed information on the temporal characteristics of the 'leak' have not been available. In our study, we have taken advantage of the high resting input impedence of Xenopus muscle cells (100 MΩ) in combination with the whole cell patch clamp technique to measure the 'leak' currents flowing across cell membranes of nerve contacted muscle cells in 1-day and 3-day old nerve-muscle cultures. The background current noise can be small enough (≤ 1 open ACh channel at -80 mV holding potential) so that 'leak' release can be measured directly and continuously, i.e., without addition of blockers. With these conditions, 'leak' release is seen to occur in episodes of current fluctuations separated by periods of quiet baselines (interrupted only by miniature endplate currents, MEPCs). As expected, application of α-bungarotoxin (20 μg/ml) to the bath blocks these episodic current fluctuations, leaving only the stable baselines. 'Leak' release is not often observed at very young (1-day culture) nerve-muscle contacts, occuring in only 1 out of 8 contacts. In continuing experiments with older (3-day) cultures, this fraction increases to 37% of contacts which show 'leak'. The leak does not occur continuously, but in episodes at an average rate of 0.75/min. Average episode duration is 1.2 sec. The frequency of MEPCs does not change during an episode of 'leak'. At one synapse, MEPC frequency was 1.50, 1.50, and 1.52 MEPCs/sec before, during, and after a large duration 'leak' episode.
Supported by NSF grant BNS 85-1079, and by grants from the Muscular Dystrophy Association.

373.2 QUANTAL RELEASE OF NEUROTRANSMITTER IS NOT ASSOCIATED WITH THE OPENING OF LARGE SINGLE CHANNELS ON THE NEURONAL MEMBRANE. S.H.Young,I.Chow,and A.D.Grinnell. Jerry Lewis Neuromuscular Research Center, UCLA School of Medicine, Los Angeles, CA 90024.

In recent years, some investigators have challenged the traditional view that quantal release of neurotransmitter occurs through fusion of transmitter-containing vesicles with the neuronal plasma membrane. A common element of this challenge is the involvement of cytoplasmic transmitter in the quantal release process, although specific mechanisms for this proposed form of release are varied. We have examined one such mechanism-- that cytoplasmic acetylcholine (ACh) could be released through large channels in the neuronal plasma membrane in order to produce miniature endplate potentials (MEPPs). We see no evidence for such channels. Chow and Poo (J.Neurosci. 5:1076, 1985) have shown using cultured nerve and muscle cells of Xenopus that when a muscle cell is placed into contact with the soma of a neuron, MEPP-like depolarizations are seen in the muscle cell within 5 min. of contact (57% of contacts). In our experiments, a muscle cell was impaled with a microelectrode and placed into contact with soma of an isolated neuron with short (≤30μm) neurites not in contact with the muscle cell membrane. After the appearance of MEPPs, the soma was held under voltage clamp with a whole-cell patch clamp. The high resting membrane resistance of the soma (>200MΩ) provides high resolution recording of neuronal membrane currents (resolution of 2 pA and 1 ms), which are recorded simultaneously with muscle membrane potential. Neuronal currents from 8 nerve-muscle contacts which produced over 1,000 MEPPs were examined before, during, and immediately after each MEPP. No neuronal channels were observed in association with the MEPPs. Consideration of the size of ACh (M.W. 146), makes it seem unlikely that we would not detect the opening of a channel large enough to pass this cation, making it unlikely that such channels are involved in the production of MEPPs. Supported by NSF grants BNS 85-1079, BNS 84-19893 and by grants from the Muscular Dystrophy Association.

373.3 VOLTAGE/TIME DEPENDENCE OF K^+-INDUCED EXOCYTOSIS OF TRANSMITTER. C. Haimann*, R. Fesce*, F. Grohovaz* and B. Ceccarelli* (SPON: European Neuroscience Association). - CNR Ctr Cytopharmacol. - Ctr. Periph. Neuropath. - Dept. Pharmacol. - Un. Milano - Italy - 20129.

At the frog neuromuscular junction, exocytosis of quanta of ACh generally occurs near specialized structures called active zones. After 15 min in 20 mM K^+, however, vesicle fusions are observed all over the presynaptic membrane. This might reflect late onset of endocytosis, or the activation of latent fusion sites either by the prolonged depolarization or by some specific effects of potassium (J. Cell Biol. 81:178-192, 1979).

We have studied the changes in the distribution of vesicle fusion images on freeze-fractured presynaptic membranes from junctions fixed in 20 mM K^+ either 0, 1 or 5 min after exposure to 20 mM K^+. These changes were correlated with the rate of quantal secretion, measured by fluctuation analysis (J. Gen Physiol. 88: 25-57,1986) of intracellular recordings before and during fixation.

Mepp rate increased and began to decline from 30 to 60 sec after the addition of the fixative solution, until mepps disappeared within about 1½ min. During the decline (which might correspond to the fixation time) totals of 15,000, 20,000 and 30,000 quanta were secreted at 0, 1 and 5 min. Replicas from these junctions showed densities of 4.7, 3.3 and 4.0 fusions/μm^2, respectively. Almost all the fusions (96%) were located near the active zones at 0 min, 54% at 1 min, and only 26% at 5 min (i.e. fusions were distributed almost uniformly on the presynaptic membrane).

In spite of the changes in distribution, the densities of fusion images were similar at 0, 1 and 5 min. Since the quanta secreted did not decline with time it is unlikely that an important contribution to the number of fusions at late times arose from the onset of an endocytotic process absent at early times. Furthermore, asynchronous quantal secretion induced by hypertonic solution (150 mM sucrose) was equally intense and sustained, but fusions were predominantly located near the active zones at 5 as well as 15 min.

In preparations exposed to 20 mM K^+ for 5 min in the absence of Ca^{2+} and for 30 more sec in the presence of Ca^{2+} before fixation, fusions were uniformly distributed on the presynaptic membrane. This indicates that K^+ activates an additional population of sites for exocytosis through the prolonged depolarization.

The occurrence of fusions over the whole membrane is accompanied by a decreased density near the active zones. Such a decrease does not occur during prolonged electrical stimulation, suggesting that K^+-induced secretion undergoes partial inactivation. Preliminary data on the time course of mepp rates observed at the same junction with different concentrations of K^+ support this interpretation.

The changes in fusion localization might reflect different voltage/time dependences of two population of fusion sites (calcium channels ?). *partially supported by MDA grant, B.C.*

373.4 EFFECT OF INTRACELLULAR SODIUM ON STIMULATION-INDUCED CHANGES IN NEUROTRANSMITTER RELEASE. D.R. Mosier* and J.E. Zengel. Depts. of Neuroscience and Neurosurgery, Univ. of Fla. College of Medicine and Veterans Administration Medical Center, Gainesville, FL 32610.

Repetitive stimulation of presynaptic nerve terminals often leads to an increase in the amount of neurotransmitter released by a nerve impulse. A number of investigators have proposed that this increase in release results from an accumulation of intracellular Ca^{++}. It has also been suggested that Na^+ may play a role in stimulation-induced increases in release, either by a direct effect on release or indirectly by affecting intracellular $[Ca^{++}]$.

Previous studies in our laboratory have shown that reductions in extracellular Na^+ concentration not only elevate transmitter release, but also selectively enhance an early component of the increase in transmitter release which occurs during repetitive stimulation. To further investigate the role of sodium in stimulation-induced increases in release, we have examined the effects of agents known to alter intracellular $[Na^+]$.

End-plate potentials (EPPs) were recorded from frog (Rana pipiens) sartorius muscles under conditions of reduced quantal release (0.4-0.7 mM Ca^{++}, 5 mM Mg^{++}). The muscle nerve was conditioned with trains of 10 impulses at 20 impulses/sec. Changes in EPP amplitude were expressed as V(t), the fractional increase over the control EPP amplitude, such that

$$V(t) = (EPP_t/EPP_c) - 1$$

where EPP_c is the amplitude of the first EPP of the train and EPP_t is the EPP amplitude at time t during the train.

Addition to the bathing solution of 0.5-4 µM monensin, an ionophore known to raise intracellular $[Na^+]$, led to substantial increases in V(t) in five of ten preparations tested. The effect of monensin appeared to be primarily on an early component of increased release, similar to the effect of reduction in extracellular $[Na^+]$ described previously. In the remaining five preparations, either no change or a small decrease in V(t) was observed. No consistent effects were observed on control levels of transmitter release.

Another way to increase intracellular $[Na^+]$ is to inhibit the plasmalemmal Na/K ATPase with the cardiac glycoside ouabain. Although addition of 3-20 µM ouabain led to large increases in control EPP amplitude in eight of nine preparations, we observed no consistent changes in V(t). In most experiments, the effects of ouabain were irreversible and led eventually to failure of release.

The results of the monensin experiments support the suggestion that intracellular $[Na^+]$ may be involved in one or more processes underlying changes in transmitter release with repetitive stimulation. Although the results of the ouabain experiments appear to be inconsistent with this hypothesis, it is possible that additional effects of ouabain, e.g., on the nerve terminal action potential, may be acting to obscure the effect of increased intracellular $[Na^+]$ on stimulation-induced increases in release.

373.5 ADENOSINE IS AN ENDOGENOUS MODULATOR OF STIMULATION-INDUCED DEPRESSION AT THE FROG NEUROMUSCULAR JUNCTION. Stephen D. Meriney and Alan D. Grinnell. Jerry Lewis Neuromuscular Research Center, UCLA, CA 90024.

Adenosine has been shown to inhibit transmitter release (Ginsborg and Hirst, J. Physiol. 224:629 (1972)). ATP (co-released with ACh) is hydrolyzed by enzymes present in the junctional region, and adenosine becomes available for modulation of subsequent release from the presynaptic terminal (Rebeiro and Sebastiao, J. Physiol. 384:571 (1987)).

We have investigated the effect of adenosine in the context of stimulation-induced depression of neuromuscular transmission. Classically, depression has been attributed entirely to depletion of ACh from the presynaptic terminal. Identified terminals (visualized with peanut lectin-FITC) were studied in partially curarized cutaneous pectoris muscles of Rana pipiens by intracellular techniques. Following physiological characterization, the lengths of these junctions were quantitated by camera-lucida drawings of NBT-stained terminals.

The depression of transmitter release during 20 Hz nerve stimulation is closely correlated with the amount of ACh released/unit length. Strong terminals can depress by as much as 80% while weak ones frequently maintain facilitation during a 30 second tetanus. The effect of tetanic stimulation on endplate potential size is predominately a balance between facilitative effects and depression due to depletion of ACh. However, tetanic stimulation in the presence of adenosine deaminase (which hydrolyzes endogenous adenosine) can reduce depression by as much as 50%, often resulting in significant facilitation. Sensitivity to adenosine deaminase is correlated with release/unit length such that weak junctions are influenced to a greater extent than strong ones. It is not surprising that modulation by endogenous adenosine represents a larger percentage of stimulation-induced depression at weaker junctions, since these would not be expected to have significant depletion of ACh. A large amount of depletion-mediated depression at strong junctions may mask the effects of endogenous adenosine. We conclude therefore, that adenosine is a potent endogenous modulator of synaptic depression during repetitive nerve stimulation, especially when transmitter depletion is not severe.

373.6 ACETYLCHOLINE RELEASE DURING REPETITIVE ACTIVITY AT THE FROG NEUROMUSCULAR JUNCTION. R.S. Manalis and M.B. Wildermuth*. Indiana-Purdue Univ., Fort Wayne, IN 46805.

One approach to the study of transmitter release has been to use certain chemicals, such as pharmacological agents or heavy metal ions, as specific probes to disrupt the release process. However, most of the electrophysiological studies that have been performed along this line have used rather simple experimental designs in which ACh release has been evoked following single shocks to the motor nerve. Such investigations have neglected the more subtle aspects of transmitter release which become apparent when ACh is released repetitively during a train of stimuli. Therefore, we have begun to perform such studies. The combined use of conventional electrophysiological and digital recording techniques allows for a systematic study of the kinetics of ACh release. Sciatic nerve-sartorius muscle preparations of the frog (Rana pipiens) were bathed in normal Ringer's solution containing (in mM): NaCl (111); KCl (2.5); $CaCl_2$ (2.0); tris maleate (4) (pH = 7.1-7.2; temp. = 15° C). Endplate potentials (EPPs) were recorded from curarized preparations ([dTC] = 4.31 µM. Trains of stimuli were applied to the nerve. For a given train, the stimulus frequency was usually constant and was within the range of 20-63 Hz. Stimulus trains lasted 4 sec and were applied every 8 min. Changes in evoked ACh release were measured electrophysiologically as variations in EPP amplitude. Moderate stimulus frequencies (30-40 Hz) applied to the nerve produce the following changes in ACh release: a rapid facilitation, a rapid depression and, finally, a slow depression. There is also a marked temporal summation which underlies the facilitation and rapid depression phases. The data also clearly show an inflexion point between the two phases of depression. EPP amplitudes were normalized relative to the maximally facilitated one in the train. This inflexion point as extrapolated to the Y-axis (normalized EPP amplitude) is referred to as the mobilization coefficient, which was found to be .5 at 40 Hz. Preliminary experiments have shown an inverse relationship between stimulus frequency and the time constant of decay during the rapid depression phase. This time constant (in sec) was 1.38, .960, .919, .525, .491, 1.22, and .290, respectively, at the following stimulus frequencies (in Hz): 20, 25, 31, 40, 50, 20 (repeat), and 63. (Supported by NSF grant BNS-8609047.)

373.7 MECHANISMS OF PRESYNAPTIC FACILITATION AT THE CRAYFISH OPENER NEUROMUSCULAR JUNCTION.
S.Sivaramakrishnan[1], G.D. Bittner[1] & M.S. Brodwick[2]. [1]Department of Zoology, University of Texas at Austin, and [2]Department of Physiology & Biophysics, UTMB, Galveston,Texas.

Presynaptic facilitation is defined as an increased probability of transmitter release resulting from repetitive stimulation of an axon terminal. Facilitation at many synapses may be regulated by both sodium and calcium ions. At frog neuromuscular junctions, for example, reduction of extracellular sodium increases quantal content (Birks & Cohen, Proc. R. Soc., Lond., B 170: 381, 1968), while an increase in intracellular sodium facilitates transmitter release at crayfish neuromuscular junctions (Atwood, Swenarchuk & Gruenwald, 1975, Brain Res., 100: 198,1975). Sodium is thought to act indirectly on transmitter release by raising the internal calcium concentration.It has been proposed that this secondary regulation of transmitter release by sodium ions could be due to either a competition between sodium and calcium ions at the neuromuscular junction or the presence of a sodium-calcium exchange mechanism in the presynaptic terminal.

We are investigating the sodium-dependence of presynaptic facilitation at excitatory neuromuscular junctions made by a single axon on opener muscle fibers in the crayfish walking leg. Two electrodes are inserted in the excitor axon close to a presynaptic terminal. One electrode is used to pass current into the terminal and the other to record membrane potential. A third electrode is used to record post-synaptic potentials intracellularly from an adjacent muscle fiber.

Partial reduction or complete removal of sodium ions from the bathing medium results in a hyperpolarization of the presynaptic terminal of the excitor axon and, usually, a decrease in the resting frequency of spontaneous miniature potentials (MEPPS). However, if the membrane potential of the terminal is clamped at its resting level, reduction of the external sodium concentration causes a large increase in the resting MEPP frequency. The lower the external sodium concentration, the greater the MEPP frequency.

The crayfish opener muscle is also innervated by a GABA-ergic inhibitor axon which makes synapses on both the excitor axon and on opener muscle fibers. We tested the possibility that the inhibitor is tonically active and that this tonic inhibition affects the MEPP frequency in low-sodium solutions. Addition of picrotoxin to a bathing medium containing normal sodium results in small changes in membrane potential of the excitor axon but has no effect on the resting MEPP frequency. When picrotoxin is added to a bathing medium containing low sodium and the membrane potential of the excitor axon clamped at its resting level, an increase in MEPP frequency is still observed. Tonic inhibition is therefore probably not present in this preparation.

373.8 TIME COURSE AND CHARACTERISTICS OF STRETCH-INDUCED INCREASE IN TRANSMITTER RELEASE FOR FROG MOTOR NERVE TERMINALS. S. Hulsizer* and A. D. Grinnell, (SPON: S. Bodine-Fowler) Dept. of Physiology and Jerry Lewis Neuromuscular Research Center, Univ. of Calif. Los Angeles, Los Angeles, Calif, 90024.

In response to stretch, the presynaptic terminal of the frog sartorius neuromuscular junction increases transmitter release. Previous studies employing static changes in length have shown an increase of up to 100% in EPP size, MEPP frequency and quantal content with a 20% increase in stretch (Hutter and Trautwein, J. Physiol., 133:610-625, 1956 and Turkanis, J. Physiol., 230:391-403, 1973). However the degree of increase is quite variable for different junctions and little is known about the rate of onset of the phenomenon. With the aim of understanding better the mechanism of the effect and its physiological relevance, we have investigated the time course of the effect.

The preparation utilized both sartorius muscles from Rana pipiens, coupled in series by a string connecting the tibial tendons, with the pelvic ends pinned into a Sylgard dish such that both muscles were initially at rest length. The muscles were bathed in normal frog Ringer's solution with enough curare to block nerve-induced contraction (typically 3 uM). The left muscle was stimulated electrically inducing a contraction that stretched the right muscle. During the stretch, the nerve to the right muscle was stimulated via a suction electrode, producing EPPs that were recorded with a "floating" intracellular electrode. This electrode was placed near a terminal and recorded EPPs at rest length and at varying degrees of stretch, up to 115% of rest length. The interval of time from the onset of stretch to the EPP was varied in order to determine the rate of development of the response. At 18°C for any measured degree of stretch, the response reached steady state levels within 20 msec although no effect was seen at 10 msec. This effectively establishes that the stretch effect is fast enough to be of physiological significance in supplementing the spinal stretch reflex and suggests that second messenger systems are probably too slow to cause this effect. Further studies are underway to correlate the degree of stretch effect with morphological and physiological properties of the junction.

373.9 LONG-TERM FACILITATION OF SYNAPSES BETWEEN NEURONS OF APLYSIA GROWN IN VITRO INVOLVES INCREASED TRANSMITTER RELEASE: A QUANTAL ANALYSIS. N. Dale*, S. Schacher and E.R. Kandel. (SPON: J.S. Eisenman) HHMI, Ctr. for Neurobiol. & Behav., Columbia Univ., and NYS Psychiat. Instit., NY, NY 10032.

Both short- and long-term sensitization of the gill withdrawal reflex in Aplysia involve corresponding short- and long-term facilitation of the synaptic connections between siphon sensory and gill motor neurons. Whereas the short-lasting synaptic facilitation involves an increase in the amount of the transmitter released by the presynaptic sensory neuron (Castellucci and Kandel, 1976), the mechanisms by which this same sensorimotor synapse can be facilitated in a long-lasting way remain unknown.

To determine whether long-term facilitation involves an increase in transmitter release, a quantal analysis was performed on sensorimotor synpases reconstituted in vitro, which can exhibit long-term facilitation following repeated applications of 5-HT (Montarolo et al., 1986). L7 motor cells were co-cultured with either one or two sensory neurons for 4-5 days. The amplitude of the synaptic connections between the sensory and motor neurons and the amplitudes of any spontaneously-occurring miniature synaptic potentials (mEPSPs) were measured before and 24 hours after 5 applications of 1 uM 5-HT. The amplitude of the mEPSPs ranged from 92 to 156 uV; they were characterized by a short rise time and a roughly exponential falling phase, giving them a shape very similar to that of the evoked EPSP. Five repeated applications of 5-HT caused a twofold facilitation of the synaptic connection; however, in no case did the mean amplitude of the spontaneous mEPSPs change significantly. Overall evoked EPSPs were facilitated by 113% (s.e.m. 36.8, n = 8), while the mean amplitude of the spontaneous mEPSPs showed a slight, but not significant, increase of 2.3% (s.e.m. 2.63, n = 8). Long-term synaptic facilitation is not therefore accompanied by an increase in the size of the unit quantum of transmitter released by the sensory neuron.

Amplitude histograms of EPSPs, evoked under conditions of low release (120 mM Mg, 7 mM, Ca), indicated that the size of the unitary evoked potential did not change with facilitation. Instead, there was a decrease in the number of failures (mean = -79%, s.e.m. 9.6, n = 6) and an increase in the number of multiple release events. This suggests that the size of the quantum not only stays constant, but that the quantal content of the EPSP increases during long-term facilitation. We therefore conclude that long-term synaptic facilitation, like short-term modulation of the same synapse, involves an increase in the amount of transmitter released by the sensory neuron. While our experiments allow us to rule out certain types of postsynaptic change (e.g., changes in receptor affinity or density), it remains likely that long-term facilitation does involve some postsynaptic alterations such as growth and formation of new contact points.

373.10 USE-DEPENDENT REGULATION IN A SYNAPTOSOMAL PREPARATION FROM THE SYMPATHETIC GANGLION. M. W. McCaman*, C. A. Briggs and D. A. McAfee. Div. of Neuroscience, Beckman Research Institute/City of Hope, Duarte, CA 91010 and Abbott Laboratories, Abbott Park, IL. 60064.

We are developing a preparation of synaptosomes from the rat superior cervical ganglion, a tissue that has been valuable in many neurophysiological studies. As little as one rat ganglion pair (2 mg wet weight) sufficed in preparing the P2 and the subsequent fractions enriched by centrifugation in a Metrizamide density gradient. Qualitative electron microscopy demonstrated the presence of intact synaptosomes. Cholinergic function was demonstrated by Na^+-dependent uptake of ^{3}H-choline, by apparent synthesis of ^{3}H-acetylcholine (^{3}H-ACh) from the ^{3}H-choline, and by stimulated release of ^{3}H-ACh. The uptake of ^{3}H-choline at a concentration of 1 μM was reduced more than 90% at 4°C and by 80% in the presence of 136 mM LiCl/24 mM NaCl at 34°C.

To study ^{3}H-ACh release, the synaptosomal preparation was preincubated with 1 μM ^{3}H-choline for 15 min and then perifused on a Uniflo filter (0.45 μm pore) with media containing 20 μM eserine. Thus, the ^{3}H-ACh was synthesized by the synaptosomal preparation. ^{3}H-ACh and ^{3}H-choline were separated by the cholinekinase-ion pair method. In perifusates ^{3}H-ACh accounted for only 5-10% of the total ^{3}H-cpm released spontaneously. Exposure to high K^+ (15 mM for 5 min, n = 10) or to veratridine (50 μM for 5 min, n = 7) increased the release of ^{3}H-ACh by 35 and 63%, respectively, and of ^{3}H-choline by 24 and 52%, respectively. The evoked release of both compounds was reduced more than 50% in a low Ca^{++} medium.

A long term potentiation of endogenous ACh release is observed in the intact ganglion after brief preganglionic tetany (Briggs, McAfee and McCaman, J. Physiol. 363:181, 1985). To determine if such a potentiation could be observed in the synaptosomes, we homogenized ganglia 15 min after tetany (10 Hz for 60 sec), with the contralateral non-stimulated ganglion as control. Neither ^{3}H-choline uptake nor the release of ^{3}H-ACh or ^{3}H-choline was increased in the synaptosomal preparations from the stimulated ganglion (n = 5). However, when ganglia were homogenized 1 min after tetany, the synaptosomal preparation increased ^{3}H-choline uptake by 155% (n = 4) and increased K^+-evoked release of ^{3}H-ACh and ^{3}H-choline by 74 and 83%, respectively (n = 4). (Supported in part by NIH grants: NS 23272 and 18966).

373.11 NICOTINIC MODULATION OF GABAERGIC TRANSMISSION IN THE HIPPOCAMPUS. S. Wonnacott*1, L. Fryer*1, G. G. Lunt*1, R. K. Freund2, D. A. Jungschaffer*2, and A. C. Collins2 (SPON: V. G. Erwin). 1Dept. of Biochemistry, University of Bath, Bath BA2 7AY, U. K. and 2Institute for Behavioral Genetics, University of Colorado, Boulder, CO 80309 U. S. A.

Nicotine-induced seizure susceptibility in different mouse strains is governed by genetic factors, and some correlation with numbers of [^{125}I] α-bungarotoxin binding sites in the hippocampus has been demonstrated (Miner et. al., IPET, 231 (1984) 545). We have explored the possible mechanisms underlying the convulsive property of nicotine by investigating its interaction with GABA systems in the hippocampus.

Electrophysiological recording of population spikes from CA1 pyramidal cells in mouse hippocampal slices indicates that nicotine (800 uM) produces an increase in the population spike amplitude and the appearance of multiple population spikes. These effects are abolished by the addition of the GABA uptake inhibitor nipecotic acid (5 mM). We interpret the nicotine-enhanced excitability as the result of a reduction in synaptic GABA levels following nicotine-induced release of the transmitter.

To test this hypothesis, we have examined the effect of nicotine on [^{3}H]GABA release from hippocampal synaptosomes. Rat synaptosomes preloaded with radiolabelled transmitter were perfused with Kreb's bicarbonate buffer into which pulses (100 ul) of nicotine were introduced. This agonist resulted in a dose-dependent release of discrete peaks of [^{3}H]GABA over the concentration range 5-100 uM. The nicotine-induced release is prevented by the nicotinic antagonist dihydro-ß-erythroidine (10 uM), and agents thought to interact with the ion channel at peripheral nicotinic receptors also diminished the nicotine-evoked [^{3}H]GABA release. α-Bungarotoxin (10^{-7}M) however, failed to have any effect, even after long exposure. Thus it appears that nicotine can act at presynaptic nicotinic receptors on GABAergic nerve terminals in the hippocampus to release the inhibitory neurotransmitter, and this may subsequently lead to a depletion of GABA and removal of inhibition, resulting in seizure activity.

373.12 ACTIVATION OF $GABA_B$ RECEPTORS INDUCES PRESYNAPTIC INHIBITION AT MUSCLE SPINDLE AFFERENT-MOTONEURON SYNAPSES IN THE FROG SPINAL CORD. Y-Y. Peng and E. Frank. Dept. of Neurobiology, Anatomy and Cell Science, Univ. of Pittsburgh Med. School, Pittsburgh, PA 15261.

Synaptic transmission between muscle spindle afferents and motoneurons can be inhibited by stimulating other primary sensory afferents. Although GABA is known to mediate this inhibition, its mechanism of action has been difficult to determine. In this study, pharmacological agents were used to dissect the functional roles of the $GABA_A$ and $GABA_B$ receptors in this inhibition in the bullfrog. Quantal analysis using a deconvolution technique was used to study whether the inhibition caused by $GABA_B$ receptor activation was pre- or post-synaptic.

Baclofen, a specific $GABA_B$ receptor agonist, was used to study the effects of activation of the $GABA_B$ receptors on the monosynaptic EPSP evoked by stimulating triceps muscle afferents. Extracellular recording from the ventral root and intracellular recording from motoneurons showed that baclofen (5μM) reversibly reduced the peak amplitude of the EPSP by 40% without altering its falling phase. A similar result was obtained for the intracellularly recorded unitary EPSP's evoked by activating single triceps muscle spindle afferents. This suggests that activation of $GABA_B$ receptors inhibits the EPSP either postsynaptically on remote motoneuronal dendrites or presynaptically at sensory terminals. Quantal analysis was carried out to distinguish between these alternatives since numerical analysis of the fluctuations of the unitary EPSP showed that transmission is quantal. Baclofen (5μM) lowered the quantal content but did not alter the amplitude of the EPSP evoked by a single quantum. Thus the inhibition produced by activation of $GABA_B$ receptors is entirely presynaptic.

In contrast, activation of $GABA_A$ receptors (by 100μM muscimol, which is primarily a $GABA_A$ receptor agonist) shortened the falling phase of both unitary and composite triceps EPSP's, as indicated by a 66% reduction in EPSP halfwidth, suggesting a large increase in the conductance of the motoneuronal membrane. Furthermore, this effect was reversibly blocked by bicuculline (100μM), a specific competitive $GABA_A$ antagonist. Primary afferent depolarization (PAD) of sensory axons is also produced by the activation of $GABA_A$, not $GABA_B$, receptors. 50 μM bicuculline produced a reversible 78% reduction in the peak amplitude of the PAD recorded intra-axonally in muscle afferents evoked by stimulating individual brachial muscle or cutaneous nerves. At 100 μM it reversibly blocked more than 90% of the dorsal root potential evoked by stimulating adjacent dorsal roots. Thus the same type of receptors that produce GABA-mediated PAD, whose role in synaptic inhibition is currently under study in our laboratory, also produce a postsynaptic effect. Activation of $GABA_B$ receptors, on the other hand, does not evoke PAD but causes presynaptic inhibition.

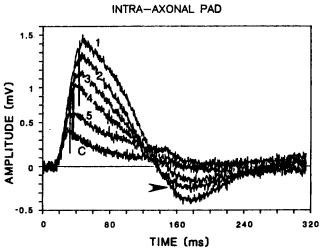
373.13 POSTTETANIC CHANGES OF PRIMARY AFFERENT DEPOLARIZATION AFTER INTRA-AXONAL TETANIZATION OF GROUP IA AFFERENTS. A. Lev-Tov, D. E. R. Meyers, and R. E. Burke. Lab. of Neural Control, NINCDS, NIH, Bethesda, MD 20892 and Hebrew University Medical School, Jerusalem, Israel (A.L.T.).

In a previous study (J. Neurophysiol. 50:413, 1983), we reported that primary afferent depolarization (PAD) produced in medial gastrocnemius (MG) group Ia afferents by 4 group I volleys in the posterior biceps-semitendinosus (PBSt) nerve was markedly enhanced following prolonged, high frequency (20s, 500 Hz) tetanization of the whole MG nerve. The augmented PAD had increased time to peak and was accompanied by hyperpolarizing undershoot that decayed more rapidly than the enhanced PAD. These effects could not be explained simply by the well-known post-tetanic afferent hyperpolarization; it seemed possible that whole nerve tetanization may activate other segmental pathways or change extracellular ionic concentrations. We have re-examined these phenomena in pentobarbital-anesthetized cats, with intra-axonal recording and tetanization of individual, functionally identified triceps surae group Ia afferents. The figure below illustrates superimposed average records (8 sweeps each) of the transmembrane potential (extracellular fields subtracted) in a soleus group Ia afferent, produced by 4 PBSt volleys (200 Hz, 2xT for group I) before (C) and after (1-5) intra-axonal tetanization (500 Hz, 20 s). Immediately after the tetanus, phasic PAD was markedly enhanced, had prolonged time to peak, and was followed by hyperpolarizing undershoot (arrow), which disappeared more rapidly than the enhanced PAD. These results are qualitatively and quantitatively identical to those obtained using whole nerve tetanization. We conclude that the dramatic changes in PAD must be due to mechanisms intrinsic to the tetanized afferents and not to extrinsic factors. In other experiments, application of a series of short trains (500 Hz, 1s), repeated at 5s intervals after the 20s tetanus, maintained the augmented PAD and hyperpolarizing undershoot for several minutes. We are using this paradigm to study the effect of the post-tetanic changes in PAD on Ia synaptic transmission to motoneurons.



374.1 SIMULATION OF THERMAL EFFECTS ON FOUR MEMBRANE CHANNELS IN HIPPOCAMPAL PYRAMIDAL CELLS. M. P. Thomas and J. M. Horowitz. Dept. of Animal Physiology, University of California, Davis, CA 95616.

We are developing a model for hippocampal pyramidal neurons in hibernators (e.g., hamsters) and nonhibernators (e.g., rats) comprised of four types of ion channels. The model is an extension of one presented by Traub (Neuroscience 7:1233-1242, 1982) to include the effects of temperature. A preliminary version of this model (Fed. Proc. 45:408, 1986) covered basic equations for the four types of channels. This study focuses on channel parameters that should be modified to extend the scope of the model to cover wider changes in temperature.

Following Traub, we have simulated channels using equations of the Hodgkin-Huxley form to describe membrane currents. In addition to voltage-gated sodium channels and delayed rectifier potassium channels, a voltage-gated calcium channel and a calcium-activated potassium channel corresponding to I_{AHP} were included. Rate constants used to describe the activation and inactivation of the four channel types were multiplied by a function that defined the temperature sensitivity of the channel kinetics. The model matched intracellular waveforms well over a range of temperature from 35°C to 40°C. Single spikes were generated at low stimulus currents and bursts of action potentials were produced with higher currents.

At temperatures below 35°C, low stimulus currents evoked a burst of action potentials rather than single spikes. Since in vitro experiments show that single spikes can be evoked at these temperatures, we examined waveforms of individual channel currents at the time of maximum repolarization following the first spike of the burst, time T_{mr}. At T_{mr} for 32°C, ICa was -112.4 uA/cm^2 and I_K was 109.6 uA/cm^2, while at T_{mr} for 37°C, I_{Ca} was -92.6 uA/cm^2 and I_K was 90.3 uA/cm^2. Thus at time T_{mr} there was a slightly larger net inward current at 32°C compared to 37°C. It appears that at 32°C the increased duration of the first spike resulted in activation of g_{Ca} such that the added inward current contributed to the subsequent generation of a burst. When calcium channels are blocked (by setting g_{Ca} to zero) only a single spike is generated at 32°C. To extend the model to simulate data at temperatures below 35°C additional channel types can be included and/or differential temperature sensitivity can be assigned to individual channel types. (Supported by NASA grant NAG2-341.)

374.2 **EXTRACELLULAR UNIT ANALYSIS OF SPIKE DISCHARGE IN SOMATA AND DENDRITES OF CA1 HIPPOCAMPAL PYRAMIDAL CELLS.** R.W. Turner, D.E.R. Meyers and J.L. Barker. Lab of Neurophysiology, Bldg 36, Rm 2C02, NIH, Bethesda MD.

Laminar profile analysis of extracellular field potentials in the CA1 region has shown that the shortest latency population spike is evoked in stratum (st) pyramidale, suggesting that spike discharge in hippocampal pyramidal cells (HPCs) originates in the cell body region. The spike subsequently conducts in a retrograde fashion through the dendritic arborization.* The present study examined the properties of over 400 HPC extracellular single units in st pyramidale (SP), st oriens (SO) and st radiatum (SR) in the rat hippocampal slice to further assess the point of origin for spike discharge. HPC units could be identified on the basis of discharge characteristics, evoked by alvear antidromic stimulation or orthodromic activation via st oriens or st radiatum. The most common single unit response (approx. 95%) in somatic and dendritic regions was a biphasic large positive-small negative (PN) waveform, distinct from the "giant" PN units indicative of cell membrane damage. Other waveforms included small triphasic fiber potentials and small positive-large negative (N) units.

HPC units were superimposed on the population spike of anti- and orthodromic field potentials at all levels of the cell axis. The shortest latency for PN units at threshold intensity was thus found in the region of st pyramidale. Subtraction of underlying field potentials revealed that positive and negative components of PN units were largest in the cell body region, exhibiting a sharp decline in SO and at approx. 130um into SR, similar to that of HPC intradendritic spikes. The properties of HPC units support results of field potential and intracellular analyses suggesting that spike discharge originates in the region of the cell body layer, leading to a retrograde spike invasion of dendritic arborizations.*

Local application of TTX to HPC dendrites selectively blocks the negative phase of SO and alvear-evoked dendritic population spikes, suggesting that the retrogradely conducted depolarization activates voltage-dependent Na^+ conductance in dendritic membrane. The more infrequently encountered N units may in fact be indicative of focal recordings from TTX-sensitive sites. The response of somatic and dendritic single units to TTX application is presently under investigation.

*Turner RW, Richardson TL & JJ Miller. Intracellular analysis of somatic and dendritic spike discharge in CA1 hippoocampal pyramidal cells. IUPS Vancouver 1986.

374.3 **MODELLING OF STRENGTH-DURATION AND CURRENT-FREQUENCY CURVES OF HIPPOCAMPAL GRANULE CELLS OBTAINED FROM INTRACELLULAR RECORDING.** **G.L.F. Yuen and D. Durand. Applied Neural Control Laboratory, Department of Biomedical Engineering, Case Western Reserve University, Cleveland, OH 44106.**

Data from intracellular studies of the hippocampal granule cell were fitted to a previously developed Hodgkin-Huxley type computer model for this neuron with a sodium and a potassium conductance (see Yuen and Durand, Soc Neurosci Abstr 235.6, 1986). With minor adjustments in the cable and active properties, the model can generate action potentials that have proper threshold voltage, maximum rate of rise, peak amplitude, spike duration and EPSP responses. The shape of the postspike potential also resembles that in the intracellular recordings and reflects a fairly weak potassium conductance. The model at this stage exhibits a tendency to fire repetitively especially with dendritic activation. Since vertebrate neurons tend to have more divergent sodium inactivation (h) and potassium (n) conductance characteristics and these properties have been implicated in controlling repetitive firing in neurons (Jack et al., Electric current flow in excitable cells, 1975), we proceed to further compare this aspect of the model to the intracellular data. Furthermore, for a point-polarized cable such as the granule neuron, the Hodgkin-Huxley equations with proper active parameters should adequately describe its strength-duration relationship (Noble and Stein, J Physiol 187:129,1966), approximating the predictions by Hill's equation. An acceptable fit between the model and the observed strength-duration curve would indicate the overall validity of the active properties in the model, even though voltage clamp data is not available for computing these neurons' behavior.

Preliminary comparisons indicate some deviation of the current model from the data at long pulse durations for the strength-duration curve, although further data analysis and model adjustments are necessary to support this observation. Inadequate data is currently available for evaluating the simulated current-frequency relationship. However, the model exhibits a convex current-frequency curve extending from a firing frequency of 70 to 370 Hz as the current was increased from (repetitive firing) rheobase to 20 times rheobase for a duration of 250 ms. Beyond this current magnitude, the model exhibits damped oscillations aborting the rhythmic firing pattern. The steady-state spike amplitude also decreases noticeably with increasing current magnitude. Further intracellular studies will focus on testing these specific predictions so as to refine the active properties of the model. The resulting model will subsequently be applied to evaluate the effects of ethanol on the active conductances.

Supported by NIH Grant #1ROI-AA 06773-01.

374.4 CHARACTERISTICS OF CA3 HIPPOCAMPAL PYRAMIDAL CELLS ACUTELY DISSOCIATED FROM IMMATURE RATS. C.N. Allen, R.J. Brady, K.L. Smith*, J.W. Swann and D.O. Carpenter. Wadsworth Laboratories, NYS Department of Health and School of Public Health, University at Albany, Albany, NY 12201.

Hippocampal pyramidal cell neurons are an important component of a variety of physiological and pathological processes including learning, memory and epilepsy. An understanding of the neurotransmitter and ionic current mechanisms which control pyramidal cell excitability is therefore important. Single channel recording using the patch clamp technique is one approach which can be used to record the activity of ionic currents which underlie neuronal function. Toward this end Kay and Wong dispersed CA1 pyramidal neurons and studied the ionic currents controlling cellular excitability using the whole cell patch clamp technique (Kay and Wong, J. Neurosci. Meth. 16:227-239, 1986). We now describe a modification of this technique for the isolation of CA3 pyramidal cell neurons from 12 to 15 days old rats. Hippocampal minislices containing only the CA3 pyramidal cell subfield were incubated for 1.5 hr with trypsin at 37°C, washed with fresh PIPES buffered saline for 1 hr and titurated using a Pasteur pipette. This procedure yields isolated pyramidal-shaped neurons with variable lengths of dendrites attached. Giga-ohm seals were obtained using standard techniques, the membrane ruptured with gentle suction and the membrane response recorded in the whole cell configuration. The CA3 neurons had resting membrane potentials of -50 to -60 mV and fired action potentials spontaneously. The action potentials had an amplitudes of 60-80 mV and overshoots to +40 mV when held at -70 mV. The isolated neurons fired a bursts of action potentials in response to a depolarizing pulse of current. This action potential firing pattern is similar to that observed from slices of CA3 neurons recorded from animals of the same age. Spontaneous membrane potential fluctuations were present which often reached the threshold to fire single or a burst of action potentials. The ionic mechanism underlying these spontaneous events is currently being investigated. The neurons have a membrane time constant of about 25-30 msec and resistances of 100-150 Mohm. 374.5 ELECTROPHYSIOLOGICAL EFFECTS OF COCAINE IN THE IN VITRO RAT HIPPOCAMPUS. J.L. Tyma, W.R. Proctor, and T.V. Dunwiddie, Dept. of Pharmacology, Univ. of Colo. Hlth. Sci. Ctr., and Veterans Admin. Med. Research Service, Denver, CO.

Cocaine and other local anesthetic agents are known to produce central nervous system excitation which can result in generalized seizure activity. Previous studies have demonstrated that systemic injections of cocaine reduce the threshold for stimulation-induced afterdischarges in hippocampus (Lesse and Collins, Biochem. Behav. 13:695). In the present study, we have examined the electrophysiological effects of cocaine in the in vitro hippocampus in order to determine whether the proconvulsant effects of cocaine reflect an intrinsic hippocampal action of this drug.

Rat hippocampal slices were prepared and recorded from using standard electrophysiological methods, and drugs were applied via addition to the superfusion medium. The evoked presynaptic fiber spike, field excitatory postsynaptic potential (epsp) and population spike responses in the CA1 region were reduced by superfusion with cocaine (threshold ca. 5 uM). The rate of interictal spiking (IIS) induced by adding penicillin G (1500 units/ml) and increased potassium (8 mM) to the perfusion medium was also reduced by similar concentrations of cocaine. Cocaine-induced inhibition of IIS ranged from 17% (5uM; n=5) to 100% (100uM; n=3).

Intracellular recordings showed that perfusion with cocaine (3-100uM) did not consistently alter either resting membrane potential or input impedance of CA1 pyramidal neurons. The epsps recorded following stimulation of stratum radiatum were not markedly affected by 3-30uM cocaine, but were reduced by 30% by 100uM. Recurrent ipsps evoked by stimulation of the alveus were more sensitive to cocaine; 30uM cocaine reduced the initial chloride-dependent component of the ipsp by 20%, while the potassium component was reduced by 30%. The greater sensitivity of ipsps to cocaine may be due to the fact that the antidromic population spike evoked by alvear stimulation was approximately 2X more sensitive to cocaine than was the presynaptic fiber spike evoked by stratum radiatum stimulation, suggesting that the axons of the CA1 cells are more sensitive to the local anesthetic effect of cocaine than are the Schaffer and commissural fibers.

These results demonstrate that cocaine (10-100uM) has well-defined local anesthetic actions on hippocampal neurons, but does not have a proconvulsant effect upon interictal spiking within this range of concentrations. Experiments using intracellular recording did not suggest that cocaine has a differential depressant effect upon hippocampal interneurons.

374.6 IN VITRO EXCITABILITY OF HIPPOCAMPAL NEURONS FROM EPILEPTIC (TOTTERING) MICE. G. Kostopoulos and C.Psarropoulou* (SPON: A. MITSACOS). Dept. of Physiology, University of Patras, Medical School, Patra, 26110 Greece.

In order to elucidate the neuronal mechanisms underlying epilepsy in the tottering mutant,we prepared hippocampal slices from tg/tg (n=7) and phenotypicaly normal (tg/+ or +/+) mice (n=10) and maintained them in a complete submersion chamber (one slice from each mouse). Stimulating str. radiatum by stepwise increasing current (I, 200 μsec, 0-300 μA) we recorded at str. pyramidale of CA_1 the respective field EPSP slopes and population spikes (POP) amplitudes.Using a computer we derived from these data the sigmoidal curves: EPSP/I, POP/I and POP/EPSP and compared them in the two groups of slices. The POP/EPSP curves from the epileptic slices had signifficantly higher maximal slopes (8.5 ± 2.9 - mean ± SD - vs. 5.2 ± 1.6, $p<0.05$) possibly indicating a more homogeneous firing threshold of pyramidal neurons as compared to normal. On the average the POP_{50} corresponded to smaller EPSP in the epileptic as compared to normal slices (0.46 ± 0.3 mV/msec vs. 0.72 ± 0.3 mV/msec) but this difference did not reach statistical signifficance. Exposure to perfusing medium containing mildly elevated potassium concentration (from 3.25 mM to 5.25 mM) shifted all three curves (EPSP/I, POP/I and EPSP/POP) to the left in both groups of slices. However this effect was signifficantly less pronounced in the epileptic slices. The I for $EPSP_{50}$ was decreased by elevated $[K^+]$ by 4.7% ± 3.1% in epileptic as compared to 14.7% ± 9.4% in normal slices. The area under the POP/I curve was increased by 24.4% ± 10.7% in epileptic and by 117.3%±40.5% in normal slices ($p<0.001$). Finally in the postsynaptic excitability curves (POP/EPSP) the EPSP for POP_{50} was decreased by 15.8% ± 5.6% in epileptic as opposed to 49% ± 19.1% in normal slices ($p<0.01$). The demonstrated decreased responsiveness to elevated $[K^+]$ can contribute to a protection from nonsynaptic spread of hyperexcitability during seizures. It could be interpreted as being either part of the epileptogenic mechanism or an accomodation which developed after repeated seizure episodes.

374.7 INTRACELLULAR RESPONSES OF HIPPOCAMPAL NEURONS IN ZERO-MAGNESIUM. L.S. Jones, D.V. Lewis, and R.D. Andrew, Dept. of Pediatric Neur., Duke Univ. Med. Ctr., Durham, NC 27710, and Dept. of Anatomy, Queen's Univ. Kingston, Ontario, Canada K7L 3N6.

Previous work has shown that exposing hippocampal slices to magnesium-free artificial cerebrospinal fluid (0-Mg ACSF) can activate ictal-like events, in addition to spontaneous and triggered interictal bursts, particularly in young rats (26-36 days). The ictaform activity begins within 10-20 min of 0-Mg perfusion and continues for up to 40 min before giving way to interictal bursting. In this study, the effect of 0-Mg on cells from CA1 and CA3 of both young and adult rats were examined.

Hippocampal slices (400 u) were prepared from adult (40-43 days) and young male, Sprague-Dawley rats. 0-Mg ACSF consisted of ACSF with magnesium salts simply removed ($[Mg^{++}]$ about 10 uM).

Perfusion with 0-Mg produced bursting in all neurons studied within ten min of being washed on. Most neurons were not bursting spontaneously in ACSF, but would proceed to burst with as many as 8 spikes per burst. Burst frequency ranged from 0.6 to 3.3 Hz in 0-Mg. Prior to 0-Mg treatment, all cells exhibited prolonged after-hyperpolarization following either spontaneous bursts or bursts produced by antidromic or orthodromic stimulation. This post-burst hyperpolarization decreased in most cells during exposure to 0-Mg; however, the membrane potential hyperpolarized with 0-Mg in most cells also, therefore it is unclear as yet if recurrent circuitry is affected. Response thresholds to extracellular stimulation were determined by stimulating in stratum radiatum until a burst was produced. In the absence of extracellular magnesium, less current was necessary to trigger a burst than in ACSF. The thresholds usually returned to pre-0-Mg levels when the slice was washed with ACSF. This corresponded to the observation that the 0-Mg-evoked spontaneous bursting slowed and often stopped when the slice was returned to ACSF.

374.8 MODELLING DIVERSE HIPPOCAMPAL PYRAMIDAL CELL CURRENTS WITH HODGKIN-HUXLEY-LIKE MECHANISMS SUGGEST DESCRIPTIONS OF PUTATIVE Na+ CURRENTS AND ROLE OF Ca++ MEDIATED K+ CURRENTS IN THE REGULATION OF REPETITIVE FIRING. Lyle J. Borg-Graham* (SPON: N. Grzywacz) Center for Biological Information Processing, Massachusetts Institute of Technology, Cambridge, MA 02139.

Over the past decade a wide variety of non-linear conductances have been described with varying degrees of quantitative success for hippocampal pyramidal cells (HPCs). The difficulty in obtaining complete kinetic data for these conductances results from the small size and extended electrotonic structure of these cells, limitations of the single electrode clamp technique, and the diverse cell population and preparations used in experiments. Modelling the electrical behavior of HPCs with computer simulations is one method of integrating data from a variety of sources in order to develop a consistent description for this cell type. The sparseness of the data, however, requires various assumptions regarding mechanisms underlying the conductance of ion channels. In the model described here, each conductance is assumed to be mediated by one or more two-state gating particles which, in turn, are either voltage- or calcium-dependent. The voltage-dependent gating particles are based on a single-barrier model similar to that proposed by Hodgkin and Huxley. The parameters of each particle type (order, valence, symmetry, base rates, and voltage mid-points) are adjusted in order to reproduce the data (voltage clamp or current clamp) for the current in question. In addition, simple two-state calcium-mediated gating particles and a simple model of intercellular calcium accumulation and diffusion are constructed based on first principles in order to reproduce the relevant data.

The model presently includes descriptions of eleven somatic currents mediated by non-linear conductances. These include three putative sodium currents -- I-Na-trig, I-Na-rep, and I-Na-tail; six potassium currents that have been reported in the literature -- I-DR (Delayed Rectifier), I-A, I-C, I-AHP (After-Hyperpolarization), I-M, and I-Q; and two calcium currents, also reported previously -- I-Ca and I-CaS. The electrotonic structure of the hippocampal pyramidal cell is modelled with a soma/short-cable approximation, and the dendrites are assumed to be linear.

Model simulations qualitatively or quantitatively reproduce a wide range of somatic electrical behavior in HPCs. Present results include the suggestion of multiple sodium currents in these cells and possible mechanisms by which both I-AHP and I-C can mediate repetitive firing in response to changes in the concentration of intracellular calcium. In addition, the model has been used to suggest experimental protocols designed to test the validity of simulation results.

374.9 CHANGES IN EXTRACELLULAR $[K^+]$ AND $[Ca^{2+}]$ EVOKED BY ANOXIA IN RAT HIPPOCAMPAL SLICES. M. E. Morris, K. Krnjević and J. Leblond. Departments of Pharmacology, University of Toronto, Toronto and Anaesthesia Research, McGill University, Montreal, Canada, H3G 1Y6.

O_2 lack leads to translocations of ions in anoxia-sensitive tissues which reflect metabolic imbalance and changes in membrane permeability and/or ion pump activity: the definition and manipulation of underlying mechanisms may provide methods to enhance anoxic tolerance. Ion-sensitive microelectrodes have been used to record extracellular concentrations of potassium ($[K^+]_o$) and calcium ($[Ca^{2+}]_o$) in the CA1 pyramidal cell layer of isolated rat hippocampal slices during brief periods of anoxia (95% N_2/CO_2 for 2-4 min). Reversible increases of 0.5-1.0 mM $[K^+]_o$ were typically evoked; although similar changes were observed at different depths (50-300 µm), simultaneous recordings in different slices from the same hippocampus showed marked differences in rates of rise of $[K^+]_o$ and susceptibility to spreading depression (SD)-like increases of $\geq$20 mM. Stimulus-evoked increases in $[K^+]_o$ were inversely related to temperature; but anoxic-induced accumulations at 23° were small and delayed, in contrast to the more rapid onset of larger, more sustained changes at 33°. The time course of the $\Delta[K^+]_o$ during anoxia closely resembled that of large membrane hyperpolarizations ($\leq$20 mV) and falls in resistance ($\leq$75%) recorded in cells $\leq$50 µm away and of sustained outward currents seen with single-electrode voltage clamp (SEVC) (V_h = -50 to -70 mV) (previously shown to be Cl^--independent, sensitive to Cs and TEA and presumed due to an ↑ in K^+ conductance (G_K) (*Krnjević & Leblond, J. Physiol. 382:791,1987*)). Secondary post-anoxic hyperpolarizations -- believed to reflect electrogenic ion transport -- were recorded during recovery while $[K^+]_o$ levels were still elevated. In association with SD-evoked paroxsymal large ↑s in K^+ membrane and tissue potentials were markedly depolarized, and there was an early, large transient and smaller and prolonged inward current during SEVC (with 0.5 µM TTX, 3 mM CsCl, V_h = -50 mV). $[Ca^{2+}]_o$ changes evoked by anoxia were small ($\leq$ 0.1-0.5 mM) and variable and consistently began before the onset of hyperpolarization. At low temperature either a ↓ or an initial ↑ followed by ↓ was observed; at 33° the falls were either attenuated or replaced by a fluctuating, sustained ↑ in $[Ca^{+}]_o$. Concomitant with changes in $[Ca^{2+}]_o$ and $[K^+]_o$ large, brief inward Ca-inward currents (which were evoked in the presence of TTX, Cs and TEA (10 mM) by 30 mV depolarizations from V_h = -70 mV) were rapidly blocked by N_2 and restored on re-oxygenation. The relatively small and variable changes in $[Ca^{2+}]_o$ during anoxia are clearly insufficient to explain the marked diminution of Ca-inward current which was observed. An anoxic-induced accumulation of intracellular $[Ca^{2+}]$ may however be responsible for both inactivation of Ca-channels and the production of G_K-mediated hyperpolarization.

374.10 K^+ AT CONCENTRATIONS REACHED IN THE EXTRACELLULAR SPACE DURING NEURONAL ACTIVITY PROMOTES A Ca^{++}-DEPENDENT GLYCOGEN HYDROLYSIS IN MOUSE CEREBRAL CORTEX. P.R. Hof and P.J. Magistretti. Dept of Pharmacology, CMU, 1211 - GENEVA 4, Switzerland.

The concentration of K^+ in the extracellular space increases during neuronal activity from basal levels ranging between 2.5 and 3.5 mM, to 5 and 12 mM. This increase in $[K^+]_o$ is accompanied by a marked decrease in $[Ca^{++}]_o$. During pathological conditions such as spreading depression, hypoxia or ischemia $[K^+]_o$ can reach even higher levels, up to 30 to 40 mM. The hydrolysis of glycogen elicited by various neuroactive agents such as norepinephrine, serotonin, histamine, vasoactive intestinal peptide and adenosine in mouse cerebral cortical slices has been previously described (see Magistretti *et al.*, J. Neurosci., 6:2558, 1986). In view of the fact that adenosine, like K^+, is released in the extracellular space during neuronal activity, we have examined the effect of K^+ on ^{3}H-glycogen levels. K^+ stimulates in a time- and concentration-dependent manner the hydrolysis of ^{3}H-glycogen. Over 60 % of the maximal effect is reached within 30 sec and the EC_{50} for the glycogenolytic action of K^+ is 11 mM. A significant ^{3}H-glycogen hydrolysis (12 to 55 % of basal ^{3}H-glycogen levels) occurs at 5 to 12 mM $[K^+]_o$. The K^+-evoked glycogenolysis is Ca^{++}-dependent, and is blocked by Ca^{++}-channel blockers such as Co^{++} at 5 mM, Ni^{++} at 0.1 mM and Mn^{++} at 1 mM but not by Cd^{++} at 20 µM. This type of pharmacological profile has been suggested to indicate the activation of voltage-sensitive Ca^{++} channels of the T subtype. We also examined the effect of various K^+-channel blockers. Ba^{++}, Cs^+ at 1 mM and TEA at 10 mM produced a small glycogenolytic effect when tested alone; TEA potentiated the ^{3}H-glycogen hydrolysis elicited by K^+ 10 mM, whereas Ba^{++} and Cs^+ were without effect. Interestingly, blockade of K^+ channels of the A-type by 4-aminopyridine at 1 mM strongly enhances the glycogenolysis evoked by K^+ at low concentrations (5-10 mM). In contrast, apamin at 1 nM and 1 µM did not influence the K^+-evoked glycogenolysis. The effect of TTX, a selective Na^+-channel blocker, was also examined. At 2 µM, TTX did not significantly influence the glycogenolytic response of K^+ up to 8 mM, but gradually shifted to the right the concentration-response curve of higher K^+ concentrations, indicating that the contribution of the voltage-sensitive Na^+ channels in membrane depolarization, and in the subsequent entry of Ca^{++}, can be estimated to commence at 8 mM $[K^+]_o$.

These observations further delineate the role of K^+ in intercellular communication and in the coupling between neuronal activity and energy metabolism. They suggest that K^+, released from active neurons, could mobilize energy substrates in regions of increased neuronal activity where the $[K^+]_o$ can reach values up to 10-12 mM; these are concentrations at which K^+ promotes a significant glycogenolysis.

374.11 INTRACELLULAR INJECTION OF PHORBOL ESTERS INCREASES EXCITABILITY OF NEURONS OF THE MOTOR CORTEX OF AWAKE CATS. M. B. Szente, A. Baranyi, and C. D. Woody, Mental Retardation Res. Ctr., Brain Res. Inst., Depts. of Anatomy and Psychiatry, UCLA Med. Ctr., Los Angeles, CA 90024

Protein kinase C (PKC) is present in high concentrations in neurons of the neocortex, but as yet there is no direct evidence that this enzyme can influence the excitability of neocortical neurons in vivo. In this study electrophysiological effects of two intracellularly injected phorbol esters (PhEs) which activate PKC, phorbol 12,13-dibutyrate and phorbol 12-myristate, 13-acetate, were investigated in neurons of the motor cortex of awake cats. In order to study direct, postsynaptic actions, we applied PhE (1-10 uM PhE dissolved in 1 M potassium citrate containing 50 ug/ml phosphatidyl serine) into the recorded cells by pressure injection.

Signs of increased neuronal excitability were observed in each of 65 cells injected with PhE. Enhancement of excitatory background synaptic activity resulted in an elevated rate of spontaneous firing. The number of spikes evoked by depolarizing constant current pulses gradually increased. The latency of the first action potential produced by delivery of the depolarizing current pulses decreased as did the threshold level of current needed for spike initiation. The slow afterhyperpolarization (AHP) following action potentials and current-induced depolarizations decreased. In some neurons the increase in background firing activity resulted in burst generation. PhE also increased the peak amplitude of action potentials (but not their duration) and the amplitude of fast AHPs following action potentials.

All changes occurred within 2-8 min after injection and lasted for 50 min or longer. Neither increases in input resistance nor depolarizations of the resting membrane potential sufficient to account for these excitability changes were found.

Control injections (n=15 cells) of 4 alpha-phorbol 12,13-didecanoate, which does not activate PKC, failed to induce changes in neuronal excitability.

The results show that activation of PKC by PhE can increase the postsynaptic excitability of neurons of the motor cortex of awake cats. (Supported in part by AFOSR F49620-85-C-0100 and HD 05958.)

374.12 INTRACELLULAR INJECTION OF PHORBOL ESTERS INDUCES LONG-TERM CHANGES OF POSTSYNAPTIC RESPONSES IN VOLTAGE-CLAMPED CELLS OF THE MOTOR CORTEX OF AWAKE CATS. A. Baranyi, M. B. Szente, and C. D. Woody, Mental Retardation Res. Ctr., Brain Res. Inst., Depts. of Anatomy and Psychiatry, UCLA Med. Ctr., Los Angeles, CA 90024

It is not known how protein kinase C (PKC) regulates long-term changes of excitatory/inhibitory postsynaptic potentials (EPSP/IPSP) and their currents (EPSC/IPSC) in neurons of the neocortex. Accordingly, we investigated effects of phorbol esters on postsynaptic responses of neurons in the motor cortex of awake cats.

Intracellular pressure injections of 1-10 uM phorbol 12,13-dibutyrate (PdIB) dissolved in 1 M potassium citrate containing 50 ug/ml phosphatidyl serine induced long-term, reciprocal changes in EPSPs and IPSPs, without proportionate changes in resting potential and input resistance. As measured in 16 identified fast PT neurons, the amplitudes and decay time constants of monosynaptic VL EPSPs increased from 5.8±1.3 to 13.9±2.4 mV, and 9.2±0.6 to 13.1±1.1 ms, respectively (Student's two-tailed t-test, $p<0.005$). The amplitudes and decay time constants of recurrent PT IPSPs decreased from 7.4±1.9 to 2.5±2.1 mV and 74.0±16 to 24.0±6.2 ms ($p<0.01$).

Corresponding changes in EPSCs and IPSCs were measured by single electrode voltage-clamp technique. The peak currents and slope conductances of VL EPSCs increased from 0.86±0.11 to 1.49±0.36 nA ($p<0.01$) and 15.8±2.9 to 26.1±3.3 nS ($p<0.005$). The peak currents and slope conductances of PT IPSCs decreased from 1.01±0.20 to 0.34±0.18 nA ($p<0.02$) and 37.2±4.0 to 13.6±2.2 nS ($p<0.005$). The synaptic reversal potentials did not change after injections, indicating that the ion specificity properties of contributing ion channels were not influenced by PdIB. The effects began within 2-8 min after injection and lasted for 50 min or longer. PdIB suppressed voltage-dependent outward currents (thought to be I_A and $I_K(Ca)$ since they were also reduced by 3-aminopyridine and apamine, respectively) and facilitated an inward tail current following depolarizing command pulses. Control injections of 4-alpha - phorbol 12,13-didecanoate, which does not activate PKC, failed to induce changes in the measured electrophysiological parameters (n=5 fast PT cells).

The results demonstrate that activation of PKC induces sustained changes in synaptic responses of in vivo neocortical neurons through modifications of postsynaptic ion channel conductivities. Since these PKC-induced postsynaptic changes last for 50 min or longer, they could support changes in synaptic efficacy underlying learning and memory in the motor cortex. (Supported in part by AFOSR F49620-85-C-0100 and HD 05958.)

374.13 A SLOW, SODIUM-DEPENDENT K^+ CONDUCTANCE IN LAYER V NEURONS FROM CAT SENSORIMOTOR CORTEX. P.C. Schwindt, W.J. Spain*, R.C. Foehring and W.E. Crill. Dept. Physiol. Biophys., Univ. of Washington Sch. of Med., Seattle WA 98195

Slow outward ionic currents of large neurons from layer V of cat sensorimotor cortex were studied in an *in vitro* brain slice preparation using current clamp and single microelectrode voltage clamp. Following sustained repetitive firing evoked by constant injected current, these neurons exhibit a slow afterhyperpolarization (sAHP) lasting up to 30 s. The sAHP reduces excitability for seconds, and the corresponding slow outward current contributes to a slow adaptation of firing rate. Only the initial 1-3 s of the sAHP (the early sAHP) is reduced by Ca^{2+} channel blockade, whereas the late sAHP (the last 3-30 s duration) is unaffected. Corresponding slow relaxations of outward current follow depolarizing voltage clamp steps in normal perfusate. Like the late sAHP, the slow outward current relaxations are not affected by Ca^{2+} channel blockade. They are abolished by TTX, however, indicating that they depend on Na^+ entry through voltage gated channels. Spikes are not necessary to evoke the slow Na^+-dependent outward current ($I_{K(Na)}$); it is evoked by small depolarizing voltage steps that activate the persistent Na^+ current, I_{NaP}. By comparing current records obtained before and after blockade of $I_{K(Na)}$, its onset can be detected about 100 ms after a step depolarization. The following observations suggest that $I_{K(Na)}$ results from an increase of K^+ conductance rather than from stimulation of an electrogenic Na^+ pump: Outward current amplitude varies with membrane potential as expected for a K^+ current and is reduced in raised $[K^+]_o$. In addition, $I_{K(Na)}$ is blocked by muscarine (5-10 μM) and norepinepherine (10-50 μM), and it is reduced by TEA (5-10 mM). The mechanism by which Na^+ entry increases K^+ conductance is under investigation.

374.14 INTRACELLULAR INJECTION OF CALCIUM CHELATORS INDUCES BURST GENERATION IN NEOCORTICAL NEURONS. M.J.Gutnick and A. Friedman*, Physiology Unit, Faculty of Health Sciences, Corob Center for Medical Sciences, Ben-Gurion University, Beersheva, Israel.

In intracellular experiments, evidence of voltage-dependent Ca^{++} conductance may be readily obtained in most cortical neurons. Since Ca^{++} influx and consequent intracellular Ca^{++} accumulation can affect membrane excitability through several mechanisms, we examined the effect of intracellular injection of Ca^{++} chelators on electroresponsive properties of neurons in coronal slices of guinea pig parietal cortex maintained in vitro (36°C). Forty eight neurons from all cortical depths were impaled with electrodes that contained EGTA or BAPTA (0.4 M) and K-Acetate (0.2 M) (pH 7). In 83% of these, spike broadening and prominent afterdepolarization appeared within a few minutes of impalement. As this tendancy progressed, most neurons became bursters. That is, they responded to a brief, depolarizing pulse by generating an all-or-none train of Na^+-dependent action potentials superimposed on a slow envelope of depolarization. Addition of 3 mM Mn^{++} to the bath eliminated chelator-induced bursting, yet caused spike broadening in neurons not injected with chelator.

Previous studies have revealed that a small population of burster neurons is normally present at a subpial depth of 0.9-1.3 mm in this preparation. Our data, which indicate that burst generation can be induced in most neocortical neurons regardless of layer, suggest that bursts may be mediated by a Ca^{++} current and that when intracellular Ca^{++} is allowed to accumulate, their generation is prevented by activation of a Ca^{++}-dependent K^+ conductance.

374.15 **FIRING ADAPTATION AND LONG LASTING AFTERHYPERPOLARIZATIONS (AHP) IN HUMAN NEURONS IN THE DEEP LAYERS OF EPILEPTOGENIC NEOCORTEX MAINTAINED "IN VITRO".** M Avoli. MNI & Dept of Neurol & Neurosurg McGill Univ.

Neurons in the deep layers of slices of temporal neocortex removed from epileptic patients were studied with conventional intracellular recording and stimulation techniques. Intracellular injections of lucifer yellow revealed that they were large spiny pyramidal neurons. In over 30 neurons repetitive firing of fast action potentials was evoked by depolarizing square pulses of intracellular current. In the major- ity of the cells the firing rate decreased smoothly over a few tens of ms and (eventually) reached a steady level. Prolonging further the depolarizing pulse a late and more pronounced adaptation appeared. This late phenomenon was capable of blocking action potential generation. A long lasting (up to 4s) AHP followed at the end of the depolarizing square pulse and displayed two distinct components. The early one appeared as a fast undershoot upon termination of the depolarizing pulse, was not clearly related to the amount of injected current and was not affected by changing the resting membrane potential. Conversely the amplitude of the late component was dependent upon the amount of current injected and displayed an equilibrium potential 15-30mV negative to rest. This value and the fact that the AHP could be recorded with KCl filled microelectrodes suggested that it was caused by an increased conductance to K+. Bath application of Cd++ or Co++ decreased and eventually blocked the late component but not the early phase of the AHP. These changes, which are suggestive for a Ca++ dependent K+ conduct- ance as mechanism underlying the late component of the AHP, were accompanied by a marked decrease of firing adaptation during the step of depolarizing current. These electrophysiological properties are compared with, and appear indeed similar to those recorded in cat, rat or guinea pig neurons located in the deep layers of neocortical slices maintained "in vitro". Furthermore the values of the parameters measured in the present experiments are distributed in a unimodal manner suggesting that "in vitro", minimal or no difference might exist among cells located in slices of neocortex displaying different degrees of epileptogenicity "in situ"

375.1 ELECTROPERMEABILIZATION AS A MEANS OF GAINING ACCESS TO THE CYTOSOL OF INDIVIDUAL CELLS UNDER PATCH CLAMP. D.G. Owen* and W. Piotrowski* (SPON: F.M. Scalzo). MRC Neuropharmacology Group, The School of Pharmacy and Sandoz Institute for Medical Research, London, UK.

The permeability of the plasmalemma to ions and small molecules is increased following transient high intensity electrical fields, thus providing 'access' to the cytosol (Knight, D.E. and Scrutton, M.C., Biochem. J., 234:497, 1986). This facilitates modification of the intracellular milieu and the study of 2nd messenger-mediated signal transduction mechanisms. A major advantage of electropermeabilization over other methods (eg. use of detergents) is that permeabilization of the plasmalemma is highly localized and intracellular organelles are spared. We have applied the method to single selected cells which have been patch clamped for electrophysiological recordings. Bipolar permeabilizing electrodes were made of teflon-insulated platinum/iridium wire (120μ diam.) with a terminal gap of 120μ. The electrode was positioned straddling single cultured rat hippocampal neurones or cultured neuroblastoma/glioma hybrid cells (NG108cc15). Gigohm seals (5-10Gohm) were made between the cell and a patch electrode before permeabilization, in either extracellular or intracellular types of solution. Brief (10us) electrical pulses of 3-5 kV/cm intensity were sufficient to permeabilize the cell as verified by changes in membrane potential and conductance or the accumulation of Trypan Blue, applied to the cell by pressure ejection from a nearby pipette. No change in pipette seal resistance was associated with these events. In extracellular bathing solutions, field intensities of ca. 3kV/cm caused transient depolarizations of 10-20mV, cells resealing over periods of 10s to 1min. Stronger field intensities caused larger increases in permeability which became irreversible. On-cell patch clamp recordings were made from NG108cc15 cells using an intracellular bathing solution. In previously quiescent patches, two types of K^+ channels (14pS non-bursty channel and 100pS bursty channel which opened less often) were recorded following a stimulus of 4kV/cm (10us) with simultaneous application of 3uM Ca^{2+} but not with either Ca^{2+} or pulse alone. This method of permeabilizing cells has proved to be simple, rapid and reproducible and should find wide application in the investigation of the role of intracellular signalling in the regulation of membrane currents.

375.2 A NEW APPROACH TO THE MODELING OF SINGLE CHANNEL CURRENTS AND THE POSSIBLE ROLE OF DIFFUSIVE PROCESSES IN DETERMINING CONDUCTANCE CHANGES IN ION CHANNELS. G.L. Millhauser and R.E. Oswald, Department of Pharmacology, New York State College of Veterinary Medicine, Cornell University, Ithaca, N.Y., 14853.

The kinetics of whole cell and single channel data are usually modeled by assuming that there are several open and closed channel conformations and that the channel protein undergoes random transitions among these conformational states. In single channel experiments the number of closed states, for example, can be estimated by counting the number of exponentials in the closed time histogram. It is usually agreed that kinetic schemes should be as simple as possible, and simplicity refers to minimizing the number of states in the kinetic scheme. This view of gating kinetics has existed since long before the discovery of the patch clamp experiment.

We support the idea that the simplest model is preferable, but we interpret the concept of simplicity in a different way. Instead of taking this concept to mean the least number of kinetic states, we interpret the concept of simplicity as meaning the highest degree of symmetry. The number of adjustable parameters remains small but the number of kinetic states can become quite large. We use the concept of high symmetry to mean that there is a relationship among the rate constants in the kinetic scheme. Thus, no single rate constant can be varied independently of the others.

The specific model that we have pursued is one with all of the rate constants being equal. We studied the closed time distribution of a model with one open state and a variable number of closed states. The basic qualitative characteristic of this model is that the longer a channel is in a closed state the less likely a transition out of that state becomes. The single channel current shows burst-like character such as that seen in a number of systems including the nicotinic acetylcholine receptor.

A recent observation by other workers in the field suggests that there is a fractal scaling of the rate constants in ion channel kinetic schemes. The fractal dimension, D, can vary between one and two. We have numerically calculated the closed time histogram for our model and fit the data to the distribution from the fractal scheme. We find that the fit is excellent and, furthermore, we find that D can be related to the number of closed channel states. When there is one state, D is equal to one; as the number of states becomes infinite, D asymptotically approaches two. Our model also provides an excellent fit to distributions from the brief closures of gramicidin channels and to the open time distribution of the acetylcholine receptor. In both cases the number of states is large (>10).

The most important aspect of this model is that it suggests a physical basis for the ocurrence of bursts, brief closures, fractal scaling and related phenomena. Although a large number of states may seem improbable, it is actually quite consistent with recent molecular dynamics calculations that show proteins actually sample thousands of energy minima as they undergoe random fluctuations. When the number of states is large the protein motion is more like diffusion and less like random kinetic transitions between a small number of well defined protein conformations. We can calculate diffusion constants from our model and we find that fits to real data yield diffusion constants that are completely consistent with processes that occur in membranes.

375.3 Is the acetylcholinesterase level in Rat and Mouse muscle cells cultures related to the level of free cytoplasmic Ca^{2+} ?

Koenig J.[1], Courbin P.[1], De la Porte S.[1], Powell J.[2], Desmazes J.P.[3], Grouselle M.[3], Georgescaud D.[3].

1 Neurobiologie Cellulaire, Université Bordeaux II, Avenue des Facultés 33405 TALENCE, France ; 2 Smith College Northampton USA 3 CRPP Bordeaux, France.

The role of the calcium ion Ca^{2+} as an intracellular control agent in a variety of physiological processes is well established. In vertebrate skeletal muscle fibers Ca^{2} is involved in muscle contraction, modulation of membrane permeability and regulation of metabolic activity.

Recently it has been suggested that the ionic fluxes through the membranes regulated the level of 2 cholinergic macromolecules the acetylcholine receptors and the A_{12} acetylcholinesterase (AChE) form, the presumed synaptic form of the enzyme. Muscle cells paralysed by veratridin which maintains the Na^{+} channel in the open state showed a dramatic increase in total AChE and in the level of A_{12} form. The effect of veratridin on AChE was blocked in the presence of agents that block Ca^{2+} permeability suggesting that Ca^{2} is involved in this effect.

To verify that the level of AChE synthetized by the muscle cells is related, in a some way to the level of free cytoplasmic Ca^{2}, we analysed the variations of Ca^{2} levels in normal Rat muscle cells treated by agents which modify the ionic permeabilities.

Mainly they are 2 sources for increased muscle Ca^{2} during action potentials and contractions : Ca^{2} flux through membrane ions channels and release from the sarcoplasmic reticulum.

In the mutant mouse, muscular dysgenesis (mdg), the muscle cells did not contract but possess normal membrane properties. This inability to contract could be related to a selective lack of functional slow Ca^{2} channels which may be involved in the excitation contraction coupling. We determined the concentration of free Ca^{2} in these non-contracting muscles (mdg) and analyzed its modulation by different drugs.

The levels of intracellular free Ca^{2} were determined by spectrofluorometry using the Ca^{2} fluorescent indicators : Quin 2 and INDO 1.

375.4 COMPUTER STUDIES OF NEGATIVE FEEDBACK IN NEURONS, Michael Mascagni* (SPON: J. Rinzel). Courant Institute of Mathematical Sciences, New York University, New York, New York 10012.

We study the problem of negative feedback in the nervous system by numerically solving a mathematical model describing a neuron in the presence of feedback. The equations solved model a neuron, composed of a dendritic cylinder attached to a cylindrical axon, in which the axon is synaptically connected back onto the dendrite. The nominal input to this system is a constant current injected into the dendrite. This nominal input can then be modulated by the synaptic feedback current. By varying the synaptic efficacy of this feedback connection one can compare a neuron without feedback to one subject to different amounts of negative feedback.

The mathematical model describing our axon is the Hodgkin-Huxley model for the dynamic electrical behavior of the giant axon of the squid *Loligo* (Hodgkin, A. L., and Huxley, A. F., J. Physiol., **116**: 497, 1952). Our dendritic model is merely the linear cable equations with cable properties chosen to be compatible with the resting values of the Hodgkin-Huxley axon. Our model for the synapse was chosen to be a postsynaptic current injection with a fixed time course that is triggered by the arrival of an action potential at the presynaptic membrane. Evaluation of the behavior of the neuron involved the measurement of the frequency of repetitive firing of the axon as a function of constant background dendritic current injection. This function was computed for various values of the feedback parameters, including parameters corresponding to no feedback.

Studies carried out without feedback showed repetitive firing over a relatively narrow range of currents with firing rates close to that limited by the axon's refractory period. These studies also showed a temperature dependence in the onset of repetitive firing. This temperature dependence is manifested in an hysteresis phenomenon that is insignificant at low temperature (6.3 C°) and dramatic at high temperature (18.6 C°). With negative feedback the range of currents where repetitive firing is observed is substantially increased. The neuron also fires at rates lower than without feedback, leading to a larger relative dynamic range. Also the region of approximately linear current versus frequency response is greatly magnified. This observed phenomenology is consistent with the electrical engineer's use of negative feedback to linearize and stabilize the response of a nonlinear, high-gain amplifier.

375.5 MEMBRANE POTENTIAL AND INTERBURST INTERVAL OF APLYSIA BURSTING PACEMAKER NEURONS ARE MODULATED BY WEAK ELECTRIC FIELD STIMULATION AT HIGH FREQUENCY. A.R. Sheppard, A.J. Godwin*, S.M. Bawin and W.R. Adey. Departments of Physiology and Neurosurgery, Loma Linda University, and Research Service, VAMC, Loma Linda, CA 92357.

We exposed isolated Aplysia abdominal ganglia to 60-Hz electric fields of 10 mV/cm rms. The goal of this study was to evaluate the interaction of extracellular fields with repetitively firing neurons. Fields at this level and frequency do not directly entrain firing of the Aplysia neurons. We examined R15 cells (n=11) and bursters of the left upper quadrant (n=13) at a fixed temperature between 17 and 21 C. Intracellular recordings were begun after stability was reached following recovery from impalement. Following a one hour observation period, electric fields were applied for 20 min along the rostral-caudal axis of the ganglion by a pair of Ag-AgCl electrodes energized by a constant current amplifier. Field stimulation produced changes of 2 to 8 mV in the maximum hyperpolarization recorded during the interburst interval. In correlation, there were shifts in the duration of the interburst interval. The gradual (usually minutes) onset and reversal of field effects varied from cell to cell. Among the various cells, both hyperpolarizing and depolarizing shifts were found. Extreme responses included depolarizations which changed bursting patterns to beating patterns, and hyperpolarizations which inhibited all firing activity for several minutes.

Our results may be generalized to suggest that the extracellular fields generated by the high frequency firing of a group of neurons could influence the much slower firing rate of nearby pacemaker cells and perhaps modulate physiological functions such as neurosecretion. (Supported by the Department of Energy.)

375.6 VOLTAGE CLAMP OF IONIC CURRENTS IN LEECH HEART MUSCLE CELLS. K.J. Thompson and R.L. Calabrese, Dept. Biology, Emory Univ., Atlanta, GA 30322.

The central nervous system of the leech, Hirudo medicinalis, contains a pattern generator for heartbeat (Thompson and Stent, 1976). This central pattern generator paces the activity of heart motor neurons. Isolated hearts are capable of producing intrinsic rhythmic myogenic contractions and rhythmic activity in heart motor neurons entrains this activity. After enzymatic dissociation of the hearts, a myogenic polarization rhythm and associated contractions can occur in individual isolated muscle cells (Maranto and Calabrese, 1984).

The present study was undertaken to determine the ionic basis of the electrical activity of the heart cells. In current clamp, brief depolarizing pulses elicit both action potentials and slow plateau-like potentials in isolated cells. The action potentials are abolished in Na^+-free salines, but are present in Co^{++}- and Mn^{++}-containing salines. The plateau-like potentials persist in Na^+-free saline, are enhanced in Ba^{++} (10 mM) saline, and are absent in Co^{++} (10 mM) and Mn^{++} (5 mM) salines.

For voltage clamp studies the cells were suspended in a low melting point agarose solution. Under two-electrode voltage clamp, large net outward currents flow in response to depolarizing steps from near rest (-65 mV). One outward current exhibits time- and voltage-dependent inactivation at potentials more depolarized than -40 mV, similar to A-current. The other predominant outward current does not inactivate and appears similar to the delayed rectifier. With hyperpolarizing steps the cells show low leakage current, corresponding to a measured input resistance of approximately 100 megohms.

In salines with TEA substituted for Na^+, depolarizing steps elicit a small inward current. In Ba^{++} (40 mM) TEA solution a large, non-inactivating inward current is observed which is blocked by the addition of Co^{++}, suggesting that Ba^{++} flows through Ca^{++} channels.

These results suggest that sodium dependent action potentials, calcium plateaus, and potassium currents contribute to the electrical activity of heart cells.

375.7 IDENTIFICATION AND CHARACTERIZATION OF IONIC CURRENTS IN HEART INTERNEURONS OF THE LEECH USING SINGLE-ELECTRODE VOLTAGE CLAMP. J.D. Angstadt and R.L. Calabrese. Dept. of Biology, Emory University, Atlanta, GA 30322.

Heartbeat in the leech, Hirudo medicinalis, is controlled by a central pattern generator composed of a set of identified interneurons (HN cells). Spontaneous activity in HN cells consists of repetitive bursts of action potentials terminated by barrages of IPSPs. This bursting pattern depends in part on the intrinsic cellular properties of the HN cells (Arbas and Calabrese, 1987). Current clamp studies have demonstrated that HN cells actively escape from inhibition via the combined actions of a Na-dependent depolarizing "sag" in membrane potential and a depolarization-activated Ca-dependent plateau potential.

We have investigated the intrinsic ionic currents of HN interneurons directly using the switching single microelectrode voltage clamp technique. A slow, non-inactivating inward current produced by hyperpolarizing voltage steps from a holding potential near -40 mV is described which can account for the membrane potential "sag" observed in current clamp. This current persists in salines containing 10 mM Co^{++}, but is not observed in Na-free saline. A second inward current (I_{Ca}) was found which persists in Na-free saline and is blocked by addition of 10 mM Co^{++} to the saline. The Ca^{++} current appears to be completely inactivated at holding potentials more depolarized than -50 mV. A slow outward current ($I_{K(V)}$) similar to the delayed rectifier is also observed. This current exhibits little inactivation over a time course of 100-200 ms and is blocked in salines containing 40 mM Ba^{++}. Finally, a fourth current, which resembles molluscan A-current (I_A) has been identified. This rapidly developing outward current, unlike $I_{K(V)}$, exhibits significant inactivation over a 100-200 ms time course. Like I_{Ca}, the transient outward current appears to be nearly completely inactivated at holding potentials more depolarized than -50 mV. Since HN cells typically oscillate around a membrane potential of -50 mV, the voltage sensitivities of these membrane currents are consistent with the hypothesis that they contribute significantly to the pattern of activity observed in normally bursting HN interneurons.

375.8 DIFFERENT ACTIONS OF BARBITURATES AND BENZODIAZEPINES ON NA- AND K-CONDUCTANCES IN INVERTEBRATE AND VERTEBRATE NEURONS. A.L. Kleinhaus, J.Johansen, J. Yang & C.F. Zorumski, Dept. Neurol. Yale U. Sch. Med. 333 Cedar St. New Haven, CT. 06510 and Depts. Anat. & Neurob. & Psych. Wash. U. Sch. Med. 660 S. Euclid, St. Louis, MO 63110.

It has previously been reported that benzodiazepines (BZ) and barbiturates (BA) in micromolar concentrations inhibit Ca-dependent action potentials in vertebrate neurons in culture (MacDonald & McLean Adv.Neurol. 44:1986) as well as in identified leech neurons (Johansen et al. PNAS 82:1985; Johansen & Kleinhaus Brain Res.376:1986). The effective concentrations for this effect were similar in the mammalian and invertebrate neurons suggesting that the underlying mechanisms may be related.

In this study, we compare the effects of μM concentrations of Medazepam (MDZ) and Methohexital (MTX) on the voltage-gated Na and K conductances of Retzius cells in the leech *Macrobdella* and chick dorsal root cells (DRG) in culture. Under current clamp conditions, MDZ and MTX prolonged the Na-dependent action potential of leech neurons without reducing their maximum rate of depolarization. These prolonged action potentials were identical to those recorded in the same neurons in the absence of outward currents *i.e.* in Ca-free Ringer's solution containing Mn, tetraethylammonium chloride (TEA) and 4-aminopyridine (4-AP). They consisted of an initial spike followed by a plateau lasting several hundreds of milliseconds. Both components were Na-dependent and TTX-resistant, while the plateau was selectively blocked by saxitoxin (STX) suggesting that it originated from the flow of Na through a conductance different from that underlying the spike potential (Kleinhaus & Johansen, Soc. Neurosci. Abstr.1986). Similarly, the plateau of the MTX-prolonged action potential was abolished by 50 μM STX. These results suggest that the drugs' actions resulted from a block of K-conductances. This hypothesis was substantianted by voltage-clamp experiments showing that MTX (100 -1000 μM) reduced both I_K and I_A in the Retzius cell, essentially mimicking the combined effects of TEA and 4-AP (Johansen & Kleinhaus, J. Neurophys. 56:1986).

In contrast, voltage-clamp experiments showed that in DRG cells MDZ and MTX decreased the amplitude of Na,Ca and K currents equally. This lack of specificity for a particular ionic species in the vertebrate cells suggests that in widely phylogenetically distant species the K-conductances may be very similar while significant differences may exist among their Na-conductances. Furthermore, the results suggest that the modulation of ionic conductances by BZ and BA (at μM conc.) are mediated via a common mechanism which may be important for the drugs' sedative and anesthetic actions.

375.9 DEVELOPMENT OF IONIC CURRENTS IN VARIOUS CELL LINEAGES OF THE ASCIDIAN, Boltenia villosa. L. Simoncini*, M.L. Block and W.J. Moody. Department of Zoology, University of Washington, Seattle, Washington 98195.

We are using the whole-cell voltage-clamp technique to trace the development of ionic currents in surgically isolated blastomeres of different cell lineages in the ascidian Boltenia villosa. Ascidians, which are primitive chordates, are characterized by a mosaic form of development, with very early determination of cell lineages. Boltenia was chosen because the oocyte contains orange pigment granules which partition preferentially into muscle-lineage blastomeres and enable them to be identified at all stages of development. Other cell types can be identified by pigmentation, size, and position in the embryo.

The unfertilized oocyte contains three major voltage-dependent ionic currents: a transient inward Na current, an inward Ca current, and an inwardly rectifying K current. After fertilization the Na current begins to decrease, and by the 2-cell stage is essentially absent. The Na current remains absent through at least gastrulation in all blastomeres. Ca and inwardly rectifying K current densities remain constant at oocyte levels through the 8-cell stage in all blastomeres, suggesting that these channels are added to the embryo in parallel with new membrane. This process continues for the inward rectifier through gastrulation. Ca current density appears to be lower in gastrula-stage cells than in the oocyte, but this could be explained by more efficient perfusion of these smaller cells by pipet solutions. After gastrulation, during the period of neural tube closure and tailbud extention, we see for the first time the appearance of other types of currents and differences in the electrical properties of blastomeres of different cell lineages.

375.10 PROPERTIES OF SODIUM AND CALCIUM CURRENTS IN NEURONS OF THE JELLYFISH CYANEA CAPILLATA (COELENTERATA; SCYPHOZOA). Peter A. V. Anderson. Whitney Lab. and Depts. of Physiology and Neuroscience, Univ. of Florida, St. Augustine, FL 32086.

Recent work on the structure and composition of Na^+ channels suggests that there has been considerable conservation of the Na^+ channel through evolution. Since coelenterates are the most primitive animals to possess a nervous system and to produce Na^+-dependent action potentials they may provide useful information on the properties of the "primitive" Na^+ channel. To this end, neurons in the motor nerve net of the jellyfish Cyanea were voltage clamped using the whole-cell configuration of the patch clamp technique. Outward current was blocked by a combination of internal Cs^+ and TEA^+ and external 4-AP. A space clamp was achieved by selective axotomy of the neurons.

Inward current in these cells is dominated by a fast, transient current that activates close to -10 mV, reaches peak amplitude around +15 mV and, in 390 mM Na^+, has a mean reversal potential of +62.9 ±0.9 mV (s.e.m.). This current activates with a time constant of 0.5 to 0.8 ms, reaching peak amplitude within 1 ms and inactivates more slowly, with a time constant of 1.2 to 3.7 ms. Inactivation, which is rarely complete, is voltage-dependent; in prepulse experiments, V_h, the potential at which the current is half maximally inactivated, was found to be -15 mV.

This inward current is a Na^+ current. It is abolished by the absence of external Na^+ and its reversal potential is dependent on $[Na^+]_o$. It is, however, completely insensitive to TTX (0.1 mM), STX (10 μM), veratridine (10 μM), BTX (2 μM), Leiurus venom (1 μM) and GIIIA (1 μM) but blocked, in a dose-dependent way, by Cd^{++} (5 mM), verapamil (2 μM), lidocaine (1 mM) and W7 (100 μM), a calmodulin antagonist which blocks Ca^{++} currents in Paramecium. Thus its pharmacology is somewhat reminiscent of that of Ca^{++} currents.

A second inward current is recorded in Na^+-free saline when $[Ca^{++}]_o$ is elevated. This Ca^{++} current activates more slowly, reaching peak amplitude in 2-3 ms, and inactivates in a voltage-dependent manner (V_h = +15 mV), with a time constant of 7 ms. The current/voltage relationships of this current are very different from those of the Na^+ current. In 95mM Ca^{++}, 0 Na^+, it activates at 0 to +10 mV, reaches peak amplitude at +40 mV and reverses around +90 mV. This current is insensitive to lidocaine (1 mM) and W7 (100 μM) but blocked by verapamil. Its properties are consistent with those of the presumed Ca^{++} current underlying synaptic transmission in these cells.

BASAL GANGLIA II

376.1 EXCITATORY AMINO ACID MECHANISMS IN BASAL GANGLIA STRUCTURES REGULATE LIMBIC SEIZURE ACTIVITY. S. Patel, G. De Sarro, M.H. Millan, B.S. Meldrum (SPON: A.G. Chapman). Department of Neurology, Institute of Psychiatry, London, SE5 8AF, U.K.

We have used focal injections of excitatory amino acid agonists and antagonists to study the role of the basal ganglia nuclei in both the development and spread of limbic seizures induced by pilocarpine.

Male Wistar rats, implanted at the level of the substantia nigra pars reticulata (SNr), entopeduncular nucleus (EP), lateral habenula (LH), mediodorsal thalamus (MD) or pedunculopontine nucleus (PPN) were injected with N-methyl-D-aspartate (NMDA, 500pmol-12.5 nmol), kainate (KA, 20-500 pmol), Y-D-glutamylaminomethylsulphonate (GAMS, 0.02-40 nmol) or 2-amino-7-phosphonoheptanoate (APH, 5pmol-1nmol). 15 min later, the animals received either a subconvulsant (150 mg/kg, ip) or a convulsant dose of pilocarpine (380 mg/kg, ip). Behaviour was monitored for 3h.

APH (a selective NMDA antagonist) protected against pilocarpine-induced seizures in a dose-related manner. Susceptibility to the protective effect of APH varied with the brain region studied. Mimimal effective doses were:- EP 5pmol; LH and MD 10pmol; PPN 100pmol; SNr 1nmol. GAMS (a preferential KA antagonist) injected into either SNr or EP suppressed pilocarpine-induced seizures. SNr is more sensitive to the protective action of GAMS (1 nmol for total seizure suppression) than the EP (40 nmol). Behavioural and EEG signs of motor limbic seizure activity were evident after injections of NMDA and KA into EP prior to a subconvulsant dose of pilocarpine (150mg/kg, ip). High doses of NMDA (12.5 nmol, n=8) and KA (500 pmol, n=4) resulted in motor limbic seizures in all animals tested.

Thus excitatory activity within SNr and EP can initiate limbic seizures. Decreased excitation prevents the development of limbic seizures. These structures apparently also propagate the motor components of limbic seizures to the brainstem and spinal cord via PPN. The anatomical connections of LH and MD may provide a means of interaction between the motor and limbic systems for seizure regulation.

376.2 GLUCOSE USE IN THE DORSAL NUCLEUS ACCUMBENS SHELL (AN AREA HIGH IN MU-OPIOID RECEPTORS) INCREASES DURING KAINIC ACID-INDUCED LIMBIC SEIZURES BUT NOT DURING BICUCULLINE SEIZURES . L. Churchill, R. Cross,* R.P. Dilts, T. Pazdernik,* F. Samson, S. Nelson and P.W. Kalivas. Washington State Univ. and Univ. of Kansas Med. Ctr.

The dorsal nucleus accumbens shell has unique Nissl staining properties (Paxinos & Watson atlas, Plate 15, 1987), a high density of opioid receptors (Herkenham & Pert, Nature 291: 415, 1981) and efferent connections that differ from the lateral nucleus accumbens core (Groenwegen and Russchen, J Comp Neurol 223: 347, 1984). Mu-opioid receptor autoradiography was done using ^{125}I-Tyr-D-Ala-Gly-MePhe-Gly(ol)(DAGO) at 0.2 nM for 60 min at room temperature (displacement by 1 µM naloxone). Glucose use was assessed by the 2-deoxyglucose (2DG) method. Seizures were induced with kainic acid (12 mg/kg, i.p.) or bicuculline (0.6 mg/kg, i.v.). 2DG autoradiography was performed at 2 and 3.5 hr after injection of kainic acid, which corresponded to two different phases of seizure activity, or immediately after bicuculline, which corresponded to the active seizure phase. At 2 hr after kainic acid, rats were in repetitive limbic seizures, whereas at 3.5 hr after kainic acid, rats were engaged in searching and circling activity. During the repetitive seizures (2 hr), glucose use increased in the dorsal nucleus accumbens shell within similar boundaries to the high density of mu-opioid receptor binding. During the searching and circling behavior (3.5 hr), glucose use increased throughout the nucleus accumbens shell as well as within its efferent connections: lateral septum, bed nucleus of stria terminalis, paratenial and paraventricular thalamus, ventral tegmental area and pedunculopontine tegmental nucleus. During tonic seizures induced by bicuculline, a small region of the dorsal nucleus accumbens shell did not increase in glucose use, whereas the rest of the nucleus accumbens rather uniformly increased. A relationship of the GABA-receptive and mu-opioid receptive cells within the dorsal nucleus accumbens shell may be involved within the mesolimbic locomotor circuit, which includes the nucleus accumbens shell, ventral pallidum, ventral tegmental area and pedunculopontine tegmental nucleus. The increases in glucose use within the mesolimbic locomotor circuit during limbic motor seizures may involve mu-opioid receptors.

376.3 COLCHICINE INJECTIONS INTO SUBSTANTIA NIGRA ACCELERATE KAINATE-INDUCED SEIZURE ONSET BUT ELIMINATE WET DOG SHAKES AND ATTENUATE HYPERSALIVATION. L. Grimes, C. Mitchell, P. Lee, and J. Hong. Toxicology Curr., UNC-CH, Chapel Hill, NC 27514 and Lab. of Behavioral and Neurological Toxicology, NIEHS/NIH, Research Triangle Park, NC 27709

Electrolytic lesions of the substantia nigra (SN) or those produced by local infusions of kainic acid (KA) or N-methyl-D-aspartate have been reported to attenuate seizure components induced by bicuculline, electroconvulsive shock (ECS) or kindling (Garant, D. and K. Gale, Brain Res., 273:156, 1983; McNamara, J. et al., J. Neurosci., 4:2410, 1984. In the present studies, the effects of colchicine (COL) (2.5 ug/site) injections into substantia nigra on seizure components induced by systemic KA and ECS were observed. Fifty-two male Fischer-344 rats were used in these studies. Three weeks after bilateral injections of COL or saline 2.0 mm lateral to midline into SN, rats were given 65 mA (duration =1.0 sec, pulses=50, pulse width=1.0 msec) of current through ear clips. Four days later, these rats were given 75 mA of current. Duration of forelimb and hindlimb tonic extension were measured. The duration of forelimb tonus was significantly reduced at 65 mA but not 75 mA in COL-injected rats. Duration of hindlimb tonus was significantly reduced at both levels of current in COL-treated rats. Two weeks after bilateral injections of COL or SAL 2.5 mm lateral to midline into SN, rats were injected with KA (8 mg/kg, sc) and were observed for 2.5 hr. In COL-treated rats, KA-induced wet dog shakes (WDS) were eliminated and hypersalivation was remarkably attenuated. Other seizure components did not differ from controls. This study was repeated using injections 2.0 mm lateral from midline. In treated rats, WDS were eliminated and hypersalivation attenuated as before, but the latency to onset of intense facial and forelimb clonus was significantly decreased. These studies indicate that COL lesions of SN produced effects on ECS threshold similar to those reported for other lesioning methods. However, its effects on KA-induced behaviors indicate that SN may be important for the relay of certain behaviors (WDS and hypersalivation) but that its more medial portions may have a gating or inhibitory effect on KA-induced seizure onset.

376.4 FETAL STRIATAL GRAFTS IN THE LESIONED RAT NEOSTRIATUM EXHIBIT IMMUNOREACTIVE GABA AND ENKEPHALIN NEURONS AND NADPH-DIAPHORASE POSITIVE CELLS. R.C. Roberts, A.W. Deckel and M. DiFiglia. Dept. of Neurology, Harvard Medical School and Mass. General Hospital, Boston, MA 02114 (RCR & MD) and Dept. of Psychiatry, Univ. of New Jersey, Newark, N.J. 07103 (AWD).

Previous anatomical, behavioral and biochemical studies have shown that fetal striatal cells transplanted into the neostriatum of the adult rat differentiate and partially restore motor dysfunction and some neurotransmitter deficits caused by excitotoxic lesions in the host caudate nucleus. The present study was undertaken to characterize the neurons within the transplants using immunocytochemical methods. Eight adult rats received intrastriatal unilateral or bilateral injections of 0.6 ul of a 250 mM or a 250nM solution of quinolinic acid. One week following the injections, tissue grafts of 17 day fetal striata were injected into the lesioned caudates. Six to ten weeks following the transplants tissue from the neostriatum was processed for the localization of immunoreactive GABA, enkephalin and NADPH-diaphorase activity. A separate series through each caudate was stained with cresyl violet. Omission of the primary antibody to GABA or enkephalin or preabsorption of the primary antibody with the appropriate antigen abolished all staining.

Results showed that in all rats immunoreactive GABA, enkephalin and NADPH-d positive neurons, processes and punctate structures were present within the grafts. GABA immunoreactive somata in the grafts were of medium size (14.7 um, n=30 neurons) and were relatively homogeneously distributed. Enkephalin immunoreactive neurons in the grafts were also of medium size (14 um, n=30 neurons) and were often distributed in clusters. NADPH-d positive neurons in the grafts were approximately 11.4 um in diameter (n=40 neurons). In ten 40 um thick sections selected from 3 different grafts GABA, enkephalin and diaphorase positive neurons ranged from 4-43%, 1-23% and 1.4-6.7% respectively of total grafted neurons per section as determined from counts of adjacent Nissl stained sections. These findings provide an anatomical basis for the functional recovery reported in other studies of fetal striatal transplants in rat caudate nucleus lesioned with excitatory amino acids. Supported by grants to MD from NIH (NS 16367) and the Hereditary Disease Foundation.

376.5 THE QUINOLINIC ACID MODEL OF HUNTINGTON'S DISEASE: DOSE DEPENDENT EFFECTS ON BEHAVIOR. M. Giordano, S.F. Calderon*, A.B. Norman and P.R. Sanberg, Laboratory of Behavioral Neuroscience, Departments of Psychiatry, Neurosurgery, Psychology and Physiology, University of Cincinnati College of Medicine Cincinnati, Ohio 45267-0559.

Rats which receive striatal injections of kainic acid show many of the anatomical, biochemical and behavioral abnormalities seen in patients with Huntington's disease (HD) (Sanberg and Coyle, CRC Crit. Rev. Neurobiol., 1, 1-44, 1984). Quinolinic acid (QA), an endogenous metabolite with excitotoxic properties has recently been shown to cause anatomical and biochemical changes in rats that are more consistent to those in HD (i.e., Beal et al., Nature 321, 168-171, 1986). Thus, the following study was performed to ascertain the behavioral changes of QA-induced striatal lesions in rats.

Male Sprague-Dawley rats (200-300 g) were assigned to one of four groups. Animals received bilateral striatal stereotaxic injections of QA (75nmol, 150nmol, or 225nmol in phosphate buffered saline, or vehicle alone) under pentobarbital anesthesia. Post-operative weights were monitored daily for two weeks. At two and four weeks post-lesion spontaneous nocturnal activity was monitored using Digiscan-16 monitors (Omnitech Electronics, Inc., Columbus, Ohio).

The 150nmol and 225nmol lesioned rats demonstrated aphagia and adipsia resulting in marked weight loss during the immediate post-operative period (the highest dose group needed to be fed intragastrically for a few days and in spite of this, about a third of the rats died). By four weeks all groups showed similar body weights. At both two and four weeks post-lesion, locomotor activity differences between the QA lesion groups and controls were evident and reached significance with respect to ambulation, rearing and stereotyped behaviors. At two weeks only the 150nmol lesioned group was significantly hyperactive compared to controls. By four weeks both the 150nmol and 225nmol lesion groups were hyperactive relative to both controls and the 75nmol lesioned rats in all three parameters analyzed, with the 225nmole rats tending to show the greatest activity. Interestingly, the 75nmol lesion group was slightly less active relative to controls, reaching significance on some activity measures (i.e., total horizontal activity and total number of vertical movements).

These results demonstrated that QA-induced striatal lesions produce behavioral changes similar to other excitotoxic striatal lesions in rats. Neurochemically, striatal QA lesions mimic the neurochemical pathology in HD to a greater extent than do other excitotoxins. The fact that these rats also demonstrated locomotor abnormalities supports the use of this model for basic studies on the pathogenesis and treatment of HD.

376.6 THE IMMUNOHISTOCHEMICAL LOCALIZATION OF A CERULOPLASMIN LIKE SUBSTANCE IN THE HUMAN CENTRAL NERVOUS SYSTEM. L. R. Edelstein, Dept. of Med., SUNY at Stony Brook, and F. J. Denaro, Dept. of Peds/Inf. Dis., UCSD Med. CT., San Diego, Ca.

Ceruloplasmin (CP) is a protein found in the alpha 2 globulin fraction of human serum. Research has revealed the multifunctional properties of this enzyme. Evidence supports its role in : 1). Copper metabolism and transport, 2). The mobilization and oxidation of iron, 3). It is a serum anti-oxidant, 4). It is a modulator of inflammatory response, and 5). There is evidence that CP can regulate the concentration of biogenic amines (noradrenaline and serotonin). Clinical and biochemical studies have associated CP with a number of neurologic diseases. Parkinson's disease and Huntington's disease are two diseases in which CP is believed to play a part. Further evidance for CP involvement in CNS diseases is deduced from animal experiments. It has been found by use of tritiated CP that cells of the CNS can sequester CP from the blood. While there has been extensive biochemical and clinical research on CP, there has been no immunocytochemical studies of CP in the brain.

In the present study, human autopsy material was examined by immunohistochemistry for evidence of CP staining cells. Tissue which was obtained at time of autopsy was fixed in 10% NBF. It was then paraffin embedded and sectioned. The ABC method or the PAP method was used for the immunocytochemical detection of CP. The CP primary anti-sera was obtained from DAKO and was used at dilutions of 1:500 and 1:1000. CP from Sigma was used in competion controls.

Briefly, the results show : 1. Cortex - negative. 2. Caudate and Putamen - no cells showed staining but the neuropile showed a much higher level of staining than other areas of the brain. 3. Substantia nigra - discretely staining cells and their processes were found in this nucleus. 4. Pontine N. - discretely staining cells were found in this nucleus.

Both the suggested functions of CP and the anatomical locations in which CP has been found in this study, support the theory that CP may be involved in such neurologic diseases as Parkinson's and Huntingtons's disease. In view of this, on going research is not only directed at investigating the distribution of CP in the normal brain but in various disease states as well.

We thank DAKO for supplying the immunocytochemicals and the UCLA Neurologic Tissue Bank for supplying some of the tissue used in this study.

376.7 DIFFERENTIAL LOSS OF SUBSTANCE-P-CONTAINING AND ENKEPHALIN-CONTAINING STRIATOFUGAL PROJECTIONS IN ADULT-ONSET AND JUVENILE-ONSET HUNTINGTON'S DISEASE.

R.L. Albin[1*], A. Reiner[2], K.D. Anderson[2], C. J. D'Amato[3], J.B. Penney[1], A.B. Young[1]. (Spon: N.S. Wexler)
Depts. of Neurology[1], Anatomy[2], Pathology[3], University of Michigan School of Medicine, Ann Arbor, MI 48104

Huntington's disease (HD) is characterized by prominent neuron loss in the striatum. Recent evidence (Kowall et al. TINS 10:24-29, 1987) indicates that striatal neuron loss is not uniform and that somatostatin-NPY-containing NADPH diaphorase positive interneurons and possibly cholinergic interneurons are relatively spared. The majority of striatal neurons, however, are projection neurons. These are progressively depleted in HD and show the earliest evidence of abnormality. To determine if there is differential loss of striatal projection neurons we undertook an immunohistochemical study of peptidergic striatofugal projections in HD basal ganglia and substantia nigra obtained at autopsy.

We studied five pathologically verified adult-onset cases of HD, two juvenile-onset cases of HD, and several matched control cases. Antisera directed against substance-P, Leu-enkephalin, Met-enkephalin-Arg-Gly-Leu were utilized and tissue was stained using the PAP technique.

In all control cases the normal pattern of dense fiber staining for enkephalins in the lateral pallidum and for substance-P in the medial pallidum and substantia nigra was observed. In all adult-onset HD specimens marked depletion of enkephalin fiber staining in the lateral pallidum and substance-P fiber staining in the substantia nigra pars reticulata was observed. The substance-P fiber staining in the medial pallidum and substantia nigra pars compacta was relatively preserved. In the juvenile-onset HD specimens both the enkephalin and substance-P fiber staining in the lateral and medial pallidum, respectively, were depleted.

These results indicate differential loss of striatal projection neurons in adult-onset but not juvenile-onset HD. This could aid in the identification of the biologic defect underlying HD and provides additional criteria for the evaluation of current models of HD pathogenesis. In addition, these results help to account for the chorea and oculomotor disturbances seen in adult-onset HD, and the lack of chorea characteristic of juvenile-onset HD.

376.8 LANGUAGE FUNCTIONS IN HUNTINGTON'S DISEASE. K. Podoll* and J. Noth. Department of Neurology, Alfried Krupp Clinic, Essen, FRG.

A comprehensive language test battery (Aachen Aphasia Test) was administered to 45 patients with early, middle and later stage Huntington's disease (HD) and 20 control subjects. In spontaneous speech, many HD patients exhibited a loss of conversational initiative which markedly contributed to their communicative disability. Dysarthria was a common finding, leading to occasional phonemic paraphasias. Reading skills were found to be impaired mainly as a consequence of dysarthria; some HD patients displayed visual dyslexia. In addition to the characteristic disturbances of writing skills due to the choreatic movement disorder, the writing of HD patients with advanced dementia indicated constructional dysgraphia, characterized by frequent omissions, perseverations and substitutions. HD patients exhibited no evidence of word-finding difficulty or other semantic deficits in spontaneous speech, but there was a marked impairment in visual confrontation naming with a significant rise of naming error rate across the three stages of HD. In most instances, the inproper names referred to an object visually similar to the target object, suggesting visual misperception as the main mechanism of the naming disorder in HD. Syntactical structure of spontaneous speech was typically reduced to short, simple sentence constructions. Verbal stereotypies were only rarely encountered and occurred late in the course of the disease. Tests of language comprehension reflected the general degree of dementia. In conclusion, there are apparently no primary language changes in HD, but a variety of language impairments developes secondary to other neurologic and neuropsychological changes.

376.9 EFFECTS OF SENSORY CUES AND L-DOPA ON GAIT MOVEMENT AND MUSCLE ACTIVATION PATTERNS IN PATIENTS WITH PARKINSON'S DISEASE. R. Lemieux*, C.L. Richards, P.J. Bédard, F. Malouin and M. Cioni*, Neurobiology Laboratory, Faculty of Medicine, Laval University, Quebec, G1K 7P4, and Pharmacology Institute, Medical School, University of Catania, Italy.

We studied the changes in bradykinetic movement and muscle activation patterns during gait in 11 patients with Parkinson's Disease in 2 conditions when "off" L-Dopa: 1. free gait, 2. with visual guidance by placing markers on the walkway or with auditory cues provided by a metronome. Free gait was also studied when "on" L-Dopa. Movements of the hip, knee and ankle in the sagittal plane were recorded by means of an electrogoniometer. Surface electrodes were placed on the quadriceps (Q), hamstrings, triceps surae and tibialis anterior (TA) muscles and the myosignals were fed to a Grass polygraph for amplification, rectification and time-averaging prior to being sent to a PDP 11/23 computer for recording and analysis. To define the gait cycle, signals from electronic footswitches were recorded concomitantly with the angular displacements and muscle activations as the patients walked along an 8 m walkway. At least 10 gait cycles were recorded first "off" L-Dopa (at least 12 hrs), and then consecutively with visual guidance and auditory cues and finally when "on" L-Dopa (1-2 hrs). The main finding was that visual and auditory cues induced changes in the bradykinetic (off L-Dopa) movement and muscle activation patterns which were similar in nature to those observed when "on" L-Dopa. These EMG changes varied among the patients; in some both an increased amplitude and timing modification were observed, while in others mainly the amplitude of the activation was affected. Differential effects were, however, observed among the patients for the gait conditions. The EMG changes were observed throughout the gait cycle and in the four muscles studied but could be found predominantly in proximal or distal muscles. For example in the TA, all the patients showed improvements in the activation when "on" L-Dopa, or with visual guidance, while one did not respond to auditory cues. On the other hand in Q, while all the patients demonstrated some changes with auditory cues, in 3 patients little change was observed with L-Dopa or visual guidance. These results demonstrate that, like L-Dopa, increased sensory inputs are capable of modifying both the timing and amplitude of muscle activations of bradykinetic gait patterns typical of Parkinson's Disease. Whether these modifications are mediated by similar mechanisms remains to be determined. This work was supported by a grant from Laval University.

376.10 CORRELATION BETWEEN HISTOLOGICAL AND ELECTROPHYSIOLOGICAL CHANGES IN OUTPUT NEURONS OF THE BASAL GANGLIA IN A PARKINSONIAN MONKEY. L. Tremblay and M. Filion, Lab. Neurobiol., Laval Univ. and Enfant-Jésus Hosp., Québec, Canada, G1J 1Z4.

We are studying the activity of globus pallidus neurons in monkeys (Macaca fascicularis) rendered parkinsonian by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Two animals (C and D) were studied only in the intact state, two (A and E) only in the parkinsonian state, and one (B) in both the intact and parkinsonian states. Sections of the brain of these animals were stained for Nissl bodies with cresyl violet. In the intact and in two of the three parkinsonian animals, neurons were similar in the internal (GPi) and external (GPe) segments of the globus pallidus and in the subnucleus lateralis of the pars reticulata of the substantia nigra (SNsl). In one parkinsonian animal (E), however, the majority of GPi and SNsl neurons were hyperchromatic and slightly shrunken. In GPe, inversely, the majority of neurons were hypochromatic, globular and vacuolar. Counts of nigral neurons of the compacta-type showed losses of 86%, 99% and 90% in monkeys A, B and E, respectively. This demonstrates that the neurotoxic effects of MPTP were similar in the three parkinsonian monkeys, and certainly not greater in monkey E. However, this last animal was sacrificed 14 months after MPTP, whereas monkeys A and B were sacrificed as early as 5 weeks after MPTP. Therefore, the histological changes can be associated with the long duration of parkinsonism in monkey E. An explanation for these changes is suggested by electrophysiological data from the same animals. The mean firing rate of GPi neurons was higher in parkinsonian (109/s, n=91) than in intact monkeys (77/s, n=83). A few SNsl neurons were recorded in parkinsonian monkeys and also exhibited high firing rates. Conversely, GPe neurons exhibited a lower firing rate in parkinsonian (43/s, n=123) than in intact monkeys (74/s, n=97). In parkinsonian monkeys, a group of neurons with relatively low firing rates were recorded in areas of GPi where neurons were not hyperchromatic. In conclusion, the hyperactivity of GPi and SNsl neurons and the hypoactivity of GPe neurons in parkinsonism are likely to give rise, over a period of several months, to corresponding histological changes. Supported by the MRC of Canada.

376.11 MPTP-INDUCED PARKINSONISM IN THE MOUSE: INSIGHT INTO THE PATHOPHYSIOLOGY OF DOPAMINERGIC CELL DEGENERATION. K.F. Manaye, P. Sonsalla, G. Barnett*, M.D. Baring*, R. Heikkila, and D.C. German. Depts. of Psychiat. and Physiol., U. of Texas Health Sci Cntr., Dallas, TX 75235 and Dept. of Neurol., Rutgers Medical School, Piscataway, N.J. 08854.

1-Methyl-4-(2'-methylphenyl)-1,2,3,6-tetrahydropyridine (2'-CH3-MPTP), a substituted analog of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), has been found to be significantly more toxic to midbrain dopamine (DA)-containing neurons than MPTP in the mouse (Youngster et al. Eur.J.Pharmacol. 122:283, 1986). The purpose of the present experiment was to measure the neurotoxic effects of 2'-CH3-MPTP at both the DA cell body and axon terminal region. In the first experiment we investigated the effect of 2'CH3-MPTP (2 X 20 mg/kg, i.p.) on the pattern of midbrain DA cell loss and levels of forebrain DA in BALB/c mice. After approximately 2 weeks, the animals were sacrificed and 30 um thick sections were cut through the midbrain DA cell complex and stained with an antibody to tyrosine hydroxylase (TH). The location of each TH-containing neuron was mapped on one side of the brain, using computer graphics equipment, in 4 normal and 5 treated mice. There was a significant loss (37%) of midbrain DA neurons in the treated mice (mean $\pm$ SEM = 2976 $\pm$ 241 vs. 4693 $\pm$ 345 cells). In these same mice there was a 47% loss of striatal DA and a 23% loss of nucleus accumbens DA. In the second experiment we measured the effect of 2'CH3-MPTP (2 X 20 mg/kg/day every other day X 3) on DA and DA metabolite levels in the midbrain and in the forebrain (4-5 mice/group). There was a 74 $\pm$ 8% loss of striatal DA, a 72 $\pm$ 6% loss of forebrain DA, but only a 25 $\pm$ 10% loss of midbrain DA. Both DOPAC and HVA levels were comparably affected in the forebrain and midbrain. In conclusion: (1) there was a marked loss of DA neurons within the substantia nigra, and also loss within the ventral tegmental area and retrorubral area as judged by both TH- and Nissl-staining; and (2) there was a much greater loss of DA in the forebrain than in the midbrain. These data are consistent with the hypothesis that the neurotoxicity begins initially at the level of the axon terminal. Research supported by the NIH (MH-30546, NS-21752), Biological Humanics Foundation and Dallas Area Parkinsonism Society.

376.12 ANATOMICAL SPECIFICITY OF THE EFFECTS OF L-DOPA IN MPTP-INDUCED HEMIPARKINSONISM. L.J. Porrino[1,2], E. Palombo[2]*, K.S. Bankiewicz[3], and I.J. Kopin[3]. [1]Addiction Research Center, NIDA, Baltimore, MD 21224 and [2]Lab. Cerebral Metabolism, NIMH; [3]Surgical Neurology Branch, NINCDS, Bethesda, MD 20892.

L-DOPA treatment ameliorates the clinical signs that accompany the hemiparkinsonism produced by injection of MPTP into one carotid artery in rhesus monkeys. L-DOPA also reverses the direction of spontaneous circling occurring in this syndrome. Local cerebral glucose utilization (LCGU) was determined in 5 MPTP-induced hemiparkinsonian monkeys treated with L-DOPA (200 mg L-DOPA/20 mg carbidopa) approximately 30 min prior to the 2-(^{14}C)deoxyglucose procedure for the measurement of LCGU. The behavioral response to L-DOPA, including reversal of rotational direction, and elimination of contralateral bradykinesia, rigidity and tremor, was maximal in 2 monkeys, intermediate in 2 and virtually absent in one other. The pattern of LCGU changes in the L-DOPA-unresponsive monkey was identical to that seen in untreated hemiparkinsonian monkeys. In those animals responding to L-DOPA, LCGU was increased ipsilaterally in the substantia nigra reticulata, subthalamic nucleus, and medial globus pallidus, and decreased in lateral habenula. L-DOPA treatment did not reverse the increase in LCGU in the lateral globus pallidus seen in untreated hemiparkinsonian monkeys. In addition to these alterations common to all responding monkeys, in those animals displaying maximal response to L-DOPA, intense increases in LCGU were found in anatomically discrete loci within the ipsilateral basal ganglia and thalamus: (1) the medial one third of the substantia nigra reticulata throughout its rostrocaudal extent, (2) a highly circumscribed region within the most ventromedial portion of the subthalamic nucleus, (3) the reticular nucleus of the thalamus, and (4) a region within the medial globus pallidus adjacent to the dorsal medial medullary lamina.

On the basis of these data, there appears to be a strong correlation between the degree of behavioral repsonse to L-DOPA in hemiparkinsonian monkeys and the presence of a distinctive pattern of anatomically specific alterations in glucose utilization.

376.13 MPTP-INDUCED DOPAMINE DEPLETIONS ALTER SENSORY PROCESSING IN THE CAUDATE NUCLEUS IN THE AWAKE CAT. J.S. Schneider and C.H. Markham. Department of Neurology, UCLA School of Medicine, Los Angeles, CA 90024.

Over the past several years, we have shown the basal ganglia's (BG) sensory processing capabilities to be quite complex. We have demonstrated that assessment of sensory processing capabilities of the BG can be a very sensitive measure of the functional integrity of this system. The present study has investigated whether disturbance of nigrostriatal dopaminergic activity results in defects in sensory processing in caudate nucleus (CD) neurons concomitant with sensorimotor behavioral disturbances.

Two hundred-six cells were recorded from the CD of 2 normal adult cats. These baseline recordings served to characterize the sensory responsiveness of CD neurons. Twenty-two percent of CD cells responded to tactile stimulation of the face, while 4% and 8% responded to visual and auditory stimulation, respectively. Tactile responsive cells had mostly small, discrete receptive fields. However, cells with moderate to large receptive fields had the characteristic ability to encode stimulus location on the face relative to the front of the mouth.

These cats were then given 9 injections of MPTP·HCl (5 mg/kg, i.p.) every other day. A total of 255 cells were recorded from the 2 cats during the entire post-MPTP period. In both cats, CD unit sensory responsiveness was comparable to that in the pre-MPTP state during the first 3 post-MPTP recording sessions before signs of sensory or motor impairment were evident. However, over the next 6 recording sessions, only 6% of CD cells in cat #1 and 2% in cat #2 had responses to facial tactile stimulation. Responsive cells had large receptive fields and could not encode stimulus location information. Less than 2% of sampled cells responded to visual or auditory stimulation as well. CD cells in neither animal showed distinct changes in spontaneous activity after MPTP administration. During the period of decreased sensory neuronal responsiveness, animals would no longer orient to visual, tactile, or auditory stimuli, were akinetic, and froze frequently while attempting movement.

Neurochemical analyses showed CD dopamine depletions of 92% and 95% in the 2 cats and tyrosine hydroxylase immunohistochemistry revealed extensive loss of substantia nigra pars compacta neurons and moderate loss of retrorubral neurons. These results demonstrate distinct quantitative and qualitative changes in cat CD neuronal responses to sensory stimulation after MPTP-induced dopamine depletions. These neurophysiological alterations appear to underlie the sensorimotor behavioral disturbances observed in these animals. Supported by USHHS Grant MH41645.

376.14 BROMOCRIPTINE: IN VITRO AND IN VIVO EVIDENCE FOR A SELECTIVE D-2 ACTION. J.M. Trugman, N. Touchet*, and G.F. Wooten. Department of Neurology, University of Virginia, Charlottesville, VA 22908.

Bromocriptine mesylate is a clinically effective antiparkinson agent, yet questions remain regarding its mechanism of action. In addition to being a D-2 dopamine receptor agonist, bromocriptine has been reported to be a D-1 antagonist (Markstein, J. Neural. Transm. 51:39-59, 1981). If true, this D-1 antagonist action would represent a unique property among clinically used antiparkinson drugs. We studied the ability of bromocriptine to compete for D-1 and D-2 receptors using quantitative in vitro autoradiography. The in vivo effects of bromocriptine were studied by ^{14}C-2-deoxyglucose (2-DG) autoradiography in rats with unilateral substantia nigra (SN) lesions.

Serial 20 µm sections through the striatum and substantia nigra pars reticulata (SNr) were incubated in PBS with either 0.3 nM ^{3}H-SCH 23390 (to label the D-1 receptor) or 1.0 nM ^{3}H-spiperone (to label the D-2 receptor) and 11 concentrations of bromocriptine (10^{-12} to 10^{-5} M). Nonspecific binding was defined using 2 µM (+)butaclamol for the D-1 site and 2 µM ADTN for the D-2 site. Bromocriptine potently competed for ^{3}H-spiperone binding in striatum with a K_i value of 2.8 nM. In contrast, bromocriptine did not effectively compete for ^{3}H-SCH 23390 binding in either striatum (K_i=21.6 µM) or SNr (K_i=30.9 µM).

Rats with 6-hydroxydopamine SN lesions were administered bromocriptine (10 mg/kg i.v.), followed one minute later by ^{14}C-2-DG (25 µCi/0.4 ml saline i.v.). Administration of bromocriptine resulted in contralateral rotation beginning immediately after the i.v. injection (mean 4.2 rotations per minute). RCGU remained unchanged in the entopeduncular nucleus and SNr ipsilateral to the lesion, a pattern characteristic of the selective D-2 agonist quinpirole (LY 171555) and differing from the marked RCGU increases produced by L-dopa or the D-1 agonist SKF 38393 (Trugman and Wooten, Brain Res. 379: 264-274, 1986 and Soc. Neurosci. Abs. 12:874, 1986). Bromocriptine lowered RCGU in the lateral habenula bilaterally (+54% ipsilateral to the lesion, +30% contralateral) and increased RCGU in the subthalamic nucleus ipsilateral to the lesion (+21%). Thus, in the entopeduncular nucleus and SNr, two critical basal ganglia outflow nuclei, bromocriptine produces different metabolic effects than does L-dopa.

Based on in vitro binding studies, bromocriptine has high affinity for D-2 receptors (K_i 2.8 nM) and low affinity for D-1 receptors (K_i 21.6 µM) in rat striatum, with a ratio of affinities >1000. In vivo, bromocriptine mimics the RCGU pattern of the selective D-2 agonist quinpirole. Together these studies suggest that bromocriptine is a selective D-2 agonist and does not interact with the D-1 receptor.

376.15 HLA-DR REACTIVE MICROGLIA IN PARKINSON'S DISEASE AND OTHER EXTRAPYRAMIDAL DISORDERS. P.L. McGeer, S. Itagaki* and E.G. McGeer. Kinsmen Lab. of Neurol. Res., Dept. of Psychiatry, Univ. of British Columbia, B.C., Canada, V6T 1W5

HLA-DR is a class II cell surface glycoprotein of the human histocompatibility complex usually expressed on the surface of cells that are simultaneously presenting foreign antigen to T-lymphocytes. Using double immunohistochemical staining for HLA-DR and various neurotransmitter markers, we have examined the relationship between reactive microglia and degenerating neurons in a number of basal ganglia disorders. Using antibodies to tyrosine hydroxylase and HLA-DR, we have examined the dopaminergic nigrostriatal system in Parkinson's disease with and without dementia, parkinsonism-dementia of Guam, and Alzheimer's disease without parkinsonian features. HLA-DR positive microglia were observed in the substantia nigra pars compacta (SNC) of patients with all forms of parkinsonism but not in the SNC of most controls and Alzheimer's cases. Some elderly controls and some Alzheimer's cases showed limited HLA-DR positive staining in the SNC, suggesting an early, presymptomatic stage of parkinsonism. In the various parkinsonian syndromes, HLA-DR positive microglia could be seen phagocytosing dopaminergic neurons and their processes. Positive staining was also observed in the SNC of parkinsonian cases with antibodies to the interleukin-2 receptor. In Huntington's disease (HD), HLA-DR positive microglia could be seen in the region of degenerating somatostatin-containing neurons in the caudate and of substance P-containing fibers in the substantia nigra. In HD, HLA-DR positive microglia were not seen phagocytosing tyrosine hydroxylase-containing neurons of the substantia nigra. These data indicate that an active neuropathological process, mediated by the T-lymphocytic system, is destroying SNC cells in the parkinsonian syndromes and neostriatal cells in HD.

376.16 VISUALIZING PRIMATE BASAL GANGLIA WITH MAGNETIC RESONANCE AFTER MANGANESE ADMINISTRATION. M.C. Newland*, J.H. Kordower, T.L. Ceckler*, and B. Weiss. University of Rochester School of Medicine and Dentistry, Rochester, NY 14642.

Manganese administration enabled the highlighting of regions associated with the extrapyramidal motor system when visualized with magnetic resonance imaging (MRI). This highlighting appeared in a m. fasicularis after inhalation (Newland et al., The Toxicologist, 7:157, 1987). We now replicate and extend this observation using iv exposure and an additional primate species. A cebus monkey and a m. fasicularis were administered 10 mg/kg of Mn (as $MnCl_2$) iv either 2 days or 6 days prior to MRI. T1-weighted images (TR/TE = 450/16) taken 6 days after Mn administration produced highlighting of the globus pallidus, striatum, substantia nigra, and subthalamic nuclei, indicating selective accumulation or retention of Mn in the highlighted regions. Two days after Mn administration only slight contrast was noted. Regional estimates of T1s were employed to quantify the selectivity and clearance of manganese in the extrapyramidal system. In separate experiments the clearance rate of manganese was observed to be faster in the striatum than in the other regions of the extrapyramidal motor system. The brain of an unexposed control monkey was also imaged using identical parameters, but no highlighting appeared. Both the kinetics and dose of systemically administered manganese are important in determining the quality of the images obtained. Although excessive doses of manganese are neurotoxic, it may be possible to exploit its kinetics to enhance contrast at lower doses or to lower its levels in brain with a complexing agent. The utility of this phenomenon in assessing MPTP toxicity and subsequent treatment with adrenal medullary implants in nonhuman primates are under investigation. [Supported by AO5188, ES01248, CA40699, General Electric Corporation, and the John Douglas French Foundation.]

376.17 NIGROTECTAL GABA UTILIZATION RESPONDS TO STRIATAL DOPAMINE RECEPTOR SUPERSENSITIVITY. S. E. Bachus, N. Hayman* & K. Gale. Dept. Pharmacology, Georgetown Univ. Sch. Medicine & Dentistry, Washington, D.C. 20007.

Systemic dopamine (DA) agonists have been shown to reduce GABA turnover in the nigrotectal terminal region in deep layers of superior colliculus (SC)[1]. This effect is relayed via substantia nigra and is dependent upon nigral GABA transmission. In the present studies we investigated whether behavioral supersensitivity to DA agonists would be associated with enhanced sensitivity to the apomorphine (APO)-induced decrease in tectal GABA turnover.

Adult male Sprague-Dawley rats received unilateral microinfusions of 6-hydroxydopamine (6-OHDA) or saline into the medial forebrain bundle, under Equithesin anesthesia. Successful lesions resulted in > 95% depletion of striatal DA, a condition associated with marked behavioral supersensitivity to APO. Unsuccessfully lesioned rats were included with sham lesioned rats. At least 2 weeks later, GABA turnover in superficial and deep layers of SC was estimated by measuring the accumulation of GABA 90 min after local microinfusion of the irreversible GABA transaminase inhibitor, gamma-vinyl-GABA.[1] During this 90 min period, rats received 3 s.c. injections of either APO (1 mg/kg) or water.

APO (1 mg/kg) proved subthreshold for reducing GABA turnover in deep layers of SC in sham lesioned rats, as compared to sham lesioned rats injected with water (water:69.41 + 2.33, APO:66.97 $\pm$ 3.98). However, this dose significantly ($p<.005$) reduced, by 19.3%, GABA turnover in deep layers of SC in 6-OHDA lesioned rats, relative to lesioned rats receiving water (water:75.36 + 3.63, APO:60.83 + 2.65). This reduction is comparable to that seen in nonlesioned rats following 3 injections of 3 mg/kg APO.[1]

A reduction in GABA turnover is found also in superficial layers of SC, in response to APO (3 X 3 mg/kg), but this effect is independent of nigral GABA transmission.[1] Thus, we also examined effects of 6-OHDA lesions on responsiveness of GABA turnover in superficial layers of SC, which do not contain nigrotectal GABA terminals, to determine the anatomical specificity of the supersensitivity. The 1 mg/kg dose of APO did not significantly affect GABA turnover in superficial layers of SC in either 6-OHDA lesioned rats (water:81.72 + 5.79, APO:89.67 + 6.44), or sham lesioned rats (water:93.68 $\pm$ 6.57, APO:85.15 $\pm$ 5.57).

We conclude that nigrotectal GABA transmission is responsive to alterations in striatal DA receptor sensitivity. Moreover, this effect is specific to the target region of GABAergic tectal afferents from substantia nigra, consistent with mediation via nigral relays. It should prove interesting to explore whether other treatments which affect DA receptor function, such as chronic neuroleptic exposure, also shift responsiveness of nigrotectal GABA projections. [1]Melis & Gale, J.P.E.T. 226:425, 1983)

376.18 ENHANCED SUSCEPTIBILITY OF DOPAMINE NEURONS TO DEPOLARIZATION BLOCK AFTER PARTIAL DOPAMINE LESIONS. J.R. Hollerman and A.A. Grace, Depts. of Behavioral Neuroscience & Psychiatry, Center for Neuroscience, University of Pittsburgh, Pittsburgh, PA 15260.

Acute administration of haloperidol (HAL) to rats is believed to activate nigral dopamine (DA) neurons via striatonigral feedback pathways. In contrast, repeated HAL treatment leads to a time-dependent inactivation of DA cell firing as a result of this maintained depolarization. This depolarization block (DB; Bunney & Grace, 1978) can be induced in acute preparations, but extreme depolarizing conditions, such as the extended iontophoresis of excitatory neurotransmitters or intracellular injection of depolarizing current (Grace & Bunney, 1986). Nonetheless, acute administration of HAL alone, even at high doses, will not induce DA cell DB. We now report that acute HAL administration can induce DB if the DA system is first compromised by partial lesioning of nigrostriatal DA afferents.

Albino male rats, following DMI and pargyline pretreatment, received bilateral i.c.v. injections of 200 ug 6-hydroxydopamine (6-HDA) or vehicle. Behavioral assessments of akinesia were made 4-8 days and 4-6 weeks postlesion, followed by extracellular recordings from identified nigral DA neurons. The effects of HAL on DA cell activity were examined in each group by administering HAL i.v. in increasing doses, with maximal doses of 5 mg/kg. In control or vehicle-injected rats, HAL increased DA cell firing rates and induced burst firing, but did not induce DB. In contrast, after behavioral recovery following striatal DA lesions of 80% or more, HAL in doses of 0.1 to 0.2 mg/kg i.v. also caused DA cells to increase firing rates, with a progressive reduction in spike amplitude and prolongation of spike duration, until there was complete cessation of spontaneous spike activity. The absence of cell activity after HAL was not due to the cell drifting away from the electrode, since DB was always preceded by lengthened spike duration and an increase in firing frequencies. Furthermore, administration of the DA agonist apomorphine, which normally inhibits DA cells, caused these inactivated cells to begin firing at fast rates. Subsequent doses of apomorphine then produced their typical inhibition of DA cell firing.

Previous studies in our group have shown that, after recovery from 6-HDA lesions, akinesis could be reinduced by administering HAL at doses subthreshold to those required to induce akinesia in nonlesioned rats (Snyder et al, 1985). The experiments reported here suggest that this enhanced lability to DA antagonists is due at least in part to the constraints placed on DA neurons secondary to the compensations in activity required for behavioral recovery. Indeed, DA neurons partially compensate for DA loss after lesions by increased levels of activity in the remaining DA neurons (Hollerman et al, 1986). However, as a consequence of this compensatory mechanism, the DA neuronal population is compromised in its ability to respond to acute stressors. This is reflected in the enhanced susceptibility of DA cells to DB after partial DA lesions. This finding may have particular relevance to clinical pathologies, such as in the stress-induced exacerbation of Parkinson's disease symptoms. (Supported by NS19608)

376.19 ALTERATIONS IN SUBCORTICAL DOPAMINERGIC FUNCTION FOLLOWING DOPAMINE DEPLETION IN THE MEDIAL PREFRONTAL CORTEX. D. L. Rosin*, A. Y. Deutch, and R. H. Roth (SPON: E.F.S. Kaufman). Depts. of Pharmacology and Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06510.

Behavioral studies suggest that the different forebrain dopamine (DA) projections subserve different functions. However, there is a growing body of literature which suggests that there may be a functional interdependence of the mesocortical, mesolimbic, and nigrostriatal DA systems. In particular, 6-hydroxydopamine (6-OHDA) lesions of the prefrontal cortex (PFC) have been reported to result in an increase in DA turnover in the striatum. DA in the PFC appears to hold cortical projection neurons under tonic inhibition; disruption of such a regulatory control over corticostriatal glutamatergic projections may be expected to have profound consequences for striatal DA function. We have therefore attempted to characterize the effect of selective DA depletion in the PFC on various biochemical indices of subcortical DA function. Adult male rats received 10 ug 6-OHDA in 2.5 ul ascorbate-saline into the PFC, 30 min after pretreatment with desmethylimipramine (25 mg/kg, ip) to minimize concurrent depletion of the cortical noradrenergic innervation. Rats were sacrificed two weeks later and striatal levels of DA and its metabolite 3,4-dihydroxyphenylacetic acid (DOPAC) were measured. In a second study, in vivo tyrosine hydroxylation was estimated by measuring DOPA accumulation after decarboxylase inhibition in both lesioned and vehicle-injected controls. In neither experiment was striatal DA function altered, as reflected by alterations in DOPAC, DOPAC/DA, or DOPA accumulation. A third experiment was therefore performed in which in vitro tyrosine hydroxylase activity was measured in tissue from lesioned and control animals, and from control and lesioned animals treated with haloperidol (100 ug/kg) in order to submaximally activate TH. TH activity was assayed at pH 7.0 under two different cofactor concentrations (0.1 mM and 1.0 mM). Furthermore, in this experiment the medial strip of the striatum (i.e., that region of the striatum which receives projections from the PFC) was dissected separately from the lateral (non-PFC recipient zone) striatum; the nuc. accumbens was also removed. TH activity at both cofactor concentrations was markedly increased by haloperidol treatment. However, DA depletion in the PFC did not result in an increase in TH activity in either the medial or lateral striatum, nor in the nuc. accumbens. These data therefore suggest that specific 6-OHDA lesions of the PFC do not result in significant alterations in striatal or mesolimbic DA function. These studies may suggest that disturbances of affect in schizophrenic reactions are not secondary to primary dysfunction of the PFC. GLIA IV

377.1 α-AMINOISOBUTYRIC ACID TRANSPORT IN ASTROCYTE MONOLAYER CULTURES. N. Brookes. Dept. of Pharmacol. and Exptl. Therap., Univ. of Maryland Sch. of Med., Baltimore, MD 21201.

Glia possess high-affinity, Na-dependent transporters for a number of neurotransmitters. The function of these systems in relation to neurotransmission have attracted much interest. By contrast, the systems responsible for transport of non-neurotransmitter amino acids in glia have received little attention. α-Aminoisobutyric acid (AIB) is a non-metabolized, synthetic amino acid often used to study neutral amino acid transport. Stöcklin et al. (Soc. Neurosci. Abstr. 11: 394, 1985) reported evidence that AIB is taken up in rat brain astrocytes by a single, Na-dependent system. The present study shows that transport of AIB in mouse brain astrocytes is predominantly independent of Na.

Primary cell suspensions derived from cerebral hemispheres of newborn mice were plated in 35mm collagen-coated plastic dishes and grown to confluence (2-3 weeks) in medium supplemented with 15% fetal calf serum. The monolayer cultures were washed and equilibrated in Tris-buffered (20mM) salts solution (pH 7.0) for 10 min at 34.5°C before addition of ^{14}C-labeled AIB. Na-free solutions were choline-substituted. Na-independent uptake was substantial and consistent in all cultures, whereas Na-dependent uptake was negligible in most batches and variable in a few. The Na-dependent component was not increased by treatment with insulin 0.1 μM and glucagon 0.1 μM or by removal of amino acids for 3 hr before uptake measurement. (Amino acid deprivation and hormone treatment stimulate the ubiquitous A system for neutral amino acid transport; Christensen, Biochim. Biophys. Act. 779: 255,1984).

The initial rate of ^{14}C-AIB uptake in Na-free solution was linear for 20-30 min at 0.2 mM AIB, and for 10 min at 5 mM AIB. A concentration curve was constructed in the range 0.05-10 mM AIB, using 10 min incubations to determine initial rate. These data closely approximate the theoretical curve for a single saturable process with K_m of 5.5 mM and V_{max} of the order of 50 nmol/min/mg protein, similar to the kinetic parameters for Na-dependent uptake found by Stöcklin et al. However, not only were the present kinetic parameters determined in Na-free solution, but ^{14}C-AIB uptake (0.2-5 mM AIB) was 90% inhibited by 2-aminobicyclo[2,2,1]heptane-2-carboxylic acid (BCH, 10 mM), a selective inhibitor of Na-independent L systems. Uptake appeared unusually concentrative for an L system. An astrocyte culture with a cell water content not exceeding 0.5 μL was able to clear 10 μL of incubation solution (0.2 mM AIB) in 10 min. Whether the marked contrast with the results of Stöcklin et al. is based on differences in species, cell type or conditions of culture and uptake remains to be determined. (Supported by MIH grant ES03928).

377.2 ADENOSINE UPTAKE BY LRM55 ASTROGLIAL CELL. W. Shain and V. Madelian. Lab. of Neurotoxicology & Nervous System Disorders, Wadsworth Center for Labs and Research, New York State Department of Health, Albany, NY 12201.

Neurons and glia respond to exogenously applied adenosine. We have previously demonstrated that stimulation of adenosine receptors on LRM55 astroglial cells results in activation of adenylate cyclase and subsequent release of taurine. Analysis of intracellular adenine nucleotides after long-term exposure of cells to adenosine (=>30 min) indicated a significant accumulation of adenosine. Examination of the kinetics of adenosine uptake into LRM55 astroglial cells revealed that the apparent Michaelis constant (K_m) for uptake decreased with the length of exposure to adenosine (K_m > 1200 uM at 0.5 min, = 254 uM at 10 min, = 46 uM at 30 min). Adenosine uptake was independent of adenine uptake since at equimolar concentrations adenine did not inhibit adenosine uptake. When tested at equimolar concentrations adenosine uptake was not significantly inhibited by other nucleosides (thymidine, uridine, inosine, guanidine, and hypoxanthine). However, equimolar concentrations of AMP, ADP, and ATP inhibited uptake by approximately 30%. cAMP did not inhibit uptake. Of the adenosine receptor analogs tested, only cyclopentyl-, cyclohexyl-, and chloro-adenosine significantly inhibited uptake. This inhibition was dose-dependent but inhibition at equimolar concentrations did not exceed 30%. Uptake was inhibited by the adenosine uptake inhibitors dipyridamole (EC_{50} = 5 uM) and papaverine (EC_{45} = 100 uM). The phosphodiesterase inhibitors RO 20-1724 and isobutylmethylxanthine (IBMX) did not inhibit uptake. Since IBMX is also an adenosine receptor antagonist, the latter result indicates a differential selectivity of adenosine receptors and the recognition site for the uptake process. Adenosine uptake was not effected by changes in extracellular Na^+ concentrations. Thus, while adenosine uptake in LRM55 astroglial cells appears to be kinetically different from that reported in synaptosomes, inhibition of uptake by dipyridamole and papaverine is similar to that in synaptosomes. This work was partially supported by grants NS21219 and AA07155.

377.3 **STUDIES ON ASTROGLIAL BINDING OF A POTENT NATURAL MITOGEN: EPIDERMAL GROWTH FACTOR.** K. Huff, L. Ibric*, and L. Schultz*. Neurology Research Labs, Childrens Hospital of Los Angeles, Univ. of Southern California School of Medicine, Los Angeles, CA, 90027.

Astrocytes proliferate as a part of normal brain development, many disease processes such as infection, stroke, and trauma, and neoplastic transformation in gliomas. Epidermal Growth Factor (EGF) is a proliferation signal, is transcribed from an highly conserved base sequence involved in specification of nervous system ontogenic cell lineage, is found immunohistologically in the brain, and is a ligand for a receptor which is the product of a proto-oncogene highly expressed in gliomas. We have studied the response of astrocytes in tissue culture to EGF and demonstrated stability despite several weeks in culture witnout serum, but changes occur with culture density, and with basic fibroblast growth factor (FGF) pretreatment but not dibutaryl cAMP pretreatment. We have further studied the transduction of the EGF signal by means of binding studies using 125-Iodine- labelled EGF.

Astrocytes have a single type high affinity binding site for EGF with a dissociation constant (Kd) of 2.0 x 10-9 not competed for by FGF, Nerve Growth Factor (NGF), or Multiplication Stimulating Activity (MSA II). In a competitive binding assay, insulin at 1 microgram/ml concentration and triiodothyronine (T3) and thyroxine (T4) may have slightly enhanced EGF binding, although at a lower concentration (50 ng/ml) insulin did not show this effect. Lowering the assay temperature increased the number of binding sites. Binding in meningeal cells, apparently similar to fibroblasts, and in C3H 10T1/2 cells, a fibroblast line, was significantly less than astrocyte-EGF binding in our culture conditions. Pretreatment of the astrocytes with lectins concanavalin A and phytohemagglutinin increased EGF binding in a dose dependent way. Pretreatment with Vicia villosa and tunicamycin reduced EGF binding. FGF caused a 70% reduction in specific EGF binding when the cells were pretreated for 18 hours and this inhibition was not duplicated by NGF, Insulin, MSA II, T3, T4, or dexamethasone pretreatment and was FGF dose dependent. The FGF-induced EGF binding inhibition was not as great as EGF down regulation however. This binding inhibition remained at the same ratio at either high or low temperature.

Our data is in support of specific saturable EGF binding sites on astrocytes with little likelihood of fibroblast contamination influencing the culture results. Temperature effects may suggest receptor internal processing. The lectin and tunicamycin effects may imply a glycosylated region of the receptor containing N-acetyl glucosamine and galactoseamine residues. Insulin may be affecting EGF binding through a steric interaction on the cell surface. FGF pretreatment may be producing a heterologous down regulation of the EGF receptor.

377.4 LOCALIZATION OF OUABAIN BINDING SITES IN RABBIT CEREBRAL CORTEX AND HIPPOCAMPUS BY QUANTITATIVE AUTORADIOGRAPHY. M.C. Antonelli*, W.R. Anderson*, D.G. Baskin and W.L. Stahl. V.A. Medical Center and University of Washington School of Medicine, Seattle, WA 98108.

The role of different isoenzymic forms of the Na,K-ATPase in potassium homeostasis during normal development and in neurological disorders remains controversial. Two forms of the enzyme, with different affinities for ouabain, have been identified by biochemical studies and each may function more effectively at different concentrations of K^+ in the extracellular space. However, relatively little is known about regional and cellular distribution and in situ characteristics of these Na,K-ATPases in nervous tissue. The aim of the present study is to establish distribution and ouabain binding characteristics of Na,K-ATPases in brain by quantitative autoradiography (QAR). Quantitative analysis of ouabain binding was done with a microcomputer digital imaging system. For these studies 10 µm cryostat sections were incubated from 4°C to 37°C. Superior autoradiographs were obtained by longer incubations of tissue sections at low temperature and by addition of EDTA to incubation media; both may minimize endogenous protease activity. Maximum binding was achieved within four days at 4°C and within 1.5 hr at 26°C. Maximum binding of [^{3}H]-ouabain to high affinity sites was stimulated in the presence of a) Mg^{2+},P_i or b) Na^+, Mg^{2+} and ATP(nucleotide conditions) and binding was inhibited by N-ethylmaleimide and erythrosin B. High affinity binding (Kd 100nM) was completely blocked under nucleotide conditions by less than 1 mM K^+ and at [^{3}H]-ouabain concentrations of 1-500 nM non-specific binding was nil.

QAR measurements in cerebral cortex showed that the highest concentration of high affinity ouabain binding sites was found in the pyramidal/granular layers, laminae known to have the highest Na,K-ATPase activity in cerebral cortex by both biochemical and histochemical methods (Stahl, Neurochem. Int. 8:449-476, 1986). On the other hand a relatively uniform distribution of high affinity ouabain binding sites was found in adult rabbit hippocampus, a result which differs from histochemical studies. An examination of the distribution and properties of both high and low affinity ouabain binding sites in regions of the hippocampus may help to resolve this apparent discrepancy and to delineate the role of different forms of the Na,K-ATPase in K^+ homeostasis. (Supported by the Veterans Administration and NIH grant NS 20482; M.C.A. was supported by a fellowship from CONICET, Argentina)

377.5 DIFFERENTIATION OF CULTURED RAT ASTROCYTES: EFFECTS OF GROWTH CONDITIONS. E.T. Browning, D.U. Panek*, S.E. Farinelli*, and W.J. Nicklas (SPON: H.E Lowndes) Depts. of Pharmacology and Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

During the past several years it has become possible to obtain nearly pure cultures of astrocytes from neonatal rodent brain as determined by the presence in nearly every cell of the astrocytic marker, glial fibrillary acidic protein (GFAP) (McCarthy and deVellis, J. Cyc. Nuc. Res., 4:15-26,1978; J. Cell Biol, 85:890-902, 1980). Monoamine oxidase-B (MAO-B) and glutamine synthetase (GS), two enzymes that reflect specialized astrocytic functions, are enriched in astrocytes of brain tissue. By culturing in basal medium Eagle (BME) containing Hank's salts we have obtained monolayer cultures which are virtually exclusively flat, tightly adherent cells bearing few if any processes and which express GFAP. Examination of these cultures for MAO-B and GS revealed very low levels of activity, approximately 10-20% of those of adult rat brain. Transfer of such cultures to Dulbecco's modified Eagle's medium (DMEM) at the time of subculture resulted in increases in MAO-B and GS activity of 20- and 10-fold, respectively. Culture in DMEM from the outset resulted in similarly increased activities of MAO-B and GS. These activities were comparable to or exceeded those of adult rat brain. In addition, the cultures grown in DMEM throughout contained cells expressing an increased variety of morphologies essentially all of which were positive for GFAP by immunofluorescence. Of the several differences in composition between these two media, increased bicarbonate concentration and the associated elevation of pH was a major factor producing increased specific activities of MAO-B and GS. Cultures grown in DMEM accumulated cellular protein more rapidly than did those grown in BME of comparable bicarbonate concentration. DMEM grown cultures continued to increase their specific activities of MAO-B for up to 60 days in culture to levels approximately 4-fold higher than adult rat brain. Treatment of such cultures with dibutyryl cAMP produced a further doubling of MAO-B activity. These observations suggest that growth conditions play a substantial role in determining the state of differentiation of astrocytes in culture and that monitoring the presence of macromolecules associated with specialized functions in addition to monitoring GFAP is important in characterizing astrocytic cultures. (Supported by NSF Grant BNS 84-06889 and USPHS Grant NS 17360).

377.6 **METABOLISM OF MPTP AND SEVERAL ANALOGS BY CULTURED ASTROCYTES.** D.U. Panek*, E.T. Browning, P.K. Sonsalla and R.E. Heikkila, Depts. of Pharmacology and Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) produces a selective destruction of the dopaminergic cells of the substantia nigra in primates and mice resulting in a syndrome which resembles Parkinson's disease. A necessary step in the toxicity of MPTP is its biotransformation by monoamine oxidase-B (MAO-B) to a dihydropyridinium intermediate ($MPDP^+$) which is further oxidized to the pyridinium species (MPP^+). Since only MAO-A has been found within dopaminergic neurons, the bioactivation of MPTP by MAO-B is thought to occur outside of the neuron, perhaps in astrocytes. The purpose of the present studies was to investigate the metabolism of MPTP and several MPTP analogs by MAO within cultured astrocytes. Most recent work has focused on the formation only of the more stable MPP^+. However, we have utilized reverse phase HPLC with diode-array UV detection to measure the levels of both $MPDP^+$ and MPP^+ produced by astrocytes.

Astrocytes were obtained from 1 to 3 day old rat cortex and grown in Dulbecco's modified Eagle's medium. Cultures were passed once at 10-14 days and assayed 4 to 8 weeks later. Intact cell cultures expressed about 8 fold higher MAO-B than MAO-A activity when using [^{14}C]-benzylamine and [^{3}H]-serotonin as substrates. Five cm^2 cultures were incubated with various concentrations of MPTP in a bicarbonate buffered balanced salt solution for 2 hours, the medium was acidified and analyzed by HPLC. Greater than 95% of the total $MPDP^+$ and MPP^+ formed was measured in the medium. Preincubation for 20 min with 0.1 µM deprenyl, a concentration selective for inhibiting MAO-B, almost completely blocked the metabolism of MPTP. In contrast, preincubation with 0.1 µM clorgyline, a concentration selective for inhibiting MAO-A, had no significant effect. When cultures were similarly incubated with 2'methyl-MPTP, an analog which has greater dopaminergic neurotoxicity than MPTP in mice, the 2'methyl-$MPDP^+$ and 2'methyl-MPP^+ metabolites were formed. The metabolism of 2'methyl-MPTP was blocked partially by preincubation with either deprenyl or clorgyline. Complete inhibition was observed only in the presence of both inhibitors. The metabolism of other MPTP-analogs will be presented. These data demonstrate that intact astrocytes convert MPTP to $MPDP^+$ primarily via MAO-B but that both forms of the enzyme are involved in the metabolism of 2'methyl-MPTP. Furthermore, the metabolites were almost exclusively present in the surrounding medium. These findings support a role for astrocytes in the neurotoxicity of MPTP-like substances. (Supported by NSF grant BNS 84-06889 and NIH grant NS21752.)

377.7 GLUCOCORTICOIDS REGULATE THE CONCENTRATION OF GLIAL FIBRILLARY ACIDIC PROTEIN IN THE RAT CNS. J.P. O'Callaghan[1], R.E. Brinton[2], M.D. Browning[3] and B.S. McEwen[2]. U.S. Environmental Protection Agency, Research Triangle Park, NC 27711[1] and Laboratories of Neuroendocrinology[2] and Molecular and Cellular Neuroscience[3], The Rockefeller University, New York, NY 10021.

The molecular basis for steroid action in brain appears to involve an alteration in the synthesis of specific proteins, many of which are localized to specific neuronal or glial cell types. One cell-type specific protein in brain that appears to be subject to glucocorticoid control is glial fibrillary acidic protein (GFAP), the major intermediate filament protein of astrocytes. Previously, we reported that the concentration of GFAP in hippocampus (HIP) and cortex (CTX) was affected by exogenous corticosterone (CORT) and adrenalectomy (ADX) (O'Callaghan and Miller, Neurosci Abs. 12: 1282, 1986). We now report the time course of these effects in various regions of the CNS. In addition, CORT supplements were used to assess reversibility of ADX effects on GFAP. Finally, other key nervous system proteins were assayed to determine the generality of the observed effects on GFAP.

Adult male rats were treated with CORT (50 mg/kg/day) for 12 days, adrenalectomized or adrenalectomized and given CORT supplements (50 mg/kg/day). GFAP and other CNS proteins were assayed by solid-phase RIA (Brock and O'Callaghan, J. Neurosci. 7:931, 1987). Twenty-four hours after the last dose of CORT, the concentration of GFAP was decreased by 15-25% in HIP, CTX, striatum, hypothalamus and cerebellum in comparison to vehicle controls. In all regions, GFAP values returned to control levels by 3 weeks post-CORT. In contrast to these results, ADX caused a time-dependent increase in the concentration of GFAP; by 3 weeks post ADX increases of 44% and 58% over intact controls were observed in HIP and CTX, respectively. Daily CORT supplements following ADX reduced GFAP to below control values after 5 days. In rats receiving CORT alone, ADX alone or ADX plus CORT, the concentration of the following proteins did not differ from corresponding controls in any brain region: the neurofilament triplet protein, NF-200; the microfilament protein, actin; the microtubule protein, tubulin; and the synaptic vesicle proteins, synapsin I and p38. The data indicate that the astrocyte protein, GFAP, is under extrinsic control of the adrenal gland. Because this phenomena is observed throughout the CNS and does not appear to involve major neuron-specific proteins, it is most likely mediated through low-affinity type II steroid receptors present in glial cells.

377.8 EFFECTS OF EXTRACELLULAR POTASSIUM ON DNA SYNTHESIS AND GLIAL FIBRILLARY ACIDIC PROTEIN EXPRESSION IN CULTURED NORMAL GLIAL CELLS. K. S. Canady*, F. Ali-Osman*, E. W Rubel (SPON: D. Durham). Departments of Physiology and Biophysics, Neurological Surgery and Otolaryngology, University of Washington School of Medicine, Seattle, WA 98195.

Astroglia are thought to play an important role in the regulation of neuronal excitability by buffering against acute fluctuations in extracellular potassium (K^+) levels. Gliosis, characterized by increased glial proliferation and expression of glial fibrillary acidic protein (GFAP), has been observed in injured and epileptic brain. It has been hypothesized that gliosis is a direct result of the high levels of extracellular K^+ associated with these conditions. In the present study, we examine the effects of varying K^+ levels on synthesis of DNA and protein and on expression of GFAP in cultured glial cells.

Glial cells from the cerebrum and brain stem of 4-day old hatchling chicks were grown in monolayers. Synthesis of DNA and protein was determined by measuring the incorporation of ^{3}H-thymidine and ^{3}H-leucine into cellular DNA and protein, respectively. Cells were plated at a previously determined optimum density in 96-well microtiter plates and treated with potassium chloride (KCl) to achieve final K^+ concentrations of 5-75 mM. After 24-48 hours at 37 °C, cells were treated with ^{3}H-thymidine or ^{3}H-leucine for an additional 24 hours. Cells were then harvested and prepared for liquid scintillation counting. To study the effects of K^+ on GFAP expression, cells were plated on glass slides in medium containing 5-75 mM KCl over 24-72 hours, fixed in cold acetone and processed for immunocytochemistry.

Preliminary results suggest that both ^{3}H-thymidine uptake and GFAP-like immunoreactivity increase in cultured glial cells with higher concentrations of extracellular K^+. These effects are a function of both the K^+ concentration and the duration of exposure of the cells to K^+. We conclude that extracellular K^+ levels may play a key role in the glial reaction observed *in vivo* in conditions of neuronal injury or altered activity levels. Supported by PHS grants NS24522 and GM07108.

377.9 **ASPARTATE AMINOTRANSFERASE PLAYS A SUBSTANTIAL ROLE IN THE OXIDATION OF EXOGENOUS GLUTAMATE IN RAT CORTICAL ASTROCYTE CULTURES.** S.E. Farinelli* and W.J. Nicklas (Spon. C. VanderWende) Dept. of Neurology, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ 08854.

In addition to their ability to convert glutamate (GLU) to glutamine (GLN) via GLN synthetase (GS), astrocytes metabolize a portion of GLU to 2-oxoglutarate (2-OG) which is subsequently decarboxylated in the citric acid cycle. The present study has been undertaken to determine the relative roles of the enzymes aspartate aminotransferase (AAT) and GLU dehydrogenase (GDH) in the formation of 2-OG from GLU in the astrocyte. Primary astrocyte cultures were prepared essentially according to the method of McCarthy and de Vellis. Following elimination of overlying neurons and oligodendrocytes, the astrocytes were replated at a confluent density onto 25 mm poly-L-lysine coated coverslips and studied within one week. Greater than 95% of the cells in culture stained positively for the astrocytic marker protein, GFA. At this time, the activity of the astrocyte specific enzyme GS was > 60% found in adult rat brain.

To measure GLU oxidation, astrocytes were incubated at 37° in Dulbecco's Modified Eagle's Medium in an airtight apparatus under an atmosphere of 95% O_2/5% CO_2. Thirty minutes after the injection of 50 μM [1-^{14}C]-GLU (1 $\mu C_i/\mu$mole), the medium was acidified with perchloric acid and the liberated $^{14}CO_2$ trapped in a well containing phenethylamine. Because C_1 is the only carbon which is labeled in the GLU, any $^{14}CO_2$ production comes only from the decarboxylation of 2-OG by 2-OG dehydrogenase or from the decarboxylation of GLU by GLU decarboxylase. Since the inclusion of 20 μM rotenone in the assay medium inhibits $^{14}CO_2$ production by >90%, $^{14}CO_2$ production from [1-^{14}C]-GLU can safely be used as an indicator of GLU flux into the citric acid cycle via 2-OG. Addition of the transaminase inhibitors aminooxyacetic acid (0.5-5.0mM) or β-methylene-D,L-aspartate (0.5-5.0mM) to the incubation medium inhibits $^{14}CO_2$ production from GLU by 60-70% suggesting a major role for the transamination pathway. Substantial GDH activity was present in the astrocytes (50% adult rat brain). Previous studies by others indicated that astrocyte cultures prepared from mouse brain appeared to metabolize exogenous GLU solely via GDH even though those cells had substantial AAT activity [Yu, et al.,J. Neurochem.,39:954-960 (1982)].

The data strongly indicate that in rat cortical astrocyte culture, a substantial portion (up to 70%) of 2-OG production from GLU is mediated by the transamination reaction via AAT. This suggests that GLU oxidation by GDH would at most represent 30-40% of the flux from GLU into the citric acid cycle. (Supported in part by USPS grants NS 17360 and NS 21469).

377.10 BRAIN LIPOPROTEINS AND APOLIPOPROTEIN B,E(LDL) RECEPTORS MAY PROVIDE A MECHANISM TO MAINTAIN CHOLESTEROL HOMEOSTASIS IN THE CENTRAL NERVOUS SYSTEM. R.E. Pitas*, J.K. Boyles*, K.H. Weisgraber*, D. Hui*, and R.W. Mahley* (SPON: Y.M. Yao). Gladstone Foundation Laboratories, Univ. of California, San Francisco, CA 94140-0608

The brain of adult mammals derives cholesterol both from de novo synthesis and from the blood, through the blood-brain barrier. Since no net accumulation of cholesterol occurs in the brain, the CNS must have efficient mechanisms to transport cholesterol and maintain cholesterol homeostasis. In plasma these functions are performed by lipoproteins and lipoprotein-receptor interactions. We have previously demonstrated that apolipoprotein (apo-) E is secreted by astrocytes of the brain, and Roheim et al. (Proc. Natl. Acad. Sci. USA [1979] 76, 4646-4649) reported that apo-E is present in cerebrospinal fluid (CSF). Apolipoprotein E-containing lipoproteins are known to interact with apo-B,E(LDL) receptors on cells and to regulate intracellular cholesterol synthesis. The current study was undertaken to determine whether apo-E-containing lipoproteins could provide a mechanism for lipid transport and cholesterol homeostasis within the CNS.

To investigate the mechanism of lipid transport and cholesterol homeostasis within the CNS, the lipoproteins in human and canine CSF were characterized and brain tissue was examined for the presence of apo-B,E(LDL) receptors. Apolipoprotein E (synthesized in the brain) and apo-A-I (a plasma protein not synthesized in the brain) were present in human and canine CSF. Both apolipoproteins are complexed with cholesterol and phospholipid. These lipoproteins had a density of ~1.09 to 1.15 g/ml. In human CSF, the lipoproteins were primarily spherical (~140 A), whereas in canine CSF the lipoproteins were a mixture of discs (200 x 65 A) and spheres (~130 A). The apo-E and apo-A-I in CSF were present on separate populations of lipoproteins in both species. Although the apo-E of CSF was more highly sialylated than plasma apo-E, the apo-E-containing lipoproteins in canine CSF bound to apo-B,E(LDL) receptors with the same affinity as plasma apo-E, as demonstrated by their competition for binding of ^{125}I-LDL to the apo-B,E(LDL) receptors on human fibroblasts. The presence of apo-B,E(LDL) receptors in both rat and monkey brain was demonstrated by immunocytochemistry. Astrocytes abutting on the arachnoid space and pial cells of the arachnoid itself, both of which contact CSF, expressed apo-B,E(LDL) receptors. Relatively few receptors were present in the cells of the grey matter of the cortex. Receptors were more prominent on the astrocytes of white matter and in the cells of the brain stem. Expression of apo-B,E(LDL) receptors by brain cells and the presence of lipoproteins in CSF suggest that the mechanism for lipid transport and cholesterol homeostasis in the CNS is similar to that in other tissues.

377.11 TIME-COURSE OF IN SITU PROTEOLYSIS OF GLIAL FIBRILLARY ACIDIC PROTEIN FOLLOWING TRIMETHYLTIN-INDUCED DAMAGE OF THE RAT CNS. [1]D.M. Niedzwiecki and J.P. O'Callaghan (Spon.: F.E. Gregory). Neurotoxicology Division, Health Efffects Research Laboratory, U.S. Environmental Protection Agency, Research Triangle Park, NC 27711.

Physical or chemical-induced damage of the central nervous system results in complex cellular responses at the site of injury, one of which is proliferation and hypertrophy of astrocytes. Previously, we demonstrated that the temporal and regional patterns of astrocytic response to chemical-induced injury can be characterized by measuring glial fibrillary acidic protein (GFAP), the major intermediate filament protein of astrocytes (J. Neurosci. 7: 931, 1987). Using the neurotoxic organometal, trimethyltin (TMT), to produce consistent region-specific damage to the adult CNS, we found large dose-dependent increases in GFAP that declined over several months time. Because in situ proteolysis may play a dominant role in the degradation of glial as well as neuronal filaments following injury, the present study examined in situ proteolysis of GFAP following exposure to TMT. Total GFAP immunoreactivity was determined by RIA. Degradation of GFAP was assessed by immunoblot analysis. Light microscopy and RIA of the synaptic vesicle protein, synapsin I were used to monitor neuronal loss following TMT.

Adult male LE rats were killed 4, 7, 14, 21, or 35 days after administration of a single 8 mg/kg (i.v.) dose of TMT or saline vehicle. Hippocampus (HIP), entorhinal cortex (EC) and striatum (ST) were rapidly dissected and homogenized in 95°C 1% SDS or in buffer containing a protease inhibitor cocktail. The latter samples were used to prepare a total particulate fraction and a 150,000 x g supernatant fraction. Samples from TMT-treated rats showed large (150-350%), time-dependent increases in the concentration of GFAP in all regions. In HIP and EC GFAP was elevated at 4 days post TMT, a time point corresponding to the early phases of neuronal damage in these regions. Increases in GFAP in ST were smaller than those in HIP and EC and did not appear until 14 days post TMT, findings consistent with the small degree of neuron damage in this region. Maximal increases in GFAP were observed in HIP, EC and ST by 21 days post TMT. In all preparations, samples obtained from saline treated rats showed only a single 50 K band corresponding to native GFAP. In HIP and EC from TMT-treated rats GFAP-immunoreactive breakdown products were not observed until 2 weeks post dosing, with most fragments appearing in the supernatant fraction. TMT induced increases in GFAP concentration in ST did not result in the appearence of GFAP-immunoreactive breakdown products. The data indicate that injury-induced increases in GFAP do not coincide with the appearance of proteolytic fragments of this protein. In situ proteolysis of GFAP may not be involved in the initiation of glial response to injury but may play a physiological role in the degradation of glial filaments. ([1]NRC Associate)

377.12 ALTERATIONS OF ASTROCYTE MORPHOLOGY AND PROTEIN EXPRESSION IN RAT OPTIC NERVE AFTER CRUSH. G. Stoll* and H.W. Müller (SPON: H.J. Freund). Molecular Neurobiol. Lab., Depart. of Neurology, University of Düsseldorf, F.R.G.

Crushing rat optic nerve (ON) induces a sequence of distinct changes in astroglial morphology and the expression of specific proteins. At the molecular level one of the most prominent effects following ON injury was the rapid disappearance of apolipoprotein E (apo E) from GFAP-positive astroglial cell bodies within 3 days post crush as revealed by immunocytochemical methods (Stoll and Müller, Neurosci.Lett.72:233,1986). Simultaneously, typical reactive astrocyte morphology was expressed and maintained for several weeks in degenerating ON. During this period of time no significant myelin phagocytosis and degradation could be observed. However, between 6 to 8 weeks after lesion the morphology of the GFAP-positive astrocytes was markedly altered by retraction of processes and rounding of the cell body. Numerous intracellular vesicles and myelin inclusions appeared indicating phagocytic activity. Despite these morphological changes into "giant phagocytes" the astroglial marker GFAP (glial fibrillary acid protein was continuosly exprssed within these cells. When acquiring phagocytic properties. however, the astrocytes additionally expressed macrophage-specific antigens. Our results demonstrate molecular, physiological and structural properties shared by astrocytes in the injured ON and macrophages of the immune system indicating significant astroglial plasticity in response to central nervous system injury. Supported by the Deutsche Forschungsgemeinschaft SFB 2oo (C6 and B5)

377.13 HEIGHTENED EXPRESSION OF AN ASTROCYTIC PROTEIN FOLLOWING SPINAL CORD INJURY. S. K. Malhotra[1]*, R. Predy[2], R. Singh[1] and G.D. Das[3]. Departments of Zoology[1] and Pathology[2], University of Alberta, Edmonton, Alberta T6G 2E9, Canada, and Department of Biological Sciences[3], Purdue University, West Lafayette, Indiana.

We are involved in investigations on the role of astrocytes in wound healing following injury to the central nervous system (CNS) and demonstrate that following a laceration-type lesion of the rat spinal cord, the expression of an astrocytic protein (J1-31 antigen) is greatly enhanced in the region of the wound relative to that in the adjacent uninjured region. For this study, laceration-type surgical lesions were made at the mid-lumbar level in spinal cords of Long Evans hooded rats. At intervals following surgery the spinal cords were fixed and the wound site was examined using Golgi-Cox preparations and by immunofluorescence microscopy using antiserum to glial fibrillary acidic protein (GFAP, 50KD), the well-known "marker" for astrocytes. (GFAP is the principal constituent of intermediate filaments in astrocytes.) In addition, we employed a monoclonal antibody (MAb J1-31) which recognizes a protein (J1-31 antigen) of 30KD under reducing conditions for SDS gel electrophoresis (Singh et al., BioSci. Reports, 6:73, 1986). The hybridoma secreting MAb J1-31 was raised using homogenized plaque regions from a multiple sclerosis patient (autopsy sample, Malhotra et al., Microbios. Lett., 26:151, 1984). MAb J1-31 immunostains GFAP positive cells in the CNS (human and rat), but it does not cross-react with GFAP. Also there is evidence that MAb J1-31 does not cross-react with vimentin, another of the intermediate filament core proteins. We have been unable to detect fluorescent staining due to MAb J1-31 outside the CNS or during prenatal CNS development of the rat when vimetin is known to be abundant (Bovolenta et al., Dev. Biol., 102:248, 1984). J1-31 antigen (30KD) appears to be associated with the intermediate filaments of astrocytes as determined by immunoelectron microscopy. Double-label immunofluorescence microscopy performed six months following laceration-type surgical lesion shows that J1-31 antigen is abundant in the region of the glial scar whereas it is barely detectable in the adjacent uninjured region. This enhanced expression may be related to the abundance of intermediate filaments in the reactive astrocytes (Maxwell and Kruger, J. Cell Biol. 25:141, 1965). (Supported by grants awarded by the M.S.I. Foundation and the National Sciences Engineering Research Council of Canada).

377.14 THE GLIAL REACTION IN THE RAT FACIAL NUCLEUS FOLLOWING SELECTIVE NEURONAL DEGENERATION INDUCED BY TOXIC RICIN IN COMPARISON WITH NERVE CRUSH LESIONS. W.J. Streit* and G.W. Kreutzberg. Dept. of Neuromorphology, Max Planck Institute of Psychiatry, D-8033 Martinsried n. Munich, F.R.G. (SPON: M. Reddington)

Following transection of the rat facial nerve, a profound glial reaction characterized by rapid proliferation of microglial cells and a gradual increase in GFAP immunoreactivity of fibrous astrocytes can be observed in the facial nucleus (Streit, W.J. and Kreutzberg, G.W., J. Neurocytol. in press; Graeber, M.B. and Kreutzberg, G.W., J. Neurocytol. 15: 363, 1986). It was shown that resting as well as reactive microglia can be labelled with an α-D-galactose binding lectin-HRP conjugate derived from Griffonia simplicifolia seeds (GSA I-B_4-HRP). The present study was undertaken to examine the glial response after degeneration of facial motor neurons induced by injection of the toxic lectin from Ricinus communis into the facial nerve. Nerve crush lesions were performed on the ricin-injected nerve as well as on the contralateral uninjected side. Within 2-3 days the majority of motor neurons on the ricin-injected side had degenerated, and a conspicuous hypercellularity of non-neuronal cells was apparent. These glial cells were identified by lectin staining to consist for the most part of microglia, and showed high mitotic activity as revealed by the incorporation of tritiated thymidine. By light microscopy the microglial cells were seen to surround dead and dying neurons, often forming clusters of several cells. In the electron microscope enlarged microglia were found to bear the lectin-HRP reaction product on their plasma membrane, and to be actively involved in phagocytosing neuronal debris. In contrast, the contralateral facial nucleus demonstrated no phagocytes, although a similarly high index of dividing microglial cells. Unlike after nerve crush lesions where microglia started to disappear after about 2 weeks, the phagocytic microglia on the ricin-injected side persisted for several weeks. No apparent phagocytic activity of oligodendrocytes was noted. The astrocytic expression of GFAP on the crush side appeared to proceed gradually similar to that described after nerve transection. However, on the ricin-injected side hypertrophic astrocytes displaying thick filament-laden processes were present after 3-4 days where they persisted forming a lasting dense glial scar.

These results show that the expression of GFAP by fibrous astrocytes can be intensified under conditions of neuronal death. Moreover, since no changes in the blood brain barrier could be detected after intravenous injections of HRP, we conclude that resident microglia can be stimulated by neuronal degeneration to transform into macrophages. Thus, our findings do not support the notion that blood-borne macrophages invade the CNS under the experimental conditions employed.

377.15 **INFILTRATION OF MONOCYTES INTO THE DORSAL MOTOR NUCLEUS OF THE VAGUS FOLLOWING AN INTRANEURAL INJECTION OF RICINUS COMMUNIS AGGLUTININ-60 IN RATS.** E.A. Ling and S.K. Leong (Spon : S. Tay). Department of Anatomy, National University of Singapore, Kent Ridge, Singapore 0511.

This study examines the possibility of infiltration of blood monocytes into the dorsal motor nucleus (DMN) of the vagus nerve following an intraneural injection of Ricinus communis agglutinin-60 (RCA-60) in rats. Albino rats ranging between 200-250 gms were each given an intravenous injection of 0.6 ml of carbon suspension of Pelikan India ink (Batch No. C11-1431a) to label the circulating monocytes. The carbon was administered either 4 days before, simultaneously, or 4 days after the administration of 3 ul of RCA-60 in 0.01M phosphate buffer. The RCA-60 was injected into the right vagus nerve at the level where it is crossed by the omohyoid muscle. The animals were all sacrificed by perfusion with 10% neutral formalin 6 days after the injection of RCA-60. The brainstem was then removed, embedded in paraffin and sectioned at 10 um thickness. All sections were stained with Cresyl Fast Violet or Haematoxylin and Eosin.

A variable number of degenerating neurons were observed in the DMN ipsilateral to the side of RCA-60 injection. Destruction of the neurons by the cytotoxic RCA-60 was evidenced by the total vacuolation of their cytoplasm. There was a massive increase in the number of non-neuronal cells when compared with the contralateral DMN. These non-neuronal cells were either closely associated with the blood vessels, the degenerating neuronal somata or in the neuropil. No carbon labelled non-neuronal cells were observed in the DMN in rats given carbon 4 days prior to RCA-60 injection. Occasional labeled cells, however, were observed in rats given RCA-60 and carbon simultaneously. On the other hand, in rats given carbon 4 days after the injection of RCA-60, numerous carbon-labeled cells were observed in the DMN. These carbon-labeled cells were observed in the wall of blood vessels, in the perivascular region or at a satellite position to a degenerating neuron. It is concluded from this study that the non-neuronal carbon-labeled cells in the DMN are derived from circulating monocytes which were earlier labeled by carbon injected intravenously. They could have been attracted by the dying neurons in the DMN killed by the injected RCA-60. It appears that most of the monocytes infiltrated the DMN 4 days after the RCA injection. The absence of carbon-labeled cells in the DMN of rats given carbon prior to RCA injection indicates the complete turnover of carbon-labeled monocytes within the period of 4 days.

NEUROENDOCRINE CONTROLS: PITUITARY VII

378.1 EFFECT OF HEAD-UP TILT ON PLASMA VASOPRESSIN, HEART RATE, AND BLOOD PRESSURE IN ANESTHESIZED RATS. R. Golin*, L. Keil* and W.F. Ganong. Department of Physiology, University of California, San Francisco, CA 94143.

To determine the effect of tilting on vasopressin secretion and the cardiovascular system, male Long Evans rats were anesthetized with inactin to eliminate extraneous stimuli, placed in the supine position, and subjected to 60° head-up tilt for 5 - 30 minutes. Plasma vasopressin increased in a linear fashion with time, from 6.9 ± 3.0 to 17.9 ± 5.9 pg/ml at 5 minutes; from 10.6 ± 2.5 to 28.5 ± 5.3 pg/ml at 15 minutes; and from 7.9 ± 1.3 to 54.2 ± 15.0 pg/ml at 30 minutes. Heart rate tended to increase, but the only statistically significant increase was at 15 min. Blood pressure was variable at 5 and 15 min and there was a decline at 30 min from 93.3 ± 4.0 to 84.6 ± 4.0 mmHg. After bilateral lesions that destroyed 80% or more of both paraventricular nuclei (n=5), tilting produced an increase in plasma vasopressin from 16.8 ± 4.0 to 48.5 ± 11.4 pg/ml in 30 minutes, and there were no significant changes in blood pressure or heart rate. After bilateral vagotomy, 30 minutes of tilting produced an increase in plasma vasopressin from 15.8 ± 2.2 to 30.1 ± 4.3 pg/ml with a significant increase in heart rate and no change in blood pressure. However, after sinoaortic denervation (n=3), plasma vasopressin before tilting was increased to 51.0 ± 8.0, and after 30 minutes of tilting, it fell to 46.3 ± 4.5 pg/ml. In the sinoaortic denervated rats, heart rate did not change and blood pressure fell from 105.8 ± 5.8 to 90.0 ± 8.7 mmHg. The data demonstrates that under these experimental conditions, 60° head-up tilt produces an increase in plasma vasopressin, presumably due to increased vasopressin secretion. The vagally innervated low pressure baroreceptors in the chest play little role in the vasopressin and cardiovascular responses to this stimulus, and they are mediated instead via the arterial baroreceptors in the carotid sinus and aortic arch. The changes in vasopressin secretion occur after lesions of the paraventricular nuclei and hence do not appear to depend on neurons in these nuclei or ascending pathways that end in or pass through them.

Supported by NASA grant NAGW 490, NIH grant HL29714, and NATO.

378.2 BRAIN SEROTONIN DEPLETION ALTERS THE VASOPRESSIN SECRETORY RESPONSE TO OSMOTIC STIMULATION AND THE PLASMA LEVELS OF ANGIOTENSIN II TO HYPOVOLEMIA. M.S. Brownfield, J. Gildner*, J. Greathouse*, J. Armstrong*, and L.D. Van de Kar. Dept. of Comp. Biosci., Univ. of Wisc. Sch. Vet. Med., Madison, WI 53706, and Dept. of Pharmacology, Loyola Univ. Sch. Med., Maywood IL 60153.

We have recently used pharmacological methods to provide evidence for a role for central serotonin (5HT) in stimulating vasopressin secretion in the rat via a 5HT2 receptor mechanism (Fed. Proc. 46:976, 1987). This conclusion was based on the demonstration that 5HT1 agonists were without effect while 5HT2 agonists stimulated plasma vasopressin (pAVP) levels which could be prevented by pretreatment with selective 5HT2 receptor antagonists. That the effect might be due to central mechanisms was suggested by the fact that posterior hypothalamic deafferentation blocked p-chloroamphetamine (a 5HT releaser)-induced increase in pAVP that was seen in sham operated rats.

In order to explore the physiological relevance of these findings we challenged rats with normal saline (NS),hypertonic saline (HS; 2 ml 1000 mosmol/kg per 100 g bw, ip), or polyethylene glycol (PEG; 2 ml 300 mg/ml PEG 6000 per 100 g bw, ip) 12 days following intracerebroventricular injection of vehicle (NS with 0.1% ascorbic acid) or 5,7-dihydroxytryptamine (5,7dHT; 200 ug following pretreatment with desipramine, 25 mg/kg). Rats were killed 30 minutes after challenge. RIA was used to measure pAVP and pAII. HPLC was used to evaluate destruction of 5HT neurons.

Serotonin depletion had no effect on the resting levels of either hormone since there was no significant difference between vehicle-NS and 5,7dHT-NS groups. The effect of osmotic challenge on pAVP was inhibited by brain 5HT depletion ($p<0.05$) while there was no effect on pAII. In contrast PEG-induced volume depletion caused significant increase in pAVP that was not affected by 5HT depletion. However, 5HT depletion caused a significant increase ($p<0.05$) in the pAII response to hypovolemia.

These studies suggest that brain 5HT neurons are involved in the osmotic regulation of pAVP by stimulating secretion, but not in its volume regulation. Conversely, a central serotoninergic mechanism appears to play a restrain-ing influence on the volume regulation of pAII.

378.3 AGING AND WATER DEPRIVATION ALTER VASOPRESSIN CONTENT IN LYMPHOID TISSUE AND GUT. Paul F. Aravich*, William F. Silverman, Celia D. Sladek, Suzanne Y. Felten, David L. Felten and John R. Sladek, Jr. Dept. Neurobiology and Anatomy, Univ. of Rochester Med. School, Rochester, NY 14642. (SPON: W. M. Williams).

There is great interest in the effects of aging on various regulatory systems, including those related to the immune system. While vaspopressin (VP) and oxytocin (OT) are the classic hormones of the hypothalamo-neurohypophysial system (HNS), recent evidence suggests that they may be produced in at least 16 other locations, including the thymus and the gut (Endoc Revs '86 7:449; Anat Rec '86 214:5A; Histochem '86 84:401). We now report that aging and water deprivation exert independent and differential effects upon the VP content of certain lymphoid tissues and the gut.

The subjects were young adult (4 mo old), middle aged (i.e., 15 mo) and elderly (25 mo old) male Fischer-344 rats given free access to water or subjected to 72-hrs of water deprivation. Following sacrifice, tissues were collected, analyzed via a specific RIA and saved for immunocytochemical examination. It was found that, relative to protein content, thymic VP content was independently increased by both aging ($p=.047$) and water deprivation ($p=.028$). Thus young adult rats or nondeprived rats had less VP than the older rats or water deprived rats. Because thymic VP expression has been shown to be influenced by the mineralocorticoids but not by the glucocorticoids, the water deprivation effect may be related to aldosterone abnormalities. When thymic VP content was expressed relative to wet weight or relative to the entire gland, VP content also was increased by deprivation ($p<.003$), though age effects no longer occurred. Because of the presence of VP in the thymus, mesenteric lymph nodes were examined. We found that not only is VP-like immunoreactivity present in lymph nodes, but that aging markedly ($p<.001$) reduces its expression. Finally, aging reduced ($p<.001$) the VP-like content of the fundus, which was increased ($p=.039$) by water deprivation. Immunocytochemical examination of the various tissues is in progress, as is an assessment of the effects of the independent variables on OT content.

Vasopressin, like various other peptides, has now been demonstrated to be produced by neural, endocrine and immune tissues. As with many of these peptides, VP exerts specific effects on the immune sytem. Hence, the functional consequences of the aging and water deprivation alterations reported here must be assessed. In view of our recent demonstration that nutrition and exercise exert region specific effects on central VP systems, the impact of various life style factors on the VP content of these peripheral tissues also should be evaluated.

378.4 BIOCHEMICAL INDICES OF OXYTOCIN AND VASOPRESSIN FUNCTION IN AGED FISHER RATS. W.F. Silverman, P.A. Aravich*, M. Gallagher*, J.R. Sladek, Jr. and C.D. Sladek, Depts. of Neurobiology & Anatomy and Neurology, University of Rochester School of Medicine and Dentistry, Rochester, N.Y. 14642.

Significant differences exist among investigators with regard to the fate of the classical neurohormone arginine-vasopressin (AVP) during senescence in rodents. Most previous studies have examined basal plasma levels of this peptide, and increased (Fliers and Swaab, Peptides 4:77, 1983), decreased (Zbuzek and Wu, Exp. Gerontol. 17:133) and unchanged levels (Sladek et al., Peptides 1:141) have all been reported. Sladek et al., in addition, reported that plasma AVP levels from 30 month old Fisher rats were lower than young controls following 72 hours of water deprivation, a known stimulus for AVP release from the neurohypophysis. The present study examined AVP as well as OXY levels in serum and posterior pituitary under basal and stimulated conditions in Fisher 344 male rats. 4 and 25 month old subjects were housed in metabolic cages and provided food and water *ad libitum*.. Animals in the stimulated group were deprived of water for 72 hours prior to sacrifice. Serum was collected from trunk blood and AVP and OXY extracted following the method of Robertson et al. (J. Clin. Invest. 52:2340, 1973). Also, posterior pituitaries were removed, weighed, homogenized in acetic acid and centrifuged to provide samples for AVP and OXY RIA. The RIA procedure and the antisera used have been previously described (Sladek et al., Am J. Physiol. 250:H443).

Measurement of plasma osmolality and hematocrit indicated a consistant degree of water deprivation stress was present in both age groups ($p<0.01$ and $p< 0.004$ respectively). Serum AVP in the aged rats showed no statistically significant change with respect to young controls under either basal or stimulated conditions. Vasopressin concentrations in the neurohypophysis, however, were reduced ($p<0.04$) relative to their 5 month old counterparts. In contrast, serum OXY levels were significantly higher in the aged subjects ($p<0.04$) compared to 4 month old rats, though no changes were observed in the neurohypophyseal concentrations. The latter finding suggests that clearance of OXY at the level of the kidney tubules is affected in aging rather than central regulatory mechanisms.

378.5 VASOPRESSIN SECRETION IN AGED RATS: WATER BALANCE AND URINARY VASOPRESSIN MEASUREMENT IN SPRAGUE-DAWLEY AND FISCHER 344 STRAINS. C.J. Phelps, S.W. Carlson*, M.J. Gallagher*, and C.D. Sladek. Departments of Neurobiology and Anatomy and of Neurology, University of Rochester School of Medicine, Rochester, NY 14642

In order to provide physiological baseline values for future experimental procedures, indices of vasopressin secretion were assessed in male Sprague-Dawley and Fischer 344 rats 3 and 20 months of age housed in metabolic cages with food and water ad lib. Daily water intake, urine volume, urine osmolality, and urine vasopressin (VP) levels were measured. Urine samples were prepared for radioimmunoassay (RIA) using a modification of the acetone-ether extraction method of Robertson et al. (J. Clin. Invest. 52:2340, 1973). The RIA for VP was adapted from that developed for tissue determination, using an antiserum produced in conjunction with Arnel Laboratories (Sladek et al., Amer. J. Physiol. 250:H442, 1986); the assay has a sensitivity of 1.0 pg, and oxytocin crossreactivity of 0.02%. Assay aliquots of 50 to 300 ul were adequate for VP detection. Values for individual Sprague-Dawley rats showed similar baseline urinary VP, after housing acclimation (2-9 days), for 30 to 50 days. Sample means over time, with standard errors based on n samples:

	Urine VP Conc. (pg/ml)	24 hr VP Excretion (pg)
rat #4, 20 m.o. (n=10)	8.5 ± 1.1	101.5 ± 17.5
rat #5, 20 m.o. (n=17)	7.9 ± 0.8	214.3 ± 24.4
rat #7, 3 m.o. (n=21)	7.5 ± 0.5	106.3 ± 9.1
rat #8, 3 m.o. (n=21)	10.4 ± 0.8	157.2 ± 16.7

Markedly higher VP (6-10 x baseline) concentrations were recorded in young rats when the animals were initially housed. When new animals were placed in the same room, aged rat #4 showed urine VP concentrations 150-200 pg/ml, while aged rat #5 showed no response. Urine osmolalities showed proportional increases. Preliminary sampling (6 days) of F344 males suggests higher urine VP concentration in this strain: 102.0 ± 19.1 pg/ml for 3 m.o. (n=10); 93.3 ± 18.2 pg/ml for 20 m.o. (n=10), and total VP excretion (627.3 + 15.3 pg/24 hr for 3 m.o.; 361.1 + 28.2 pg/24 hr for 20 m.o). These initial samples indicate significantly lower ($p<0.001$, Student's t-test) total VP secretion in aged versus young 344 males.

Supported by PHS grants AG06139 (CJP) and DK19761 (CDS).

378.6 NICOTINE STIMULATES THE RELEASE OF VASOPRESSIN AND OXYTOCIN FROM SUPRAOPTIC CULTURES. Mariana Morris* and Barbara A. Bennett (Spon: N.Alexander). Department of Physiology and Pharmacology, Bowman Gray School of Medicine of Wake Forest University, Winston-Salem, NC 27103

The cholinergic system is known to have potent effects on vasopressin and oxytocin secretion in vivo. The objective of these studies was to investigate the effects of nicotine and high potassium on the release of vasopressin (AVP) and oxytocin (OT) from specific brain regions. An explant culture system was used. Microdissected explants of the supraoptic (SON) and paraventricular (PVN) regions were collected from the brains of male rats (5 weeks of age). The explants were cultured for 2 days and the explants were tested with Earles salt solution containing nicotine (4 x 10-3 M) or K+ (55 mM). There were 4 incubation periods (30 mins): control, nicotine, control and potassium. Media levels of AVP and OT were measured by RIA.

Table. Effect of Nicotine on Media Peptides.

	AVP (pg/well)		OT (pg/well)	
	Control	Nicotine	Control	Nicotine
PVN	16.8±5.5	12.5±3.8	31.1±3.5	39.8±5.2
SON	23.0±1.7	32.0±3.0*	11.8±2.8	29.0±3.6**

* = $p < .05$; ** = $p < .01$

Nicotine produced a significant stimulation of both vasopressin and oxytocin, but only in the SON region. The increase was greater for oxytocin, with release stimulated 2.5 fold. Depolarizing levels of potassium did not produce any change in peptide release in either region. This lack of stimulation by high K+ was also seen using acute cultures of the nuclear regions. This was in contrast to the marked effects observed in the isolated posterior pituitary.

These results show that there is a difference in the neurosecretory regions, the PVN and SON, in terms of both structural organization and secretory control. They suggest that in the isolated system nicotinic receptors still function to activate hormone secretion.

378.7 OPIOID PEPTIDE DIRECTLY HYPERPOLARIZES NEURONS IN RAT HYPOTHALAMIC SLICES. J.-P. Wuarin* and F. E. Dudek. Dept. of Physiology, Tulane Univ. Sch. of Med., New Orleans, LA 70112.

Opiates and opioid peptides have been shown to hyperpolarize neurons in the rat locus coeruleus (North, R. A. and Williams, J. T., J. Physiol. 364: 265, 1985). Several previous studies with extracellular recordings from supraoptic and paraventricular neurons have reported that these substances decrease spontaneous firing in about half of the cells. We have undertaken a preliminary study with intracellular recording to examine the mechanism of action of opioid peptides on these cells.

Using rat hypothalamus slices, we found a hyperpolarization in 4 out of 7 cells recorded from the supraoptic nucleus after bath application of the mu receptor agonist [D-Ala^2, NMe-Phe^4, Gly^5-ol] enkephalin (DAGO, 10^{-6}M). A decrease in input resistance accompanied the hyperpolarization of 4-8 mV (n=2). These effects persisted in tetrodotoxin (1 µg/ml, n=4), which suggests a direct action of the peptide. The recordings were made with KCl-filled electrodes, and the IPSPs reversed polarity within minutes after impalement of a cell. Since the chloride equilibrium potential was presumably positive with respect to resting potential, the persistence of a DAGO-induced hyperpolarization allowed us to rule out an increased chloride conductance.

Two cells recorded in the region of the paraventricular nucleus were also hyperpolarized by DAGO in the presence of tetrodotoxin, and their membrane conductance was also increased.

These results suggest that opioid peptides hyperpolarize some of the neurons in the supraoptic and paraventricular nuclei of the rat hypothalamus. This effect seems to be direct, accompanied by an increase in membrane conductance, not mediated by a chloride current and possibly due to the action of a mu-type receptor.

378.8 LOW-THRESHOLD CALCIUM SPIKES RECORDED IN THE REGION OF THE RAT HYPOTHALAMIC PARAVENTRICULAR NUCLEUS. J. G. Tasker* and F. E. Dudek (SPON: J. Weber). Dept. of Physiology, Tulane Univ. Sch. of Med., New Orleans, LA 70112.

Intracellular electrophysiological studies of the hypothalamus have been performed primarily on neurons of the supraoptic nucleus, whereas relatively little intracellular work has been done on the paraventricular nucleus (PVN). From these studies has emerged a general picture of the electrical properties of magnocellular neuroendocrine cells (MNCs).

We have recorded intracellularly from the PVN region in slices of rat hypothalamus. Eight of 11 cells showed electrical properties different from those characteristic of MNCs. After the fast Na^+ spikes (about 60 mV amplitude, 3 msec duration), these cells showed depolarizing potentials of 20-30 mV amplitude and 100-250 msec duration. These potentials were all-or-none, spike-like events which were seen with suprathreshold depolarizing current pulses or after hyperpolarizing pulses. Steady hyperpolarizing currents (0.1-0.3 nA) were often necessary to detect them. These potentials, but not the faster spikes, persisted in tetrodotoxin (TTX) but were abolished in 0.2 mM Ca^{2+}, 0.5 mM Cd^{2+} and thus appear to be generated by a Ca^{2+} conductance. Hyperpolarizing after-potentials (2-6 mV amplitude, 0.5-3.5 sec duration) were seen after the depolarizing potentials. They were also TTX-resistant and Cd^{2+}-sensitive, and are probably caused by a Ca^{2+}-dependent K^+ conductance.

In sharp contrast to MNCs, spontaneous synaptic activity in these cells was very sparse. Graded EPSPs and synaptically mediated action potentials could be evoked in these cells, as in putative MNCs, by extracellular electrical stimulation medial to the fornix.

Our results corroborate recently acquired evidence from another laboratory (Poulain, P. and Carette, B., Brain Res. Bull., in press) that a non-MNC cell type in or near the PVN can be distinguished on the basis of its electrical properties alone. These large depolarizing potentials have not been reported in hypothalamic MNC's, but resemble the low-threshold Ca^{2+} spikes seen in neurons of other areas of the brain. They appear to be generated by the de-inactivation, at hyperpolarized membrane potentials, of a voltage-dependent Ca^{2+} conductance.

These cells may be parvocellular neurons or perhaps interneurons situated outside of the PVN.

378.9 α-BUNGAROTOXIN FACILITATES MUSCARINIC CHOLINERGIC STIMULATION OF VASOPRESSIN RELEASE FROM THE RAT HYPOTHALAMO-NEUROHYPOPHYSIAL SYSTEM IN VITRO. K.M. Michels, R.B. Meeker and J.N. Hayward. Neurobiology Curriculum and Dept. Neurology, University of North Carolina, Chapel Hill, N.C. 27514.

Acetylcholine (ACh) is generally considered to exert direct excitatory control of vasopressin (VP) release via nicotinic cholinergic receptors (nAChR) in the supraoptic nucleus (SON) and via muscarinic cholinergic receptors (mAChR) in the neural lobe (Gregg, 1985, 1986; Sladek, 1983). However, alpha-bungarotoxin (α-BTX), which is the only cholinergic probe that binds selectively and with high affinity to the SON magnocellular neurons (Clarke et al., 1985; Meeker et al.,1986; Michels et al., 1986), is now known to recognize a brain protein which is distinct from the neuronal nAChR (Whiting & Lindstrom, 1987). We therefore examined the possible role of the α-BTX binding site in the cholinergic control of VP secretion in the acutely prepared rat hypothalamo-neurohypophysial system (HNS) in vitro. Following 60 min of perifusion with oxygenated DMEM-H medium at 35°C, stable basal levels of VP release were attained (3-6 pg/min). Subsequent stimulation with ACh (10^{-4}M) for 5 min caused an immediate rise of VP to 9.6 ± 1.2 pg/min with a return to baseline within 5 to 15 min. Atropine (10^{-5}M) blocked this stimulatory effect of ACh but hexamethonium (10^{-4}M) had no effect, suggesting a sole action of ACh at muscarinic cholinergic receptors (mAChR).

The combination of ACh and α-BTX (10^{-6}M) resulted in a potentiation of VP release to a peak level of 44.3 ± 7.1 pg/min and was sustained for more than 25 min. α-BTX alone produced a smaller, delayed VP release peaking at 13.2 ± 1.2 pg/min. Atropine eliminated the potentiating effect of α-BTX, reducing VP release to the level stimulated by α-BTX alone.

In summary: 1) ACh stimulation of VP release, in our acutely prepared rat HNS in vitro, is muscarinic in nature with no evidence for involvement of nAChR; 2) The ability of α-BTX to potentiate the ACh-induced release of VP does not fit a classical nicotinic or muscarinic cholinergic pharmacology, suggesting a unique functional role for the α-BTX binding protein within this hypothalamo-neurohypophysial system (HNS).

378.10 REGULATION OF VASOPRESSIN SECRETION BY SOMATOSTATIN-28. M.R. Brown. Autonomic Physiology Laboratory, UCSD Medical Center, San Diego, CA 92103.

Somatostatin-28 (SS-28) injected into the lateral cerebroventricle (icv), but not when given intravenously, produces a dose dependent 100 ng-1 µg) elevation of plasma concentrations of vasopressin (AVP). This increase of plasma concentrations of AVP mediates the elevation of mean arterial pressure (MAP) and the lowering of heart rate (HR) observed following the icv administration of SS-28. This conclusion is based on the observation that SS-28 does not increase MAP or decrease HR in Brattleboro rats or in rats pretreated with a vasopressin V_1-receptor antagonist (given systemically). To evaluate what role endogenous somatostatin-like peptides may play in the regulation of vasopressin secretion, experiments have been performed to identify a site of action of SS-28 and to measure stimulus-provoked vasopressin secretion in animals depleted of endogenous SS concentrations. All experiments have been performed in awake, male Sprague-Dawley rats equipped with chronic brain ventricular and/or parenchymal cannulae, and right atrial and femoral artery catheters. AVP was measured by radioimmunoassay. SS-28 has been injected into multiple brain regions in an attempt to localize its site of action. SS-28 (30 ng) when injected into the paraventricular nucleus of the hypothalamus, but not when injected into the anterior or posterior hypothalamus, central nucleus of the amygdala (Ce), nucleus of the solitary tract and lateral ventricle, produced a significant elevation of MAP. Higher doses of SS-28 (1-3 µg) injected into the Ce increased MAP and lowered HR.

The role of endogenous brain SS in the regulation of vasopressin release and MAP was assessed in animals treated with cysteamine. Cysteamine administration (90 mg/kg given subcutaneously 3 hr prior to experiments) depleted brain concentrations of SS-like peptide, as confirmed by radioimmunoassay. This treatment did not significantly alter basal plasma concentrations of vasopressin, MAP, HR or animal behavior. Cysteamine treatment did not change the MAP responses to hemorrhage or to SS-28 or angiotensin-II given icv.

Water deprivation for 24 hr, hypertonic saline and 30% hemorrhage were used in separate experiments as stimuli for AVP secretion. Cysteamine treatment attenuated the elevation of plasma concentrations of AVP following water deprivation and hemorrhage. In contrast, cysteamine pretreatment did not prevent the elevation of plasma AVP levels in animals given hypertonic saline. Icv injection of SS-28 (300 ng) to cysteamine-treated animals receiving 30% hemorrhage resulted in normalization of plasma concentrations of AVP.

These observations are consistent with the hypothesis that a SS-related peptide may participate in the central nervous system regulation of pituitary AVP secretion under some circumstances.

378.11 IMMUNOHISTOCHEMICAL EVIDENCE FOR MODULATION BY ESTROGEN OF NEUROPEPTIDE COEXPRESSION IN THE MAGNOCELLULAR NEUROSECRETORY SYSTEM OF THE FEMALE RAT. P.E. Sawchenko and M.C. Levin*, The Salk Institute, La Jolla, CA 92037.

Double immunohistochemical staining methods were used to assay the effect of gonadal steroids on the expression of coexisting peptides in the magnocellular neurosecretory system of the female rat. It was confirmed in colchicine-treated animals that immunoreactive corticotropin-releasing factor (CRF) and cholecystokinin (CCK) coexist in subsets of oxytocinergic neurons. In addition, dynorphin-immunoreactivity was also detected in a majority of oxytocin containing magnocellular neurons. Also consistent with previous studies, magnocellular vasopressinergic cells were found to display angiotensin II-(AII), dynorphin- and galanin-immunroeactivities. All these results occurred in colchicine-treated ovariectomized (OVX) rats independent of whether or not the animals received replacement injections (10 µg/day for four days) of estradiol benzoate (EB). Comparisons of staining patterns were also carried out between groups of non-colchicine treated OVX rats that received replacement injections of either EB or vehicle. Relative to vehicle-treated controls, animals that received EB replacement showed enhanced staining (increased cell number and staining intensity) for each of the peptides that was found to coexist in vasopressinergic neurons, while staining for those colocalized with oxytocin was not discernably affected. Consistent with this pattern, immunoreactive dynorphin, which was colocalized in both oxytocinergic and vasopressinergic magnocellular neurons in colchicine-treated animals, showed enhanced staining only in magnocellular vasopressinergic neurons in response to EB treatment. Repetition of these experiments in normal animals sacrificed at the estrus, as opposed to the diestrus II, phases of the reproductive cycle yielded a similar pattern of results. The results suggest that circulating gonadal steroids affect peptide expression differentially in oxytocinergic versus vasopressinergic neurons. All peptides examined that could be colocalized in vasopressinergic cells showed evidence of enhanced expression in the presence of estrogen, while none of those colocalized with oxytocin appeared affected. The results in normally cycling rats indicate that this kind of influence may be manifest under normal physiologic conditions. These phenomena provide interesting parallels and contrasts with adrenal steroid influences on the expression of coexisting peptides in an adjoining population of parvocellular neurosecretory neurons.

378.12 OXYTOCINERGIC NEURONES IN RAT HYPOTHALAMUS: DEXAMETHASONE-REVERSIBLE INCREASE IN THEIR CORTICOTROPIN RELEASING FACTOR-LIKE IMMUNOREACTIVITY IN RESPONSE TO OSMOTIC STIMULATION. J. Dohanics*, K.J. Kovacs* and G.B. Makara* (SPON: A.J. Martinez) Inst. Exptl. Med., Hungarian Acad. Sci., POB 67, H-1450 Budapest, Hungary

Recent results have shown altered corticotropin releasing factor (CRF) content of the neurointermediate lobe (NIL) of the pituitary in response to various manipulations including osmotic stimulation. This study was undertaken to elucidate whether the changes in the NIL are accompanied by changes in CRF-like immunoreactivity of neurosecretory neurones of the hypothalamus in response to osmotic stimulation.

Wistar rats of both sexes were given either tap water ad lib., 2% saline or their access to tap water was limited to 20 min daily. Some rats were adrenalectomized (ADX) or treated with dexamethasone (DEX) for 7 days. Thirty six to 48 hours before perfusion with fixative consisting of buffered formaldehyde and picric acid, animals received 75 µg colchicine icv. Forty µm thick vibratome sections were stained for CRF-like (CRF-LI), arginine vasopressin-like (AVP-LI) and oxtyocin-like (OXY-LI) immunoreactivities using the avidin-biotin-peroxydase complex method. Magnocellular neurones of the paraventricular (PVN), anterior commissural and supraoptic nuclei (SON) showed increased CRF-LI, AVP-LI and OXY-LI in response to both types of osmotic stimulation, while CRF-LI of parvocellular perikarya of the PVN decreased. Increased staining intensities were observed in magnocellular neurones in ADX rats challenged osmotically. Systemic DEX administration, as well as implantation of DEX near the SON, sharply attenuated CRF-LI but not AVP-LI or OXY-LI of magnocellular neurones in osmotically-stimulated rats. The enhanced CRF-LI seemed to coexist with OXY-LI but not with AVP-LI in magnocellular neurones.

The results suggest that osmotic stimulation causes increases in CRF-LI in addition to increases in AVP-LI and OXY-LI of magnocellular neurones presumably due to increased systhesis of these peptides. DEX seems to inhibit synthesis of CRF but not that of AVP and OXY in these cells in response to osmotic stimulation.

378.13 **DIFFERENTIAL LOCALIZATION OF CORTICOTROPIN RELEASING FACTOR IN THE RHESUS MONKEY MEDIAN EMINENCE DURING DEVELOPMENT.** P.C. Goldsmith, K.K. Thind and C.A. Padula*. Dept. of OB/GYN and Repro. Sci., Univ. of Calif., San Francisco, CA 94143.

In order to assess the neurosecretory role of corticotropin releasing factor (CRF) containing nerve terminals in the median eminence (ME) of developing primates, immunostaining for CRF was performed in pre- and postnatal female rhesus macaques. Medial basal hypothalami (MBH) from late fetal (140-160 day) animals were obtained following cesarean section and fixed by immersion in buffered 3% paraformaldehyde/0.2% glutaraldehyde. MBH tissue from colchicine-treated juvenile (7-8 month) females was obtained following perfusion with the same fixative. Vibratome sections (40 microns) in the frontal plane were immunostained with 1:500-1:1,000 rabbit anti-oCRF (oC30, W. Vale) using colloidal gold or PAP, and examined under the light and electron microscopes.

CRF immunopositive (CRF+) staining in juveniles extended throughout the external layer of the ME to the hypophyseal portal capillaries and their loops, even along the ventral infundibulum (INF). Abundant CRF+ nerve terminals were usually prevented from direct access to the parenchymal basal lamina (BL) only by tanycytic processes. In contrast, CRF+ staining in fetal sections was absent or only faintly apparent in the ME zona externa. Some beaded CRF+ axons projected as far as the palisade layer along the ventral INF, but none approached within 50-100 microns of the BL.

Although these results might have reflected the superior structural preservation and poorer immunogold penetration in the fetal than the juvenile ME [Lamberts and Goldsmith, J Histochem Cytochem 34: 389 (1986)], we obtained these same results with PAP, which is much less dependent upon membrane permeability for reliable labeling. Furthermore, CRF+ staining was even more intense with PAP than with colloidal gold, especially in ME nerve terminals in juveniles. This confirms our results, since more CRF was probably lost from the perfusion-fixed ME in juveniles than the immersed fetal ME.

Taken together these results suggest that CRF+ nerve terminals show a differential distribution in the late fetal versus juvenile monkey ME in which CRF+ terminals were more numerous and intensely stained. Although such staining characteristics might also reflect quantitative differences (relative to the conditions at the time tissues were obtained), qualitative dissimilarities in the location of CRF+ terminals were apparent. Whereas CRF+ nerve terminals in the human ME display the adult pattern by mid-gestation, the distinctive localization observed here may signal differences in response to stress in intrauterine versus postnatal life.

378.14 SIMULTANEOUS DETERMINATION OF CRF AND ACTH RELEASE FROM HYPOTHALAMIC-PITUITARY BLOCKS PERFUSED IN VITRO: RESPONSES TO PHYSIOLOGICAL AND PHARMACOLOGICAL MANIPULATION. J.C. Ritchie, P.K. Liu*, C.B. Nemeroff and M.D. Davis*. Dept. of Psychiatry, Box 3870, Duke Univ. Med. Ctr, Durham, N.C. 27710.

The hypothalamic-pituitary-adrenal axis (HPA) is mobilized during certain external and internal stimuli and is a major component in the homeostatic response to physiological and psychological stresses. A major regulatory factor of ACTH secretion is cortocotropic releasing factor (CRF) which is a 41 amino-acid peptide synthesized by hypothalamic neurons originating within the medial border of the paraventricular nucleus. These neurons send their projections to the hypothalamic median eminence where they terminate within the portal capillary bed. When CRF is released, it enters the vascular network, and is transported to the pituitary where it binds to corticotroph receptors, initiating ACTH release. Other putative hypothalamic-hypophyseal releasing and inhibiting factors may be involved in ACTH regulation, as well. In order to study the dynamic integration between CRF and ACTH in this neuroendocrine axis, we utilized the excised and perfused hypothalamic-hypophyseal block as a model to preserve the functional vascular supply in vitro.

Male Sprague-Dawley rats were sacrificed and the entire hypothalamus with attached pituitary removed and pinned to the bottom of a small chamber. After closing most of the major blood vessels, a small drawn-glass catheter (100 um dia. tip) was inserted into the anterior cerebral artery (a.c.a.) of the Circle of Willis and was used to perfuse and sustain the tissue block with warm, oxygenated media (300 ul/min; Earle's balanced salts + 0.1 % BSA) via a peristaltic pump. The pituitary was inserted into one end of a collection tube through which the exudate from gland was withdrawn. The perfused media was collected over a 10 minute sampling period (3 ml/10 min), then acidified and split into two equal aliquots for separate determinations of CRF- and ACTH- like immunoreactivity (-LI) by radioimmunoassay. At the completion of each experiment, a bolus of india ink was introduced through the catheter to verify patency of the vessels.

Infusion of synthetic human CRF (courtesy of W. Vale) evoked a concentration-dependent release of ACTH-LI, doubling basal values at 20 pM CRF while quadrupling them at 1.0 nM CRF. Elevating the potassium concentration in the perfusion media to 40 mM, elicited a 5-fold increase in CRF and a 6-fold increase in ACTH secretion. In preliminary experiments, electrical stimulation (2 - 30 Hz) of the hypothalamus, via bipolar electrodes placed superficially on the median eminence, initiated a frequency-dependent rise in ACTH secretion, which appeared to be at least partially independent of intrinsic CRF release. We are currently exploring CRF- and non-CRF-mediated ACTH regulation using this model.

378.15 ROLE OF VASOPRESSIN IN THE ACTH RESPONSE TO HYPOTENSION IN NEUROHYPOPHYSECTOMIZED, CONSCIOUS DOGS. H. Raff*, M.M. Skelton*, D.C. Merrill*, and A.W. Cowley, Jr.* (SPON: M. McQuillen). Dept. of Physiology and Medicine, Medical College of Wisconsin, St. Luke's Hospital, Milwaukee, WI 53226.

It is well known that vasopressin (AVP) increases ACTH secretion and potentiates the action of corticotropin-releasing factor (CRF) at the corticotrope. We have previously shown that neurohypophysectomy attenuates the ACTH response to hypotension suggesting that increased release of vasopressin from the posterior pituitary is necessary for normal ACTH responses (AJP 249:R281, 1985). The purpose of the present study was to determine if acute infusion of vasopressin could normalize the ACTH response to hypotension in neurohypophysectomized dogs. Four dogs underwent clamped decreases in blood pressure by a controlled iv infusion of sodium nitroprusside. Then, at least one month after transbuccal neurohypophysectomy, dogs underwent a hypotensive stimulus without (NHX) and with (NHX+AVP) simultaneous acute iv infusion of AVP (6 ng/kg/min). This infusion rate resulted in plasma AVP levels similar to those achieved during hypotension in the intact dog. The results were as follows:

	Mean Art. Pressure (mmHg)			Plasma ACTH (pg/ml)		
	CTL	15 min	45 min	CTL	15 min	45 min
Intact	100±4	70±5*	70±4*	43±6	276±66*#	285±78*#
NHX	99±4	70±3*	70±3*	50±8	83±15*	86±14*
NHX+AVP	94±4	66±2*	66±2*	52±6	173±30*‡	131±27*‡

*diff from control, ‡NHX+AVP > NHX, #intact > NHX+AVP ($p<0.05$)

Neurohypophysectomy had no effect on basal (CTL) mean arterial pressure or ACTH. All three treatment groups exhibited similar degrees of hypotension. Neurohypophysectomy significantly attenuated but did not eliminate the ACTH response to hypotension. Infusion of exogenous AVP during hypotension (NHX+AVP) significantly increased the ACTH response as compared to hypotension alone (NHX) but did not restore the ACTH response to that exhibited in the intact dogs. We conclude that (1) neurohypophysectomy attenuates the ACTH response to hypotension and (2) a component of the ACTH response to hypotension is due to elevated peripheral levels of vasopressin. We hypothesize that stimulation of ACTH secretion during hypotension is in part due to elevated peripheral vasopressin levels acting either by recirculation to the adenohypophysis or by activation of afferent pathways to CRF-ACTH secretion. (Supported by NIH HL36681).

378.16 DIFFERENTIAL EFFECT OF REMOVAL OF THE NEUROINTERMEDIATE PITUITARY LOBE ON OXYTOCIN AND VASOPRESSIN CONTENT IN DISCRETE AREAS OF THE RAT HYPOTHALAMUS. C. A. Johnston, K. D. Fagin*[1] and A. Negro-Vilar. Reprod. Neuroendo. Sect., Lab. Reprod. Dev. Tox., NIEHS, NIH, Research Triangle Park, NC 27709 and [1]AMGEN, Thousand Oaks, CA 91320.

Recently, much evidence has accumulated concerning the possible role for the neurointermediate pituitary lobe (NIL) in the neuroendocrine regulation of anterior pituitary hormone secretion. Although investigations have provided evidence for possible direct influences of the NIL upon anterior pituitary hormone secretion, the question of whether the NIL can influence higher brain components involved in the regulation of anterior pituitary secretion remains virtually unanswered. For example, little is known concerning the ability of the NIL to influence neuropeptide levels in discrete areas of the brain, which may be involved in that regulation. Two neuropeptides which have been implicated in the neuroendocrine regulation of anterior pituitary secretion and which are located in the NIL in considerable amounts are oxytocin (OXY) and arginine vasopressin (AVP). In the present study, we evaluated whether the in vivo content of OXY and AVP in discrete areas of the brain containing cell bodies, fibers and/or terminals of these neuropeptide neurons was affected following surgical removal of the NIL (NIL-X). Adult male rats were subjected to NIL-X or visualization of the NIL (SHAM) using a parapharyngeal approach. Animals were sacrificed by decapitation thirteen days following NIL-X or SHAM operation and the two neuropeptides were measured by specific radioimmunoassays in the median eminence, arcuate nucleus and in the paraventricular nucleus. The concentration of OXY was dramatically increased following NIL-X in the paraventricular nucleus and the median eminence while the level of OXY in the arcuate nucleus was not affected by the removal of the NIL for thirteen days. On the other hand, AVP concentrations in the paraventricular nucleus and median eminence were not significantly altered following NIL-X and were somewhat decreased in the arcuate nucleus compared to SHAM controls. These results demonstrate that removal of the NIL can differentially influence the concentrations of two neuropeptides which have been implicated in the neuroendocrine regulatory control of anterior pituitary hormone secretion, and which share similar characteristics in terms of structure and anatomical distribution. The data also suggests that, in addition to its apparent ability to directly influence anterior pituitary secretion, the possibility that the NIL may also influence this neuroendocrine regulation by interacting at a higher brain level should also be considered.

378.17 THYROID HORMONE REGULATION OF THYROTROPIN-RELEASING HORMONE mRNA IN THE PARAVENTRICULAR NUCLEUS IS INDEPENDENT OF THYROTROPIN. K.J. Koller, R.S. Wolff*, and R.T. Zoeller Laboratory of Cell Biology, National Institute of Mental Health, Bethesda, MD 20892.

Thyroid hormones exert a negative feedback effect on thyrotropin (TSH) secretion from the pituitary. However, while thyrotropin-releasing hormone (TRH) is known to regulate pituitary-thyroid function, the effect that thyroid hormones have on TRH has remained unclear. We have shown previously that TRH mRNA levels in the paraventricular nucleus (PVN) increase after thyroidectomy and decrease after T_3 treatment (Endocrine Soc. Abs., 1987, in press). The influence of TSH on thyroid hormone regulation of TRH, however, is ambiguous.

To examine this question, seventeen male Sprague-Dawley rats were thyroidectomized (TX) and hypophysectomized (HX) and given food and a salt- and glucose-enriched water solution ad. lib. Daily subcutaneous injections of saline (0.9%; n=6), T_3 (20 µg/kg; n=5), or T_3 and TSH (20 µg/kg & 1 U; n=6) were made for twelve days. Sixteen additional animals were sham operated and injected with either saline or T_3 as above. On day thirteen, the animals were weighed and decapitated; trunk blood was collected, and brains were removed and frozen on dry ice. Twelve micron cryostat sections were cut through the PVN of each brain, thaw-mounted onto gelatin-coated slides, and stored at -80°C until hybridization. Sections were then warmed to room temperature, fixed in 4% formaldehyde, dehydrated through a series of ethanol solutions, and delipidated in chloroform. After rehydration, an ^{35}S-labeled 48-base oligonucleotide complementary to the TRH mRNA was applied to each section overnight in a hybridization buffer containing 4x SSC and 50% formamide at 37°C. Optical densities of the film over the PVN was analyzed using a Loats image analysis system, and the results expressed as percent of controls (sham operated, saline injected). The results were as follows (mean ± SEM): Sham-saline: 100 ± 5%; Sham-T_3: 75 ± 4%; TX/HX-saline: 125 ±8 %; TX/HX-T_3 : 65 ± 5%; TX/HX-T_3/TSH: 60 ±5%. These results confirm that thyroid hormones negatively regulate TRH mRNA levels in the PVN and demonstrate that TSH has no effect on this regulation.

378.18 ADRENERGIC INNERVATION OF THYROTROPIN RELEASING HORMONE (TRH) SYNTHESIZING NEURONS OF THE RAT HYPOTHALAMUS. Zs. Liposits*[1], R.M. Lechan[2], W.K. Paull*[1], P. Wu*[3], and I.M.D. Jackson[3]. (SPON: J.D. Dexter). [1]Dept. of Anatomy, University of Missouri-Columbia, Columbia, MO 65212; [2]Endocrine Division, Tufts-New England Med. Center, Boston, MA 02111; [3]Div. of Endocrinology, Brown University, Rhode Island Hospital, Providence, RI 02902.

Thyrotropin releasing hormone synthesizing neurons, residing in the parvocellular subnuclei of the hypothalamic paraventricular nucleus (PVN) (Lechan and Jackson, Endocrinology, 111:55-1982), contribute to the central regulation of the pituitary-thyroid endocrine axis. The central catecholaminergic system has previously been demonstrated (Krulich, L., Neuroendocrinology, 35:139,1982) to influence the thyrotropin secretion. In order to elucidate the possible involvement of the central epinephrine system in the innervation of TRH-immunoreactive (IR) neurons of the PVN, ultrastructural immunocytochemical double labelling studies (Liposits et al., Histochemistry, 85:95, 1986) were performed on the hypothalami of colchicine treated (80µg/100 g. b.w.; 36 h before sacrifice) male rats.

Free and membrane-bound ribosomes, numerous neurosecretory dense core granules (80-130 nm in diameter) were intensely labelled in TRH-IR neurons. Unlabelled axon terminals formed asymmetric synapses with dendrites and cell bodies of TRH-IR neurons. The axons of TRH-synthesizing neurons were also observed to establish asymmetric synaptic specializations with parvocellular neurons of the PVN.

The immunocytochemical dual antigen localization technique revealed that phenylethanolamine-N-methyltransferase (PNMT)-IR, adrenergic axons overlapped TRH-synthesizing paraventricular neurons. Dendrites and perikarya of TRH-IR neurons were heavily surrounded by PNMT-IR axons. The ultrastructural analysis of these juxtaposed elements demonstrated that PNMT-IR axon terminals formed asymmetric synapses with both dendrites and somata of TRH-synthesizing neurons.

These data indicate that the thyrotropin releasing hormone synthesizing neurons of the PVN receive a direct, synaptic input from the central epinephrine system. The results are in harmony with recent pharmacological (Terry, L.C., Neuroendocrinology, 42:102, 1986) and ultrastructural (Shioda et al., Cell Tissue Res., 245:247, 1986) observations related to the role of catecholamines upon the central TRH system. The data also support the concept of a neurotransmitter action of TRH within the neuronal circuits of the PVN. Supported by NIH Research Grants NS 19266 and AM 34540.

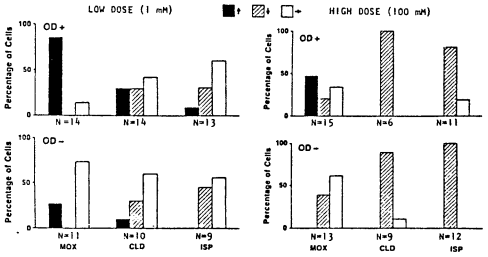
378.19 THREE-DIMENSIONAL (3D) COMPUTER RECONSTRUCTION OF MICROCAPILLARY MODULES IN THE MEDIAN EMINENCE OF THE HYPOTHALAMUS.
L. S. Hibbard, B. J. Dovey-Hartman*, and R. B. Page. The M. S. Hershey Medical Center, The Pennsylvania State University, Hershey, PA 17033.

The capillary plexus in the median eminence forms a humoral connection for the transfer of information between the brain and the anterior pituitary. It is organized in a modular pattern of repeating vascular loops standing on a base of hexagonally arrayed capillaries. Capillary loops may have a simple hairpin shape or may arborize in the internal zone of the median eminence to form complex vascular formations. To establish these modules as independent units it is necessary to identify mechanisms which regulate blood flow into each unit. We have developed a system of computer programs for the 3D reconstruction of capillaries from digitized transmission electron micrographs (TEMs) of thin sections of the rabbit median eminence to ascertain whether the physical means for such control exists (smooth muscle sphincters strategically-located in the loops and arbors). Using digital imaging techniques, capillary lumens are extracted from serial TEMs, mosaics of multiple overlapping images are generated, and the mosaic-images are placed in register. The lumen features are detected by a spatial-domain operator which searches for pixels having high gray levels, low local variance, and contiguity with other pixels having the same properties. The mosaics are assembled using fast Fourier transform (FFT) correlation of the lumen edges. Image alignment is carried out in two stages: coarse alignment is effected by the superposition of image centroids and principal axes, and fine alignment consists of alternating rotational and translational refinements of the coarse alignment, by FFT correlation of the high-frequency image features. In two early studies (Hibbard, et al., Comput. Biomed. Res. 16:411, 1986), bundles of parallel capillaries were observed, with connections, at intervals, between them. Currently, a much larger study is underway, in an attempt to reconstruct an entire capillary loop, with automatic detection of endothelial and smooth muscle cell features. The endothelial cell nuclei give rise to particularly high-valued parallel edges in gradient images derived from smoothed, digitized TEMs. This property, along with the proximity of endothelial nuclei to the lumens (already detected above), is incorporated into a routine which identifies regions which are likely to contain nuclei. Current progress on the reconstruction and the elaboration of cellular features will be presented. (Supported by NSF grant BNS 8506479 and NIH grant NS 15962.)

378.20 TYPES OF ADRENORECEPTORS MEDIATING A1 NORADRENERGIC NEUROTRANSMISSION TO MEDIAL PREOPTIC-MEDIAL SEPTAL NEURONS.
Y.I. Kim, C.A. Dudley and R.L. Moss, Dept. Physiol., UTHSCD, Dallas, TX 75235.

It has been demonstrated that norepinephrine (NE) neurons in the A1 region project to the medial preoptic-medial septal (MPO-MS) area and that electrical stimulation of the A1 region orthodromically alters the electrical activity of MPO-MS neurons. Since the A1-stimulation-bound orthodromic excitation (OD+) and inhibition (OD-) could be mimicked by locally applied NE of low and high doses, respectively, the orthodromic events are presumed to be mediated through different types of adrenoreceptors. Thus, the present study was designed to determine the types of adrenoreceptors involved.

Ovariectomized, estradiol-progesterone-primed Sprague-Dawley rats anesthetized with urethane were used for the study. Multi-barrelled glass micropipettes were used to record single unit activity and to locally apply various adrenergic agonists and antagonists. The effects of the adrenergic agonists (1 or 100 mM in-drug barrel concentration, pressure-ejected) on the activity of MPO-MS neurons that orthodromically responded to A1 stimulation are summarized below.



MOX: methoxamine (alpha-1), CLD: clonidine (alpha-2), ISP: isoproterenol (beta)
↑ : excitation, ↓ : inhibition, → : no effect

A1-stimulation-bound excitatory responses were reliably mimicked only by a low dose of MOX while inhibitory responses were reliably mimicked by a high dose of CLD and ISP. To corroborate the results of the synaptic mimicry study, NE-induced neuronal responses that matched the A1-stimulation-bound responses were subjected to possible blockade by the alpha and beta adrenergic blockers, phentolamine (PT, 0.1 M) and timolol (TM, 0.1 M), respectively. The excitatory effects of NE (0.5 mM in-drug barrel concentration, pressure ejected) on neurons excited by A1 stimulation were blocked by iontophoretically applied PT (5 of 5 cases), but not by TM (8 of 8 cases). On the other hand, the inhibitory effects of NE (50 mM) on neurons inhibited by A1 stimulation were blocked by TM (6 of 9 cases), but not by PT (7 of 7 cases).

It was concluded that the excitatory A1 noradrenergic input to MPO-MS neurons is mediated by alpha-1 adrenoreceptors while the inhibitory A1 input is mediated by beta receptors. Supported by NIH grants NS-10434 and HD-09988.

CHARACTERIZATION OF MUSCARINIC CHOLINERGIC RECEPTORS

379.1 THE ONTOGENY OF CHOLINERGIC MUSCARINIC RECEPTORS IN MOUSE TELENCEPHALON: AN IN VITRO AUTORADIOGRAPHIC STUDY WITH [^{3}H]PIRENZEPINE.
H.S. Singer*, C. Searles*, P.A. Slesinger, P.R. Lowenstein and J.T. Coyle (SPON: P. Hoffman). Depts. of Neurology, Pediatrics and Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, MD 21205

Recent studies have demonstrated the existence of two distinct populations of muscarinic receptors, M_1 and M_2, in mammalian tissues. Of these, M_1 receptors are generally considered post-synaptic markers of brain cholinergic pathways. Since the cholinergic system has been implicated in the regulation of cortical plasticity, detailed knowledge of M_1 receptor site distribution during ontogeny is essential for understanding cholinergic influences on the development of the cortex. In this investigation, we evaluated the development of M_1 sites in mouse cortex, caudate-putamen, and hippocampus, using in vitro autoradiography with the ligand [^{3}H]pirenzepine.

M_1 muscarinic receptor binding was detected in all areas of the immature cortex as early as E15. At one day after birth (P1), receptor binding was distributed uniformly (10-16 fmol/mg) throughout the entire somatosensory cortex, except in layer 1. Labelling increased rapidly between P5-P15. After P15, the tendency was for higher receptor binding to occur in bands over layers II-IV and over layer VI, which were separated by a band of lower binding over upper layer V. Between P20 and adulthood, total binding decreased by 22-34%. In the caudate-putamen, binding also increased most noticeably between P5-P15 with subsequent 50-60 fmol/mg greater binding in the lateral portions. Islands of higher intensity labelling were also observed from P15 to adulthood, predominantly over the lateral aspect. Total binding decreased by about 30% between P15 and adulthood. In the hippocampus, M_1 receptor density was quite low through P5; the largest increases occurred after P10. The pyramidal cell layer in CA1 showed higher density of binding than the dentate granular cell layer. Labelling in the hippocampal white matter exceeded that in the cellular layers in CA3, CA4, and dentate gyrus. In contrast to the cortical and caudate-putamen regions, [^{3}H]pirenzepine binding in the hippocampus continued to increase into adulthood.

These results demonstrate an early appearance of M_1 receptors in the fetal mouse telencephalon, a rapid increase in receptor density beginning at the end of the first week of post-natal development, and changes in receptor distribution during maturation. Differences between the ontogeny of the M_1 receptor and total muscarinic binding, as measured by the specific binding of [^{3}H]propylbenzilylcholine mustard, suggest differential roles in development supported by PO1 HD19920 and the McKnight Foundation.

379.2 AUTORADIOGRAPHIC STUDIES OF SUBTYPES OF MUSCARINIC RECEPTORS IN THE RAT BRAIN.
W. Lee, S.J. Wall and B.B. Wolfe (Spon: E. Stellar). Dept. Pharmacol., U of PA Med. Sch., Phila., PA 19104

The purposes of the present studies are 1) to characterize the binding assays for muscarinic antagonists ^{3}H-quinuclidinyl benzilate(^{3}H-QNB) and ^{3}H-pirenzepine(^{3}H-PZ) using autoradiographic methods, and 2) to examine ontogeny of subtypes of muscarinic receptors using these methods.

Using 24 μ brain sections, experiments were performed to determine the time required for ^{3}H-QNB to reach equilibrium. The binding reached maximal values only after at least 14 hr of incubation at 23°C in the presence of 0.32 nM of ^{3}H-QNB. The amount of ligand bound remained constant between 14 and 22 hr of incubation. Several possibilities exist to explain why the binding of ^{3}H-QNB plateaus at 14 hr. 1) True equilibrium for the binding of ^{3}H-QNB to muscarinic receptors is reached. 2) Degradation of the ligand occurs and/or 3) Degradation of the binding sites occurs upon prolonged incubation at 23°C. To examine the second possibility, incubation buffers containing ^{3}H-QNB were stored at 4°C or 23°C for 16 hr and were subsequently used to label muscarinic binding sites on tissue sections. There was no significant differences in the amount of specific binding using ^{3}H-QNB stored at the two different temperatures after 4 hr of incubation at 23°C. To examine the third possibility, tissue sections were first stored in incubation buffer at 23°C for various periods of time, then incubated in ^{3}H-QNB containing buffer for 5 hr. Tissue sections which were not exposed to 23°C prior to labelling with ^{3}H-QNB were used as control. The specific binding was 69±7% and 64±3% of control when tissue sections were preincubated 12 hr and 17 hr, respectively. These observations suggested that tissue sections are not stable for extended periods of incubation and that equilibrium for the labelling of muscarinic binding sites by ^{3}H-QNB in 24 μ sections could not be reached before a significant loss of the binding sites occurred. To find out if equilibrium could be obtained using ^{3}H-QNB as a ligand, 6 μ and 12 μ tissue sections were incubated with 1.2 nM of ^{3}H-QNB for various amount of time. For both thicknesses equilibrium was reached within 1 hr and remained stable up to 7 hr of incubation at 23°C. In addition, the same amount of specific binding was obtained when 12 uM tissue sections were labelled with 1.2, 2.2 and 4.2 nM of ^{3}H-QNB for 2 hr at 23°C, indicating that saturation of muscarinic binding sites has been achieved. Thus, 12 μ tissue section incubated in nanomolar concentrations of ^{3}H-QNB for 2 hr at 23°C was adopted as the standard procedure for labelling muscarinic binding sites.

The time course for the binding of ^{3}H-PZ was also examined using 24 μ tissue sections. Equilibrium was reached after 2 hr and remained constant up to 8 hr of incubation in 4.3 nM of ^{3}H-PZ. All subsequent studies were carried out with 12 μ tissue sections incubated in various concentrations of ^{3}H-PZ for 2 hr at 23°C. Scatchard analysis performed on cortex layers 1-3 and 4 yielded K_d values of 3 to 6 nM, in good agreement with K_d values generated from studies using cortical homogenates.

The localization of the changes in muscarinic receptor subtypes with age is being examined currently. (Supported by GM31155)

379.3 REGIONAL DIFFERENCES IN MUSCARINIC RECEPTOR STIMULATED GTP-ASE ACTIVITY IN RAT BRAIN. S. Ghodsi-Hovsepian*, W.S. Messer, Jr. and W. Hoss (SPON: C.L. Hinman). Dept. of Medicinal Chemistry, Univ. of Toledo, College of Pharmacy, Toledo, OH 43606.

The activity of low K_m GTPase associated with the stimulation of muscarinic receptors was measured in several different areas of the rat brain including cerebellum, cortex, hippocampus, medulla, midbrain and striatum. GTPase activity was monitored by determining [^{32}P]-P_i released from [gamma-^{32}P]-GTP essentially as described earlier (P.H. Franklin and W. Hoss, J. Neurochem. 43:1132, 1984). The activity of the enzyme was increased selectively by the cholinergic agonist carbachol and inhibited by the M_1-selective muscarinic receptor antagonist pirenzepine. The relative increase (over the basal level) of low K_m GTPase activity stimulated by 1 mM carbachol was greatest in cortex, hippocampus and medulla, which had increases of >40 %, intermediate in midbrain and striatum and least in cerebellum (18%). Pirenzepine inhibited carbachol-stimulated (but not basal) GTPase activity, displaying differential potencies among the brain regions. Medulla and cortex were the most sensitive to pirenzepine with IC_{50} values of 0.03 and 0.5 μM, respectively, whereas hippocampus and striatum were less sensitive with values of 10 and 4.5 μM. The midbrain, however, was insensitive to inhibition by pirenzepine even at concentrations >10 μM. With the exception of the medulla, there was in general a good correlation between the inhibition of carbachol-stimulated GTPase activity by pirenzepine and the distribution of M_1 muscarinic receptors determined by autoradiographic methods. Areas such as medulla may have small populations of M_1 receptors that are very efficiently coupled to G-proteins. Supported in part by NIH grant DA04068 to W.H.

379.4 FUNCTIONAL STUDIES OF A CEREBRAL CORTICAL M2 MUSCARINIC RECEPTOR. D.J. Anderson and M. McKinney. Abbott Laboratories, North Chicago, IL 60064.

The functional interaction of muscarinic receptors with the adenylate cyclase system was studied in rat neocortex. Dispersed cellular aggregates were prepared from adult rat fronto-parietal cortex by teasing finely minced tissue through Nitex filters. ATP stores in the aggregates were prelabeled with [3H]adenine and the [3H]cAMP formed during incubations was isolated by ion exchange chromatography. Forskolin (FORSK) elevated cAMP levels 10-fold over basal by 15 min with an EC50 value of 10-30 uM. Carbachol (CARB) mediated a dose-dependent inhibition (EC50=1.3 uM) of 10 uM FORSK-elevated cAMP production with maximal inhibition of 25-35%. Oxotremorine was fully efficacious in mediating this response. Atropine completely blocked the response to 10 uM CARB (IC50=18 nM), indicating that the inhibition of cAMP formation in this preparation is mediated by the muscarinic receptor. Pirenzepine, a M1-selective antagonist, blocked the response to 10 uM CARB with low potency (IC50=3.5 uM), indicating that a M2 muscarinic receptor subtype mediates the effect. 4-DAMP methbromide and secoverine were relatively potent blockers of this muscarinic response. The response to 10 uM CARB was not affected by 10 mM EGTA, 50 uM d-tubocurarine, or 100 nM tetrodotoxin. Propylbenzilylcholine mustard (PBCM) alkylated muscarinic receptors in this preparation; a 20 min treatment with 100 nM PBCM completely blocked specific [3H]N-methylscopolamine binding; half-maximal occupancy of PBCM occurred at a concentration of 5 nM. PBCM (10 nM) reduced the maximal CARB response without a large shift of the CARB concentration-response curve, indicating that there is not a large component of "spareness" in the system. Further characterization of this cortical receptor-effector system should elucidate the relationship between adenylate cyclase and other biochemical systems linked to the M2 receptor subtype.

379.5 HIGH AFFINITY PIRENZEPINE BINDING ASSOCIATED WITH PHOSPHOINOSITOL HYDROLYSIS IN INTACT HUMAN NEUROBLASTOMA (SH-SY5Y) CELLs. Lin Mei,* W.R. Roeske, H.I. Yamamura. Department of Pharmacology and Internal Medicine, University of Arizona Health Sciences Center, Tucson, AZ 85724.

Muscarinic agonist carbarchol (CCh) stimulates phosphoinositol hydrolysis in intact human neuroblastoma (SH-SY5Y) cells. This model system was further characterized by comparing the inhibition effects of pirenzepine (PZ), a M_1 selective antagonist and AF-DX 116, a M_2 selective antagonist and the effects of phorbol ester treatment.

Accumulated formations of IP_1, IP_2 and IP_3 in the presence of 10 mM LiCl were both agonist concentration-dependent and agonist incubation time-dependent under our conditions. Of these three inositol phosphates, the formation of IP_1 was always the highest. The radioactivities (fmol/1,000 cells) eluted from the anion exchange resin column for IP_1 were 0.06 after 3 min, 0.11 after 10 min, and 1.2 after 60 min incubation. In the following, therefore, phosphoinositol hydrolysis refers to the accumulated formations of IP_1.

The EC_{50} value of CCh stimulated IP_1 formation was 10 uM with the Hill coefficient of the dose-response curve being 0.91. Active phorbol esters PMA and beta-PDD decreased CCh-stimulated IP_1 formation. In the presence of 10 uM PMA and beta-pDD, Emax was reduced to 25 % the effect of CCh alone. This inhibitory effect was not reversed by 10^{-2} M taurine. 10 uM alpha-PDD did not reduce the Emax.

PZ (10^{-4} - 10^{-8} M), AF-DX 116 (10^{-4} - 10^{-6} M) and atropine (3 x 10^{-7} - 10^{-9} M), a classical muscarinic antagonist, all shifted the CCh dose-response curves to the right without reducing the maximal effects of CCh. The pA_2 value from Schild regression analysis of AF-DX 116 inhibition of CCh-stimulated phosphoinositol hydrolysis was 6.5 with the slope being 1.1. The K_I value converted from the pA_2 value was 320 nM which is in agreement with the apparent disociation constants (K_d) from AF-DX 116/[^{3}H](-)QNB inhibition studies (250 nM). However, the slope from the Schild plot of the PZ inhibition over the whole range of concentrations was less than one. Schild analysis revealed that PZ inhibited CCh-stimulation IP_1 formation by interaction with two affinities. The K_I value converted from the high affinity site's pA_2 value was 10 nM, which was in good agreement with the K_d values of PZ from [^{3}H]PZ direct binding, PZ/[^{3}H]PZ and PZ/[^{3}H](-)QNB indirect binding studies. Supported by NIH grants.

379.6 CHARACTERIZATION OF MUSCARINIC RECEPTORS IN THE ANTERIOR PITUITARY CLONE CELL LINE GH_3. M.D. Collado*, P.G. Lysko* and R.C. Henneberry. (SPON: H. deF. Webster). Molecular Neurobiology Section, Laboratory of Molecular Biology, NINCDS, NIH, Bethesda, MD. 20892.

Muscarinic receptors have been described in anterior pituitary homogenates and anterior pituitary primary cultures. Effects of muscarinic agonists on secretion of anterior pituitary hormones have been described as well; muscarinic agonists stimulate thyrotropin and growth hormone and inhibit corticotropin and prolactin secretion. Two different biochemical responses have been associated with stimulation of the different muscarinic receptor subtypes M_1 and M_2. Phosphoinositide hydrolysis is coupled to stimulation of M_1 receptors and stimulatory secretory responses while inhibition of cAMP formation is associated with M_2 receptors and inhibitory secretory responses.

The aim of the present work has been the characterization of muscarinic receptors in a homogeneous population of intact GH_3 cells using the muscarinic antagonist [^{3}H]-Methylscopolamine ([^{3}H]-MSC) and the selective antagonist piranzepine to differentiate M_1 and M_2 subtypes. The effect of muscarinic agonists on phosphoinositide breakdown were also studied to correlate the presence of M_1 with physiological function.

The binding experiments on intact cells were performed at 37°C and pH 7.4 in Krebs-Ringer-Hepes. Binding equilibrium was reached in 15 min and was stable for 1 h. Scatchard analysis showed one binding site for [^{3}H]-MSC with high affinity (K_d 180 pM) and B_{max} 271 fmols/mg protein. Comparing these results with [^{3}H]-MSC binding to GH_3 membranes under the same conditions also showed one high affinity binding site with K_d 230 pM and B_{max} 76 fmols/mg protein.

Competition experiments using different agonists (acetylcholine, carbamylcholine and oxotremorine) and antagonists (imipramine and atropine) to displace [^{3}H]-MSC binding, showed IC 50s in the nM range for atropine and in the μM range for the agonists and imipramine. Using the partially selective antagonist piranzepine in the competition experiments a biphasic curve was obtained, suggesting the presence of two binding sites. To confirm this suggestion the effect of muscarinic agonists acethylcholine and carbamylcholine was tested measuring the levels of inositol phosphates IP, IP2 and IP3 in the presence of Li^+. We found that muscarinic agonists in uM concentrations induce a significant increase in IP3 levels within 20 min., supporting the presence of M_1 binding sites.

379.7 MUSCARINIC RECEPTORS IN TWO CELL LINES THAT HAVE DIFFERENTIALLY COUPLED RECEPTORS. J. Baumgold. Membrane Biochemistry Section, DMNB, NINCDS, Bethesda, MD. 20892

Activation of muscarinic receptors leads to several cellular responses, including inhibition of adenylate cyclase and stimulation of phosphoinositide (PI) turnover. Whether each of these responses is mediated via distinct muscarinic receptor subtypes, or whether a single receptor subtype can mediate any of these responses, is a question that we have addressed in the following work. We identified and studied two cell lines that have muscarinic receptors coupled to separate and distinct effector systems. Activation of muscarinic receptors in NG108-15 cells leads to the inhibition of prostaglandin E1 (PGE1)-stimulated cAMP accumulation. Stimulation of PI turnover could not be detected in these cells. On the other hand, activation of muscarinic receptors in SK-N-SH neuroblastoma cells resulted in stimulation of PI turnover but not in inhibition of cAMP accumulation.

The muscarinic antagonist pirenzepine inhibited the effect of carbachol on both the cAMP accumulation response in NG108-15 cells, and the PI turnover in SK-N-SH cells. The IC50 for the pirenzepine inhibition curves for both of these effects was 2 ± 2 μM, consistent with an M2 receptor subtype. Furthermore, binding studies revealed that both of these cell lines had identical pirenzepine inhibition curves for [^{3}H]-N-methyl-scopolamine binding, with Ki values of 1-3 μM, again consistent with an M2 receptor subtype. In addition, McN-A-343, a selective M1 agonist, failed to either inhibit PGE1-stimulated adenylate cyclase in NG108-15 cells, or to stimulate PI turnover in SK-N-SH cells.

Muscarinic receptors have also been subtyped on the basis of their agonist affinity. In order to determine the agonist affinity state of the receptor for each response, we determined the carbachol dose-response relationship for the appropriate response in each cell type. The dose-response relationship for carbachol stimulation of PI turnover in SK-N-SH cells was sigmoidal and had an IC50 of 8 ± 2 μM, consistent with a high-affinity state of the receptor. Similarly, the dose-response relationship for carbachol inhibition of PGE1-stimulated adenylate cyclase in NG108-15 cells was also sigmoidal and had an IC50 of 3 ± 2 μM, again consistent with an agonist high-affinity state of the receptor.

These results demonstrate that the agonist high-affinity state of the M2 receptor subtype is capable of mediating both adenylate cyclase inhibition and PI turnover.

379.8 [^{3}H]PBCM-LABELLING OF MUSCARINIC CHOLINERGIC RECEPTORS THAT SELECTIVELY COUPLE TO PHOSPHOLIPASE C OR ADENYLATE CYCLASE IN TWO CULTURED CELL LINES. M. Liang*, M. W. Martin* and T. K. Harden (SPON: B. S. Pallotta). Dept. of Pharmacology, Univ. of North Carolina School of Medicine, Chapel Hill, N. C. 27514.

Although both second messenger response systems are fully functional in both cell lines, activation of muscarinic cholinergic receptors (MR) only results in inhibition of adenylate cyclase in NG108-15 neuroblastoma x glioma cells and stimulation of phosphoinositide hydrolysis in 1321N1 human astrocytoma cells. MR on both NG108-15 and 1321N1 cells were covalently labelled by the MR antagonist, [^{3}H]-propylbenzilylcholine mustard hydrochloride ([^{3}H]-PBCM) and the properties of the [^{3}H]-PBCM-labelled species of both cells were compared by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). 1321N1 and NG108-15 cells each primarily expressed a single [^{3}H]-PBCM-labelled species with an apparent size of approximately 92,000 and 66,000 daltons, respectively. [^{3}H]PBCM-labelling was completely inhibited by 1 μM atropine or by down-regulation of MR by an overnight incubation with carbachol. The apparent size of the [^{3}H]-PBCM-labelled species of both cell lines was not altered by treatment with a series of protease inhibitors or by treatment with dithiothreitol and iodoacetamide. Since MR are glycoproteins, the contribution of carbohydrate groups to the difference in apparent size of the [^{3}H]-PBCM-labelled proteins on 1321N1 and NG108-15 cells was determined by treatment of [^{3}H]-PBCM-labelled membranes with endoglycosidase F (Endo F), an enzyme that removes both complex and high mannose type N-linked carbohydrate chains. Endo F treatment reduced the apparent size of the [^{3}H]-PBCM-labelled species in 1321N1 cells from 92,000 daltons to approximately 77,000 daltons and in NG108-15 cells, from 66,000 daltons to 45,000 daltons. Higher concentrations of Endo F, longer incubation times, or readdition of fresh enzyme did not produce a further reduction in apparent size of the [^{3}H]-PBCM-labelled protein in either cell line. Neuraminidase produced no further reduction of the apparent size of the [^{3}H]-PBCM-labelled species from either cell type after Endo F treatment, suggesting the absence of sialic acid containing 0-linked carbohydrate chains on MR. These results suggest that different MR proteins may be responsible for the different biochemical responses mediated by MR, i.e. inhibition of adenylate cyclase and stimulation of phosphoinositide hydrolysis. (Supported by USPHS grants GM 38213 and NS23019).

379.9 ANTIMUSCARINIC ACTIVITY OF S-ISOBUTYL-ADENOSINE (SIBA) AND ITS ANALOGS WITH RESPECT TO MUSCARINIC RECEPTORS IN RAT BRAIN AND GUINEA PIG ILEUM. R.M. Smejkal*, I.M. Abalis*, Marvin C. Pankaskie*† and P.K. Chiang (SPON: R. T. Borchardt). Walter Reed Army Institute of Research, Washington, DC 20307-5100, and †University of Nebraska, Omaha, NE 68105.

S-Isobutyl-adenosine (SIBA), an attributed inhibitor of transmethylation reactions, and its analogs were tested for their effects on acetylcholine-induced contraction of guinea pig ileum and on the specificity of various ligands with respect to muscarinic receptor subtypes in different regions of rat brain. At 100 μM, SIBA and its analogs caused a 15-20% inhibition of [^{3}H]N-methylscopolamine ([^{3}H]NMS) binding to homogenates of both whole brain and cerebral cortex (rich in M_1 subtype). In comparison, a 20-30% inhibition was observed for SIBA and a subset of the analogs in brain cerebellum (rich in M_2 subtype). At high concentrations, SIBA and most of the analogs tested inhibited the binding of [^{3}H]quinuclidinyl benzoate ([^{3}H]QNB) to the total population of muscarinic receptors. However, at low concentrations, these drugs showed small stimulatory effects on [^{3}H]QNB binding sites. Interestingly, the stimulation of NMS-inaccessible [^{3}H]QNB binding sites (a subpopulation of [^{3}H]QNB sites) to whole brain homogenates was observed in the presence of low concentrations of SIBA and several analogs. The maximal stimulation was about 137% of control at 1 μM, after which stimulation decreased. On the other hand, SIBA and all the analogs tested inhibited the binding of [^{3}H]pirenzepine ([^{3}H]PZ), in a dose-dependent manner with a K_i value within the μM range, to the whole brain and cerebral cortex. The rank order of potency for the inhibition of [^{3}H]PZ binding is N^6-methyl-S-benzyladenosine > N^6-methyl-S-cyclohexyladenosine > N^6-methly-S-phenyladenosine > N^6-N^6-dimethyl-SIBA > SIBA > N^6-methyl-SIBA > S-isopropyl-adenosine > 7-deaza-SIBA. Some of these analogs were tested for their ability to antagonize the acetylcholine-induced contraction of guinea pig ileum, a tissue containing predominantly M_2 subtype receptors. The potency of the analogs was slightly better than that of pirenzepine, but several orders of magnitude lower than atropine. The order of potency for these analogs was opposite that described above: N^6-methyl-SIBA > N^6-methyl-S-phenyl-adenosine > N^6-methyl-S-cyclohexyladenosine > N^6-methyl-S benzyladenosine. These results suggest that SIBA and some of its analogs have differential effects on muscarinic receptor subtypes both in rat brain and in guinea pig ileum. Their actions appear to be more similar to those of pirenzepine than to the other antagonists tested, implying some specificity for the M_1 receptor subtype.

379.10 DIFFERENTIATION OF MUSCARINIC CHOLINERGIC RECEPTOR SUBTYPES IN GUINEA PIG BRAIN: COMPARISON OF RADIOLIGAND AND NEUROPHYSIOLOGICAL DATA. B.G. McCarthy and S.J. Peroutka (SPON: M.K. Floeter). Departments of Neurology and Pharmacology, Stanford University, Stanford, CA 94305.

Radioligand binding studies were used to analyze muscarinic cholinergic receptor subtypes in guinea pig cortex and thalamus. Muscarinic cholinergic receptors were labeled with ^{3}H-quinuclidinyl benzilate (QNB) in the absence or presence of 10^{-5} M carbachol. Specific binding in all experiments was defined as the excess over blanks taken in the presence of 10^{-6} M scopolamine. Muscarinic cholinergic agents that were tested included DMPP, MCN-A-343, metacholine, pilocarpine, propionyl-choline, and suberyldicholine. None of the agents tested significantly distinguished muscarinic cholinergic receptors labeled by ^{3}H-QNB in guinea pig cortex from those in thalamus. The greatest selectivity observed was with pilocarpine, which showed a 4-fold selectivity for thalamic muscarinic cholinergic receptors labeled by ^{3}H-QNB over those in cortex. The presence of 10^{-5} M carbachol (added to theoretically block ^{3}H-QNB binding to M_2 binding sites) did not alter significantly the drug affinities for ^{3}H-QNB labeled receptors.

The data in the present study will be compared to the recent physiological data of McCormick and Prince (PNAS 82:6344-6348, 1985) which suggest that the tested agents are able to differentiate between muscarinic cholinergic receptor subtypes in guinea pig brain. Neurophysiological data indicate that muscarinic cholinergic receptor subtypes can be distinguished in guinea pig brain. However, the differentiation of muscarinic cholinergic receptors into M_1 and M_2 binding site subtypes, based on radioligand data, does not correlate with the pharmacological characteristics of M_1 and M_2 muscarinic cholinergic responses observed neurophysiologically.

379.11 BINDING OF THE PUTATIVE CARDIOSELECTIVE MUSCARINIC ANTAGONIST, [3H]AF-DX 116, TO M2 MUSCARINIC ACETYLCHOLINE RECEPTORS IN RAT CEREBRAL CORTICAL MEMBRANES. M. Watson. Dept. of Pharmacology, University of Medicine and Dentistry of New Jersey- New Jersey Medical School, Newark, N.J. 07103-2757.

Previous data obtained from the use of selective antagonists such as pirenzepine (PZ) and AF-DX 116 (11-2-[[2-[(diethylamino) methyl]-1- piperidinyl] acetyl] -5,11-dihydro-6H-pyrido (2,3-b) (1,4) benzodiazepine-6-one) in many binding and functional assays has lead to the recent subclassification of muscarinic acetylcholine receptors (mAChR) into at least two (M1/M2) subtypes (Watson et al., TIPS Suppl. II: 46, 1986). While PZ has high affinity at M1 mAChRs, the novel "cardioselective" antagonist AF-DX 116 has emerged as a competitive selective inhibitor at M2 mAChRs. AF-DX 116 inhibits binding of the highly specific but non-subtype selective mAChR antagonist [3H](-)quinuclidinylbenzilate ([3H](-)QNB) to freshly prepared cardiac membranes with uniform high affinity (Ki=40nM; Hill=1.0). The recent availability of [3H]AF-DX 116 of high specific activity (62.0 Ci/mmole, New England Nuclear, Boston, MA) now permits the validation of these data and the characterization of [3H]AF-DX 116 binding sites by the direct study of the specific binding of [3H]AF-DX 116 to rat cerebral cortical and cardiac homogenates. A rapid filtration technique was used to separate bound from free ligand, and the filters were presoaked in aqueous polyethylenimine (1hr, 0.1%, Sigma) to minimize filter binding. Atropine sulfate (1uM) was used to define specific tissue binding. [3H]AF-DX 116 (10nM, 25°C) binding to cerebral cortical membranes showed fast association kinetics, reaching steady state in 45 min. Dissociation kinetics were very rapid. Although non-specific binding was relatively high (>50% at Kd), nearly 70% of counts were specific at 10nM. Stereospecificity of [3H]AF-DX 116 labeled mAChR binding sites was revealed by inhibition studies (10nM, 25°C, 2hr) of benzetimide stereoisomers, with dexetimide showing ~500x greater potency than levetimide. Inhibition studies of agonists produced shallow curves (Hill<1), while antagonists generally were steep. The order of potency was determined to be atropine=dexetimide=scopolamine>AF-DX 116>oxotremorine>PZ>>acetylcholine=carbamylcholine>levetimide. A specific regional distribution was seen in the brain, with cerebellum>pons-medulla>hypothalamus>cerebral cortex>hippocampus>corpus striatum. [3H]AF-DX 116 bound to cerebral cortex and heart homogenates, yielding data comparable to indirect studies. High affinity AF-DX 116 binding is seen in the cerebral cortex after 2-site analysis of [3H](-)QNB inhibition data, with 25% of sites showing high (Ki=50nM) affinity and 75% of AF-DX 116 sites showing low (Ki=500nM) affinity. Thus, [3H]AF-DX 116 labels a subclass of mAChRs labeled by [3H](-)QNB, suggesting it may be a useful ligand for M2 mAChR identification and studies of M2 mAChR mechanisms and possible heterogeneity.

379.12 N-Substituted piperidinyl benzilates: affinities for brain muscarinic cholinergic receptors. G.R. Luthin, D.J. Brunswick, B.B. Wolfe, and S.M. Tejani-Butt, Depts. of Psychiatry and Pharmacology, U. of PA. Sch. Med., and Neuropsychopharmacology Unit, V.A. Medical Center, Philadelphia, PA 19104.

The piperidinyl and quinuclidinyl esters of benzilic acid are potent antagonists of muscarinic cholinergic receptor activity. N-substitutions using small-chain alkyl groups have been demonstrated to modulate the binding affinities of these ligands. It was of interest in the present study to clarify further the effects of N-substitutions on binding affinities for some benzilate esters. For these studies, piperidinyl benzilate was chosen as a model compound, as this ligand possesses high affinity for muscarinic receptors, and unlike the quinuclidinyl benzilates does not have a chiral center.

N-Substituted derivatives of 4-piperidinyl benzilate were formed by reaction of the sodium salt of 4-piperidinol with the appropriate alkyl halide, followed by reaction with ethyl benzilate. The affinity of each compound for muscarinic receptors was estimated from its ability to compete for (^{3}H)-QNB binding to membranes prepared from rat forebrain. Measured IC(50) values were corrected to Ki values using the Cheng and Prusoff equation. The Ki values obtained for atropine and QNB under these conditions were approximately 0.5 and 0.02 nM, respectively. Unsubstituted (R = H) piperidinyl benzilate exhibited a Ki value of 2 nM. Addition of a methyl or an ethyl group increased the affinity to 0.5 nM, while isopropyl and n-propyl substitutions decreased the affinity to 10 and 30 nM, respectively. From this, it appeared that modest 1, 2 or 3 carbon alkyl substitutions could alter the potency of piperidinyl benzilate over a 50-fold range of affinity. Further substitutions were used to introduce an aromatic ring one or two methylene groups removed from the nitrogen atom. The following compounds were tested, and the potencies obtained were: R = CH_2-phenyl (benzyl), 0.24 nM; R = CH_2-CH_2-phenyl (phenethyl), p-nitrobenzyl, or p-aminophenethyl, 10 nM; R = p-fluorobenzyl, 150 nM. The ΔG values were calculated for the derivatives as $-RTlnK_a$, where $K_a = 1/K_i$. In the benzyl series, the relative changes in ΔG values associated with p-nitro and p-fluoro substitutions were + 2.23 and + 3.87 kcal/mol, respectively, compared to the benzyl substitution alone. These relative changes in ΔG presumably were not solely the result of an electronic effect on the piperidinyl nitrogen, as the Hammett function did not predict the relative affinity changes. Because this binding region could tolerate rather bulky (eg, benzyl or phenethyl) substitutions as well or better than short-chain alkyl substitutions (eg, propyl), it is not clear that this binding interaction is a stabilization due to simple hydrophobic forces. It can be tentatively concluded that secondary sites of interaction near the piperidinyl nitrogen may exist, and may in fact contribute to the overall binding energy as a result of a specific form of hydrophobic interaction. 379.13 STUDIES ON THE DIFFERENTIAL INHIBITION OF MUSCARINIC RECEPTOR SUBTYPES BY PYRIDINIUM OXIMES IN RAT BRAIN AND HEART. I.M. Abalis, R.G. Andre and P. K. Chiang. Walter Reed Army Institute of Research, Washington, DC 20307-5100.

The pyridinium oxime 2-PAM, bispyridinium bis-oxime TMB-4 and the H-oximes HI-6 and HS-6 are antidotes for organophosphate poisoning. We investigated the nature of the interaction of these oximes with their binding sites in various regions of rat brain and heart through the use of the muscarinic antagonist ligands [^{3}H]quinuclidinyl benzilate ([^{3}H]QNB), [^{3}H]N-methyl-scopolamine ([^{3}H]NMS) and [^{3}H]pirenzepine ([^{3}H]PZ). All four oximes tested inhibited the binding of [^{3}H]QNB, [^{3}H]NMS and [^{3}H]PZ to rat brain and heart with K_i values in the micromolar range. The rank order of potency is: TMB-4 > HS-6 > 2-PAM > HI-6. All four were more potent inhibitors of the labeled ligands to homogenates of cerebral cortex (an area rich in M_1 subtype receptors) than to homogenates of cerebellum or heart (an area rich in M_2 subtype receptor). Furthermore, these inhibitors were more potent in inhibiting [^{3}H]PZ binding, in comparison to their effects on [^{3}H]QNB or [^{3}H]NMS binding to muscarinic receptors of cerebral cortex. Scatchard analysis of the binding of [^{3}H]NMS, [^{3}H]QNB and [^{3}H]PZ to cerebral cortex in the presence of I_{50} concentrations of each oxime gave lower affinity constants (K_D), but similar or slightly lower B_{max} values with Hill coefficients equal to unity, suggesting competitive inhibition. However, in the presence of I_{50} concentrations of the oximes, a decrease in the number of NMS-inaccessible [^{3}H]QNB binding sites (a subpopulation of [^{3}H]QNB binding sites) was observed in the cerebral cortex and cerebellum; but the binding affinity was not affected. Interestingly, most of the oximes significantly altered the rate of dissociation of the [^{3}H]NMS binding in receptors from cerebellum but had no effect on the dissociation rate in receptors from the cerebral cortex. On the other hand, these oximes failed to change the rate of dissociation of the [^{3}H]PZ binding to the pirenzepine-sensitive M_1 muscarinic receptor subtype in cerebral cortex, also indicative of competitive inhibition. These results showed that all of the oximes have differential effects on muscarinic receptor subtypes and may exert their therapeutic action by blocking the high affinity sites of the central muscarinic receptors and, thus, counteract the effect of excess acetycholine at muscarinic receptor sites.

379.14 ONTOGENY OF PHARMACOLOGICAL SPECIFICITY OF THE CEREBRAL CORTICAL MUSCARINIC RECEPTOR IN THE RAT. D.C. Serbus* and K.E. Light Center for Addiction Studies, College of Pharmacy, University of Arkansas for Medical Sciences, Little Rock, AR 72205.

Development of the cortical muscarinic receptor system in the rat is known to be essentially a postnatal phenomenon (Evans et al., **JPET 235(3):612, 1985**; Serbus et al., **Neurotoxicol. 7(2):257, 1986**), but the question of the interaction of the emerging receptors with a variety of pharmacological agents has not been addressed. Male Sprague Dawley rats were reared in litters of ten and cortices were obtained by decapitation on postnatal (PN) days 4, 8, or 20; lactating female rats provided adult cortical tissue. Ten-point (0.1nM to 10uM) competition assays were performed on P_2-level synaptosomal aliquots (10 ug protein/assay) of each cortex to determine the potency of a series of non-radiolabelled ligands for competition with (^{3}H)-quinuclidinyl benzilate (QNB, 0.3nM) for binding to muscarinic receptors. K_i values were calculated (Cheng and Prusoff, **Biochem. Pharmacol. 22(23):3099, 1973**) from ALLFIT-determined IC_{50} estimates obtained by duplicate analysis of replicate cortices.

K_i for Competition with (^{3}H)-QNB Binding (uM)

Age	Oxo	Phentol	Pyril	Curare	Dex ($x10^{-3}$)	Lev
PN4	0.008	0.049	0.117	0.412	0.245	0.014
PN8	0.144	3.37	1.36	3.39	0.214	0.256
PN20	0.219	11.9	2.78	4.12	0.127	0.247
Adult	0.111	2.55	>100	>100	0.200	0.310

(Oxo=oxotremorine; Phentol=phentolamine; Pyril=pyrilamine; Dex=dexetimide; Lev=levetimide)
Neither (+) bicucculine nor methysergide showed measurable competition at 10^{-5}M, regardless of age.

CONCLUSION: Cortical muscarinic receptor pharmacospecificity develops early in postnatal life. As evidenced by a time-dependent increase in K_i for non-muscarinic drugs, the developing muscarinic receptor increasingly refines its ability to screen-out the influence of non-muscarinic drugs. Stereoisomeric discriminative power (the potency ratio of Dex:Lev) was in turn found to develop within the first postnatal week, primarily due to a loss of competitive potency of Lev. We conclude that the postnatal ontogeny of the cortical muscarinic system entails refinement of pharmacological specificity of the emerging receptors as well as the previously demonstrated increases in receptor number, associated enzymes, and coupled processes. 379.15 CHARACTERIZATION OF MUSCARINIC BINDING IN ASTROCYTE CULTURES FROM RAT CEREBRAL CORTEX. D.E. Rosenblatt[1], D. Mash[3], and W.F. White[2], Division on Aging[1] and Department of Neuroscience[2], Harvard Medical School, Boston, MA 02115, Dept. of Neurology[3], University of Miami School of Med., Miami, FL 33136.

Astrocytes have receptors for a number of neurotransmitters. Pharmacological studies suggest the presence of muscarinic receptors on astrocytes (Murphy, S. et al., Br. Res. 364:177, 1986) and Repke and Maderspach (Br. Res. 232:206, 1982) have reported ^{3}H-quinuclidinylbenzilate (QNB) binding on chicken astrocytes. In light of the importance attributed to changes in the cholinergic system in aging and Alzheimer's disease and the frequency with which the rat has been used as a model for both of these conditions, we have undertaken the characterization of cholinergic binding in rat cortical astrocytes.

Primary astrocytes were prepared from one day old rat pups by a modification of the method of McCarthy and DeVellis (JCB 85:890, 1980). Cultures were seeded using one cortex per 150 cm^2 flask in DMEM; Ham's F12 1:1 with 15 per cent fetal calf serum (FCS). Cultures were fed every three days with medium containing 10 per cent FCS and shaken overnight on day seven to remove oligodendrocytes. Secondary cultures were prepared by trypsinization and seeding into six well plates. Cultures were 95 per cent or more pure based on staining for GFAP, fibronectin, and galactocerebroside.

Total muscarinic binding was assayed using ^{3}H-QNB. Pirenzepine and oxotremorine were used to assay for receptor subtypes. Attempts to study binding in whole cells were hampered by cellular trapping of ^{3}H-QNB. Studies were therefore carried out either on saponized secondary cultures (0.05 per cent saponin for 10 min. at room temperature) or membrane preparations from primary cultures.

QNB binding was done in phosphate buffer pH 7.5 at 20°C. Binding was terminated by filtration on Whatman GFC glass filters. Radioactivity on the dried filters was measured by scintillation counting.

QNB binding in membranes and saponized cells gave slightly different results. The KD in the membrane preparation was similar to that for whole brain but the Bmax was much lower. Further characterization of the muscarinic site and elucidation of the sub-type is in progress.

379.16 AGONISTS AND ANTAGONISTS INTERACTION WITH THE RAT LARGE AIRWAY MUSCARINIC CHOLINERGIC RECEPTOR. K.K. McMahon* (SPON: J. Buggy). Dept. Pharmacol., Univ. South Carolina, School of Medicine, Columbia, SC 29208.

The neurotransmitter acetylcholine causes bronchioconstriction and glandular secretions in large airways by interacting with muscarinic cholinergic receptors on the smooth muscle and gland cells of the respiratory tract. Reported is the characterization of these muscarinic receptors of the large airway by determining the receptors affinities for a variety of agonists and antagonists. The large airways used are from the first to the third biforcations of the airways. The adjoining and peripheral lung tissues were stripped away. Radioligand binding and competition displacement were used to determine the density of receptors, affinities of ligands, and the effect of the additions of Mg^{+2} and guanine nucleotide on affinities of ligands. The radioligand used was [^{3}H]-QNB. The receptor density was 141 fmol/mg protein and the K_D for QNB was 40 pM. The order of affinities of the antagonists tested was: atropine, Ro 2-3773, ipratropium > telenzepine > AF-DX116, hexahydrosiladifenidol, pirenzipine. With the exceptions of ipratropium and Ro 2-3773, the competition curves of the antagonists had Hill coefficients of 1. This suggests that the receptor population was homogeneous with regard to antagonists binding. The order of affinities of the agonists tested was: oxotremorine > acetylcholine, oxotremorine-M > carbachol, RS86 HB > McN-A-343 > AHR 602. Comparisons of binding data in rat large airways, cortex, ileum and heart for several agonists and antagonists were made. All the competition curves of the agonists had Hill coefficients of less than 0.8. This suggests that the receptor population was heterogeneous towards the agonists. Multiple agonist affinity states of the receptor-population were determined by nonlinear regression analysis of these data. The addition of 10 mM Mg^{+2} to the assay mixture causes the affinities of agonists to increase. When the guanine nucleotide, 0.1 mM Gpp(NH)p, was also present in the assay the affinity for all of the agonists was diminished but to differing degrees. The Hill coefficients for the agonists were increased in the presence of Gpp(NH)p. The data suggest that an M_2cardiac type muscarinic receptor population which is coupled to a G protein is present in the rat large airway. (Supported by the American Lung Association, South Carolina Affiliate.)

379.17 CHARACTERIZATION OF MUSCARINIC CHOLINERGIC RECEPTORS IN RABBIT THORACIC AORTA. T. Tsukahara, N.F. Kassell, K. Hongo, H. Ogawa. Dept. of Neurosurgery, Univ. of Virginia Sch. of Med., Charlottesville VA 22908.

Vascular endothelium was shown to release vascular relaxing factors(s) (EDRF) when stimulated by acetylcholine (ACh). This response is considered to be mediated by muscarinic receptors as the relaxing effect of ACh is inhibited by atropine. However, the existence of muscarinic cholinergic receptors on the vascular endothelium is still controversial, since EDRF is not released by ACh from cultured endothelium cells from bovine aorta. An autoradiographic study was performed to characterize the muscarinic receptors on the vascular endothelium of rabbit thoracic aorta, using 3H-propylbenzilyl choline mustard (PrBCM), a potent muscarinic antagonist, which binds specifically and irreversibly to muscarinic receptors. Ten μm cryostat sections taken through rabbit thoracic aorta were mounted on glass slides and incubated with 1 nM and 25 nM 3H-PrBCM. After developing autoradiography on the tissue, the silver grains on the endothelium and the smooth muscle layer were counted and quantified under light microscopy. Total binding was sensitive to pretreatment with 10^{-6}M atropine or 10^{-6} M cold PrBCM. The specific bindings (cold-PrBCM sensitive bindings) were saturable. The saturation time of the bindings was not significantly different between the receptors in the endothelium and those in smooth muscle. The density of the specific binding was higher in the smooth muscle layer than in the endothelium. These results suggest the existence of muscarinic cholinergic receptors on the endothelium of rabbit thoracic aorta and that the affinity to PrBCM of the receptors on the endothelium and

379.18 **IMPAIRED MUSCARINIC TRANSDUCTION IN HAMSTER CARDIOMYOPATHY.** P. Chidiac*, A. Nagy*, M.J. Sole* and J.W. Wells. Departments of Pharmacology and Medicine, Faculty of Medicine, and Faculty of Pharmacy, University of Toronto, Toronto, ON M5S 1A1, Canada.

The antagonist N-[^{3}H]methylscopolamine ([^{3}H]NMS) has been used to label muscarinic receptors in left ventricular homogenates from cardiomyopathic Syrian hamsters (TO strain) during late stages of the disease and from age-matched, random-bred (RB) controls. The inhibitory behavior of carbachol versus the specific binding of 1 nM [^{3}H]NMS was studied in the presence and absence of 0.1 mM GMP-PNP as described by Wong et al. (Biochemistry 25:6995, 1986). Three classes of sites were required for a multi-site model to provide an adequate description of the data acquired with myopathic tissue in the absence or presence of GMP-PNP; data acquired with control preparations required 3 and 2 classes in the absence and presence of nucleotide, respectively.

Simultaneous analyses indicated that four dissociation constants (K) are sufficient for the model to describe all of the data taken together: one each for the sites of highest (log K_1 = -7.72 ± 0.11) and lowest affinity (log K_3 = -4.51 ± 0.05) observed with both strains both with and without GMP-PNP, and one each for the sites of medium affinity with both strains either in the absence (log K_2 = -6.10 ± 0.06) or in the presence (log K_2 = -5.67 ± 0.09) of the nucleotide. The values obtained for the relative capacities of each class (F_S, S = 1, 2, or 3) are listed in the Table. Further simplification involving single values of F_S for both strains caused the variance of residuals to increase significantly ($P < 0.01$) in all cases except F_3 in the absence of nucleotide ($P = 0.73$). The variance also increased significantly in analyses with 12 values of K_S and various arrangements involving fewer values of F_S.

	without GMP-PNP			with GMP-PNP		
STRAIN	F_1	F_2	F_3	F_1	F_2	F_3
RB	0.13	0.65±0.03	0.22±0.02	0.04	0.55±0.04	0.41±0.04
TO	0.30	0.46±0.03	0.23±0.02	0.11	0.31±0.04	0.58±0.04

The activity of GTP-stimulated adenylate cyclase was measured in left ventricular homogenates according to a procedure modified from that of Salomon et al. (Anal. Biochem. 58:541, 1974). The inhibitory potency of carbachol was the same for RB and TO hamsters (log IC_{50} = -5.94 ± 0.04), but maximal inhibition decreased from 31 ± 1% in normal tissue to 16 ± 2% in diseased tissue ($P = 0.0019$). The value of IC_{50} compares favorably with the values of K_2 obtained in the binding assays; moreover, the disease-related decrease in maximal inhibition recalls the corresponding decrease in F_2. The data indicate that hamster cardiomyopathy is accompanied by a defect in G-protein-mediated regulation of adenylate cyclase by muscarinic receptors. (Supported by the Medical Research Council of Canada, the Heart and Stroke Foundation of Ontario, and the US Public Health Service)

380.1 ROLE OF CERVICAL LYMPHATICS IN THE SYSTEMIC HUMORAL IMMUNE RESPONSE TO HUMAN SERUM ALBUMIN (HSA) MICROINFUSED INTO CEREBROSPINAL FLUID (CSF). C. Harling-Berg*, P. Knopf*, K.D. Pettigrew* and H.F. Cserr. Brown University, Providence, RI 02912.

A significant fraction of HSA (13%-50%) infused into brain or CSF drains via the olfactory nerve sheath and cribriform plate into deep cervical lymph, reaching cervical lymph nodes in high concentration (Bradbury & Cserr. In: Exp. Biol. Lymph Circ., Elsevier, 1985,355-394). We have evaluated the role of cervical lymphatic drainage in systemic immunization against antigen leaving the CNS, by examining 1) the effect of cervical lymph obstruction on serum antibody titers to centrally administered HSA and 2) the role of deep and superficial cervical lymph nodes in systemic antibody secretion. Experiments were conducted in 4 groups of male Sprague-Dawley rats: normal, cervical lymph obstructed (CLO), sham operated controls, and inguinal lymph obstructed (ILO). A sterile HSA saline solution (90 μg in 10μl) was infused into lateral ventricular CSF (0.5 μl/min) through a catheter implanted 7 days previously. Lymph flow was obstructed 10 days prior to antigen infusion in CLO rats, by surgical removal of nodes and ligation of large cervical lymph vessels, and in ILO rats, by node removal. Serum HSA antibody titers were measured 14 days post infusion using an enzyme-linked assay. In control rats, HSA infusion into CSF yielded serum titers with a geometric mean of 234 (N=12). Serum titers were significantly reduced in CLO rats (N=11) as compared to normals (P<.02), sham operated controls (P<.01, N=5) and ILO rats (P<.02, N=10) (Smirnov Test). In an additional series of normal CSF-infused rats (N=11), cell culture techniques were used to localize the site of antibody secreting cells. Deep and superficial cervical lymph nodes, inguinal nodes, and spleen were removed aseptically, and cells cultured for 4-5 days. White blood cell (WBC) concentrations of lymph node and spleen cultures for each rat were equal ($1\text{-}2 \times 10^7$ WBC/ml media). 100% of cervical node cultures and 54% of spleen cultures had detectable antibody titers, whereas there was no detectable antibody (ND) at starting dilutions of 1:5 in inguinal node cultures. The range of titers (expressed per 10^7 WBC) for superficial and deep cervical nodes and spleen were 5-94, 5-111, and ND-14, respectively. Results indicate that drainage of brain extracellular fluids into cervical lymphatics plays a significant role in brain-immune system interactions. Supported by USPHS Grant NS-11050.

380.2 INTERLEUKIN-1 IMMUNOREACTIVE STRUCTURES IN PERIPHERAL ORGANS M. Schultzberg*, S.B. Svenson*, A. Undén* and T. Bartfai (SPON: H. Aldskogius). Dept. of Pathology, Karolinska Inst., Huddinge Hosptl; Dept. of Vaccine Production, National Bacteriol. Lab.; Dept. of Biochem., Stockholm University, Stockholm, Sweden.

Interleukin-1 (IL-1) is a 17 kD polypeptide, which is synthesized in macrophages and monocytes upon stimulation by e.g. bacterial endotoxins. Among its biological activities are stimulation of thymocyte proliferation and acting as an endogenous pyrogene. The human and murine IL-1 have several homologies in their amino acid sequence. Antiserum was raised in rabbits to a synthetic peptide corresponding to the amino acid residues 169 to 194 in the murine IL-1 precursor (Lomedico et al.,1984). The antibodies were used in immunohistochemical studies of peripheral organs. Sprague-Dawley rats were perfused with 4% paraformaldehyde containing 0.2% picric acid. Pieces of the gastrointestinal tract, the coeliac-superior mesenteric ganglion complex, urinary bladder, vas deferens, liver, kidney, adrenal gland and the lymphatic organs, thymus, spleen and lymph nodes were dissected out, immersed in fixative and rinsed in 10% sucrose before sectioning and staining. Interleukin-1 immunoreactive structures with a varicose appearance were found to follow the distribution pattern of nerve fibres in these organs. In the gastrointestinal tract, IL-1 immunoreactive fibres were observed in the smooth muscle layers, the myenteric and submucous plexus and in the connective tissue, where they often surrounded blood vessels. A dense network of immunoreactive fibres was also seen in the coeliac ganglion, and particularly numerous fibres could be seen in smooth muscle layers of the urinary bladder and vas deferens. Blood vessels surrounded by IL-1 immunoreactive fibres were found in all organs including the lymphatic organs.
In conclusion, IL-1-like immunoreactivity was found in fibrous structures in several peripheral organs, with a distribution resembling that of nerve fibres. The exact localization of the IL-1 immunoreactive material needs further investigation. It may reside within neurones, but the possibility exists that the antibodies react with IL-1 bound to specific receptors. High-affinity binding sites for IL-1 have recently been demonstrated on e.g. T cells (Dower et al.,1985) and nerve cells (Farrar et al.,1986). The role of neuronal IL-1 or IL-1 receptors on peripheral neurones awaits further studies.

380.3 PROLIFERATION OF BOTH CONNECTIVE TISSUE MAST CELLS (CTMC) AND INTESTINAL MUCOSAL MAST CELLS (IMMC) IN NEONATAL RATS IS STIMULATED BY NERVE GROWTH FACTOR INDEPENDENTLY OF THYMUS. M.D. Coughlin, M.Tomioka*, R.H. Stead*, R.W. Hamill§ and J. Bienenstock*. Depts. of Neurosciences and Pathology, McMaster Univ., Hamilton, Ont., Canada L8N 3Z5, and §Dept. of Neurology, Univ. of Rochester, Rochester, N.Y. 14603

The effects of nerve growth factor (NGF) on mast cell development were studied in neonatal rats. Newborn Lewis rats were treated daily with 0.05, 0.5, and 5.0 ug/g body weight of 2.5S NGF, or with vehicle alone, and sacrificed on day 14 after birth. NGF caused a marked increase in the number of mast cells [CTMC, 3x; IMMC, 10x; Spleen mast cells, 50x; at high dose] and histamine levels, in a dose dependent manner. Alcian blue/Safaranin staining at pH 0.5 differentially colored the hyperplastic mast cell population: tongue, pinna and skin mast cells mostly stained red; and stomack, duodenum, ileum, spleen and liver mast cells stained blue. Berberine sulphate produced fluorescence in the tongue, pinna and skin mast cells only. These cells contained rat mast cell protease (RMCP) type I only; whereas the mucosa of the gut contained only RMCP type II positive cells. Both types of protease were evident in spleen and liver. The experiment was repeated on litters of CR:NIH-RNU (athymic) rats using the middle dose of NGF. Both euthymic and athymic animals exhibited a similar degree of mast cell hyperplasia in the gut and increased histamine content in all tissues, suggesting that the NGF effect was not mediated by T-cells. This contrasts with our recent observation that the hemopoietic colony stimulating activity of NGF depends on the presence of T-cells [Matsuda et al, submitted for publication]. Our present study indicates that NGF affects both CTMC and IMMC in neonatal animals and that the effect is thymus independent. This stimulatory effect of NGF on mast cell growth is consistent with a role for NGF in promoting tissue repair. (Supported by the Medical Research Council of Canada.)

380.4 PEPTIDERGIC INNERVATION OF THE BURSA OF FABRICIUS, THE LYMPHOID ORGAN NECESSARY FOR DEVELOPMENT OF HUMORAL IMMUNOCOMPETENCY IN BIRDS. C.B. Lacey and R. Elde. Dept. of Cell Biology and Neuroanatomy, University of Minnesota, Minneapolis, MN 55455

Recent evidence has suggested that the nervous system plays a role in immunoregulation. For example, innervation of the thymus, spleen, and lymph nodes by postganglionic noradrenergic fibres has been demonstrated (Felten *et al.*, J. Neuroimmunol. 10:5, 1985). These findings prompted us to investigate the possible innervation of the bursa of Fabricius, a dorsal diverticulum of the caudalmost portion of the GI tract which is recognized as the site of B-cell development and differentiation in avian species.

The presence of various peptidergic nerve fibres and terminals was investigated using indirect immunofluorescence on the bursa, duodenum, and colon from 5 to 7 day old chicks. The tissues were immersed in Zamboni's fixative overnight and ten micron sections were cut on a cryostat. Series of tissue sections were incubated overnight with the following antisera: rabbit anti-vasoactive intestinal peptide (VIP), rabbit anti-calcitonin gene related peptide (CGRP), rabbit anti-serotonin, rabbit anti-FMRF-NH_2, rabbit anti-met-enkephalin, and goat anti-tyrosine hydroxylase (TH). Sections were then washed in PBS and incubated in fluorescein-labelled goat anti-rabbit IgG or swine anti-goat IgG.

All antisera stained fibres and terminals in the enteric nervous system of the duodenum and colon. Within the bursa of Fabricius, VIP- and CGRP-immunoreactive fibres were observed among the subserosal layers of smooth muscle, as well as within the interplical extensions of smooth muscle. In some cases there appeared to be an association of immunostained nerve fibres with vascular elements. In addition, both types of immunoreactive fibres were identified in the bursal follicles containing developing lymphocytes. CGRP-immunoreactive fibres were noted penetrating into the mucosa and epithelium, often in close association with lymphocytes. Less frequently, FMRF-NH_2- and TH- immunoreactive nerve fibres and terminals were noted within the muscular layers. The remaining antisera failed to reveal specific staining of neural elements in the bursa of Fabricius.

These results suggest that VIP- and CGRP-immunoreactive nerve fibres and terminals may participate in regulation of B-lymphocyte development and differentiation within the bursa.

380.5 THE LOCALIZATION OF RECEPTOR BINDING SITES FOR SENSORY NEUROPEPTIDES AND SENSORY NERVE FIBERS IN LYMPH NODES. P. Popper, C.R. Mantyh*, S.R.Vigna*, J.E. Maggio and P.W. Mantyh. Center for Ulcer Research and Education; Brain Research Institute, UCLA, Los Angeles, Ca 90024 and Harvard Medical School, Boston Ma 02115

Clinical and experimental findings point towards an interaction between the nervous and immune systems. The two major routes by which the CNS can directly modulate peripheral tissues are via the sensory and the autonomic nervous systems. In the present report we have used immunohistochemistry and quantitative receptor autoradiography to explore the sensory and sympathetic innervation of lymph nodes and to define the sensory neuropeptide receptor binding sites expressed by lymphoid tissue. Canine mesenteric lymph nodes were dissected out and fixed in Bouins fixative, 4% paraformaldehyde for immunohistochemistry or embedded in Tissue Tek and frozen on dry ice. Fixed and unfixed lymph nodes were cut at 30 um on a cryostat and stored at -20°C. Fixed sections were processed for tyrosine hydroxylase (TOH), calcitonin gene related peptide (CGRP), substance K (SK), substance P (SP), somatostatin (SOM), and vasoactive intestinal polypeptide (VIP) using fluorescence or the avidin-biotin technique. Unfixed sections were processed for CGRP, SK, SOM, SP, and VIP receptor autoradiography. CGRP, SP, TOH and VIP-containing fibers were present in lymph nodes in the hilus, capsule, and throughout the medullary and T cell region, while few if any were observed within cortical nodules. These fibers were coarse and varicose in appearance. TOH containing fibers were mostly associated with blood vessels, although these adrenergic fibers were also detected along trabeculae in the medullary cords with no obvious relationship to blood vessels. CGRP, SP and VIP fibers were mainly seen in association with blood vessels although some CGRP fibers were seen leaving the blood vessels and ending in the parenchyma. For the receptor autoradiography, CGRP binding sites were seen in the germinal follicles and on blood vessels and trabeculae in the medullary and T cell regions. SP binding sites were restricted to the germinal follicles and VIP binding sites were found in germinal follicles and along blood vessels in the medulla. These findings suggest that the sensory and sympathetic innervation of lymph nodes regulates blood and lymph flow through the node and that immune cells express a variety of receptors and therefore may be targets for released sensory neuropeptides. 380.6 CORTICOSTERONE AND β-ENDORPHIN LEVELS IN PERIPHERAL BLOOD AFTER ANTERIOR HYPOTHALAMIC LESIONS AND ENDOTOXIN ADMINISTRATION. L.T. Chen*, C.P. Phelps, C.L. Chen* and W.I. Li* (SPON:M.F. Nolan) Dept. of Anatomy, Univ. South Florida, Tampa, FL and Department of Reprod., Univ. of Florida, Gainesville, FL

In an effort to better understand mechanisms for hypothalamic modulation of immune function we have measured blood levels of corticosterone (B) and β-endorphin (End) at intervals after brain damage with and without acute immune challenge (endotoxin-LPS, 0.5 mg/100g bw iv). The anterior hypothalamic area (AHA) was approached stereotaxically in anesthetized adult male rats with a triangular-shaped (2.0x2.5mm) knife. In order to produce AHA lesions (AHAL) the knife was lowered in a median sagittal plane and rotated bilaterally in the AHA 1.0mm from the midline. Sham (Sh) surgery consisted of only a 3.0mm midline descent and a third group of controls (C) were unoperated. In the first experiment, rats from all groups were rapidly decapitated during 10:00-12:00 hr 1, 2 and 3 wk after surgery. Trunk blood was collected for measurement of B and End by RIA and thymus weights were measured. AHAL caused a significant increase in non-stress serum B concentrations (107±1.4 vs 6.7±1.1 ng/ml for C and Sh) one wk after surgery. Two wks after AHAL serum B had returned to C levels (10±1.5 ng/ml), but concentrations in Sh rats had increased to 34±2.0 ng/ml. At 3 wks after AHAL serum B levels increased to 31±7.9 ng/ml, whereas B concentrations in Sh blood were again decreased to C levels. Thymus weights in both AHAL and Sh groups showed a gradual 25% decline from starting weights during this experiment. Plasma End concentrations were very low 1 wk after AHAL and gradually increased (186±20 pg/ml, wk2; 200±49 pg/ml, wk3) approaching C levels (308±18 pg/ml, all intervals). Plasma End levels after SH (166±45 pg/ml, wk1) were similar at subsequent intervals. In the second experiment, LPS was administered 1 wk after AHAL and Sh surgery and the rats were killed 48hr later. LPS caused a 2-3x increase in serum B in Sh and C rats, but AHAL rats showed no further change in what were already elevated serum B levels at 48 hr (134±17.6 vs. 123±11.8 after LPS). The overall effect of LPS on thymic involution was highly significant with AHAL rats showing the greatest (70%) reduction in weight. Plasma End levels were considerably ($p<0.01$) increased after LPS in both AHAL and Sh rats, but not in controls. In summary, specific AHA damage produces dynamic changes in hormones known to modulate lymphoid function. Thymic involution was further intensified after AHA lesion plus exposure to endotoxin. These effects may reflect in part the chronology of post-AHA lesion adrenal steroid imbalances. Significant increases in plasma β-endorphin after brain damage plus endotoxin challenge also suggest opiod modulation of immune response in this preparation. Supported by BRSG SO7 RR05749.

380.7 DEVELOPMENTAL CONSEQUENCES OF PRENATAL EXPOSURE TO THYMOSIN: LONG TERM CHANGES IN IMMUNE AND ENDOCRINE PARAMETERS. M.P. O'Grady, N.R. Hall and A.L. Goldstein*. Biochemistry Dept., George Washington Univ. Medical Center, Washington, D.C. 20037

A growing body of evidence supports the concept of a bidirectional interaction between the neuroendocrine and immune systems. A thymic extract, thymosin fraction 5 (TF5), has been shown to modulate secretion of ACTH, beta-endorphin, GH, PRL, LHRH and TSH. However, almost all of the research on neuroendocrine actions of TF5 has been in adult animals or in vitro models. The neuroendocrine effects of TF5 in adults are temporary and depend on continuous presence of TF5. This experiment was designed to determine if an intrauterine critical period exists during which TF5 can cause long term changes in immune and/or neuroendocrine function.

Pregnant Swiss-Webster mice were injected (i.p.) with TF5 (0.5 mg in 0.05 cc saline) on days 16, 17 and 18 of gestation. The offspring were studied in adulthood. Immune measures included mitogen assays (PHA, Con A and PWM) and IL-2 production. Various organ weights were recorded: thymus, spleen, heart, kidneys, adrenals, ovaries, testes and preputial glands. Serum levels of thymosin alpha-1 (Ta1), a purified, biologically active component of TF5, were determined by radioimmunoassay.

The TF5-treated group had enlarged thymus glands compared to vehicle-injected controls ($p<0.02$) and TF5-treated females showed a decrease in ovary weight ($p<0.02$) compared to saline-treated females. TF5-treated males had larger adrenals than the saline males ($p<0.01$). Ta1 levels did not differ between the TF5 and vehicle groups. However, females had higher Ta1 levels than males ($p<0.001$) irrespective of treatment. Thymosin treatment lowered IL-2 production in females compared to saline females ($p<0.03$). The TF5-treated males also tended towards decreased IL-2 production but this was not statistically significant ($0.05<p<0.10$). The TF5-treated females displayed a reduced stimulation index to the mitogens, Con A and PWM ($p<0.005$).

These data suggest that intrauterine exposure to an immune system product, TF5, can alter neuroendocrine and immune function during adulthood. TF5 could affect endocrine development, which, in turn, alters immune responsiveness.

380.8 TYROSINE HYDROXYLASE POSITIVE NERVE TERMINALS CONTACT LYMPHOCYTES IN THE PERIARTERIOLAR LYMPHATIC SHEATH OF THE RAT SPLENIC WHITE PULP. S.Y. Felten, J. Olschowka and D.L. Felten. Dept. of Neurobiol. and Anat., Univ. of Rochester, Sch. of Med., Rochester, NY 14642.

The abundant evidence that sympathetic noradrenergic nerve fibers innervate smooth muscle associated with the splenic capsule and trabeculae (causing splenic contraction) and vascular smooth muscle (causing vasodilation and increased blood flow) has led to the assumption that NE containing nerve fibers in the spleen have no other functions. This bias persists even though several of the reports of innervation, including studies at the electron microscopic level mentioned the existence of nerve fibers that are surrounded by splenic cells with no relationship to smooth muscle, or nerve terminals in very close contact with lymphocytes, erythrocytes and reticular cells. Due to the bias that the autonomic nervous system innervates only cardiac muscle, smooth muscle and secretory gland, these findings were dismissed, usually with the statement that they were really platelets rather than nerve terminals. This study used immunocytochemistry of tyrosine hydroxylase to positively identify noradrenergic nerve terminals in the spleen at the electron microscopic level in order to determine whether there was any direct relationship between these terminals and cells other than smooth muscle.

Immunocytochemistry was used to demonstrate tyrosine hydroxylase (TH) positive profiles in the spleen of the adult Fischer 344 rat. At the light microscopic level, numerous varicose nerve profiles were seen in the white pulp, particularly surrounding the central arteries and their arteriole branches. At the electron microscopic level, varicosities were seen in close proximity to smooth muscle cells of the arteries, and directly abutting lymphocytes (presumable T-lymphocytes) of the nearby periarteriolar lymphatic sheath. There were no intervening cell processes between the TH-positive terminals and the lymphocyte. The opposing membranes were smooth and evenly spaced approximately 6 nm apart. Additional TH-positive nerve profiles were seen in the inner marginal zone, and within trabeculae. The correlation between this immunocytochemical staining and previously demonstrated histofluorescence for norepinephrine leads to the conclusion that lymphocytes in the splenic white pulp have direct associations with noradrenergic fibers of the sympathetic nervous system. This association provides a route by which the autonomic nervous system could directly influence specific immune system effector cells.

380.9 DEVELOPMENTAL COMPARTMENTATION OF TYROSINE HYDROXYLASE (TH) - POSITIVE NERVE FIBERS IN THE SPLEEN OF FISCHER 344 RATS. K.D. Ackerman, D.L. Felten, and S.Y. Felten, Dept. of Neurobiol. and Anat., Univ. of Roch. Sch. of Med., Rochester, NY 14642.

In the adult rat spleen sympathetic noradrenergic (TH - positive) nerve fibers distribute principally within the white pulp, forming close associations with T lymphocytes in the periarteriolar lymphatic sheath and with ED-3 positive macrophages at the marginal sinus. This study was undertaken to explore the developmental sequence of this compartmentation using double-labelled immunocytochemistry for TH - positive nerve fibers and specific markers for lymphoid cells, including OX19 for T lymphocytes, ED3 for macrophages, and OX-4 for Ia positive cells.

TH - positive fibers were present in the hilar region at birth and first associated with the primitive PALS as a ring of fibers along the zone of seperation between a mixed lymphocyte population on the inside and macrophages and B lymphocytes on the outside. TH - positive fibers were not associated with the central artery at this stage. By day 7, a central arteriolar nerve plexus was present, extending between the central artery and the outer ring of nerve fibers. At 10-14 days, the central arteriolar nerve plexuses increased in density and there was a greater seperation between the central arteriolar plexus and the outer zone of fibers now present along the developing marginal sinus. From 14 days to adult, the central arteriolar nerve fibers decreased somewhat in density, but kept pace with the rapid increase in size of white pulp, while maintaining their compartmentation.

The early presence of TH - positive nerve fibers associated with developing compartments of the white pulp may provide an opportunity for bidirectional interactions affecting growth, differentiation, or compartmentation.

380.10 NEONATAL THYMECTOMY ALTERS THE DEVELOPMENT OF NORADRENERGIC INNERVATION OF THE SPLEEN IN FISCHER 344 RATS. T.A. Romano*, K.D. Ackerman, S.L. Carlson, S.Y. Felten, and D.L. Felten (SPON: R.M. Herndon). Dept. of Neurobiol. and Anat., Univ. of Rochester Sch. of Med., Rochester, NY 14622.

Past studies from our laboratory have shown a parallel course of neonatal development for sympathetic postganglionic noradrenergic nerve fibers innervating the splenic white pulp, and migration of T lymphocytes into the periarteriolar lymphatic sheath (PALS) of the white pulp. Tyrosine hydroxylase (TH)-positive nerve fibers are visible along the central artery at postnatal days 1-3, extend outward from these arteries into the parenchyma where T lymphocytes form discernible PALS by 7-10 days, and further keep pace with the full extent of PALS development into adulthood. We hypothesized that if the arrival of T lymphocytes into the PALS plays a role in guiding the compartmentation of the nerve fibers or maintaining their presence, then neonatal thymectomy might alter this influence. Neonatal (3 day old) Fischer 344 rats were surgically thymectomized and were sacrificed at day 15 or 28. Sham-operated and unoperated rats were used as controls. Spleens were examined with fluorescence histochemistry (SPG method of de la Torre) for presence and appearance of catecholamine fibers. Spleens from sham-operated and unoperated rats showed robust innervation of both the vasculature and parenchyma at 15 and 28 days of age, as reported previously. Spleens of thymectomized rats showed apparently normal compartmentation, density of varicosities, and intensity of fluorescence at 15 days of age, compared with controls. However, by 28 days of age, the noradrenergic innervation of the spleen in thymectomized rats showed considerable variability. In rats where thymectomy appeared complete and the white pulp of the spleen was reduced significantly in size, the innervation of that white pulp was reduced compared with controls. In rats where thymectomy appeared incomplete, the splenic innervation did not appear reduced. These preliminary findings support a role for thymic development in the maintenance of noradrenergic innervation of the splenic PALS at 28 days of age. We hypothesize that this influence is due to arrival of T lymphocytes into the PALS, where they may exert either a direct or indirect effect on the nerve fibers.

380.11 MAINTENANCE OF NORADRENERGIC SYMPATHETIC FIBERS IN AGED INVOLUTING THYMUS. D.L. Bellinger, D.L. Felten and S.Y. Felten. Department of Neurobiology & Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

Sympathetic postganglionic noradrenergic fibers innervate both primary and secondary lymphoid organs. Nerve fibers derived from neurons in the superior cervical ganglion enter the thymus with the vasculature and distribute in the cortex, particularly in the subcapsular region and around the vasculature at the cortico-medullary junction. Noradrenergic innervation of secondary lymphoid organs distributes into compartments where T lymphocytes reside; this innervation declines with age in both lymph nodes and the spleen. This study was undertaken to determine whether a similar decline in noradrenergic innervation occurs in the thymus. Thymuses were examined in Fischer 344 rats at 3, 8, 12, 17, 21, 24, and 27 months of age. The noradrenergic innervation remained stable in appearance at 3, 8, and 12 months of age. At 17 months of age and older, the density of innervation appeared to increase in the thymic cortex; however, the thymus at these ages was reduced significantly in weight compared with younger ages due to involution. Therefore, it appears that the total noradrenergic innervation is maintained in aged Fischer 344 rats even in the face of involution, resulting in an increased density of fibers. This increase in density of noradrenergic fibers may contribute a higher concentration of norepinephrine in the local microenvironment, where it can interact with adrenergic receptors on thymocytes.

380.12 TIME COURSE OF DEPLETION OF NORADRENERGIC INNERVATION OF THE SPLENIC WHITE PULP IN AGED FISCHER 344 RATS AND ITS RELATIONSHIP TO DECLINING POPULATIONS OF SPECIFIC IMMUNE CELLS. D.L. Felten, K.D. Ackerman, D.L. Bellinger, and S.Y. Felten, Department Neurobiology & Anatomy, University of Rochester School of Medicine, Rochester, NY 14642.

The sympathetic postganglionic noradrenergic innervation of the splenic white pulp is reduced significantly in 27 month old Fischer 344 rats compared with 8 month old rats (S.Y. Felten et al., Neurobiol. of Aging 8: 159-165, 1987). The number and density of fluorescent varicosities, assessed by morphometry, are reduced in all compartments of the spleen, and the norepinephrine content, assessed by high performance liquid chromatography with electrochemical detection, also is reduced. In the present study, we examined the noradrenergic innervation of the spleen with fluorescence histochemistry of catecholamines and double-labelled immunohistochemistry for tyrosine hydroxylase (TH)-positive nerve fibers and specific markers for T lymphocytes (OX-19) and macrophages at the marginal sinus (ED-3), to assess intermediate ages between 8 and 27 months of age. Fischer 344 rats were sacrificed at 3, 8, 12, 17, 21, 24, and 27 months of age. Noradrenergic innervation of the splenic white pulp, assessed by both methods, remained constant through 12 months of age. By 17 months of age, a noticeable decline in the number and density of nerve fibers was evident. This decline continued through 27 months of age. Observations with double-labelled immunohistochemistry also revealed a decline in the number of OX-19-positive T lymphocytes, as well as a diminution of white pulp by 17 months of age. Similarly, the number of ED-3-positive macrophages at the marginal sinus decreased with age. This remarkable parallel in decline of noradrenergic fibers and specific populations of immune cells supports the notion that regulatory influences may be exerted in either direction, and that the decline of one may precipitate or influence the decline of the other. This is consistent with evidence from past observation in our laboratories that the presence of noradrenergic innervation of the spleen and lymph nodes in adults is necessary for immunocompetence (Livnat et al., J. Neuroimmunol. 10: 5-30, 1985).

Supported by N00014-84-K-0488 from ONR, F32 NS07980 from NINCDS, and T32 GM07356 from NIH.

380.13 SPLENIC NOREPINEPHRINE TURNOVER IS INCREASED DURING AN IMMUNE RESPONSE IN MICE. S.L. Carlson, S.Y. Felten, S. Livnat* and D.L. Felten. Dept. of Neurobiology and Anatomy, University of Rochester School of Medicine, Rochester, NY 14642

The noradrenergic (NE) innervation of the spleen follows the vasculature and extends into the T cell zones of the splenic white pulp. NE released from the nerve terminals into the local splenic microenvironment may modulate or regulate lymphocyte function via interaction with adrenergic receptors on the target cells.

As part of a larger study of the role of NE innervation of the murine spleen, we have found that immunization induced by repeated injections of normal rabbit serum (NRS) is accompanied by alterations in NE content and turnover in the spleen. Adult male C3H/HeN mice were injected intraperitoneally four times over 8 days with 0.2ml of NRS (NRS-4x) or saline, and were sacrificed one day after the last injection. A second group of mice received one injection of NRS (NRS-1x) or saline, and were sacrificed two days later. The spleens were removed, weighed and frozen for subsequent measurement of catecholamines and their metabolites with HPLC, and for histofluorescence of the nerve profiles.

The spleens of the NRS-4x group were 2.8 times larger by weight than the saline controls, indicative of the lymphocyte proliferation occurring due to the immune response. Quantification of the total splenic NE (pmol/spleen) revealed that NE was decreased 43% in the NRS-4x and 37% in the NRS-1x groups. MHPG, a metabolite of NE, was significantly increased in the NRS-4x group, but was decreased in the NRS-1x group. The concentration of NE (pmol/mg protein) also was decreased in the NRS-4x and NRS-1x groups, while the MHPG concentration was decreased in the NRS-1x group.

Previous studies from our laboratory have shown that at least 95% of the NE in the spleen is contained in the nerve terminals, and therefore is not due to the presence of circulating catecholamines in the blood. We conclude that during an ongoing immune response, splenic NE is decreased due to a higher rate of turnover of the transmitter from the nerve terminals. The lack of an increase in MHPG at an early time point in the immune response (NRS-1x) may indicate that the NE turnover rate has not yet increased to the extent seen later during the immune response, or that different mechanisms may be involved during the early phase of a developing immune response. These results give additional support to the hypothesis that NE plays a role in the bidirectional communication between the peripheral autonomic nervous system and the immune system.

380.14 **ß-ENDORPHIN INHIBITS PRIMARY HUMORAL IMMUNE RESPONSE IN RATS.** L.M. Hemmick and J.M. Bidlack. Center for Brain Research, Univ. of Rochester, School of Medicine and Dentistry, Rochester, NY 14642.

$ß_h$-endorphin 1-31 suppressed the rat primary humoral immune response to sheep red blood cells (SRBC). Sprague-Dawley male rats weighing 150-175g were injected i.p. with SRBC (10^8 cells/rat). Seven days after immunization, splenocytes sterilely prepared from immunized rats were cultured with $ß_h$-endorphin 1-31 at 10^{-7} cells/ml in RPMI 1640 medium containing 5% fetal bovine serum for 48 hr at 37°C in a 5% CO_2 incubator. Splenocytes were then tested for their ability to lyse SRBC targets in the presence of guinea pig complement. Plaques were counted under low magnification using an indirect light source. Treatment with 1 μM $ß_h$-endorphin 1-31 suppressed the primary humoral immune response by 31.4% ± 10.2%. Studies are underway to determine if this suppression is naloxone reversible and if other opioids are capable of suppressing the primary humoral immune response.

$ß_h$-endorphin 1-31 enhanced concanavalin A (Con A)-stimulated uptake of $^{45}Ca^{2+}$ by rat thymocytes (Soc. Neurosci. Abst., 12: 340, 1986). $ß_h$-endorphin 1-31 suppression of the humoral immune response to the T-cell dependent antigen SRBC may correlate to its enhancement of Con A-stimulated thymocyte $^{45}Ca^{2+}$ uptake, if the $^{45}Ca^{2+}$ uptake of the T-suppressor cell sub-population is selectively enhanced. In contrast to the thymocyte data, $ß_h$-endorphin 1-31 did not significantly affect either basal or Con A-stimulated $^{45}Ca^{2+}$ uptake by rat splenocytes, a more heterogeneous cell population than thymocytes.

In order to investigate possible long-term modulation of lymphocyte $^{45}Ca^{2+}$ uptake by opioids, 150-175g Sprague-Dawley male rats were made dependent on morphine by subcutaneous implantation of a pellet containing 75 mg morphine base. After 1 week, naloxone-precipitated withdrawal was used as the index of dependence in a representative morphine-treated rat. Thymocyte and splenocyte populations were prepared from morphine and placebo-treated rats. The basal and Con A-stimulated $^{45}Ca^{2+}$ uptake of addicted vs. placebo-treated thymocytes and splenocytes were then compared. Preliminary data showed that morphine dependence had no significant effect on thymocyte basal or Con A-stimulated $^{45}Ca^{2+}$ uptake. Dependence also did not significantly affect the ability of $ß_h$-endorphin 1-31 to enhance Con A-stimulated $^{45}Ca^{2+}$ uptake by rat thymocytes. In addition, morphine dependence did not significantly affect basal or Con A-stimulated $^{45}Ca^{2+}$ uptake by rat splenocytes.

380.15 METHIONINE-ENKEPHALIN IS A MODULATOR/REGULATOR OF IMMUNE REACTIONS. B.D.Janković* and D.Marić* (SPON: S.K.Sobrian). Immunology Research Center, Vojvode Stepe 458, 11221 Belgrade, Yugoslavia.

During the past few years, several studies have provided evidence that opioid peptides can modulate immune function. A wide range of in vitro immunomodulatory effects have been described for neuropentapeptides. However, the in vivo manipulations with these opioids are still in the initial phase. We report here on variations in immune responsiveness in mice and rats treated with methionine-enkephalin (Met-Enk). Several schedules of intraperitoneal and intracerebroventricular injections, and various doses of Met-Enk (0.1 to 10 mg/kg) were employed in different immune paradigms. The following findings support the view that Met-Enk may be involved in mechanisms underlying the integrative function of the nervous, endocrine and immune systems. (a) Met-Enk exerted a dose-dependent, bidirectional effect on humoral and cell-mediated immune reactions. Thus, high doses (2-10 mg/kg) suppressed plaque-forming cell response, antibody production to particular and soluble antigens, local Arthus reactivity, delayed skin hypersensitivity, allograft rejection and inflammatory immune reactions. In contrast, low doses of Met-Enk (0.1-0.5 mg/kg) potentiated immune responsiveness. (b) Immunoregulatory activity of this peptide was much more pronounced after its administration through a cannula permanently inserted into the lateral ventricle of the rat brain. (c) Met-Enk treatment of rats sensitized for anaphylactic shock completely protected the animals from fatal shock. (d) Anti-inflammatory effect of Met-Enk was evident in rats sensitized with mycobacterial adjuvant for adjuvant arthritis. (e) High doses of Met-Enk suppressed both the incidence of neurological symptoms and intensity of histological lesions in the brain and spinal cord in rats sensitized for experimental allergic encephalomyelitis. In addition, high doses of Met-Enk affected the passive transfer of the disease and prevented further development of clinical signs. (f) The experiments with antagonists of mu- and delta-opioid receptors revealed that Met-Enk acts primarily via delta-receptors. These results suggest that Met-Enk is an important constituent of the signal repertoire operating in the neuroimmune system. (Supp. by the Republic of Serbia Research Fund, Belgrade, and Thymoorgan Pharmazie, Vienenburg, F.R.G.)

380.16 SUPPRESSION OF NATURAL KILLER (NK) CELL ACTIVITY IN RATS BY VARIOUS NARCOTIC AGENTS. B. Beilin*, F.C. Martin, Y. Shavit, S. Ben-Eliyahu*, S.H. Sohn*, J.C. Liebeskind. (SPON: S.C. Lee). Dept. of Anesthesiology, Brain Research Institute, and Dept. of Psychology, UCLA, Los Angeles, CA 90024-1563.

Surgical stress and general anesthesia are known to suppress immune function. This effect may contribute to the problem of post-operative infections. Exposure to a form of stress known to activate endogenous opioids suppresses NK activity and accelerates tumor growth in rats. Systemic morphine mimics these effects. In the present study, we examined the effects of 3 opiates commonly used in general anesthesia on NK activity in rats.

Male Fischer 344 rats were injected (s.c.) with morphine (30 mg/kg), fentanyl (0.3 mg/kg), or sufentanil (0.06 mg/kg) at 3, 12 or 24 hours before splenectomy. Controls received saline. Animals were anesthetized with halothane, and spleens removed and dissociated into single cell suspensions. Spleen cells were co-cultured with chromium labeled YAC-1 target cells, and NK cell cytotoxicity was determined in a 4 hrs chromium release assay.

All 3 drugs significantly suppressed NK cytotoxicity by 25-50% of control values at 3 hrs after administration, and this effect was blocked by naltrexone. Fentanyl and sufentanil, and to a lesser degree morphine, also caused a significant suppression (15-40%) 12 hrs after drug administration. Sufentanil still caused a substantial but not significant suppression 24 hrs later.

These results show that the commonly used anesthetic opiates can suppress NK cell activity for up to 24 hrs. In light of the increasing clinical use of high-dose narcotic anesthesia, it will be important to investigate this phenomenon in human beings and to study the mechanisms by which opiates exert their immunological effects. (Supported by NIH grant NS07628 and the David H. Murdock Foundation for Advanced Brain Studies. Y.S. was supported by the MacArthur Foundation).

380.17 EFFECTS OF CORTICOSTERONE ON NATURAL KILLER (NK) CELL ACTIVITY *IN VITRO*. F.C. Martin, L. O'Farrell, S.E. Holley*, J.C. Liebeskind. Brain Research Institute and Dept. of Psychology, UCLA, Los Angeles, CA 90024.

The effects of acute stress on immune activity in rats have received considerable attention in recent years. Our group has reported NK suppression in rats 3 h after either footshock or 30 mg/kg morphine. The role of the pituitary-adrenal axis in these effects is important to understand, since corticosterone is immunosuppressive. We showed that adrenalectomy but not demedullation blocks the morphine-induced NK suppression, but we have not established whether adrenal cortical hormones are solely responsible for these effects. The goal of this study was to determine whether levels of corticosterone seen in morphine-treated animals suppress NK activity *in vitro* .

Corticosterone levels were measured in morphine and saline treated rats. From these results we chose 100 ng/ml as baseline and 500 ng/ml as the morphine-induced level.

Spleen lymphocytes from untreated rats were suspended in RPMI cell culture medium containing 0 (control), 10 (below physiological), 100 (baseline), 500 (morphine) or 1000 (upper end of physiological) ng/ml corticosterone, and incubated for 3 h at 37^{o} C. Cells were washed and tested in a standard chromium-release NK assay.

Even 10 ng/ml corticosterone caused suppression of NK activity (22%) compared to control, and 100 ng/ml suppressed NK activity by about 40%. However, 500 or even 1000 ng/ml caused only a slight further suppression over that produced by 100 ng/ml. The finding that there is little differential effect of corticosterone over the physiological dose range calls into question the hypothesized role of corticosterone in mediating the NK suppressive effects of stress and morphine. (Supported by NIH NS07628 and the David Murdock Foundation for Advanced Brain Studies)

380.18 MORPHINE SUPPRESSES THE CYTOTOXIC ACTIVITY OF NATURAL KILLER (NK) CELLS SIMULTANEOUSLY HARVESTED FROM SPLEEN, BONE MARROW, AND PERIPHERAL BLOOD. Y. Shavit, F.C. Martin, R. Yirmiya*, S. Ben-Eliyahu*, G.M.L.H. Angarita*, S.H. Wald*, R.P. Gale*, and J.C. Liebeskind. Departments of Psychology and Medicine, Brain Research Institute, UCLA, Los Angeles, CA 90024-1563.

Recent evidence suggests that opiates and endogenous opioids play a modulatory role in immune function. We have previously shown that systemically administered morphine suppresses splenic NK cell cytotoxicity in rats, an effect blocked by the opiate antagonist, naltrexone (Shavit, et al., Science, 223: 188-190, 1984). Moreover, intracerebroventricularly administered morphine suppresses splenic NK activity at a dose 1,000 times smaller than the systemically required dose; this effect also is blocked by naltrexone (Shavit, et al., PNAS, 83: 7114-7117, 1986). Some drugs are known to cause redistribution of lymphocytes in the different compartments of the immune system, and this process might account for the observed splenic NK suppression. The present study, therefore, examined the effect of systemically administered morphine on the cytotoxic activity of NK cells derived from several immune compartments: spleen, bone marrow, and peripheral blood.

Fischer 344 male rats were injected with morphine (30 mg/kg, s.c.) or saline. Three hours later, rats were anesthetized with halothane, peripheral blood was collected by heart puncture, bone marrow was collected from the femur, and spleens were removed. All cells were dissociated into single cell suspensions and incubated with carbonyl iron for 30 min at 37°C. Cells were then separated using separation media (Sepracell), washed twice in PBS, counted, and their final concentration adjusted to 1X10^{7} cells/ml. Cells were co-cultured with chromium labeled YAC-1 target cells, and NK cytotoxicity was determined in a 4-hr chromium release assay.

Morphine significantly suppressed the cytotoxic activity of NK cells derived from all three immune compartments to about 60-70% of control values. These data suggest that morphine-induced NK suppression is an overall suppression of a particular host-defense mechanism, rather than specific emigration of NK or other regulatory cells out of the spleen.

380.19 STRESS-INDUCED IMMUNOSUPPRESSION IN RATS: A NALTREXONE-INSENSITIVE PARADIGM. S. Ben-Eliyahu*, R. Yirmiya*, F.C. Martin, P.G. McKinley*, Y. Shavit, J.C. Liebeskind. (SPON: J.W. Lewis). Department of Psychology, UCLA, Los Angeles, CA 90024-1563.

Stress can adversely affect both cellular and humoral aspects of immune function. However, stress can also augment immune function. In our laboratory, we have shown that a form of footshock stress known to activate endogenous opioid systems suppresses the cytotoxic activity of NK cells in rats, an effect blocked by the opiate antagonist, naltrexone (Shavit et al., Science, 223:188, 1984). In contrast, a very similar form of footshock stress, which induces a nonopioid form of analgesia, had no effect on NK cell activity. We also found that several well established stressors, such as isolation, crowding, and restraint, had no effect on NK cytotoxicity. We now report that another stress paradigm, forced swimming, causes NK suppression not blocked by naltrexone.

Fischer 334 male rats, 11 weeks old, were assigned to 3 groups. Thirty minutes before the stress session, one group (n=12) was injected with saline, another (n=12) was injected with naltrexone (10 mg/kg, s.c.), and a third (n=14), which served as non-stressed control, was also injected with saline at this time. During the stress session, a weight of 45 g/kg b.w. was attached to the tails of rats of groups 1 and 2. Each rat was then placed in a tank of 37°C water for 3 minutes, followed by a 3-minute rest period. This procedure was repeated 5 times consecutively. One hour later spleens from all animals were removed and dissociated into a single-cell suspension. Cells were co-cultured with chromium-labeled YAC-1 target cells, and NK cytotoxicity was determined in a 4 hour chromium release assay.

Swimming stress significantly suppressed NK cell cytotoxicity in both saline- and naltrexone-treated rats compared with controls. The magnitude of the suppression (to about 75% of control levels) was similar in the two groups. These results suggest the existence of opioid and nonopioid mechanisms in stress-induced immunosuppression. More generally, these results reinforce the idea that stress is not uniform with respect to its effects on the immune system. (Supported by NIH grant NS07628 and the David H. Murdock Foundation for Advanced Brain Studies. Y.S. was supported by the MacArthur Foundation).

380.20 NATURAL KILLER (NK) CELL ACTIVITY IN VASOPRESSIN DEFICIENT RATS (BRATTLEBORO STRAIN). R. Yirmiya*, Y. Shavit, S. Ben-Eliyahu*, F.C. Martin, P.G. McKinley* and J.C. Liebeskind. Neuroscience Program, Brain Research Institute, and Department of Psychology, University of California, Los Angeles, CA 90024-1563.

Several lines of evidence suggest that the neurohypophysial hormone vasopressin is involved in regulation of the immune system. We explored this possibility in 3 experiments in which the cytotoxic activity of NK cells was compared between Brattleboro rats, which are homozygous for diabetes insipidus (DI) and lack vasopressin, and Long Evans (LE) rats (the strain from which the DI rats were derived). Additionally, we compared the effects of swimming stress and morphine administration on NK activity in these two strains.

In Exp. 1, spleens from 10 DI and 10 LE rats were removed and dissociated into single cell suspensions. Cells were co-cultured with chromium-labeled YAC-1 target cells, and NK cytotoxicity was determined in a 4 hr chromium release assay. In Exp. 2, 12 DI and 11 LE rats were subjected to swimming stress, while another 12 DI and 11 LE rats served as non-stressed controls. During the stress session, a weight of 45 g/kg b.w. was attached to the rats' tails. Each rat was then placed in a tank of 37° C water for 3 min, followed by a 3-min rest period. This procedure was repeated 5 times consecutively. One hr after the completion of the stress session, spleens of experimental and control animals were removed, processed and assayed for NK cell activity as described above. In Exp. 3, 14 DI and 18 LE rats were injected with morphine (30 mg/kg; s.c.), while another 13 DI and 17 LE control rats were injected with saline. Three hr after the injection, spleens of all rats were removed, processed and assayed for NK cell activity.

In all 3 experiments, NK cell activity was significantly higher in DI rats compared with LE rats. In Exp. 1, and in the control groups of Exp. 2 and 3, NK activity of DI rats ranged between 140-200% above that of LE rats. Both swimming stress and morphine significantly suppressed NK activity in DI and LE rats (to about 80% of their respective non-stressed and saline-injected controls). These results suggest that vasopressin is involved in tonic regulation of NK cell activity, but not in mediating the immune-suppressive effects of stress and morphine. (Supported by NIH grant NS-07628 and a gift from the David H. Murdock Foundation for Advanced Brain Studies. Y.S. was supported by the MacArthur Foundation).

381.1 ULTRASTRUCTURAL LOCALIZATION OF AN OCTADECANEUROPEPTIDE (ODN) DERIVED FROM DBI IN THE RAT BRAIN. H. Alho, D. Jenkins, P. Bovolin, A. Guidotti and E. Costa. FIDIA-Georgetown Institute for the Neurosciences, Georgetown University Medical School, Washington, D.C. 20007

A 10-kDa endogenous neuropeptide that modulates gamma-aminobutyric acid (GABA) receptor function has been termed diazepam binding inhibitor (DBI) because of its capability to displace diazepam from its specific brain recognition sites. DBI has been shown to be localized in neurons and specific populations of glial cells in the rat brain (Alho et al., Science, 229, 1985). Tryptic digestion of DBI generates an octadecaneuropeptide (ODN) that shares with DBI the ability to displace specifically bound beta-carbolines and produce proconflict action when injected intraventricularly in rodents. ODN-like immunoreactivity (LI) is highly concentrated in neurons but is virtually absent in glial cells. In primary cultures of cortical cells ODN-LI is localized in GABAergic neurons and can be released by depolarization with high potassium and veratridine. However, a direct evidence for subcellular and ultrastructural localization of ODN in neurons is lacking. An antiserum against synthetic ODN was raised in rabbits and electron microscopical immunohistochemical studies were performed employing the peroxidase-anti-peroxidase method and biotin-avidin-colloidal gold methods. Normal and colchicine pretreated rat brains were perfused with formaldehyde/glutaraldehyde fixative and vibratome sections were used to study the ODN-LI in different brain areas at electron microscopical level. The ODN-LI was compared to the glutamic acid decarboxylase (GAD)-LI. The peroxidase ODN-LI was found in neurons throughout the cytoplasm of numerous axon terminals and few pericarya and dendrites. In the cerebellum, ODN-LI was identified in Golgi cells and axon terminals. The immunoreactive material was concentrated in synapses around the Purkinje cells and in the molecular layer of cerebellum. In the glial stuctures no specific staining was detectable. The GAD-LI was localized in identical neuronal stuctures. The present results demonstrate the localization of ODN-LI in synapses and establish the presence of ODN-LI in neuronal sructures that are important to synaptic transmission. The findings support the suggestion of the neuromodulatory role of ODN in GABAergic transmission.

381.2 ANATOMICAL LOCALIZATION OF DIAZEPAM BINDING INHIBITOR (DBI) AND OCTANEUROPEPTIDE (ODN)-LIKE IMMUNOREACTIVITY IN RAT BRAIN. P. Bovolin, H. Alho, A. Guidotti and E. Costa (SPON: M.R. Santi). Fidia-Georgetown Institute for the Neurosciences, Georgetown University Medical School, Washington, D.C. 20007.

An endogenous neuropeptide (DBI) that displaces benzodiazepines and beta-carbolines from their specific modulatory site on $GABA_A$ receptors, has been recently isolated and purified from rat, bovine and human brains. DBI injected intraventricularly into rodents has a proconflit action and antagonizes the anti-conflict action of diazepam in the Vogel behavioral test. It also decreases the duration of Cl^- channel opening bursts elicited by GABA in primary cultures of spinal cord neurons. In rat brain, DBI is the precursor of a new family of peptides including an octadecaneuropeptide (ODN) that shares with DBI the ability to displace specifically bound beta-carbolines from their binding sites. DBI- and ODN-like immunoreactivity (LI) has been localized in GABAergic neurons in primary cultures of cortical cells and DBI-LI has been localized in neurons and specific population of glial cells in rat brain at the light microscopical level. Immunohistochemical studies were performed using antisera raised in rabbit against DBI purified from rat brain and synthetic ODN. For these experiments, normal and colchicine pretreated rat brains were perfused with 4% paraformaldehyde and consecutive vibratome (25 um) and cryostat (20 um) sections were stained with the peroxidase-anti-peroxidase method. The preabsorption of anti-DBI antiserum with 10 ug/ml of DBI peptide and anti-ODN with 20 ug/ml of ODN peptide completely abolished the staining, while the preabsorption of ODN antiserum with 20 ug/ml DBI peptide did not alter significantly the staining intensity in neurons. DBI- and ODN-LI was detected in several brain regions, including cortex, hippocampus, amygdaloid area, habenular area and cerebellum. An intense DBI-LI but not ODN-LI was observed in Bergman glial cells in cerebellum and in the tanycytes around the third ventricle. After colchicine pretreatment ODN and DBI positive neurons were detected in few pyramidal cells of hippocampus, small neurons in subiculum, various size neurons in cortex, large neurons in reticulothalamic nucleus, small neurons in subgeniculate nucleus and in Golgi, Stellate and Purkinje cells of cerebellum. Studies conducted on consecutive sections detected positive reactions to ODN-LI and DBI-LI in neurons of the same brain areas and nuclei, but DBI-LI was constantly weaker and no ODN-LI was found in glial cells. The present results support the suggestion that DBI may act as an ODN precursor and that DBI might be processed differently in glial cells and neurons.

381.3 CGRP IN HUMAN NERVOUS SYSTEM AMD CEREBROSPINAL FLUID: HIGH LEVELS IN THE LOCUS CERULEUS. J. K. Tiller-Borcich M.D., H. Capili, G. S. Gordan M.D. (SPON: E.W. Yund) Departments of Pathology and Internal Medicine, UC Davis, VAMC, Martinez, CA 94553

A quantitative survey of calcitonin gene-related peptide(CGRP) in human brain, peripheral nerve and cerebrospinal fluid(CSF) was performed using radioimmunoassay(RIA) with antisera against synthetic hGRPP. High levels(approximately 2000-15000 fmol/mg protein) were found in the dorsal spinal cord, dorsal nerve and trigeminal nerve. Relatively large amounts(500-2000) were found in parts of the hypothalamic-pituitary axis, peripheral nerve and for the first time, in the locus ceruleus. Low levels of CGRP (less than 500) were detected in the cerebrum, subcortical nuclei and cerebellum. CGRP, not previously reported in the CSF, was detectable in all of 27 CSF specimens with mean values of 39 + 4.5 pmol/L(SE). Simultaneous plasma CGRP levels were higher and, when elevated by antihypertensive treatment, were not increased in the CSF, just as astronomical plasma levels of calcitonin in medullary carcinoma of the thyroid are not reflected in CSF. Our data confirm and extend the results of previous human and animal studies with species variation: humans have low CGRP levels in subcortical nuclei whereas high levels have been found in rat caudate-putamen and amygdala. The high level of CGRP in the locus ceruleus(LC), the major source of noradrenergic transmisssion in the CNS, is in harmony with the presumed functions of the LC and the very potent hemodynamic activity of CGRP. This work was supported, in part, by the Veterans Administration Medical Research Service.

381.4 Atrial Natriuretic Factor (ANF) Concentrations In Discrete Brain Regions Of Female Rats. N.W. Hoffman,* A.A. MacPhee*, and A.A. Gerall (SPON: G. Dohanich). Alton Ochsner Medical Foundation and Dep. of Psychol., Tulane University, New Orleans, LA 70118

ANF is a set of polypeptides secreted from cardiac atria that promote natriuresis, diuresis, and vasodilation. Recently, immunocytochemical, radioimmunoassay (RIA), and receptor binding studies have revealed ANF-immunoreactivity and binding sites in the rat's brain. RIA of central ANF levels has either been performed on samples from relatively large brain areas (Morii, N., Biochem. Biophys. Res. Commun., 127:413, 1985) or regionally discrete brain tissue that had not been extracted for ANF (Samson, W.K., Endocrinol., 117:1279, 1985). In the present study, ANF-immunoreactivity was compared in ANF-extracted samples of microdissected brain regions and pituitaries of female rats.

Forty eight Sprague Dawley female rats approximately 180 days of age maintained on a 14 hr light: 10 hr dark illumination cycle were studied. Whole brains and pituitaries were rapidly removed after decapitation and frozen in dry ice. The following brain regions were microdissected (Palkovits, M., Brain Res., 59: 449, 1973): organum vasculosum of the lamina terminalis (OVLT), medial preoptic area (MPOA), median eminence (ME), suprachiasmatic nucleus (SCN), supraoptic nucleus (SON), and the fourth ventricular grey region (FVG) containing locus coeruleus. Samples were boiled for 10 min and homogenized in 0.1 N acetic acid. Supernatants were applied to methanol-activated Sep-Pak C18 cartridges and eluted with 80% MeCN in .1% TFA, then taken to dryness in a Speed-Vac. Extracted ANF levels were then measured by RIA. The percent ANF recovery by this procedure is 90%, and the intra- and inter-RIA coefficients of variation are 6.4 and 9.7, respectively. Regional ANF concentrations (ng/mg protein ± SEM) are presented below.

MPOA	ME	OVLT	SCN
1.67 ± 0.06	1.13 ± 0.04	0.70 ± 0.05	0.70 ± 0.03
SON	SCN	Pituitary	
0.40 ± 0.04	0.24 ± 0.02	0.01 ± 0.00	

ANF concentrations at the seven regions significantly differed from one another ($p<.01$) with the exception of the SCN vs OVLT ($p>.05$). The finding that concentrations vary across discrete regions supports a neurosecretory role for brain ANF. Highest concentrations were present in the MPOA, a region associated with the control of vasomotor and electrolyte balance, drinking behavior, temperature, and phasic release of gonadotropins. Accordingly, ANF may participate in regulating these processes. Additionally, high ME ANF concentrations indicate a role in mediating pituitary hormonal output.

381.5 DISTRIBUTION OF NEUROPEPTIDE Y, NEUROTENSIN, SEROTONIN AND VASOACTIVE INTESTINAL POLYPEPTIDE IN RELATION TO LUTEINIZING HORMONE RELEASING HORMONE IN THE COMMON MARMOSET.
Clive W. Coen and Kevin T. O'Byrne*. Dept. Anatomy & Human Biology, King's College London & *MRC Reproductive Biology Unit, Edinburgh, United Kingdom.

Luteinizing hormone (LH) release in the common marmoset (Callithrix jacchus) is stimulated by treatment with the hypothalamic neuropeptide LH releasing hormone (LHRH). Few other details are available concerning hypothalamic involvement in reproductive processes in this species. In order to initiate various anatomical and physiological studies we have examined the distribution of hypothalamic LHRH; we have also assessed the correspondence between the distribution of processes with immunoreactivity (IR) for certain neurotransmitter-related antigens and those regions containing the LHRH perikarya.

Using peroxidase-antiperoxidase immunohistochemistry with LHRH antisera kindly donated by B. Flerko and L.H. Jennes we have detected LHRH cell bodies around the organum vasculosum of the lamina terminalis (OVLT), within the periventricular preoptic area and in the paraventricular and supraoptic nuclei. The correspondence between LHRH perikarya and other neurochemically identified processes was assessed in both adjacent and single sections, the latter being achieved with two-colour detection methods involving various combinations of the conventional brown diaminobenzidine reaction product, benzidine blue induced by ammonium nickel sulphate and the purple staining obtained with α-naphthol and pyronin.

The regions containing LHRH perikarya were characterized by a marked intensity of neuropeptide Y-IR, the supraoptic area displaying a slightly less dense distribution than the other sites and the caudal paraventricular region receiving processes predominantly medial to the LHRH cell bodies. The distribution of neurotensin-IR was strikingly similar to that of neuropeptide Y. Although serotonin-IR was predominantly lateral and medial to the LHRH perikarya at the level of the OVLT, the medial LHRH cell bodies immediately caudal to that point lay within a dense concentration of immunoreactive processes; the supraoptic region showed only a moderate density and at the level of the caudal paraventricular nuclei the intensely immunoreactive processes were predominantly situated medial to the LHRH cell bodies. Vasoactive intestinal polypeptide-IR was also located lateral to the LHRH cell bodies around the OVLT but the other sites containing LHRH demonstrated an apparently uniform medium density of immunoreactive processes.

These observations offer only indirect evidence for possible neural interactions; they do, however, indicate some of the possible transmitter candidates for the neuromodulation of LHRH release and consequently for the hypothalamic control of ovulation.

381.6 DISTRIBUTION OF NOVEL NEUROPEPTIDES, NEUROMEDIN U AND PANCREASTATIN IN THE MAMMALIAN CENTRAL NERVOUS SYSTEM (CNS).
S. Kar*, J.M. Polak, J. Steel*, J. Ballesta*, S.J. Gibson*, [1]J. Domin*, [1]M.A. Ghatei*, [1]D.G. Bretherton-Watt*, [2]K. Valentino*, [2]K. Tatemoto*, [1]S.R. Bloom* (SPON: J. Wharton). Depts. of Histochemistry and [1]Medicine, RPMS, London, W12 OHS, U.K., [2]Nancy Pritzker Lab., Dept. of Physchiatry and Behavioral Sciences, Stanford Univ. Sch. of Med., Calfornia, U.S.A.

Neuromedin U (Minamino et al., Biochem. Biophys. Res Comm., 130:1078, 1985) and pancreastatin (Tatemoto et al., Nature 324:476, 1986) are two recently discovered peptides. To determine their distribution and hence further elucidate their possible biological rôles their cellular localisation was studied by immunocytochemistry and tissue levels evaluated by radioimmunoassay throughout rodent and porcine CNS.

Neuromedin U and pancreastatin immunoreactivities were found in rat and pig tissues respectively. Neuromedin U-immunoreactive (IR) fibres were distributed throughout the brain. IR cell bodies were mostly restricted to the arcuate nucleus although a few were found in the central amygdaloid nucleus. The relative densities of neuromedin U-IR neuronal systems in the brain were reflected in the extractable tissue levels. Significant concentrations were found in the hypothalamus, thalamus, amygdala, nucleus accumbens, tegmental ganglia and medulla oblongata. In the spinal cord a few fibres were localised to the dorsal horn and the area around the central canal.

Pancreastatin-IR fibres were also found in many brain regions including hypothalamus, cortex, hippocampus and brainstem. The posterior pituitary contained a small number of fibres. IR cell bodies were present in the arcuate nucleus and large numbers of neurones were apparent in paraventricular and supraoptic hypothalamic nuclei. In the brain, the highest extractable pancreastatin IR levels were recorded in the hypothalamus, cortex, thalamus and hippocampus. In contrast to neuromedin U, pancreastatin IR was abundant in the spinal cord. IR fibres were concentrated in laminae I-II of the dorsal horn (a proportion of which presumably derive from pancreastatin-IR cells observed in the dorsal root ganglia), intermediolateral cells columns and the ventral horn. The localisation of neuromedin U and pancreastatin to extra- and hypothalamic regions suggest multiple rôles and thus both peptides are potentially important in neural regulation of the CNS.

381.7 THE VASOPRESSIN AND OXYTOCIN IMMUNOREACTIVE SYSTEMS IN THE BRAIN AND UPPER SPINAL CORD OF THE PRIMATE MACACA FASCICULARIS.
A.R. Caffé*, F.W. van Leeuwen, P.C. van Ryen*[1] and T. van der Woude*. Netherlands Institute for Brain Research, Amsterdam, and [1]Department of Neurosurgery, University Hospital, Utrecht, The Netherlands.

The various extrahypothalamic vasopressin (VP) cell groups in the rat brain are largely responsible for the extensive central VP pathways, part of which is also sexually dimorphic (De Vries et al., J. Comp. Neurol., 233: 236, 1985). Studies conducted on the human brain, demonstrated VP cells in the bed nucleus of the stria terminalis (BST) and the presence of extensive central VP and oxytocin (OXT) pathways, which are different from the rat (Fliers et al., Brain Res., 375: 363, 1986). However, due to suboptimal tissue treatment, no complete picture of the distribution of these neuropeptide systems in the human brain might have emerged.

Therefore adult monkeys of both sexes were either untreated or intraventricularly treated with 1 mg colchicine. After a survival time of 48 hours, during which Temgesic was administered to colchicine monkeys, the animals were perfused with 6% paraformaldehyde. 100 um Vibratome sections of the brain and cervical spinal cord were stained for the presence of VP (using antisera directed against: VP, rat neurophysin and guinea pig glycopeptide) and purified OXT.

Apart from the known hypothalamic paraventricular, supraoptic and suprachiasmatic nuclei, VP cell groups were found in the diagonal band of Broca (DBB), BST, medial amygdaloid nucleus, dorsomedial hypothalamic nucleus, locus coeruleus (LC), nucleus tractus solitarius (NTS) and the substantia gelatinosa of the dorsal horn. In addition, dense VP innervation was observed in the medial septum, DBB, BST, anterior and cortical amygdaloid nuclei, molecular layer of the subiculum and CA1 region of the hippocampus, paraventricular nucleus of the thalamus, nucleus reuniens, periaquaductal gray, area of Forel, ventral tegmental area, LC, parabrachial nuclei and the NTS. In contrast to the rat, areas such as the lateral septum and the lateral habenula were not innervated and no sexually dimorphic extrahypothalamic VP system was found in this monkey species.

No OXT cells were observed outside the monkey hypothalamus. Dense OXT innervation occurred in the cortical amygdaloid nucleus, NTS and the marginal zone of the spinal cord.

The results demonstrate that the number of extrahypothalamic VP cell groups in the monkey is much larger and their location more widespread than in the rat. In addition, the VP and OXT fiber systems in the macaca fascicularis brain is quite different from that of the rat both in density and in brain regions innervated. However, they resemble that of the human brain.

381.8 AN IMMUNOHISTOCHEMICAL STUDY OF CORTICOTROPIN-RELEASING FACTOR-LIKE IMMUNOREACTIVITY (CRFLI) IN MONKEY BRAIN.
S. L. Foote, C. I. Cha*, D. A. Lewis, and J. H. Morrison. Div. Neurosci., Res. Inst. Scripps Clinic, La Jolla, CA 92037.

Immunohistochemistry was used to examine the distribution of CRFLI in brains of two monkey species (Saimiri sciureus, Macaca fascicularis). The results indicate that both similarities and differences exist between rodent and primate in CRFLI distribution. In monkey, like rat, dense immunoreactivity was evident in parvocellular neurons of the paraventricular nucleus and in fibers extending into the median eminence. However, CRFLI perikarya previously observed in other hypothalamic nuclei in rats were not evident in monkey. Also in contrast to previous rat studies, CRFLI cells were evident in several thalamic nuclei, especially the intralaminar complex. There were also two large groups of CRFLI neurons in the brainstem which have not been previously described: a group just lateral to the mesencephalic tegmentum throughout the rostral-caudal extent of the midbrain, and labeled perikarya throughout the inferior olive. The distributions of CRFLI fibers also exhibited similarities and differences between monkey and rat. The most striking terminal fields not previously described are within and adjacent to the substantia nigra pars compacta, in certain subdivisions of the interpeduncular nucleus, and in cerebellar cortex.

Most labeled cortical neurons were small, bipolar cells with radially-oriented dendrites, although some, especially in layers II and IV, were multipolar. Regional differences were evident in the density and laminar distribution of labeled cells: anterior cingulate cortex contained the greatest density (primarily in layers II-V); prefrontal, parietal and occipital regions had an intermediate density (cells most numerous in layers II-superficial III and IV); some temporal regions exhibited a distinctive band of labeled cells restricted to layer IV; the lowest density of labeled cells was in motor cortex (confined to layers II and III). Most labeled processes were radially-oriented, with regional and laminar distributions closely paralleling those of labeled neurons. Some tangential fibers were present in layer I. These findings indicate that CRF is contained in a subpopulation of intrinsic cortical neurons that have a heterogenous distribution in primate neocortex.

Thus, there appear to be substantial differences between rodent and primate in the cellular distribution of CRFLI in brain. However, technical differences between experiments (antiserum sensitivity/specificity, lack of colchicine pretreatment in the present study) may account for some of these contrasting distributions. Antisera generously provided by W. Vale and J. Rivier, The Salk Institute.

381.9 GABA PEPTIDES IN RAT BRAIN: DISTRIBUTION AND REGIONAL RESPONSES TO GAMMA-VINYL-GABA. C.M. Mangione*, T.N. Ferraro, D.S. Garant*, G.T. Golden, T.A. Hare, R.G. Fariello. Thomas Jefferson Univ., Philadelphia, PA and VAMC, Coatesville, PA

GABA in the central nervous system exists both in free and conjugated forms. Administration of gamma-vinyl-GABA (GVG), a relatively specific inhibitor of the enzyme GABA-transaminase, has been documented to increase levels of both free and conjugated GABA. To date, the only endogenous conjugated forms of GABA identified have been dipeptides; however, their distribution is not well characterized and their physiological function is unknown. The regional profile of GABA peptides in rat brain was determined and compared to the regional profile of free GABA by measurement of GABA levels in acid extracts of discrete brain areas before (free GABA) and after (total GABA) acid hydrolysis. The difference between levels of total and free GABA is taken as a measure of conjugated (peptide) GABA. In normal rats, the level of peptide GABA was highest in substantia nigra (SN), hippocampus (HP) and superior colliculus (SC) whereas striatum (ST), cerebellum (CB) and frontal cortex (FC) contained lower levels. This order roughly corresponds to the sequence determined for free GABA. The production of GABA peptides was stimulated by treating rats with a single dose of GVG (2000 mg/kg, i.p.). Animals were sacrificed at 6 or 24 hr after treatment and regional levels of free and peptide GABA were determined. In all regions except CB, free and peptide GABA levels were greater in the 24 hr as compared to the 6 hr group. The greatest percentage increases for peptide GABA were found in SC, HP, and ST. The greatest percentage increases for free GABA were found in FC, HP and CB. In order to distinguish between metabolic and synaptic pools of GABA peptides, nigral levels were measured 24 hr after a single injection of GVG in rats having undergone unilateral transection of the striatonigral pathway. Hemitransection resulted in significant depletion of both free and peptide GABA levels in the ipsilateral nigra compared to the contralateral, non-transected nigra. This result was seen in both saline- and GVG-treated animals and suggests a relationship between GABA peptides and nerve terminal activity. (Supported by U.S. Veterans Administration and The Epilepsy Foundation of America).

381.10 LOCALIZATION OF NEUROMEDIN U-LIKE IMMUNOREACTIVITY IN RAT AND GUINEA-PIG SPINAL CORD, BRAIN AND INTESTINE. S.J. Augood*, J.R. Keast* and P.C. Emson. (SPON: B. Dixit) MRC Unit, Institute of Animal Physiology, Babraham, Cambridge CB2 4AT, England.

Neuromedin U-8 (NMU-8) is a peptide recently isolated from porcine brain by Minamino and colleagues (Biochem. Biophys. Res. Commun. 130:1078, 1985), which stimulates smooth muscle contraction in blood vessels and the uterus. Antisera were raised in two New Zealand white rabbits, against NMU-8 conjugated to bovine thyroglobulin. Animals were boosted 8 weeks later and usable antisera obtained 4 weeks after the first boost. Both antisera had similar properties and only one (Rb 59) was used for further studies. It was used at a dilution of 1:60,000 in a radioimmunoassay (RIA) to determine levels of NMU-like immunoreactivity (NMU-LI) in 0.5 M acetic acid or 0.1 N HCl extracts of rat spinal cord, brain or gut. NMU-LI in these and guinea-pig tissues was characterized by HPLC separation of extracts (on a linear gradient of 16-44% acetonitrile/water/0.1% TFA) and detection of NMU-LI by RIA. Additional samples of duodenum, ileum and distal colon were taken from both species, fixed overnight by immersion in a picric acid/formaldehyde mixture (Zamboni's fixative) and processed for detection of NMU-LI in frozen sections of whole wall thickness or whole mounts of myenteric or submucous plexuses, by fluorescence immunohistochemistry. Final antiserum dilution was 1:200.

In RIA the antiserum had < 0.001% cross-reactivity with the C-terminal hexapeptide of pancreatic polypeptide and no detectable cross-reactivity with neuropeptide Y or vasoactive intestinal peptide. Pre-incubation of antiserum with any of these peptides (up to 10^{-5}M) had no effect on the NMU-LI seen with immunohistochemistry; staining was abolished by pre-incubation with 10^{-6}M NMU-8. In rats the highest level of NMU-LI was in the ileum (7.96 ± 0.95 pmol/g, n=4) and the lowest in the cortex and striatum (0.51 ± 0.15 pmol/g, n=4); HPLC studies showed that, with either extraction method, at least two molecular forms of NMU-LI were present, in rats and guinea-pigs. None corresponded exactly with the peak position of porcine NMU-8. In rat and guinea-pig small intestine, subpopulations of submucous and myenteric neurons were stained. The reaction in guinea-pig tissues was much less intense. No endocrine cells were stained. NMU-LI was also in nerve terminals in both ganglionated plexuses, forming dense baskets around a small population of unstained cells, and in nerve fibres close to the mucosal epithelium. Innervation of the mucosa and submucosa was very sparse in the colon. The high concentrations of NMU-LI in the intestine and its location in enteric neurons suggests a possible role in regulation of gastrointestinal function.

381.11 DISTRIBUTION OF VASOACTIVE INTESTINAL POLYPEPTIDE (VIP)-LIKE IMMUNOREACTIVITY IN THE BAT BRAIN. Lois K. Laemle and John R. Cotter. Depts. of Anatomy, UMDNJ-New Jersey Med. Sch., Newark, NJ 07103 and SUNYAB, Buffalo, NY 14214.

Vasoactive intestinal polypeptide (VIP) has been shown to be involved in regulation of central energy metabolism, pituitary hormone release, body temperature, and cerebral blood circulation, however, the mechanisms governing the regulation of these functions are poorly understood. One approach is to compare the distribution of this peptide in species with differing life-styles and, if possible, under different physiological conditions. Therefore, we have mapped the distribution of VIP in the brain of the little brown bat, Myotis lucifugus, a species in which these functions undergo broad cyclical variation. Myotis hibernates for up to 8 months of the year, during which time body temperature falls from 24°C to 5°C, and heart rate drops from 64 beats/sec. to 11 beats/sec.

VIP was localized immunocytochemically in euthermic, hypothermic, and hibernating animals using Bouin's fixed, 10um paraffin sections, and the unlabeled antibody enzyme method of Sternberger ('79). Immunoreactivity was abundant in olfactory portions of the brain, in all regions of the neocortex, in certain midline hypothalamic and midbrain nuclei including the suprachiasmatic nucleus, anterior hypothalamic area (AHA), paraventricular and periventricular nuclei, dorsomedial and ventromedial nuclei, dorsal and linear raphe nuclei, central gray, and interfasicular nucleus, and in several medullary nuclei, and at least one major subcortical pathway, the stria terminalis.

Our observations in the hypothalamus are of particular interest. VIP-like immunoreactivity in the AHA varied in a manner which corresponded to changes in the physiological state of the animal. Densitometry readings and computer-assisted plots of immunoreactive varicosities showed that the density of VIP- immunoreactivity in the AHA was greatest in euthermic animals, and decreased dramatically in hypothermic and hibernating animals. The density of VIP-like immunoreactivity in other brain centers remained constant. These observations in conjunction with previous studies which indicated a role for the AHA in regulation of body temperature and cardiovascular rate suggest a causal relationship between the physiological changes associated with hibernation in Myotis lucifugus and the decreased VIP innervation of the AHA. The presence of VIP-immunoreactive neurons in the periventricular and paraventricular nuclei may suggest a mechanism for VIP mediation of pituitary hormone release.

382.1 EFFECTS OF SPINAL CORD STIMULATION ON SEGMENTAL REFLEX PATHWAYS IN MAN. J.P. Hunter, P. Ashby, and R.G. Vanderlinden. Dept. of Anatomy and Playfair Neuroscience Unit, University of Toronto. Toronto, Ontario, Canada. M5T 2S8.

Epidural spinal cord stimulators are implanted in patients suffering from chronic pain and in some instances produce symptomatic relief. The actions of these stimulators in man are unknown. We examined 16 patients with implanted stimulators. In most, the cathode was in the epidural space at vertebral level T9/10 and the anode was a metal disc implanted in the paraspinal muscles. Nerve action potentials were recorded from the common peroneal and sural nerves using fine needle electrodes insulated except at the tip. Postsynaptic potentials in single spinal motoneurons were derived from changes in firing probability of voluntarily activated motor units. Spinal cord evoked potentials were recorded using surface electrodes or an epidural electrode at the T12 vertebral level.

When activated at 25-50 Hz spinal cord stimulation (SCS) produced paresthesiae in the trunk and lower limbs. At 3 Hz muscle twitches could be observed in muscles innervated at the segmental level of the cathode and, with stronger stimuli, in muscles of the lower limbs (particularly during voluntary contraction). During SCS nerve action potentials could be recorded from both mixed and cutaneous nerves in the lower limbs. The refractory period was less than 5 msec implying that SCS produces antidromic activation of these afferents. SCS causes short latency periods of increased firing probability in the motoneurons of all lower limb muscles examined. The facilitation occurred in flexor and extensor motoneurons bilaterally. The rise times and the variations in amplitude during paired stimulation are similar to those of the composite Ia EPSP. The facilitation has been obtained in a patient with presumed degeneration of the pyramidal tract. It is likely that this facilitation most likely results from antidromic activation of Ia afferents. There are later periods of decreased or increased firing probability which have not yet been examined in detail. The effects of continuous 25-50 Hz SCS on the facilitation of motoneurons from muscle and cutaneous afferents and on spinal evoked potentials was also examined.

It is concluded that SCS of the type described generates antidromic volleys in primary afferents which could reduce orthodromic volleys by collision. SCS also produces PSP in spinal neurons at segmental levels well below the cathode and could potentially modify transmission in spinal reflex pathways.

382.2 EXCITATORY TRANSMITTERS AND VENTRAL ROOT POTENTIALS PRODUCED BY CUTANEOUS STIMULI IN AN ISOLATED AMPHIBIAN LEG-SPINAL CORD PREPARATION. J.C. Hackman, A.M. Holohean*, J.L. Vega*, D.X. Zhang* and R.A. Davidoff. Neurophysiology Lab, VAMC and Dept. of Neurology, Univ. of Miami Sch. of Med., Miami, FL 33101.

The morphology and physiology of the large diameter primary afferents which mediate touch/pressure sensations and the unmyelinated fibers which respond to noxious stimuli have been well studied, but the transmitters involved in transmission to secondary spinal neurons is still unclear. The present experiments made use of the isolated frog leg-spinal cord preparation (Syková & Vyklický, Physiol. bohemoslov. 28:227,1979) to investigate the role of excitatory amino acids (EAAs) and substance P in the generation of ventral root (VR) potentials (VRPs) produced by non-noxious and noxious stimuli.

Frogs were anesthetized and after laminectomy spinal cords, with leg attached via sciatic nerve, were placed in a plexiglass chamber. Severed VRs were placed across a sucrose gap to record VRPs. The leg still attached to the spinal cord via the sciatic nerve and dorsal roots was placed in an adjacent chamber and covered with Ringer's solution. The spinal cord was superfused with HCO_3^--Ringer's solution bubbled with 95%O_2:5%CO_2 and maintained at 15°C. Von Frey hairs were used to stimulate touch/pressure receptors and 1.0 M acetic acid was used to activate nociceptors. This concentration of acetic acid was sufficient to elicit vigorous wiping and escape behavior when applied to the leg of an intact frog.

Control VR depolarizations evoked by 10 sec applications of a 4.93 gram von Frey hair and 10 sec applications of 1.0 M acetic acid were 2.1±0.4 mV (n = 7) and 4.5±0.6 mV (n = 10), respectively. The addition of 1.0 mM Mg^{++} to the superfusate reduced the VR responses evoked by the von Frey hair and acetic acid by 40-80%. Similar results were observed when the N-methyl-D-aspartate (NMDA) antagonist 2-amino-5-phosphonovaleric acid (10 uM) was applied to the cord. The broad-spectrum EAA antagonist kyurenate (1.0 mM) completely blocked VRPs produced by both touch and noxious stimuli. In contrast, the substance P antagonist spantide (20 uM) had little effect on the touch responses, but significantly reduced the acetic acid-evoked elicited responses.

In summary, in an in vitro frog preparation EAA receptors appear to participate in both noxious and non-noxious stimuli, while substance P appears to participate in noxious responses. (Supported by VAMC MRIS #s 1769 and 3369 and USPHS #17577).

382.3 **TIME DEPENDENT CHANGES IN THE RESPONSE PROPERTIES OF DORSAL HORN NEURONS AFTER DORSOLATERAL FUNICULUS LESIONS.** L. M. Pubols, H. Hirata, and P. B. Brown, Neurological Sciences Institute, Good Samaritan Hospital and Medical Center, Portland, OR 97209.

The spinal cord dorsolateral funiculus (DLF) contains the axons of descending projections to the dorsal horn, some of which are thought to be inhibitory, particularly with regard to nociceptive inputs. In pentobarbital-anesthetized cats, the effects of unilateral DLF lesions were evaluated at < 1 (acute) to 56 days postoperatively (d.p.o.). Microelectrodes were used to record the responses of dorsal horn neurons to natural mechanical stimulation of the skin and to electrical stimulation of A fibers in the sural nerve.

As indicated by the number of cells per electrode penetration that could be driven by natural stimuli, the responsiveness of the dorsal horn was below normal both ipsilateral and contralateral to acute DLF lesions. By 28 d.p.o. responsiveness was above normal ipsilateral to the lesion, but remained depressed contralaterally. The percentage of cells that could be driven by sural nerve stimulation (% SN+) and the percentage that had a receptive field in the skin region supplied by this nerve (% RFin) were below normal at 3 d.p.o, but increased linearly over the next 4 weeks to above normal levels. Results from the two animals studied at survival times longer than 30 days (43 and 56 d.p.o.) suggested that these percentages may return to normal with prolonged survival. As shown in the following table, the differences in these percentages between 15 normal animals and 8 lesion animals studied at 14-30 d.p.o. were highly significant.

	$\bar{x}$(normal)	$\bar{x}$(14-30 d.p.o.)	t	d.f.	p
SN+	31.6%	54.8%	4.155	21	<.001
RFin	35.7%	55.2%	4.037	21	<.001

The percentage of cells exhibiting spontaneous activity as a function of survival time showed a trend which was opposite to that for %SN+ and %RFin, declining from a higher than normal level at 3 days, to below normal at 30 days. Surprisingly, the proportions of cells that responded only to low intensity mechanical stimulation, only to high intensity stimuli, or differentially to both, was very similar to normal in lesion animals at all survival times.

The spontaneous activity data of the present study support the concept of immediate release of descending inhibition by DLF lesions. Measures of responsiveness to peripheral inputs, however, indicated a more gradual increase in excitability, and may reflect a different process. Failure to see an increase in the proportion of cells responding to high intensity stimuli after DLF lesions may indicate that differential inhibition of nociceptive inputs by DLF projection is true for some, but not all, dorsal horn cells and/or descending pathways (Support: NIH, NS19523).

382.4 EFFECTS OF SODIUM PENTOBARBITAL ON THE ACTIVITY OF DIFFERENT CLASSES OF SPINAL NEURONS. S.C. Nam*, K.S. Paik* and J.M. Chung (SPON: J. Calverley). Marine Biomedical Institute and Departments of Anatomy & Neurosciences and Physiology & Biophysics, University of Texas Medical Branch, Galveston, TX 77550.

Sodium pentobarbital is used commonly as an anesthetic drug for humans and experimental animals. Its mechanism of action, however, is not yet clear. Furthermore, there are contradictory reports of its effect on the activity of spinal neurons. The purpose of this experiment was to test the effects of graded doses of sodium pentobarbital on the peripherally evoked activity of both dorsal horn cells and motoneurons in the cat spinal cord.

Twenty-five decerebrate-spinal cats were used in this study. After surgical decerebration, a tracheostomy was performed and the animal was paralyzed with gallamine triethiodide while ventilating with a respirator. The spinal cord was sectioned at the T11 level after exposing the cord by laminectomies at segments T10-L1 and L3-S1. In some animals, the activity of dorsal horn cells was recorded with a carbon filament filled glass microelectrode in the L7-S1 spinal cord. In other animals, the activity of motor axons was recorded as single unit activity from a filament of L7 ventral root. The recorded activity was fed into a computer to compile peristimulus time histograms. The activity of the spinal neurons was evoked by stimulation of the common peroneal nerve and the evoked activity was compared before and after intravenous injection of sodium pentobarbital in small increment doses. Only one cell was studied in each animal.

The activity of 10 motor axons and 15 dorsal horn cells was studied. In general, both A and C fiber evoked activity gradually declined with graded doses of sodium pentobarbital. Approximate average doses required for the reduction of activity to 50% of control values were: 5 mg/kg for the A responses of motor axons; 2 mg/kg for the C responses of motor axons; 20 mg/kg for the A responses of dorsal horn cells; and 15 mg/kg for the C responses of dorsal horn cells. The evoked activity by peripheral C fibers was more sensitive to the drug than that by A fibers. The evoked activity in motor axons was much more sensitive to sodium pentobarbital than the dorsal horn cells so that 10 mg/kg of the drug practically abolished the evoked activity in motor axons by peripheral C fibers. The effect of pentobarbital varied widely between activities of different dorsal horn cells, and the activity of many dorsal horn cells was enhanced with a smaller dose (2-5 mg/kg) of the drug followed by reduction with a higher dose.

From the above results, we conclude that different classes of spinal neurons have differential sensitivity to sodium pentobarbital. (Support by NIH grants NS21266 and NS11255 and by NIH RCDA NS00995).

382.5 SYNAPTIC INPUTS TO LUMBAR SPINAL NEURONS PROJECTING TO THE PONTO-MEDULLARY RETICULAR FORMATION IN THE CAT. Y. Sahara, Y. Xie* and G.J. Bennett. Neurobiology and Anesthesiology Branch, NIDR, NIH, Bethesda, MD 20892.

Extracellular recordings have shown that spinoreticular tract (SRT) neurons receive highly convergent inputs and suggested that excitatory and inhibitory processes interact complexly. In order to define the synaptic inputs to SRT neurons, intracellular recordings were made from antidromically identified SRT neurons in the lumbar spinal cord (L4-S1) of pentobarbital-anesthetized cats. Stable intracellular recordings were obtained from 34 neurons. The neurons were activated from the ipsilateral (n = 8) or contralateral (n = 26) medial pontomedullary reticular formation. Fifteen neurons were also activated from the contralateral spinothalamic tract, indicating that SRT neurons have branching axons. These neurons were divided into 4 groups based on their locations and responses to electrical stimulation of the ipsilateral sciatic nerve. Type 1: In 20 neurons, IPSPs were evoked by stimulation of cutaneous nerves (SP: superficial peroneal nerve and Sur: sural nerve; less than twice threshold: <2T). The central latency of the IPSP ranged from 3.5 to 5.7 ms. Stimulation of a muscle nerve (GS: gastrocnemius-soleus nerve, >2T) also evoked an IPSP. These neurons were located medially and in the deeper laminae (2.2-3.95 mm from the surface). Although some of these neurons had spontaneous discharges, receptive fields were never found. Type 2: In 5 neurons, EPSP-IPSPs were evoked by stimulation of SP, Sur (<2T) and GS (>2T). The central delay of the EPSP ranged from 1.0 to 1.7 ms. Four of these neurons were characterized as wide-dynamic-range (WDR) neurons, which had low-threshold and high-threshold mechanoreceptive inputs and large receptive fields. These neurons were located laterally and 1.0-1.7 mm below the surface. Type 3: In 6 neurons, located 1.95-3.3 mm below the surface, IPSP-EPSPs were evoked by stimulation of SP, Sur (<2T) and GS (>2T). The central latency of the IPSP ranged from 1.75 to 3.2 ms. Two of the 6 neurons were WDR neurons. Type 4: In 3 neurons, located 2.85-3.7 mm below the surface, EPSP (single spike)-IPSPs were evoked by stimulation of SP, Sur (<2T) and GS (>2T). The central latency of the EPSP ranged from 1.3 to 4.4 ms. The present results show that (1) stimulation of low-threshold cutaneous and muscle afferents produces only IPSPs in many SRT neurons, and (2) SRT neurons receive several different patterns of peripheral inputs via multiple synaptic pathways, suggesting that the SRT might be functionally heterogeneous and relay highly integrated information.

382.6 NON-UNIFORM RELEASE PROBABILITIES UNDERLIE QUANTAL TRANSMISSION AT AN EXCITATORY SYNAPTIC CONNECTION IN THE CAT SPINAL CORD. B. Walmsley, F.R. Edwards*, and D.J. Tracey. Neural Research Laboratory, School of Anatomy, University of New South Wales, P.O. Box 1, Kensington NSW 2033, Australia.

Primary afferents from muscles of the hindlimb ascend in the dorsal columns and terminate on dorsal spinocerebellar tract (DSCT) neurons in Clarke's column. Previous studies using deconvolution procedures have demonstrated that excitatory postsynaptic potentials (EPSPs), evoked in DSCT neurons by impulses in single group I muscle afferents, fluctuate in amplitude between discrete levels separated by approximately equal, or quantal, increments (Tracey & Walmsley, J. Physiol., 350, 599-614; Walmsley et al., J. Neurosci., in press, 1987). However, further interpretation of these results requires the application of some kind of probabilistic model.

In a previous study, we demonstrated that simple binomial statistics do not describe the fluctuations in amplitude of single fiber EPSPs recorded in DSCT neurons (Walmsley et al., J. Neurosci., in press, 1987). In the present study we have developed and applied two procedures to find a more appropriate model, using the deconvolution results as a guide.

In a first stage we have demonstrated that the amplitude fluctuations of single group I fiber EPSPs can be well described by a strictly quantal process, unconstrained by any general statistical model such as Poisson or binomial. The unconstrained quantal model indicates that that each EPSP is composed of the sum of a number (1-30) of underlying quantal events, and that furthermore, there is extremely little variability in the amplitude of the single quantal event (<3% C.V.).

In a second stage we have proceeded from the quantal description to examine a probabilistic model in which each underlying quantal event is associated with a particular, but independent, release probability (i.e. the most general case of a compound binomial model). The results of this analysis indicate that a compound binomial model provides a good description of the fluctuations in single group I fiber EPSPs evoked in DSCT neurons. The probability of transmitter release may be at, or close to unity for many release sites and may vary considerably between the remaining sites. In addition to these 'active' release sites, a number of 'silent', or zero-probability, release sites may also exist.

382.7 SOMATOTOPIC ORGANIZATION OF HINDLIMB CUTANEOUS AFFERENTS IN THE DORSAL HORN OF THE CHICK. C. J. Woodbury* (SPON: W. T. Newsome, III), Dept. of Neurobiology and Behavior, SUNY at Stony Brook, Stony Brook, NY, 11794.

Cutaneous afferents project somatotopically to discrete laminae of the dorsal horn (DH) in mammals. Little is known about how this map develops. As a first approach I am studying the central projections of hindlimb cutaneous afferents in hatchling chicks, in which much work has been done on the development of peripheral projection patterns.

Peripheral receptive fields (RF) and central terminations of selected cutaneous nerves have been mapped. RFs were recorded while lightly stimulating the skin. The central projections were then labeled by applying HRP or HRP-ligand conjugates to the proximal cut end of a nerve or, in the case of afferents from toe skin, by injecting markers subcutaneously. Frozen sections of spinal cord and DRGs were processed with TMB and the locations of label in the DH reconstructed. The hindlimb nerves studied include the cutaneous femoris lateralis (CFL), medialis (CFM), caudalis (CFC), and the cutaneous surae lateralis (CSL), which combined innervate most of the thigh and proximal shank. As in mammals, these nerves project heavily into ipsilateral superficial DH; surprisingly, in the chick each nerve projects not to one but to two discrete regions. These dual projections remain separated from one another throughout their rostrocaudal (RC) extent by a region devoid of label. Both projections from each nerve appear to map somatotopically. For example, nerves that innervate skin on the proximal thigh (CFL and CFC) project laterally in the DH relative to the projections from nerves with more distal RFs (CSL and CFM). Afferents from toe skin project even more medially. Further, any mediolateral shift along the RC extent of one projection is mirrored by a similar shift in the other. To test whether these dual projections represent different fiber types or modalities, cholera toxin-HRP (CT-HRP), which preferentially labels large diameter afferents (Robertson and Grant, Neurosci.Abs. 12:1568, 1986), was applied to cut nerves. In each case the medial projection of a nerve was more robustly labeled than its lateral projection, indicating that the two projections are indeed distinct.

These results suggest that two somatotopic maps representing different modalities exist across the mediolateral axis of the DH of the chick. Further, they support the assertion of Brinkman and Martin (Br.Res.56:43,1973) that in the chick, DH laminae 1 and 2 lie lateral rather than dorsal to lamina 3. (Supported by NSF grant BNS 85-18927 to S. A. Scott.)

382.8 Differences In Membrane Properties of DRG Neurons Supplying HTMRs, D-hairs and Other Low Threshold Mechanoreceptors. L. M. Mendell, H. R. Koerber and R. E. Druzinsky*. SUNY-Stony Brook, NY 11794.

Individual somata (n=176) were impaled in the L7 dorsal root ganglion of chloralose anesthetized cats. In agreement with previous results from this laboratory (Neurosci. Lett. 63: 1986) baseline duration of somal action potentials (AP) correlated with both peripheral fiber conduction velocity (PFCV) and receptor type innervated. Most notably A-delta neurons supplying HTMRs had wider spikes than those supplying D-Hairs mainly as a result of a shoulder on the descending limb of the spike. Examination of the after hyperpolarization potentials (AHP) of A-beta and A-delta neurons revealed an inverse correlation between AHP half width and conduction velocity. Within the A-delta group HTMR-AHPs exhibited substantially longer half widths than those of D-Hairs. Hyperpolarizing currents (2nA and/or 5nA; 50ms) were delivered through the microelectrode and the magnitude of inward rectification was calculated as the ratio of the membrane potential 30 ms after pulse onset to the peak membrane hyperpolarization. Over all cells (A-beta and A-delta) we noted that rectification was most prominent in cells with high values of axonal conduction velocity and low values of resistance and AHP. Accordingly, we also found an inverse relationship between cell resistance and axonal conduction velocity. Within the A-delta group D-Hair somata exhibited considerably more rectification than HTMR somata which displayed little or none. The strength of the rectifier in both HTMR and D-Hair somata diminished as axonal conduction velocity decreased but there was no correlation with somal resistance. Differences in rectification between HTMRs and D-Hairs were independent of conduction velocity. No consistent difference in input resistance or RMP was noted between HTMR and D-Hair somata, and so the magnitude and absolute level of peak hyperpolarization produced by these currents were similar. Thus the greater inward rectification associated with D-Hair somata reflects a difference in an intrinsic membrane property. D-Hair somata resemble cells with A-beta axons in having a well developed inward rectifier although A-beta cells displayed even stronger rectification. HTMRs resemble axotomized A-beta sensory neurons which lose rectification (J. Physiol. 270: 1977). Our findings confirm that somal membrane of cells supplying D-Hairs differs from that in cells supplying HTMRs. This difference is independent of parameters related to cell size such as input resistance. Furthermore, cells with A-delta axons differ on the average in AHP, resistance and rectification from those with A-beta axons. Supported by NS 23725 (HRK) and NS 16996 and NS 14899 (LMM).

382.9 Correlation of Rostrocaudal Extent of Monosynaptic Field Potentials Evoked by Single Action Potentials in Identified Single Cutaneous Sensory Afferents and Their Bouton Distributions. P. B. Brown, H. R. Koerber and L. M. Mendell. West Virginia University, Morgantown, WV 26506, and SUNY-Stony Brook, NY 11794.

Single identified fibers penetrated in the dorsal columns of alpha-chloralose anesthetized cats with microelectrodes containing HRP (12-15%; 35-50 Mohms) were stimulated (18/sec) intracellularly while averaging (n=1024) the monosynaptically evoked cord dorsum potentials (CDPs) simultaneously at four rostrocaudal locations centered over the dorsal horn. HRP was then iontophoresed into the axon (450 msec pulses; 1.67/sec; total charge 80-126 nA-min). Sections (100 um) were cut in the para-sagittal plane from a single block of tissue encompassing the full extent of the active zone and processed for HRP. Boutons were counted in 230 um rostrocaudal bins and summed mediolaterally across all sections. CDP amplitude profiles and bouton distributions were compared for fibers innervating slowly adapting type 1 (SA1), and hair follicle and field mechanoreceptors (RAs). Rostrocaudal distribution of bouton densities (4.92mm-11.55mm; 5000-8000 boutons) varied in agreement with the extent of the CDP amplitude profile for individual fibers. Extent of bouton distributions and CDPs varied according to type of peripheral receptor innervated with SAIs routinely having the greatest rostrocaudal extents for both, often being twice the rostrocaudal extent of RA afferents innervating the same area of hindlimb skin. The rostrocaudal range of boutons for an afferent never exceeded the range of active recording sites, but the extent of active recording sites activated by a single SA1 was occasionally slightly larger than the bouton distribution. Therefore, either the full rostrocaudal extent of boutons was not always labeled or volume conduction causes a potential distribution which is longer than the extent of the current sinks (EPSPs). There was no apparent correlation between fiber conduction velocity and the rostrocaudal extent of an individual fibers' bouton or CDP distribution. The relative amplitude of the CDP recorded at an electrode could be approximated from the bouton distribution and electrode location by assuming that synaptic transmission at each bouton results in an equal current sink and that the recorded potential decreases with distance from the bouton. These results show that SAIs have a larger spatial distribution of boutons in the rostrocaudal axis which produce a larger spatial distribution of amplitude profiles than do fibers innervating RA receptors. Furthermore, within the limits of resolution used, the full rostrocaudal ensemble of boutons of a primary cutaneous sensory axon is capable of generating EPSPs in dorsal horn cells, and the amplitude of the CDP appears to be proportional to the density of boutons. Supported by NS 23725 (HRK), NS 16696 and NS 14899 (LMM) and NS 12061 (PBB).

382.10 Spinal Processing of Temporal Information in Sensory Fibers Depends on Receptor Type. H. R. Koerber and L. M. Mendell, SUNY-Stony Brook, NY 11794.

The peripheral receptor of cells impaled in the L7 dorsal root ganglion of cats anesthetized with alpha-chloralose was identified as rapidly adapting (RA) - hair follicle or field - or slowly adapting (SA) using hand held probes. The cell was then stimulated intracellularly and field potentials were averaged simultaneously from 4 positions on the dorsal cord surface straddling the L7 entry zone. The field potentials at the position exhibiting the maximum response were examined following: a) 2 action potentials (APs), conditioning (C) and test (T) separated by 50ms and evoked every 1500ms (n=128) and b) a single AP evoked every 56ms (n=1024). For RA fibers the conditioning effect was consistently a reduction in the peak amplitude of the potential produced by T, with hair follicle responses exhibiting more depression than those from field receptors. The field potentials produced by SA fibers reliably displayed less depression or even facilitated in response to the same C-T sequence. Field potentials evoked at 18/sec were depressed compared to those obtained at 0.67/sec stimulation, and to a greater extent for RA afferents. Thus for these cells (all A-beta fibers- 38-85 m/s) the central amplitude modulation "matched" the frequency modulation of the cutaneous receptor: fibers supplying RA receptors exhibited frequency depression of their central responses whereas those supplying SA fibers either facilitated or were subject to modest depression. Examination of field potential waveforms revealed a longer rise time on the average for those associated with RA receptors and within this group those with the lowest peripheral threshold had the most prominent polysynaptic component. Thus frequency depression associated with RA afferents may result from the lability of their polysynaptic pathways. Therefore, one difference between the central action of SA and RA fibers may reside in the networks activated by such fibers. However, the same differences were also noted between SA afferents and a subset of RA afferents producing field potentials with correspondingly brief rise times. Further examination of RA afferent responses with long rise times but with a distinguishable early component revealed marked depression of this (monosynaptic?) component. This may imply intrinsic differences in terminals of RA and SA afferents. In addition to differences associated with receptor types we noted less depression and more facilitation as afferent CV decreased. A-delta fibers innervating D-Hairs and high threshold mechanoreceptors (HTMRs) evoked more facilitation than A-beta fibers with HTMRs consistently yielding the greatest amount of facilitation. We conclude that central processing of temporal information in the dorsal horn differs systematically for afferents supplying different receptor types. Supported by NS 23725 (HRK) and NS 16996 and NS 14899 (LMM).

382.11 RELEASE OF ENDOGENOUS AMINO ACIDS FROM THE SPINAL CORD OF FREELY MOVING RATS MONITORED BY MICRODIALYSIS. D. H. Smullin, S. R. Skilling* and A. A. Larson. Department of Veterinary Biology, University of Minnesota, St. Paul, MN 55108.

The amino acids glutamate, aspartate, GABA, glycine and taurine have been proposed as neurotransmitters in the mammalian spinal cord. We have developed a method for monitoring the extracellular fluid levels of these amino acids in the freely moving rat using microdialysis.

Male, Sprague-Dawley rats were implanted with 0.2 mm diameter, 50,000 MW cut-off dialysis tubing transversely through the dorsal half of the spinal cord at the region of T-12 or through the CSF at the region of the cauda equina. The animals were perfused with Ringer's solution at 15 µl/min and samples were collected in 10 min aliquots. The aliquots were analyzed for amino acids using HPLC with OPA derivitization. A concentration of 180 µM veratridine perfused through the spinal cord dialysis tubing for 10 min produced a marked increase in extracellular levels of glutamate and aspartate in the spinal cord. A 1mM lidocaine-HCl perfusion through the dialysis tubing for 50 min produced a decrease in the extracellular levels of glutamate, aspartate and glycine, but not taurine. A dose of 40 mg/kg pentobarbital (ip) had no detectable effect on the extracellular levels of glutamate, aspartate, glycine or taurine in either the spinal cord tissue or the CSF as compared to control injections of the vehicle.

The use of *in vivo* microdialysis in the spinal cord for studying the release of neuroactive substances promises to be a powerful tool for the investigation of spinal mechanisms. (Supported by USPHS Grants DA04090 and DA04190, and NIDA Training Grant DA07234)

382.12 EFFECT OF INTRATHECAL PRETREATMENT WITH NEUROTOXINS ON ADENOSINE RELEASE FROM RAT SPINAL CORD SYNAPTOSOMES. M.I. Sweeney*, T.D. White, and J. Sawynok. Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4H7.

Morphine increases endogenous adenosine release from dorsal spinal cord synaptosomes in a manner which is dose-dependent, Ca^{2+}-dependent and opiate receptor-mediated. Noradrenaline (NA) produces a similar increase in the release of adenosine from dorsal spinal cord synaptosomes which is due to release of a phosphorylated nucleotide. Adenosine release is implicated in spinal analgesia by morphine but not NA (Soc. Neurosci. Abstr. 1986, 12:1018). However, the neuronal source of adenosine and the phosphorylated nucleotide is unknown. In the present study, this source of adenosine released from dorsal spinal cord was investigated. Discrete subpopulations of spinal neurons were destroyed by intrathecal (i.t.) administration of the following neurotoxins: 60 µg capsaicin which destroys primary afferent terminals in the substantia gelatinosa; 100 µg 6-hydroxydopamine (6-OHDA) which destroys descending noradrenergic neurons; 100 µg 5,7-dihydroxytryptamine (5,7-DHT) which destroys descending serotonergic neurons. In all cases, appropriate vehicle solutions were administered i.t. to a control group of animals and with 5,7-DHT, animals were pretreated i.p. with desipramine to protect NA-terminals. Approximately 7 days after pretreatment, animals were sacrificed, synaptosomes prepared from the dorsal half of the spinal cord, and adenosine release evoked by K^+ (24 mm), morphine (10 µM) and NA (50 µM) assessed. Adenosine was quantitated by HPLC with fluorescence detection of the etheno-derivative. In the capsaicin pretreated group, significant increases in tail flick, hot plate and pressure test latencies were observed. In these rats, K^+- and morphine-evoked adenosine release from synaptosomes were reduced to 38 ± 11% ($p < .05$) and 47 ± 9% ($p < .05$) of control values respectively, while NA-evoked release remained unchanged. Pretreatment with 6-OHDA reduced NA levels in the ventral spinal cord to 3% of control values but had no significant effect on K^+- or morphine-evoked adenosine release. However, NA-evoked release was increased to 225 ± 20% ($p < .05$) of control values, probably due to the development of receptor supersensitivity. 5-7-DHT reduced 5-HT levels in the ventral spinal cord to 11% of control values but had no significant effect on adenosine release by any agent. These results suggest that in the spinal cord, morphine releases adenosine from primary afferent terminals, but not descending noradrenergic or serotonergic terminals. K^+-evoked release of adenosine appears to originate from the same source. The origin of purines released by NA is still not clear. (Supported by MRC Canada)

382.13 MEMBRANE PROPERTIES AND AFFERENT-EVOKED SYNAPTIC RESPONSES OF SUBSTANTIA GELATINOSA NEURONS IN RAT SPINAL CORD SLICES. M. Yoshimura* and T.M. Jessell. Center for Neurobiology and Howard Hughes Medical Institute, Columbia University, New York, N.Y. 10032

The terminals of most primary sensory neurons that convey nociceptive information synapse with neurons in the substantia gelatinosa (s.g.) of the spinal cord. The analysis of synaptic transmission between nociceptive afferents and s.g. neurons has proved difficult in vivo. We have therefore developed an in vitro slice preparation that permits intracellular recording from s.g. neurons.

Adult rats (100-150 g) were anesthetized, a lumbosacral laminectomy performed and a 1.5 cm length of spinal cord with attached dorsal roots was transferred to oxygenated Krebs solution at 4-6^{o} C. Transverse slices (500 μm) with attached dorsal roots were cut on a vibratome and maintained in a recording chamber at 36±1^{o} C. Intracellular recordings of up to 5 h in duration were obtained from 130 s.g. neurons (mean resting membrane potential -67 mV, mean input resistance 245 MΩ). Action potentials (mean amplitude: 76 mV; mean duration: 0.9 ms) were evoked by depolarizing current. Neurons could be subdivided into 3 distinct classes on the basis of their membrane properties. 20 % of neurons exhibited a time-dependent inward rectification at membrane potentials more negative than -75 mV. Rectification was blocked by extracellular Cs^{++} but not by Ba^{++}, suggesting the presence of an Ih current. In 30 % of neurons, membrane depolarization from potentials more negative than -70 mV, to -50 mV produced an early transient outward rectification that was blocked by 4-aminopyridine (2 mM), possibly reflecting the presence of IA current. The remaining 50 % of s.g. neurons exhibited both inward and outward rectification.

Stimulation of dorsal roots at low intensity (1.5-2 V, 0.2 ms) evoked monophasic epsp's (50-100 ms; to 20 mV) in over 80 % of s.g. neurons. The epsp latency was constant and followed repetitive stimulation at high frequency (5-10 Hz) suggesting that sensory-evoked monophasic epsp's are monosynaptic. The mean conduction velocity of afferent fibers that initiated short latency epsp's was 2.9 m/s (range 0.9-5.5 m/s). In some s.g. neurons, increasing the intensity of dorsal root stimulation (8 V, 0.2 ms) evoked a second class of longer but still constant-latency epsp's. The mean conduction velocity of dorsal root afferents that initiated the long latency epsp's was 0.5 m/s (range 0.4-0.6 m/s) possibly reflecting C fiber input.

Perfusion of slices with l-glutamate (0.5-3 mM) evoked membrane depolarizations that were associated with an increased frequency of spontaneous epsp's in 80 % of s.g. neurons that exhibited afferent-evoked monophasic epsp's. However, in the presence of TTX only 40-50 % of these s.g. neurons retained l-glutamate sensitivity. The amino acid antagonists kynurenate (0.9-1.5 mM) and 2-APV (0.2-0.25 mM) decreased the amplitude of afferent-evoked epsp's in some but not all s.g. neurons. These results indicate that transmission at some afferent synapses with s.g. neurons is mediated by activation of excitatory amino acid receptors.

382.14 RECIPROCAL VARIATIONS IN PLASMINOGEN ACTIVATORS (PAS) IN MEMBRANES FROM DEVELOPING MOUSE SPINAL CORDS.: B.W. Festoff, C.B. Kahler*, C.S. Maben* and J.S. Rao*. Dept. of Neurology, UKMC, Kansas City, KS. and Neurobiology Research Laboratory at VAMC, Kansas City, MO 64128.

We studied the activities of PAs in cytosol (S_2) and membrane-bound (P_2) fractions of mouse spinal cord homogenates from embryonic day 12 (ED12) to post-natal day 60 (PD60). We used a sensitive chromogenic assay based on a synthetic tripeptide specific for plasmin (HD-leu-val-lys-PNA; S-2251) and samples were assayed in the presence/absence of purified human plasminogen (plgn) with/without fibrin monomer (fm) and absorbance was read at 405 nm. Fm can discriminate tissue (tPA) from urokinase-type (uPA) PAs, since tPA must bind to fibrin before it can activate plgn. At constant protein concentrations P_2 uPA showed two sharp peaks of specific activity, at birth ED21 (OD 0.83) and at PD15 (OD 0.86). Just after birth, at PD3 P_2 uPA was at its lowest level (OD 0.22). A broader peak, from PD20-PD30 continued until two months of age (OD 0.5-0.65). P_2 tPA showed much lower activity and its troughs were exactly opposite to uPA peaks at birth and at PD15. In contrast, soluble S_2 activities for both PAs remained quite low (OD 0.05-0.21) throughout spinal cord development.

These results suggest that significant fluctuations in membrane-bound uPA activity coincide with major developmental remodelling situations in murine spinal cord. These are at birth and during the major period of synapse elimination in muscle (ED9-PD20) Other data suggest that this uPA is bound to a specific receptor on spinal cord cells.

REGENERATION: OPTIC NERVE

383.1 NEURITE OUTGROWTH FROM RETINAL EXPLANTS FROM THE ADULT MOUSE. R.L. Meyer and J. Miotke* Developmental & Cell Biology, Developmental Biology Center, Univ. California, Irvine, CA 92717.

Retinal explants from adult mammals offer an attractive system to study the effects of nerve injury and to explore methods of promoting CNS nerve regeneration with in vitro methods. We here describe our efforts at developing such a system and report some initial characterization of the neurite outgrowth.

One optic nerve of adult Swiss Webster or CJ57J mice was crushed in the orbit and 8 days later both retinas removed. Each retina was chopped into 500 μm squares and placed on glass coverslips coated with polylysine and laminin. They were then maintained in DMEM-HEPES with 10% fetal calf serum and 0.4% methylcellulose under 5%CO_2 and air.

About 90% of explants became attached. As early as 24h, neurites were observed growing out of the retinal explants with the crushed nerve and by 48h 2/3 of these explants had obvious neurites. These neurites grew directly on the substrate and extended for several hundred μm. Virtually no neurites were observed from explants from the normal retina at this time. The number of neurites increased with time and by 1 week some outgrowth from the normal retina was observed.

To further determine that these neurites originated from retinal ganglion cells, they were further characterized with immunohistochemistry using monoclonal antibodies. They were found to be strongly positive for heavy neurofilament which preferentially stains ganglion cells and horizontal cells in the intact retina. They were also positive for light neurofilament, negative for GFAP and stained with the Bodian silver method. Finally, in CJ57J mice, the neurites were positive for Thy-1.2, a ganglion cell specific marker. We suggest these neurites may represent regenerating optic axons in vitro.

383.2 IMMUNOREACTIVITY TO GAP-43 IN AXOTOMIZED AND REGENERATING RETINAL GANGLION CELLS OF ADULT RATS. A.M. Lozano, S.K. Doster, A.J. Aguayo and M.B. Willard. Neurosciences Unit, Montreal General Hospital, McGill Univ., Montreal, QUE, H3G 1A4 and Dept of Anatomy and Neurobiology, Washington Univ. Med. School, St Louis, MO, 63110.

GAP-43, a protein which is expressed at higher levels in certain neurons during developmental and regenerative axonal growth has not been observed to increase after injury to CNS neurons of adult mammals. Because axotomized retinal ganglion cells (RGCs), which do not normally regenerate in adult rats, regrow axons into peripheral nerve grafts (PNG) used as optic nerve (ON) substitutes (Soc. Neurosci. Abst. (1986) 12:700), we have investigated whether the growth of these CNS axons into the PNG is accompanied by an increase in GAP-43 immunoreactivity.

Whole-mounts of adult rat retina were stained with an affinity purified polyclonal anti GAP-43 antibody at various times after the ON was cut near the optic disc (n=19 rats) or after the ON was replaced by a PNG (n=35). In 15 unaxotomized retinas, no reactivity to anti GAP-43 was observed nor was there detectable immunoreactivity in frozen sections of the ON. However, between 6 and 25 days after axotomy, the axons and some somata of RGCs reacted with the antibody; no reactivity was observed after 25 days. The time course of the reactivity was the same regardless of whether the ON was axotomized or axotomized and replaced with a PNG to allow regeneration of RGC axons. GAP-43 immunoreactivity was also detected in axons in frozen sections of the graft, 1 and 2 months after grafting, but it was not determined if such axons originated from RGCs or from peripheral neurons that also send fibers into these grafts. The induction of RGC immunoreactivity appeared to be influenced by the location of the injury along the RGC axon. No induction was observed when the optic nerve was cut more than 6 mm from the eye (n=13), nor was immunoreactivity observed after axons which had regenerated into a graft were induced to resume growth by crushing the graft 7 to 10 mm from the optic disc (n=4). The reinduction of growth in the latter case was confirmed by retrograde labelling.

These observations indicate that some RGCs in adult rats respond to axotomy with an increased immunoreactivity to GAP-43 antibody, regardless of whether or not they regenerate into the nerve grafts. This response appears only when axons are severed near the retina. We do not know whether this immunoreactivity is a consequence of increased synthesis of GAP-43, increased accumulation of GAP-43 synthesized at a basal rate, or some other change induced by axotomy.

383.3 LONG-TERM PRESERVATION OF INTRINSIC RETINAL NEURONS AFTER AXOTOMY INDUCED DEATH OF RETINAL GANGLION CELLS. D. A. Carter*, M. Vidal-Sanz* and A. J. Aguayo. Neurosciences Unit, The Montreal General Hospital and McGill University, Montreal, Quebec, H3G 1A4, CANADA.

In adult rats, the transection of the optic nerve (ON) within the orbit is followed by the death of nearly 90% of the axotomized retinal ganglion cells (RGCs). Although RGC survival and axonal regrowth can be enhanced in these animals by peripheral nerve segments grafted to the ON stump, the RGC population that survives axotomy and grafting only approximates 25 % of normal (Vidal-Sanz et al., 1987, J. Neurosci, in press). In the present study, the long-term effects of such extensive retrograde degeneration of RGCs on intrinsic retinal neurons (IRNs)- amacrine, bipolar, horizontal and receptor cells- have been investigated using standard morphometric techniques as well as antibodies that recognize molecules expressed characteristically by certain classes and subclasses of IRNs. Because many of the IRNs synapse with RGCs in the intact retina, it was considered important to investigate protracted effects of RGC loss on the entire population of retinal neurons.

In female Sprague-Dawley rats weighing approximately 200 g, the ON was cut within the orbit (Axotomy group) or totally replaced by a 3 cm autologous segment of peripheral nerve (Axotomy and Graft group). Retinas from animals of both groups were examined up to 15 months after axotomy and compared to intact retinas of rats of the same age. Immunoreactivity to several antibodies (Ab) was used in retinal radial sections and flat mounts: Ab-MAP 1A and RT 97 for the ganglion cell and nerve fibre layer; HPC-1, an antibody that recognizes amacrine cells preferentially; Ab-tyrosine hydroxylase, Ab-somatostatin, Ab-substance P and Ab-glutamic acid decarboxylase, which distinguishes subclasses of amacrine cells; asv48 , an antibody that immunoreacts with synaptic vesicle components present in higher concentration in the external and internal plexiform layers; RET-B1 antibody for bipolar cells, VC1.1 antibody for horizontal cells and Ab-opsin for photoreceptors.

Although the loss of RGCs in both experimental groups of animals caused a 20% reduction in the thickness of the retina, the density and appearance of the different classes and subclasses of IRNs, detected by the immunocytochemical techniques used in this study, were indistinguishable from normal. These findings suggest that local interactions within the retina may suffice for the prolonged survival of local circuit neurons. It is not known if their apparent survival is accompanied by changes in their synaptic connectivity within the retina.

383.4 **GALVANOTROPIC REGENERATION IN THE MAMMALIAN VISUAL SYSTEM.** **M.F. Zanakis, M.J. Politis and B.J. Albala American BioInterface Corp., New York, NY and Anatomy Dept., Univ. of Saskatchewan, Canada**

Recent *in vivo* work has demonstrated a regenerative response in the lesioned mammalian spinal cord following the application of static DC electric fields. Unfortunately, this is not the ideal system to study central nervous system (CNS)regeneration due to the inherent problems of tissue heterogeneity. These studies utilized the lesioned rat optic nerve model in order to determine whether the mammalian CNS is indeed capable of significant regeneration following the application of electric fields. Rat optic nerves were crushed behind the orbit, and a *galvanotropic neural guide* device (TRAXON™) was placed over the lesion, with the anode just proximal to the lesion, and the cathode 3mm distal to the lesion (delivering 1µA to the tiussue). After 3 weeks, the animals were sacrificed, and the optic nerve 3mm distal to the lesion was cross-sectioned for histological analysis using fluorescent antibodies to neurofilament protein. Control animals received A) an inverted current electrode (anode distal), or B) an inactive electrode, or C) an active electrode but the retinae were avulsed 1 weeks prior to sacrifice (which destroys the retinal contribution of axons to the optic nerve, but not the possible contribution of regenerated peripheral nerves). The results demonstrated that in every animal with actively implanted (cathode distal) electrodes with intact retinae, a large number of axons had regenerated through the scar and 3mm into the distal portion of the nerve, as indicated by the presence of neurofilament-positive profiles. Additional toluidine blue staining and electron microscopy showed that the axons had grown in fascicles, and were either myelinated or unmyelinated. In contrast, none of the control nerves showed signs of axons in the distal segment. The avulsed retina animals also showed no signs of regenerated axons in the nerve, suggesting that peripheral nerves did not contribute to the regenerated axonal population observed in the cathode distal-intact retina group. Thus, these results suggest that damaged optic axons had regenerated through the lesion and into the optic nerve. In a limited number of animals in each of these groups, the optic tract (close to the optic radiations) was also sectioned for neurofilament-positive profile determination. Preliminary results indicate that the optic tract contralateral to the treated nerve contained a greater number of axonal profiles than the contralateral tracts of control animals, suggesting that regenerated axons may be capable of entering the optic tract. In summary, these studies add additional support to the claims that the CNS can regenerate following the application of electric fields.

383.5 PHOSPHORYLATION OF PROTEINS IN REGENERATING GOLDFISH OPTIC NERVE IS INDEPENDENT OF THEIR SYNTHESIS AND EXPORT INTO RETINAL GANGLION CELL AXONS. Denis C. Larrivee and Bernice Grafstein. Dept. of Physiology, Cornell Unversity Medical College, New York, NY 10021.

When ^{32}P-labelled phosphate was injected into goldfish eyes, approximately 20 optic nerve proteins became strongly labelled, as shown by two-dimensional electrophoresis and autoradiography. Most of these proteins were present in the retinal ganglion cell axons and many changed their phosphorylation during regeneration: 5 proteins (including a 45 kD protein closely related to the growth-associated protein GAP-43) showed an increase in incorporation of phosphate whereas 4 others showed a decrease. However, the changes in protein phosphorylation were not correlated with changes in incorporation of ^{3}H-proline. These results suggest that either 1) the phosphorylation of many optic axon proteins is not closely coupled to their synthesis, or 2) phosphorylation accompanies synthesis, but phosphate groups on newly synthesized proteins are actively removed by protein phosphatases. To distinguish between these possibilities we blocked protein synthesis in the retinal ganglion cells by intraocular injection of cycloheximide. The experiments were carried out on animals in which the optic tracts had been severed 3 weeks earlier, in order to maximize protein synthesis and export into the axons. One hour after injection of the inhibitor a combination of ^{32}P and ^{3}H-proline was injected into the eye. Seventeen hours later the animals were sacrificed and the nerve proteins subjected to two-dimensional electrophoresis and autoradiography. The inhibitor reduced the incorporation of ^{3}H-proline into total nerve protein by approximately 85% but reduced the incorporation of ^{32}P by only 50%. In most of the individual phosphoproteins the incorporation of proline was reduced by more than 85% whereas the incorporation of ^{32}P was reduced by less than 50% in 18 of the 20 proteins examined and by less than 30% in 11 of these. The fact that the phosphorylation of all proteins was significantly less affected than their synthesis indicates that phosphorylation of these proteins is unlikely to be closely coupled to their synthesis.

To determine whether phosphorylation occurred in the ganglion cell bodies or in the axons of the optic nerve, axonal transport was blocked by intraocular injection of vincristine in experiments that duplicated the protocol used with cycloheximide. Vincristine reduced ^{3}H-proline incorporation into total nerve protein by 90% but reduced ^{32}P incorporation by only 55%. In 17 individual proteins examined, incorporation of ^{3}H-proline was reduced by more than 90%. However, 15 of these proteins showed a reduction in phosphorylation of less than 55% and 12 of them less than 30%. Thus, most of the phosphoproteins appear to be phosphorylated in the optic nerve.

Supported by NIH grants NS-14967 & NS-09015 and a Spinal Cord Research Foundation Fellowship.

383.6 OPTIC NERVE REGENERATION IN CARP IS ASSOCIATED WITH ACCUMULATION OF APOLIPOPROTEIN-A-I (PARTICULARLY ONE ISOFORM) AND INCREASED EXPRESSION OF APOLIPOPROTEIN-A-I TRANSCRIPTS. M. Schwartz[1], A. Harel[1]*, C. Stein-Izsak[1], M. Fainaru[2]*, Z. Schafer[2]*, and T. Vogel[3]* Dept. of Neurobiology, The Weizmann Institute of Science[1], Kaplan Hospital[2] and Biotechnology General (LTD)[3], Israel.

Injury to the fish optic nerve initiates pronounced changes in the composition of proteins derived from the surrounding non-neuronal cells. One of the injury-induced alterations is in the appearance of a pulse-labeled 28kDa polypeptide in conditioned media (CM) of these nerves (Rachailovich, I. and Schwartz, M., Brain Res., 306; 149, 1984). In this report, we provide evidence that this polypeptide is immunologically cross reactive with apolipoprotein-A-I (apo-A-I) from fish plasma. Apo-A-I was found in both intact and injured fish optic nerves. Injury to the optic nerve was associated with accumulation of apo-A-I, particularly of one isoform.

Apo-A-I was purified from fish plasma by density gradient centrifugation, followed by gel filtration of the high density lipoprotein fraction on Sephadex G-200. The purified protein was identified as apo-A-I based on molecular weight (28kDa) as determined by gel electrophoresis and amino acid composition. No immunological cross-reactivity was observed between fish plasma apo-A-I and antibodies directed against mammalian apo-A-I. Therefore, antibodies were prepared against fish plasma apo-A-I. Using these antibodies, by Western blot analysis we were able to show that the 28kDA polypeptide cross-reacts immunologically with the apo-A-I from fish plasma. Immunoblotting of two-dimensional gels of substances derived from CM of non-injured fish optic nerves revealed two polypeptides (pI 6.49, 6.64) that were stained with antibodies raised against the purified plasma apo-A-I. In regenerating preparations, and additional polypeptide (pI 6.73) was stained.

Messenger RNA derived from non-neuronal cells of fish optic nerves hybridized in slot blots with nick-translated cDNA probes of human apo-A-I. The hybridization signal was higher in injured (regenerating) than in non-injured nerves. In the former, higher levels of apo-A-I transcripts were found in the distal stump than in the segment close to the optic disk.

Apolipoprotein-E (apo-E) is known to accumulate in peripheral nerve of mammals after injury. No appreciable levels of apolipoprotein corresponding to mammalian apo-E could be detected among the fish apolipoproteins by polyacrilamide gel electrophoresis. It is, therefore, suggested that apo-A-I in regenerating nerves of fish CNS plays a role similar to that of apo-E in regenerating nerves of mammalian PNS. Both may be involved in elimination of myelin-degradation products.

(This work was carried out with support from the US Army Medical Research and Development Command to MS.)

384.1 PLASTICITY OF RETINAL AND NONRETINAL AFFERENTS IN THE CHICK VENTRAL LATERAL GENICULATE NUCLEUS FOLLOWING TECTAL REMOVAL AT HATCHING. G.R.Ten Eyck,* R.M. Kraemer,* L.M. Sokolowski,* and W.J. Crossland, (SPON: J.A. Rafols) Dept. of Anatomy and Cell Biology, Wayne State Univ. Schl. Med., Detroit, MI 48201.

The chick ventral lateral geniculate nucleus receives projections from the retina, optic tectum, and visual wulst. We previously showed plasticity of the retinal projections to the chick ventral lateral geniculate nucleus (GLv) following optic tectum lesions. In this study, we examined further the effects of optic tectum removal on transneuronal atrophy and plasticity in the GLv.

Newly hatched chicks were anesthetized with ether and subjected to unilateral tectal removal. After a postoperative survival of 78 days one group of animals was perfused with formalin, embedded in paraffin, and sectioned in the frontal plane for light microscopy; a second group was perfused with an aldehyde mixture, sectioned on a vibratome, and samples of the center of the GLv embedded in epon for electron microscopy.

The volume of the GLv (both ipsilateral and contralateral to the tectal removal) was reconstructed from tissue sections which were measured using a digitizing morphometry system (Bioquant II, R & M Biometrics) in ten chicks. The GLv volume ipsilateral to the lesion was 13% larger than that of the contralateral GLv.

Eight animals prepared for electron microscopy were analyzed using point-counting stereology in a single-blind study of 1) the number of synaptic active zones per unit area in the GLv neuropil lamina, 2) the volume fraction of the tissue occupied by retinal and nonretinal synaptic terminals (containing active zones), and 3) retinal and nonretinal vesicle containing profiles (not containing active zones).

The areal density of retinal and nonretinal active zones did not differ significantly between the GLv contralateral and ipsilateral to the removed tectum, however, the volume fraction was significantly increased for both synaptic terminals and vesicle containing profiles ipsilateral to the tectal removal.

The results indicate sprouting of axonal terminals in the GLv without an increase in synaptic membrane specializations, and without any overall atrophy of the GLv volume. Furthermore, the bulk of the sprouting occurs in nonretinal terminals which may include intrinsic cells of the GLv.

This study was supported in part by NIH grants EY01796 (W.J.C.), and EY-04068 (Core Equipment Grant for Vision Research), and a Grant from the Michigan Eye Bank (W.J.C.). L.M.S. was supported by a summer fellowship from the Neuroscience Program at Wayne State University.

384.2 GUINEA PIG VAGAL MOTONEURONS EXHIBIT EXTENSIVE PERIKARYAL AND DENDRITIC SPROUTING DURING RETROGRADE REACTION

A.K. Engel and G.W. Kreutzberg
Max-Planck-Institut für Psychiatrie, Abt. Neuromorphologie
8033 Martinsried, F.R.G.

During retrograde reaction, vagal motoneurons of the guinea pig show complex changes of their perikaryal and dendritic surface in addition to chromatolysis. Within a few days, flap-like processes appear on the neuronal surface. They contain varying numbers of smooth-surfaced vesicles or cisternae, a feltwork of filamentous material and, occasionally, microtubules and dense-core vesicles. These upfoldings cover large parts of the perikarya or interdigitate with processes of adjacent neurons. Moreover, the shape of the dendrites becomes highly irregular, and growth--cone-like profiles appear in the neuropil. These changes reach their maximum two to three weeks after axotomy, but seem to persist for several months. Both perikaryal and dendritic processes are frequently seen in contact with presynaptic terminals.

Local astrocytes react with hypertrophy of their processes, an increase of glial filaments and intense lamellae formation. Within a few days, neurons seem to be completely wrapped by glial lamellae stacks.

Acetylcholinesterase (ACHE) activity was used as a cytochemical marker to distinguish neuronal from glial processes. Interestingly, the guinea pig vagal neurons do not show the rapid loss of ACHE activity that has been described in other species. Rather, a sub-cellular redistribution of activity seems to occur after nerve transection. At the light microscopical level, staining of the neuronal perikarya slightly increases. After axotomy, electron microscopic cytochemistry demonstrates strong activity in peri-nuclear cisternae, endoplasmic reticulum and Golgi complexes. Staining is also especially prominent on the neuronal plasmalemma. The newly formed processes were consistently found to be ACHE--positive.

It is concluded that the morphological changes observed correspond to a sprouting process in an unusual location, i.e. adult CNS environment. This could indicate a mechanism that possibly is involved in the reorganization of synaptic afferent inputs. It might also serve protective functions, since preliminary data suggest that guinea pig vagal motoneurons are less susceptible to cell death than those of other species.

384.3 MONOAMINERGIC ADAPTATION TO NEONATAL NOREPINEPHRINE DEPLETIONS IN RAT BRAIN. M.H. Teicher, N.I. Barber*, R.J. Baldessarini, S.P. Finklestein, E. Marsh*, J. Zorc*. Harvard Medical School; Mailman Research Center, McLean Hospital, Belmont, MA 02178.

We reported that the combination of GBR-12909, a selective inhibitor of neuronal uptake of dopamine (DA), and 6-hydroxydopamine (6OHDA) administered to 3-day-old rat pups resulted in a 95-99% depletion of cortical and hippocampal norepinephrine (NE), without acute effects on DA or serotonin (5HT) levels (Teicher et al., Devel. Brain Res., 1986, 30:124-128). In the present study we evaluated possible long-term compensatory changes in monoaminergic systems following profound neonatal NE depletion by such treatment. Stakowiak et al (Brain Res. 1984, 291:164-167) and Breese et al. (J. Pharm. Exp. Ther. 1984, 231:343-354) reported that neonatal depletion of DA was followed by increased striatal concentrations of 5HT, presumably by a compensatory process of axonal sprouting and increased innervation by 5HT-containing axonal terminals arising from raphe nuclei (Berger et al. Brain Res. 1985, 336:354-358; Snyder et al. J. Comp. Neurol. 1985, 245:247-281).

3-d-old rat pups were given GBR-12909 (40 mg/kg ip), followed in 1 h by intracisternal 6OHDA (125 µg in 20 µl saline-ascorbic acid solution), and were sacrificed at 14, 17, 22, 40 and 60 d of age. Regional HPLC/EC assays of NE, DA, and 5HT were performed in hippocampus (HIPP), hypothalamus (HYPO), striatum (STR), and prefrontal cortex (PFCTX). Data were compared to vehicle injected littermate controls sacrificed at the same time.

At 60 d of age, HIPP NE was decreased by 93%, and 5HT was increased by 71% ($p<.02$); the increase in HIPP 5HT content emerged slowly, and was not discernable at 40 d of age. At 60 d HYPO NE was 77% depleted and 5HT tended to increase (43%). Despite a 97% reduction in PFCTX NE, the 5HT content of this region was not significantly increased at this age.

Levels of DA were virtually identical to control levels in the STR, HYPO and PFCTX of 60-d-old rats. It was surprising that there were no significant effects of NE depletion on DA concentration. Perhaps a transient change in DA levels preceded slower and more sustained alterations in other neurochemical processes. In HYPO, levels of DA were transiently increased at 14 and 17 d (by 63% and 95% respectively) but had returned to control levels at 22 d. The PFCTX displayed an even greater transient change, with DA levels exceeding control concentrations by 2-fold at 17 d and 3-fold at 22 d of age, but were not significantly greater than controls at 40 d.

These results suggest that neonatal depletion of NE is followed by regionally-specific time-dependent compensatory alterations in other monoaminergic systems that include sustained slow increases of 5HT, particularly in the HIPP. Such developmental processes may enable these neonates to survive and adapt to massive damage to this presumably important neurotransmitter system.

384.4 COMBINED SEPTAL AND ENTORHINAL LESIONS PRODUCE MORE EXTENSIVE SUPRAGRANULAR MOSSY FIBER SPROUTING THAN DO ENTORHINAL LESIONS ALONE. H.H. Tjossem and J.R. West. Alcohol and Brain Research Lab, Dept. of Anatomy, Univ. of Iowa, Iowa City, IA 52242.

In the hippocampal formation of rats, the removal of CA4-derived or entorhinal afferents to the dentate gyrus causes sprouting of granule cell axons (mossy fibers) onto proximal segments of the granule cell dendrites (Laurberg, S. and Zimmer, J., J. Comp. Neurol. 200:433, 1981). We find that the removal of septal afferents in conjunction with entorhinal lesions causes additional supragranular mossy fiber sprouting. Four groups of young adult albino rats were used, three of which received electrolytic lesions while the fourth received no treatment. One group received bilateral septal lesions, one group received unilateral entorhinal cortex lesions and one group received combined septal and entorhinal lesions. Thirty days following the lesions, animals were perfused for the Timm-stain of heavy metal cations. Lesion sections were examined to document the extent of tissue destruction. Two series of coronal sections were taken from the rostral hippocampal formation and stained with either the Timm procedure for mossy fiber analysis, or for acetylcholinesterase histochemistry to document the success of the septal lesions. Qualitative analysis of the normal group showed a few bundles of black-staining mossy fibers radiating through the granule cell layer with some coursing around the free end of the infrapyramidal granule cell layer to reach the supragranular region where limited punctate staining is often seen. The mossy fiber distribution of the septal lesion group did not appear different from normal rats. Animals which received entorhinal lesions had marked, punctate mossy fiber staining in patches scattered throughout the supragranular zone of the dentate gyrus. Combined septal and entorhinal lesions enhanced this mossy fiber sprouting. The combined lesions produced a continuous, heavily stained band of mossy fiber puncta throughout the supragranular zone of the dentate gyrus. Thus, in the rat dentate gyrus, the loss of septal afferents, when combined with removal of entorhinal afferents, will augment supragranular mossy fiber sprouting even though bilateral septal lesions have no striking effect of their own. These findings have important implications for recovery of function following multiple injuries to the central nervous system and to disease processes such as those associated with Alzheimer's disease where multiple foci of pathology occur. (Supported by NIAAA grant AA06192 to J.R.W.).

384.5 SEX DIFFERENCES IN HIPPOCAMPAL REACTIVE FIBER GROWTH: STEROID INTERACTIONS J. K. Morse, S. W. Scheff, and S. T. DeKosky. Depts. Anatomy and Neurology, Lexington VA and Sanders-Brown Research Center on Aging, Univ. of Kentucky, Lexington, KY 40536.

We have previously reported that steroids play an important role in the sexually dimorphic lesion-induced fiber outgrowth observed in the hippocampus. Normal male and female rats demonstrate equivalent reactive growth. Adrenalectomy (ADX) results in a significant increase in fiber outgrowth in females but fails to alter the male's response. Gonadectomized (GDX) females significantly decrease their reactive response, while GDX males maintain control levels. The growth response in GDX females is normalized by estrogen (E) or testosterone (T) replacement. A dimorphic response is also seen in GDX/ADX animals. Females respond to control levels while males display decreased fiber outgrowth. T is apparently essential to the male mechanism of growth, while E is sufficient but not necessary for the female response. The present study further examined steroid interactions with these sexually dimorphic mechanisms of reactive outgrowth.

Ninety day Sprague-Dawley rats of both sexes were randomly assigned to one of five treatment groups: 1) Controls 2) GDX/ADX (asteroidal) 3) GDX/ADX + T 4) GDX/ADX + E and 5) GDX/ADX + glucocorticoids (hydrocortisone). Ten days after GDX/ADX surgery, all rats underwent a unilateral entorhinal cortex ablation. Fifteen days later changes in axon sprouting were determined by assessing the reactive outgrowth of the hippocampal commissural-associational afferents.

The interpretation of sexually dimorphic aspects of fiber outgrowth change depending upon the baseline used for comparison. Compared to normal controls, T enhanced outgrowth in GDX/ADX females but had no effect in GDX/ADX males. When compared to asteroidal (GDX/ADX) baseline rats, T facilitates fiber growth in both males and females. This surgical procedure (GDX/ADX) decreases outgrowth in the males resulting in a lower baseline. The baseline for the females is unchanged with GDX/ADX. Estrogen enhanced growth in both GDX/ADX females and males when compared to normal or asteroidal controls. Glucocorticoids are inhibitory in both sexes when compared to normal controls, but do not play the same role when asteroidal baselines are used. In females they appear to regulate lesion-induced outgrowth while in the male under the GDX/ADX condition they appear to have little effect making their role uncertain. (Supported by NIH grant NS21541 and the VA Medical Research Service)

384.6 THE ROLE OF CONTRACTILE ACTIVITY AND SYNAPTIC FUNCTION IN MOTOR NEURON SPROUTING. M.M. Wines, D.G. Garrett,* and M.S. Letinsky. UCLA School of Medicine, Ahmanson Laboratory of Neurobiology, Los Angeles, California 90024.

In a previous publication we demonstrated that application of the compound formamide to amphibian striated muscle selectively eliminated contractile activity without significant alterations to either presynaptic release of acetylcholine or muscle fiber action potentials. In addition, motor neurons within these paralyzed preparations were seen to sprout unmyelinated outgrowths from their terminal arborizations (Soc. Neurosci. Abstr. 11:916, 1985). More recently we have produced chronic contractile and electrical inactivity in amphibian striated muscle (cutaneous pectoris; Rana pipiens) by repetitive exposure of the tissue to the postsynaptic blocking agent alpha-bungarotoxin (α-BTX). Analogous to the response seen with formamide incubation, motor neurons in these toxin treated preparations are also seen to sprout. However, the onset of this response as well as the morphology and frequency of sprouting is notably different than that seen to occur after selectively eliminating only contractile activity. To date, postsynaptic blockade with α-BTX has been maintained without interruption for up to 35 days. Relatively small amounts of sprouting (3-8% of the observed terminals) occur up until approximately two weeks of inactivity, afterwhich the number of terminals bearing sprouts increases dramatically (up to 54% at five weeks of inactivity). The onset for the initiation of sprouting in amphibian muscle is markedly slower than the response seen to occur after α-BTX application to mammalian muscles (Holland and Brown, Science 207:649, 1980). In addition, formamide induced inactivity produces lengthy, ornate terminal outgrowths in contrast to the short, rudimentary outgrowths seen to follow α-BTX incubation. The observed results suggest that the method used to promote contractile inactivity (i.e., presence or absence of synaptic function and muscle fiber action potentials) may modify the sprouting mechanism. Periods of α-BTX induced inactivity beyond the five week maximum are currently being maintained. Supported by USPHS grant NS13470.

384.7 INTRASPINAL SPROUTING OF RAT PRIMARY AFFERENTS AFTER DEAFFERENTATION. D.L. McNeill* and C.E. Hulsebosch (SPON: K. Chung). Marine Biomed. Inst. and Depts. Anat. & Neurosci., Univ. Tex. Med. Br., Galveston, TX 77550.

In 1958, Liu and Chambers first reported increased silver deposition in the dorsal horn on the chronically denervated side in the cat spinal cord after unilateral dorsal rhizotomies above and below a spared root. The increase in silver reaction product was interpreted as terminal sprouting of the spared primary afferents in response to spinal cord deafferentation. The issue of primary afferent sprouting after spinal cord deafferentation remains controversial. Recently, Hulsebosch and Coggeshall (1981) observed a significant increase in the number of unmyelinated primary afferent fibers in the spared root of juvenile rats when compared to the contralateral control root, which was interpreted to be sprouting (or branching) elicited by spinal cord denervation. In the present study, we used fluoride-resistant acid phosphatase (FRAP), an enzyme present in a subpopulation of small diameter primary afferent perikarya and their terminals in laminae I and II of the dorsal horn, to test presynaptic sprouting of primary afferent fibers in the dorsal horn of juvenile rats using a modification of the spared root paradigm. One month old Sprague-Dawley rats were anesthetized and a unilateral dorsal rhizotomy was performed three segments above and below T9 or T10 which was the chronic "spared" root. As a control, 26 days following the initial surgery, rats were reanesthetized and the deafferentation procedure was repeated on the contralateral side three segments above and below the spared segment, thus eliminating all but the primary afferent fibers from the chronic and control spared roots. Four days later, the animals were perfused with 4% paraformaldehyde, the T8-T11 spinal cord was removed, frozen, serially sectioned at 20 µm, mounted on glass slides and reacted for FRAP enzyme activity by a modified Gomori procedure. In all rats (n=5), the density of FRAP reaction product was greater on the chronically denervated side than on the contralateral acutely denervated side. In addition, FRAP reaction product extended medially in the spared segment and cranially beyond the spared segment. To rule out normally occuring asymmetrical projections of primary afferents, the spared root surgery was performed bilaterally on 56 day old littermates which were sacrificed 5 days later. No asymmetrical projection patterns were found. We hypothesize that the increased and extended FRAP reaction product medially in the spared segment and into adjacent denervated segments on the chronic side is due to sprouting of presynaptic terminals of primary afferent fibers in the dorsal horn. Ultrastructural verification of this hypothesis is now underway.

384.8 IMMUNOLABELING OF SYNAPTIC REMODELING IN NEONATALLY DEAFFERENTED OLFACTORY CORTEX. R. E. Westenbroek*[1], L. E. Westrum[2], A. E. Hendrickson[3], J-Y. Wu[4], and N. A. Nougek-Goebl*[3]. Depts. of Neurosurg.[1,2,5], Biol. Struct.[1,2,3], and Ophthalmol.[3], Univ. of Wash., Seattle, WA 98195 and Dept. of Physiol.[4], Penn. State Univ., Hershey, PA 17033.

Plasticity and reorganization of afferents within the CNS following deafferentation is a topic of much current interest. The three-layered olfactory cortex (OC), with its well-established afferents and efferents, serves as an excellent model for such studies. Olfactory bulb (OB) removal in neonatal rats results in dramatic spread or sprouting of association fibers into the deafferented superficial apical dendritic fields (layer Ia) of the OC. We are studying the developmental plasticity in OC using immunocytochemical localization of neurotransmitters including antisera to cholecystokinin (CCK; graciously provided by Dr. M. C. Beinfeld) and glutamic acid decarboxylase (GAD). Sprague-Dawley rats are being used. Newborns under deep ether anesthesia have one OB removed. Following about 3 months survival the animals are sacrificed, perfused, and Vibratome sections from OC are processed by the PAP method of Sternberger modified for electron microscopy (EM). In normal adults, and in contralateral, unoperated control sections of OC, GAD-positive terminals mostly contain flat to pleomorphic vesicles and form symmetric type 2 contacts onto dendritic shafts and branches throughout layer I, superficial (Ia) and deep (Ib). CCK-positive terminals normally occur in deeper layer I (Ib) and cell layer II but are rare superficially (Ia). They form mainly type 2 and occasionally type 1 (asymmetric) contacts. In normals primary afferents from the OB form type 1 asymmetric contacts only. In the deafferented material there appear to be greater numbers of labeled GAD terminals throughout Ia and Ib. Here not only do these GAD-positive terminals form type 2 contacts, but several of them form clearly asymmetric type 1 synapses onto dendrites of all sizes, including spines. CCK-labeled axons and terminals now occur more frequently in superficial Ia where they were usually rare or absent in controls. These numerous CCK-positive terminals usually contain pleomorphic or round vesicles and sometimes form contacts of either type, but more often lack a distinct contact. The findings clearly show modifications in synaptic patterns of immunocytochemical-labeled terminals which might be compatible with the process of atypical reinnervation of deafferented postsynaptic sites and possible ingrowth of new axons.

384.9 NERVE GROWTH FACTOR RECEPTOR AND CHOLINE ACETYLTRANSFERASE COLOCALIZATION WITHIN THE RAT FOREBRAIN: RESPONSE TO FIMBRIA-FORNIX TRANSECTION. P.E. Batchelor*, S.N. Blaker*, D.M.Armstrong, and F.H. Gage , (Spon: A. Miller). Dept. of Neurosciences, UCSD, La Jolla, CA 92093.

The distribution of nerve growth factor receptor (NGF-R) and choline acetyltransferase (ChAT) within the rat brain were simultaneously mapped by a double immunocytochemical procedure. A specific polyclonal antibody to ChAT (gift of L.B. Hersh and G. Bruce) was used in combination with peroxidase to identify cholinergic neurons while the monoclonal antibody 192-IgG (C.E. Chandler, et al., J. Biol. Chem. 259(11) 6882-6889, 1984: gift of E.M. Johnson) in combination with alkaline phosphatase was used to visualize NGF-R distribution. It was found that a distinct subpopulation of cholinergic neurons expressed NGF-R. This population included the large long-projecting magnocellular forebrain neurons located in the septum and vertical limb of the diagonal band, the large midline cells located within the columns of the fornix rostrally and dorsal hippocampal commissure caudally, and cells of the nucleus basalis magnocellularis. By contrast, no double immunoreactivity was observed in the smaller shorter projecting intrinsic ChAT positive neurons located in the caudate-putamen, nucleus accumbens, cortex and caudal and temporal hippocampal formation.

In order to more fully determine the functional significance of the presence of NGF-R on populations of cholinergic neurons, complete aspirative lesions of the fimbria-fornix and supracallosal striae were made. Eight weeks following FF transection the large midline ChAT-positive neurons which exhibited neuronal sprouting (S. N. Blaker, et al. Soc. Neurosci. Abstr. 12:1379, 1986) also expressed NGF-R. In contrast, the small intrinsic ChAT-positive cells of the hippocampus did not express NGF-R. In addition, a second NGF-R-positive sprouting response was observed in the dentate gyrus and CA3 regions of the hippocampus. These large AChE-negative, NGF-R-positive, fibers have the distribution and morphological appearance of anomolous fimbria-fornix transection-induced sympathetic nonadrenegic fibers of the superior cervical ganglion and stain for tyrosine hydroxylase immunoreactivity (R. Loy and R.Y. Moore, Exp. Neurol. 57:645-650, 1977).

In view of the elevated levels of NGF in the hippocampus following fimbria-fornix transection (S. Korsching, et al., Neurosci. Lett. 66:175-180, 1986) and the presence of NGF-R only in sprouting neurons, we conclude that the sprouting response observed in these different cell populations may be due to their responsiveness to the increase in NGF within the hippocampus following fimbria-fornix transection.

384.10 **TRANSECTION OF THE INFRAORBITAL NERVE PROMOTES THALAMIC FIBER INGROWTH INTO EMBRYONIC NEOCORTICAL TRANSPLANTS IMPLANTED INTO THE BARRELFIELD OF ADULT MICE.** R.S. Erzurumlu and F.F. Ebner, Center for Neural Science, Brown University, Providence, R.I. 02912.

Embryonic neocortical transplants survive and differentiate within the cortex of an adult host, but the damaged host fibers from specific thalamic nuclei fail to innervate these implants. The present series of experiments was carried out to determine if blocking of sensory activity in the periphery would promote the regeneration of mature thalamic fibers from the ventrobasal nucleus (VB) into grafts of immature neocortex implanted into the PMBSF region of SI cortex. Anesthetized adult mice underwent unilateral infraorbital (IO) nerve cautery or transection at the IO foramen 2 days prior to transplantation into the contralateral cortex. The ingrowth of VB axons in this experimental group was compared to that seen after grafting into normal adult animals.

Procedure: strips of embryonic (E14) parietal cortex were dissected into Eagle's medium and suctioned into a square glass capillary filled with the same medium. The capillary was inserted into the host SI cortex parallel to the pial surface and the graft floated into place after expelling the host tissue that had been isolated within the capillary. Thirty days later both experimental and control animals received HRP injections into the VB nucleus ipsilateral to the transplant (0.02 ul, Sigma Type VI). HRP injections were made using a horizontal approach to avoid traversing the hemisphere containing the graft. HRP was visualized by $CoCl_2$ enhancement of the DAB-GOD reaction.

The control cases confirmed previous observations that very few or no labeled fibers cross the interface between normal host cortex and the grafts, even when dense anterograde and retrograde labeling is present in the host cortex both medial and lateral to the transplant. In contrast, all cases with prior IO nerve cut contained numerous large caliber thalamic fibers that traverse the border, enter the transplant and then form elaborate terminal arbors within the graft. The distribution of thalamic fibers was not uniform throughout the graft. Instead, they clustered in discrete zones that were often surrounded by aggregates of granule cells reminiscent of layer IV barrels in mouse SI cortex. Adjacent AChE-stained sections showed a completely different distribution of cells and fibers from the HRP labeling. Gross anatomical dissection of the IO nerve after perfusion showed that many fibers had regenerated into the whisker pad. We are investigating the possibility that whisker stimulation will activate neurons in the grafts that show elaborate VB fiber innervation. (supported by NS-13031 + the Mathers Foundation)

384.11 NONREGENERATIVE AXONAL GROWTH WITHIN THE MATURE MAMMALIAN BRAIN. K.A. Crutcher and C.F. Marfurt. Dept. of Anatomy, Univ. of Utah School of Med., Salt Lake City, UT 84132 and Dept. of Anatomy, NW Center for Med. Ed., Indiana Univ. School of Med., Gary, IN 46408.

Extensive axonal elongation occurs during CNS development, but is limited to the PNS in adult mammals. The favorable environment for axonal growth provided by the PNS also permits regeneration of central neurons, as demonstrated by the peripheral nerve grafting experiments of Aguayo and coworkers. The reverse situation, i.e., elongation of peripheral axons within the mature CNS, is rare but may be occuring when sympathetic axons appear in the rat hippocampal formation following septohippocampal denervation. Preliminary results presented last year suggested that sympathohippocampal fibers may be restricted to the perivascular environment. In order to extend these observations we undertook more rigorous ultrastructural analysis of HRP-labeled sympathetic fibers within the dentate gyrus.

The superior cervical ganglia were injected with WGA-conjugated HRP and the dentate was sectioned and reacted at pH 6.0 in order to preserve ultrastructural morphology. Stabilization of the TMB reaction product with ammonium molybdate resulted in significant preservation of the granules which were easily identified at the EM level. In order to obtain some index of the extent to which labeled fibers were associated with blood vessels, quantification was undertaken both from 1 micron-thick plastic sections and from random EMs.

As reported previously, HRP-labeled profiles were present in association with hippocampal blood vessels, particularly above and below the granule cell layer within the dentate gyrus. In addition, HRP-labeled axons and vesicle-filled profiles (many of the vesicles were of the small dense-cored variety) were encountered within the neuropil, without any vascular association. In one plastic section, and in a sample of electron micrographs (n=98), two-thirds of the labeled fibers were in a perivascular location and the majority of these were directly apposed to the basal lamina. The other third, however, were present within the neuropil. In some cases, labeled axons within the neuropil were present in fascicles but individual vesicle-filled varicosities were more common. In no case were membrane specializations observed indicative of synaptic contacts.

These results establish the presence of axons of peripheral origin within the neuropil of the mature mammalian brain following specific denervation. The specific changes in the target tissue that permit axonal elongation in this instance are not known but NGF has been implicated as one factor that may permit such ingrowth. Furthermore, the presence of sympathetic fibers in the hippocampal neuropil would presumably result in peripheral autonomic influences on hippocampal function. If a similar sprouting response occurs in the human hippocampal formation e.g., in Alzheimer's disease, then such an innervation could be clinically relevant.

384.12 RECEPTIVE FIELD PLASTICITY AND SOMATOTOPIC ORGANIZATION OF PLEURAL MECHANOSENSORY/NOCICEPTIVE NEURONS OF APLYSIA. A.J. Billy* and E.T. Walters (SPON: D. Johnston). Dept. Physiol. & Cell Biol., Univ. Texas Med. Sch. Houston, TX 77225.

Sensory neurons in the LE and VC clusters of Aplysia express several intensively studied forms of plasticity in their central (synaptic and soma) regions. Much of this plasticity is readily produced by noxious stimuli that injure the peripheral receptive fields of the sensory neurons (Walters, J.Neurosci. 7:400, 1987). These central forms of plasticity may normally be coordinated with (and may share cellular mechanisms with) plastic mechanisms in the peripheral regions of these cells which act to restore sensory function to injured areas of the body. To test this hypothesis we have begun to examine the effects of peripheral injury on the receptive fields of the VC sensory neurons. Because the somatotopic organization of these clusters was only partially known (Walters et al., J. Neurophysiol. 50:1522, 1983) we first examined the relationship between soma position in the VC clusters and receptive field position in normal animals. Nerve stimulation indicated that axons of VC neurons occur in all nerves of the pedal and pleural ganglia, with cells innervating the anterior part of the foot and body wall in the anterolateral part of the cluster, and cells innervating progressively more posterior parts of the body distributed in a rough continuum to the posteromedial borders. Although there is considerable variation in the size and shape of fields, a remarkably precise boundary exists along the midline, so that receptive fields of sensory cells in each cluster are restricted to the ipsilateral side of the body. At least 3 classes of peripheral plasticity are indicated: (1) Increases or decreases in the size and sensitivity of a receptive field often accompany repeated application of the test stimuli (von Frey hairs). We have not yet systematically investigated this short-term plasticity. (2) Functional denervation of a region produced by a cut across part of the tail was partially reversed in 8 of 27 preparations after 1-3 weeks by apparent reinnervation from ipsilateral VC neurons. (3) In 7 of 27 cut tail preparations there was clear extension across the midline by contralateral receptive fields near the cut. No comparable extension across the midline was seen in 9 uncut preparations. As a first step in testing whether long-term peripheral plasticity is activity-dependent we are examining the effects of explicitly stimulating the contralateral side of the tail at the time of the cut. Thus far, 40% (6 of 15) of the medial contralateral fields extend across the midline in stimulated animals while only 12% (9 of 75) show extension in animals not stimulated contralaterally.

385.1 CELL CYCLE MODULATION OF HISTOCOMPATABILITY ANTIGEN EXPRESSION ON HUMAN ASTROCYTOMA (U373MG) CELLS. Michael E. Barish and Mary E. Thornton*, Departments of Developmental and Cell Biology & Physiology and Biophysics, University of California, Irvine, California 92717.

Recent years have seen an increased interest in expression of histocompatability antigens on brain cells. In particular, cells expressing class II major histocompatability complex (MHC) gene products have been found on glial cells surrounding various types of brain lesions, and it is thought that antigen presentation by astrocytes may play a role in the genesis of autoimmune reactions in the brain such as those associated with multiple sclerosis.

Many laboratories including ours have observed that the level of expression of class II MHC antigens on cultured primary astrocytes stimulated by gamma-interferon or other agents can be variable -- within a given dish only some cells show high levels of expression. Because we felt that an understanding of this variability would give some clues as to the normal control of class II MHC expression in the brain, we have studied a human astrocytoma cell line (U373MG, ATCC HTB 17) that is normally class II MHC positive using FITC-conjugated monoclonal antibody against HLA-DR (clone L243, Becton-Dickinson).

We observed using fluorescence microscopy and flow cytometry that normal expression of HLA-DR varied greatly between cells. Within an average culture approximately 60% of cells showed fluorescence levels above background. We hypothesized that HLA-DR expression might be linked to the cell cycle. We have thus used two color flow cytometry to correlate DNA content (measured using propidium iodide) with HLA-DR expression, and have observed that cells expressing higher levels of HLA-DR are more likely to be in S, G2 or M phases than low expressors. This correlation is being investigated further. It suggests that at least in astrocytoma the proliferative state may be permissive for HLA-DR expression.

385.2 MONOCLONAL ANTIBODY 8A2 RECOGNIZES A DEVELOPMENTALLY REGULATED GLYCOLIPID IN THE CHICK RETINA. J. Drazba* and V.P. Lemmon (SPON: C.F. Lagenaur). Dept. of Neurobiology, Anatomy and Cell Science and Ctr. for Neuroscience, Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA 15261.

A monoclonal antibody, 8A2, has been obtained that binds to axons in the chick nervous system. Immunohistochemical experiments indicate that this antibody binds to an antigen that is developmentally regulated in the chick visual system. Strong binding of 8A2 to the developing retinal ganglion cell axons is seen throughout the period when they are forming topographically organized projections within the central nervous system. In vitro experiments on dissociated E-6 chicken retina indicate that the antigen is not present on all the cells, but very strongly labels the cell surface of large, multipolar cells which generate long neurites. At later developmental stages the 8A2 antigen appears on other cell types in the retina. For example, at E-15, in addition to strong staining of the optic fiber layer and optic nerve, the inner plexiform, inner nuclear and outer plexiform layers also express the antigen. In the adult retina the 8A2 antigen has largely disappeared from the optic fiber layer and optic nerve, but persists in the inner plexiform, inner nuclear and outer plexiform layers. Initial biochemical characterization of the antigen reveals that it is a lipid present in the aqueous phase of chloroform/methanol/water extraction of embryonic chick retina and is sensitive to neuraminidase but not protease digestion. The relationship between the 8A2 antigen and other glycolipids such as the JONES antigen (Constantine-Paton, M. et al., Nature, 324:459, 1986) will be discussed.

385.3 FREEZE-FRACTURE STUDIES ON UNMYELINATED AXOLEMMA OF RAT CERVICAL SYMPATHETIC TRUNK: CORRELATION WITH SAXITOXIN BINDING. J.A. Black and S.G. Waxman. Dept. of Neurology, Yale University School of Medicine and V.A. Medical Center, New Haven, CT 06510

In freeze-fracture replicas, intramembranous proteins are visualized as "bumps", or particles, within the generally smooth lipid layer background. The functional identity of these particles remains obscure, with considerable speculation regarding a population of large diameter (>10 nm) particles present in high concentration at the node of Ranvier. It has been suggested that some of these large diameter particles may represent voltage-sensitive sodium channels, which are known to be present in high density at nodes. In order to further examine the possible correspondence between large diameter particles and sodium channels, the density and size distribution of particles within unmyelinated axolemma of the rat cervical sympathetic trunk was examined. This fiber tract is composed nearly entirely of unmyelinated axons, and has been recently utilized in saxitoxin-binding studies to obtain an estimate of the density of sodium channels in unmyelinated axolemma (Pellegrino et al., 1984)

Rat cervical sympathetic trunks were excised and immersion-fixed in a solution containing 2% glutaraldehyde and 2% para-formaldehyde in 0.14 M phosphate buffer with 0.1 M sucrose. The tissue was cryoprotected, frozen in a slush of Freon 22 and fractured and replicated in a Balzers 301 device.

Unmyelinated axolemma of rat cervical sympathetic trunk exhibits a highly asymmetrical partitioning of the particles. On each fracture face, the particles appeared to be randomly distributed. Quantification of the density and size distribution of particles within the unmyelinated axolemma are summarized below and are expressed as mean ± SD:

	Density	% > 9.6 nm	Diameter
PF	1234±355.2	16.3±5.0	8.0±0.4
EF	110±52.4	27.7±13.7	8.2±0.9

From these data, the calculated density of large diameter particles within unmyelinated axolemma from rat cervical sympathetic trunk is 231/μm^2. Saxitoxin binding studies on rat cervical sympathetic trunk suggest a sodium channel density of ~200/μm^2 for unmyelinated axolemma. These observations are consistent with a correspondence between large diameter particles and voltage-sensitive sodium channels.

385.4 MACROMOLECULAR STRUCTURE OF UNMYELINATED AND MYELINATED AXOLEMMA FROM RAT CORPUS CALLOSUM. S.G. Waxman and J.A. Black. Dept. of Neurology, Yale University School of Medicine and V.A. Medical Center, New Haven, CT 06510.

The corpus callosum of the rat contains unmyelinated and myelinated fibers that exhibit a distinct overlap in their axonal diameter spectra. Thus, the largest unmyelinated fiber has an axonal diameter of ~0.6 um, while the smallest myelinated fiber has a diameter of ~0.4 um. Previously, it has been demonstrated that the axolemma of unmyelinated fibers displays a markedly different ultrastructure than that of axonal membrane ensheathed by compact myelin. However, a correlation between axolemmal ultrastructure and axonal diameter of unmyelinated and myelinated fibers has not been reported.

Adult rats were fixed by perfusion with a solution of 2% glutaraldehyde and 2% paraformaldehyde in 0.14 M phosphate buffer. Corpus callosum were excised, rinsed in buffer and cryoprotected in graded glycerol solutions. The tissue was rapidly frozen and fractured and replicated in a Balzers 301 device. Replicas were examined with a JEOL 100CX electron microscope.

Both unmyelinated and myelinated axons displayed a highly asymmetrical partitioning of intramembranous particles (IMPs). The particles appeared to be randomly distributed along the fracture faces of unmyelinated and myelinated internodal axonal membrane. Quantification of IMP densities (mean ± SD) are given:

Condition	PF	EF
Internode (all dia.)	1502±203.6	190±40.8
intern. <.5 μm dia.	1507±66.1	
intern. ≥.5 μm dia.	1498±265.2	
Unmyelinated (all dia.)	773±276.4	123±59.9
unmyel. <.5 μm dia.	711±201.8	
unmyel. ≥.5 μm dia.	1162±415.7	

The data demonstrate that the P-face ultrastructure of internodal axolemma is not dependent upon axonal diameter. However, the structure of unmyelinated axolemma appears to be dependent upon axonal diameter. Moreover, the data suggest that unmyelinated axolemma is ultrastructurally different than myelinated internodal membrane for axons of the same diameter.

385.5 **AXONAL TRANSPORT AND NEURONOTOXICITY OF A HYBRID CYTOTOXIN COMPOSED OF ANTI-THY 1.1 MONOCLONAL ANTIBODY (OX7) DISULFIDE COUPLED TO THE RIBOSOME INACTIVATING PROTEIN SAPORIN.** R.G. Wiley & F. Stirpe*. Neurology Dept., Vanderbilt University and VAMC, Nashville, TN 37212, and Istituto di Patologia Generale, Universita di Bologna, Italy.

Antibodies to neuronal surface determinants offer the possibility of targeting drugs and other agents to neurons via selective endocytosis. In the present study, we sought to determine if a monoclonal antibody (OX7) with high affinity for rat neuronal Thy 1.1 could be used as a carrier to deliver the ribosome inactivating cytotoxin, **saporin**, to rat neurons. **Saporin** was disulfide coupled to **OX7** to yield a conjugate with 0.68 moles **saporin**/mole of **OX7**. **OX7-SS-Sap** (0.025-8.9 ug) was dissolved in saline and unilaterally pressure microinjected into the cervical vagus nerve, tongue or caudate nucleus of 45 anesthetized, adult male Sprague-Dawley rats. After 1-12 days, rats were reanesthetized and perfused transcardially with aldehyde fixative. Cresyl violet stained sections of the brain and vagal ganglia were analyzed for neuronotoxicity. Doses of **OX7-SS-Sap** >0.35 ug reliably destroyed neurons of the dorsal motor nucleus and nodose ganglion of the vagus after vagal injection. At similar doses, caudate injection of **OX7-SS-Sap** destroyed ipsilateral substantia nigra neurons after caudate injection, a finding that was also evident in sections prepared for catecholamine histofluorescence (FAGLU). 8.9 ug of **OX7-SS-Sap** produced incomplete destruction of hypoglossal neurons after tongue injection. Indirect peroxidase immunohistochemistry demonstrated the presence of antibody in the nucleus tractus solitarius, dorsal motor nucleus of the vagus and nucleus ambiguus after vagal injection of **OX7-SS-Sap** or **OX7** alone. Pretreatment of **OX7-SS-Sap** with dithiothreitol to reduce the disulfide bond dramatically reduced the neuronotoxicity observed after vagal or caudate injections. Injections of **OX7** alone or **saporin** alone did not reproduce the neuronotoxicity of intact **OX7-SS-Sap**. We interpret these results to indicate that **OX7** was effective as a carrier to direct saporin into neurons resulting in suicide transport. Hopefully, this same strategy can be applied in other ways, both experimentally and therapeutically. (This work supported by the Veterans Administration.)

385.6 CONTROL OF GANGLIOSIDE GM_2 EXPRESSION IN TWO NEURONAL CELL LINES. K.M. Walton and R.L. Schnaar, Departments of Pharmacology and Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

The NG108-15 neuroblastoma x glioma hybrid cell line expresses four major ganglioside species: GM_3, GM_2, GM_1, and GD_{1a}. When the cells are induced to differentiate in culture (in the presence of 1 mM sodium butyrate), ganglioside GM_3 expression decreases to <20% of control levels, while GM_2 expression increases 10-fold. The expression of gangliosides further along the same biosynthetic pathway (GM_1 and GD_{1a}) does not change (Dahms, N.M. and Schnaar, R.L., J. Neurosci., 3:806, 1983). We previously reported that the activity of the enzyme which synthesizes GM_2, UDP-GalNAc:GM_3 N-acetylgalactosaminyltransferase, increased 4 to 8-fold during differentiation (Walton, K.M. and Schnaar, R.L., Soc. Neurosci. Abstr., 11:1066, 1985). We now report that the activity of the enzyme which uses GM_2 as a substrate to synthesize GM_1 (UDP-Gal:GM_2 galactosyltransferase) **decreases** to 10% of control levels, ensuring a selective increase in GM_2 expression. Thus, ganglioside glycosyltransferases are coordinately regulated to generate a specific change in ganglioside GM_2 expression.

In the PC12 rat pheochromocytoma cell line, GM_2 expression undergoes an unusual form of regulation. A ganglioside with relatively high chromatographic mobility (on TLC) was found to be transiently expressed during PC12 cell growth in culture. Although this ganglioside was undetectable in either sparse or dense PC12 cell cultures during a four day period at intermediate cell density it became the major ganglioside species expressed, then disappeared. This unusual mode of transient ganglioside expression may be important in normal developing neuronal tissue. The ganglioside was purified, and its chromatographic mobility compared to that of standard gangliosides. In two different solvent systems, the ganglioside co-migrated with purified human GM_2. Determination of the neutral sugar composition of this ganglioside revealed only three sugars (galactose, glucose, and N-acetylgalactosamine) at a ratio of 1.0:1.3:0.8, values characteristic of GM_2. Thus PC12 cells transiently express GM_2 as their major ganglioside during growth in culture.

The ability of these neuronal cell lines to tightly control the expression of ganglioside GM_2 during growth and differentiation may implicate it in an as yet unknown function during neuronal maturation. Supported by NIH grants HD14010 & GM07626.

385.7 ALLELIC VARIANTS OF ACETYLCHOLINESTERASE: EVIDENCE THAT A SINGLE GENE ENCODES THE FAMILY OF OLIGOMERIC FORMS IN AVIAN NERVES AND MUSCLE. R.L. Rotundo A.M. Gomez*, C. Fernandez-Valle*, and W.R. Randall*, Dept. of Anatomy and Cell Biology, University of Miami School of Medicine, Miami, FL 33101.

Acetylcholinesterase (AChE) in electrically excitable cells exists as a complex family of forms distinguished by their subunit composition, hydrophobicity, and association with non-catalytic subunits. Muscle cells synthesize and assemble dimeric and tetrameric forms of the enzyme which are destined for secretion or accumulation on the cell surface. In addition, a subset of tetramers are further assembled in the Golgi apparatus into asymmetric forms consisting of three tetramers covalently linked to a collagen-like tail. In neurons, a similar array of forms are assembled including an amphipathic tetramer which is destined for accumulation on the axonal plasma membrane (Rotundo and Carboneto, PNAS 89, 1987). The molecular basis for this diversity is unknown.

We have now found two allelic forms of the AChE catalytic subunit expressed in quail tissues, α and β, with apparent molecular weights of 110 Kd and 100 Kd respectively determined by SDS gel electrophoresis. The expression of each allele in our quail sample population is approximately α=0.7 and β=0.3 and the distribution of heterozygous and homozygous α and β individuals indicates that the two alleles segregate as a single autosomal locus. We have studied the synthesis and assembly of these allelic AChE polypeptides by metabolically labeling tissue-cultured cells with 35S-methionine, immunoprecipitation of the labeled AChE polypeptides using a monoclonal antibody and analysis by SDS gel electrophoresis under reducing and non-reducing conditions. The expression of the two allelic polypeptides is co-dominant and their assembly into disulfide-linked dimers appears to be random and proportional to the relative abundance of each allele in the culture. When tissue-cultured neurons or myotubes are prepared from single quail embryos all molecular forms of AChE isolated from a given embryo exhibit the same allelic subunit composition. Furthermore, both the cell associated and secretory forms of AChE from neurons and muscle show the same allelic composition. Together, these studies indicate that the two allelic forms of the AChE catalytic subunit are equivalent with regards to assembly into multimeric forms and subcellular distribution. The observation that all AChE oligomeric forms from neurons or muscle cells, whether membrane-bound, secreted, or intracellular, isolated from individual embryos share the same subunit composition strongly suggests that they all arise from a single gene. More definitive evidence based upon ongoing mating studies will be presented. This research was supported by grants from the NIH, Muscular Dystrophy Association, and the Sloan Foundation to RLR.

385.8 THE TWO ALTERNATIVELY SPLICED FORMS OF THE 1B236/MAG GENE TRANSCRIPTS ARE DEVELOPMENTALLY REGULATED C. Lai*, K.-A. Nave, L.H. Farber, M. Brow*, A.B. Noronha*, R.H. Quarles*, F.E. Bloom, J.G. Sutcliffe, and R.J. Milner. Research Institute of Scripps Clinic, La Jolla, CA 92037 and NINCDS, Bethesda, MD 20014.

The rat brain protein, 1B236, which was isolated and characterized as a brain-specific gene product, has been recently shown to be closely related to and possibly identical to the myelin-associated glycoprotein (MAG). We have chosen the provisional name 1B236/MAG to describe these molecules. We have characterized two full-length cDNA clones of 1B236/MAG specific mRNA that encode distinct 1B236/MAG proteins. One protein is 626 amino acids long, with a single membrane-spanning domain separating a heavily glycosylated N-terminus from a 92 residue C-terminus. The other is identical to the first except that 54 amino acids at the C-terminus are replaced by a different sequence of 10 amino acids. Both forms are encoded by the single 1B236/MAG gene which spans 16kb and contains 13 exons. A comparison of the nucleotide sequences of the two cDNAs with the genomic sequence indicates that the two mRNA forms arise by the alternative inclusion or omission of the 45 base exon 12. Exon 2 is also alternatively spliced but this event is not coordinate with the splicing of exon 12 and has no effect on the amino acid sequence. We present evidence demonstrating that these two mRNAs are developmentally regulated in the brain with one form peaking in expression at the time of most active myelination while the other form increases in expression into early adulthood. Similar measurements on 1B236/MAG expression indicate that the form encoding the shorter protein is predominant in the peripheral nervous system. We also present data showing the aberrant expression of these 1B236/MAG mRNAs in the mutant mouse *quaking*.

The common N-terminus of these proteins is composed of five domains related in sequence to each other and to immunoglobulin-like molecules. This domain organization is reflected in the structure of the gene which reveals that each Ig-like domain is encoded by a separate exon. The 1B236/MAG primary sequence is most homologous to N-CAM and is also related to the PDGF receptor and the poly IG receptor. We propose a model for the structure of these proteins and suggest that they may be involved in cell-cell or other recognition processes through interactions with the N-terminal domains. Supported in part by grants from NIH (NS 20728, GM 32355), NIAAA (AA 06420) and McNeil Pharmaceuticals.

385.9 GANGLIOSIDE "RECEPTORS" ON RAT BRAIN MEMBRANES: DETECTION USING GANGLIOSIDE-DERIVATIZED PROTEIN LIGANDS. M. Tiemeyer*, Y. Yasuda*, and R.L. Schnaar, Departments of Pharmacology and Neuroscience, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205

Gangliosides, which consist of a sialic acid-containing oligosaccharide chain linked to a ceramide lipid moiety, are major glycoconjugates of the neuronal cell surface. Although gangliosides have been proposed as recognition molecules in cell-cell adhesion and transmembrane signalling, clear evidence for complementary ganglioside binding proteins on brain membranes has been lacking. Analysis of direct ganglioside binding to membranes is complicated by their amphipathic nature, leading to non-specific binding and insertion. Therefore, we have undertaken the direct demonstration of ganglioside receptors in brain using synthetic ligands consisting of gangliosides covalently linked to a hydrophilic protein carrier. We refer to these ligands as neogangliproteins (NGP).

Gangliosides GM_1 and GT_{1b} were purified from bovine brain and derivatized to contain a primary amine in their ceramide moiety. The resulting glycolipid products, which contained the proper sialic acid/amine ratio, were covalently linked to bovine serum albumin (BSA) using a disuccinimidyl crosslinking reagent. The resulting conjugates contained 3-10 gangliosides per protein molecule. Upon SDS-PAGE analysis the derivatized protein migrated differently than underivatized BSA or ganglioside, and a ganglioside-specific toxin probe demonstrated the association of ganglioside with protein. The resulting GM_1 and GT_{1b} neoganglioproteins were readily radioiodinated, generating the desired high-specific activity ganglioside ligands.

Binding of ^{125}I-NGP's to rat brain membranes was determined utilizing a detergent-washed P2 fraction. High affinity saturable binding of both GM_1- and GT_{1b}-NGP was readily apparent. Binding was inhibited >90% in the presence of excess unlabeled ligand. The apparent K_D was 30 nM for GM_1-NGP and 1 nM for GT_{1b}-NGP. Mild trypsin treatment of the membranes eliminated NGP binding (tested with GM_1-NGP). Binding of GT_{1b}-NGP to membranes was inhibited half-maximally by 230 nM native GT_{1b}. Other gangliosides (GM_1 and GM_2) were 9- to 20-fold less potent inhibitors than GT_{1b}. No other lipid tested (phospholipids, neutral glycosphingolipid, or sulfatide) was as potent as GT_{1b} in inhibiting GT_{1b}-NGP binding to brain membranes. Oligosaccharide derived from GT_{1b} (10 µM) inhibited binding of both GT_{1b}- and GM_1-NGP to membranes more potently than did oligosaccharide derived from GM_1. These data suggest that the new ganglioside derivatives described may be fruitful tools for detecting and defining brain ganglioside receptors. Supported by NIH grants HD14010 and MH18030.

385.10 A CELL SURFACE EPITOPE WHICH IS PRESENT ON A SOME BUT NOT ALL MOTOR NEURONS. D.T. Stephenson*, P.A. St. John, J.L. Barker, and P.D. Kushner. (SPON: L.C. Fritz) ALS Research Center, Pacific Presbyterian Medical Center, San Francisco, CA 94115 and Lab. of Neurophys., NINCDS-NIH, Bethesda, MD 20892.

Motor neurons fall into different categories based on location, morphology, electrical properties, and synaptic connectivity. The issue this study addresses is whether there are categories of motor neurons based on cell surface determinants. The monoclonal antibody, Tor 23, was made to Torpedo cholinergic synaptosomes (JNC 43 775) and, in Torpedo, binds the external synaptosome membrane (PNAS 80 7342), where it recognizes two polypeptide antigens, one of which is a presynaptic form of AChE (JNC, in press). Tor 23 has a broad species cross-reactivity, binding motor neuronal elements in rodents and humans (Muscle & Nerve, in press). In the rat, Tor 23 does not appear to recognize AChE but does cytolocalize to the perimeter of the motorneurons of layers VIII and IX of the spinal cord. In addition, in each 10 µm section, one to twelve neurons of the intermediate grey, laminae III through VI, are stained. These rare neurons are typically small in size (averaging 10µm x 18µm) and fusiform in morphology. A FACS analysis provided verification that Tor 23 labels the surface of somata. Cells were dissociated from the spinal cord of embryonic rats, E15, incubated with Tor 23 and subsequently with a fluorescent second antibody. The FACS analysis of the spinal cord cell suspension indicated that 10-15% of the total viable cells gave a positive immunofluorescent signal for Tor 23, although whether the labeled cells are motor neurons has yet to be directly addressed.

Does this antibody bind all motor neurons? First, does Tor 23 bind only motor neurons? In mapping Tor 23 in the rat brain, we found that Tor 23 binding is not restricted to motor neurons but is present on rare and select neurons in several other brain areas (Neurosci. Abs XII 247.9). An examination of the brainstem has revealed that certain of the motor nuclei are positive, others are negative. Neurons of the cranial nerve nuclei, V, VII, VIII, and ambiguus, are positive. The other cranial nuclei are negative.

In summary, in the spinal cord, the major cell type identified by Tor 23 is the ventral horn motor neuron. By FACS analysis, antibody binding is to the neuronal cell body surface. And, although motor neurons represent a single class of CNS neurons, we have identified a subclass on the basis of the cell surface epitope defined by Tor 23. Because Tor 23 was made to a structure derived from the branchial arches (the electric organ), the particular property we are identifying may be related either functionally or in phylogeny and ontogeny to the branchial arch system. By this analysis, Tor 23 may be helpful 1) in defining the cellular lineages of motor neurons and their different functional categories and 2) in preparing pure motor neuron populations.

385.11 LOCALIZATION OF N-CAM mRNA AND PROTEIN IN THE DEVELOPING MOUSE CNS. D. Goldowitz, D. Barthels and W. Wille. Dept. of Anatomy, Thomas Jefferson Univ., Phila., PA 19107, and Inst. of Genetics, Univ. Koln, Koln, FRG.

Cellular recognition and adhesion must be important phenomena in forming a structure as complex as the mammalian CNS. The well characterized neural cell adhesion molecule (N-CAM) has been proposed to be involved in developmental events such as neural induction, neural crest migration, and axon fasciculation. The present study uses N-CAM in situ hybridization and immunocytochemistry of the developing normal and genetically mutant murine cerebellum and dentate gyrus to further investigate the possible role of N-CAM expression during CNS formation.

N-CAM mRNA and gene product were detected by in situ hybridization (a 600bp probe, Barthels et al., EMBO. J., in press, labeled with biotin or tritium) and immunocytochemistry (the antibody a gift of C. Goridis), respectively. These probes do not distinguish among the various forms of N-CAM. Mice of varying ages were deeply anesthetized and transcardially perfused with a solution of 3pt 95% ethanol:1pt acetic acid. Brains were removed, dehydrated, embedded in paraffin, cut and stained.

Immunocytochemical staining for N-CAM activity in the developing cerebellum was, as reported by others, densest in the developing molecular area and tracts of white matter. The most prominent N-CAM immunoreactivity in the developing dentate gyrus coincided with the appearance of the granule cells' axonal extensions, the mossy fibers. The trilaminar synaptic region of the granule cell molecular layer was highlighted by N-CAM immmunoreactivity by 10 days postnatal.

In situ hybridization allowed us to examine the cellular site of N-CAM production. As suggested by the immunocytochemistry, N-CAM mRNA is detected at high levels in almost all neuronal populations. However, two exceptions relevant to this study are: 1) migrating cerebellar granule cells, which are also extending neurites, have low-to-nil expression of hybridizable N-CAM mRNA, 2) recently generated dentate granule cells, which are presumably starting to elaborate axons, have low-to-nil hybridizable N-CAM mRNA. Examination of N-CAM expression in the cerebellum of mutant mice provides correlative information: a migrational defect, as in the reeler mouse, has no obvious effect on N-CAM expression while disruption of the granule cell-to-Purkinje cell contact, as in the lurcher mouse, is accompanied by marked decrease in N-CAM hybridization product in the granule cell but not in the Purkinje cell. These findings are suggestive that higher levels of N-CAM expression seem to be correlated with the later stages of axonal growth such as fasciculation and/or synaptogenesis rather than initial axon outgrowth.

385.12 NERVOUS SYSTEM SPECIFIC ANTIBODIES IN FROG. T. Nagy and T.A. Reh. Dept. Med. Physiol., Univ. Calgary, Calgary, Alta. T2N 1N4.

Monoclonal antibodies to neural and glial cell surface molecules have proven to be invaluable in the characterization and study of nervous system tissue cultures. However, most of these probes have been developed for use in chicks and mammals. Since the frog has long been used as an experimental animal for the study of neural development, we have been raising monoclonal antibodies directed against similar cell surface antigens in this species.

Midlarval staged **Rana pipiens** or **Rana catesbienna** were anaesthetized and the retinas and brains homogenized in 0.32M sucrose. A membrane fraction was prepared by differential centrifugation and used to immunize Balb/c mice (1 mg I.P.) at 2 to 3 week intervals (4 injections total). Five days after the final boost, their spleen cells were fused with SP2 myeloma cells by a standard protocol and the resulting hybridomas were screened by ELISA and indirect immunofluorescence on cryostat sections of tadpole retina. Positive wells were cloned by limiting dilution.

Of the nervous system specific antibodies that were produced, three were characterized more fully and are the subject of this report. One neuron specific antibody, 2D3, binds to the entire differentiated retina, with the exception of the photoreceptor outer segments, as well as to the zone of germinal neuroepithelial cells located at the peripheral margin of the larval retina. In dissociated retinal cell culture, the antigen reognized by 2D3 is present only on neurons, and on all neurons and their processes. The antigen is present throughout the larval CNS and peripheral nervous system, but is not present on any other tissue at all stages examined. This antibody also binds to all germinal neuroepithelial cells in **Rana** embryos and tadpoles, but is not present in **Xenopus laevis** or **Bombina orientalis**. Immunoblot analysis indicates that the 2D3 antibody recognizes a 180 - 200 kd sialated glycoprotein, similar to N-CAM, that is specific to **Ranids**.

The second neuron-specific antibody we characterized (2C6) does not bind to germinal neuroepithelial cells; this antigen is only present on cell surfaces of differentiated neurons. In dissociated cell cultures, all neurons, and only neurons express the antigen. While the 2C6 antigen is present throughout the CNS, it is expressed in very high levels in peripheral nerves. Initial characterization of this antigen indicates that it is a cell surface glycolipid and probably a frog specific ganglioside. We also characterized a glial-specific antibody (4D5). This cell surface antigen is present on Mueller cells in the retina and the radial glial of the CNS. In addition, the antibody binds to all germinal neuroepithelial cells in the larval CNS and in dissociated retinal cell cultures it only binds to a population of flat, phase dark cells. Immunoblot analysis indicates the antigen is a protein with two subunits (200, 66 kd). These antibodies have already proven useful in identifying various nervous system cell types in dissociated cell cultures and may also be good markers for the study of neural induction in early embryos.

386.1 ROLE OF CALCIUM AND SODIUM IONS ON PHOTOTRANSDUCTION IN CRAYFISH. B. Fuentes-Pardo and J. Hernández-Falcón*. Depto. Fisiología, Fac. Medicina, UNAM. Apdo. Postal 70250, México, D.F., MEXICO.

Light stimulation of the retinular cells in the crayfish induces a depolarization, i.e., the receptor potential (RP), which consists of an initial fast and transient phase dependent upon the stimulus intensity, and of a slow, stable phase associated to the stimulus duration. It has been stablished that in some animal species the transient phase is a function of Na^+ entrance to the cell, whereas the stable phase depends on the free Ca^{++} in the cytosol. However, in the crayfish it has not been yet possible to establish clearly the role played by these ions in the phototransduction process. The aim of this paper is to establish the role of Ca^{++} and Na^+ in the RP generation of the retinular cells in the crayfish. We made intracellular recordings of retinular cells from eyestalks placed first in darkness, then under dim light and then again under darkness immersed in Van Harreveld's saline solution normal or modified in its Ca^{++} or Na^+ concentration or in both simultaneously. The RP was evoked by light flashes of 1800 lux intensity and of 15 us duration, applied every 2 min during 70 min. In each response, the amplitude of the fast phase and of the slow phase, the depolarization and repolarization velocities, as well as the response duration were measured. In the normal solution , we found two types of behaviors in the photoreceptor response; in the first type, the RP maintained a tendency to increase in all the variables studied, and little decay during illumination accompained by a fast recovery during the dark adaptation. In the second type we found a tendency to decrease of all the variables, a great decay during illumination and a low recovery level during the last darkness stage. With the modified saline solutions, the general characteristics of both types of responses remained practically unchanged, altough slight variations were observed. Thus, in the low Ca^{++} solution, there was an increment in the stable phase amplitude and in the response duration, but a diminution in the depolarization and repolarization velocities. In the solution with low Ca^{++} and low Na^+ content, all the parameters decreased; we even found disappeareance of the stable phase. These changes were reversed when the preparation was returned to the normal saline solution. These results suggest that the two RP phases depend inversely on the extracellular Ca^{++} levels; a reduction in Ca^{++} induces both a reduction in the amplitude of the transient phase and in the depolarization velocity and an increment in the amplitude of the stable phase, which in turn, lenght the response duration. The increase of extracellular Ca^{++} seems to determine the Na^+ entrance to the cell, which produces an increment in the transient phase and a halt in the stable phase generating mechanism. This latter effect, in turn, causes a reduction in the response duration.

386.2 VOLTAGE-DEPENDENCE OF LIGHT-INDUCED CURRENTS IN TYPE B PHOTORECEPTOR SOMATA OF HERMISSENDA. C. Chen* & D.L. Alkon. Laboratory of Cellular and Molecular Neurobiology, NIH-NINCDS, Rockville, MD 20852

Previous voltage-clamp studies of the nudibranch mollusc Hermissenda Type B photoreceptor indicated that light elicits an inward Na^+ current, an outward K^+ current, and a slow reduction of a steady-state K^+ current (Alkon & Sakakibara, Biophys. J., 48: 983-995, 1985). Here we use brief (50ms) light flashes of various intensities (max. 1.8×10^3 Joules/M^2.sec) to more thoroughly characterize the current-voltage relation of these currents with a minimum of light adaption. Two-microelectrode voltage clamp was performed on the Type B photoreceptor somata. Membrane potential was changed gradually from -90mV to +50mV to minimize activation of voltage-dependent conductances. The I-V plot of the peaks of the overall light-induced current, which was clearly voltage-dependent, showed a maximum inward current at -50mV, a negative slope below -50mV and a positive slope above -50mV. Surprisingly, the current-voltage relation of the light-induced current in Hermissenda was similar to the transient Na^+ current of squid axon (Cole & Moore, J. Gen. Physiol., 44: 123-167, 1960) and the early inward dark current of Limulus ventral photoreceptor (Lisman et al., J. Gen. Physiol. 79:187-209, 1982), while it was quite different from the light-induced current-voltage relation of Limulus (Millecchia & Mauro, J. Gen. Physiol. 54:331-351, 1969). Three components underlying the light-induced current were obtained by isochronal measurements and characterized according to their kinetics and ionic selectivity. A fast inward Na^+ component, mainly responsible for the light-induced current amplitude and voltage-dependence, reversed at +20mV and reached its peak about 500ms after the onset of the light flash. Another fast component of the Hermissenda light-induced current reached its peak at 1 second, as an outward current from -60mV to -30mV. Below -60mV or above -30mV either the inward Na^+ current or a late inward component obscured the fast outward component. The fast outward component was completely blocked by 10mM Ba^{2+}-ASW and in previous studies was unaffected by removal of external Na^+ but varied with external K^+. A delayed voltage-dependent inward component reached its peak 6 seconds after the onset of the light stimulus and was reduced by external Ba^{2+}. This current is caused by the Ca^{2+}-dependent inactivation of steady-state K^+ conductances (Alkon & Sakakibara 1985). The delayed component began to appear at -70mV, nonlinearly increased from -70mV to +20mV until it reached its maximum value and then gradually decreased above 20mV. At fixed membrane potentials, the overall light-induced current increased exponentially with light intensity (log units).

386.3 REGIONAL DISTRIBUTION OF cGMP-ACTIVATED CHANNELS IN THE PLASMA MEMBRANE OF THE ROD PHOTORECEPTOR. Shu-Ichi Watanabe* and Gary Matthews, Dept. of Neurobiology, SUNY, Stony Brook, NY 11794-5230.

Ion channels are not distributed equally throughout the rod photoreceptor of the vertebrate retina: the light-receptive outer segment seems to contain only the cGMP-activated, light-sensitive conductance (1, 2, 3), while the inner segment contains a variety of other conductances (4). Thus, there appears to be a mechanism that excludes inner segment ion channels from the outer segment. To determine if this sorting process also excludes light-sensitive, cGMP-activated channels (g_{cG}) from the inner segment, we looked for cGMP-activated channels in inside-out patches obtained from inner segments of rods mechanically dissociated from toad retina.

Of 49 inner-segment patches, 39% had no detectable channel activity of any sort. Such silent patches may have been vesicles, and thus only patches showing some sort of channel activity (N=30) were examined. Of the active inner-segment patches, 57% showed a conductance increase when cGMP was applied to the intracellular membrane face. In parallel experiments on outer-segment patches from the same preparations, 100% of inside-out patches responded to cGMP. The maximal g_{cG} elicited by a saturating dose of cGMP was smaller in inner- than in outer-segment patches. In 30 inner-segment patches, maximal g_{cG} averaged 51 ± 32 pS (mean ± s.e.m.), while in 66 outer-segment patches the average was 676 ± 112 pS. The single-channel conductance was similar in inner- and outer-segment patches. Thus, although the cGMP-activated conductance was present in the plasma membrane of both inner and outer segments, channel density was considerably lower in the inner segment. It is unclear whether g_{cG} in the inner segment has a function or simply represents imperfect operation of the channel segregation mechanism.

The amplitude of maximal g_{cG} varied widely across patches in both outer- and inner-segment recordings (0 to 959 pS for inner segments and 15 to 4300 pS for outer segments), suggesting local variation in channel density in both inner and outer segments. Within the inner segment, there was no indication that channel density was higher nearer to the cilium connecting the inner and outer segments.

Inner-segment patches often contained channels other than g_{cG}. We have carefully examined only calcium-activated K-channels, which were present in 47% of inner-segment patches. These K-channels were also found in 2/23 outer-segment patches, which was surprising given the results of refs. 1-3. It seems likely that these K-channels in the outer segment do not open under physiological conditions in the intact cell. (Supported by NIH grant EY03821.)

386.4 LIGHT-STIMULATED PHOSPHORYLATION OF PROTEINS IN THE LIMULUS VENTRAL AND LATERAL EYES. S. C. Edwards, A. C. Wishart* and B-A. Battelle. C. V. Whitney Laboratory and Dept. of Neuroscience, University of Florida, St. Augustine, FL 32086.

We have been investigating light-stimulated protein phosphorylation in the lateral and ventral eyes of the horseshoe crab, Limulus polyphemus. We have demonstrated that light stimulates the phosphorylation of a 46 kD protein in the lateral eye and a photoreceptor cell body-rich fraction of the ventral eye (P-fraction) and a 122 kD protein in the ventral eye P-fraction. Now we describe the dynamics of the phosphorylation and dephosphorylation of these proteins.

Light-stimulated phosphorylation of the 46 kD protein is rapid. Intact ventral eye P-fractions and slices of the lateral eye were dark adapted overnight and incubated in the dark with $^{32}PO_4$ for an additional 1.5 hrs. When these tissues were exposed to a 1 msec burst of bright, white light, the 46 kD protein was phosphorylated within 15 sec of the flash. The 46 kD also became phosphorylated in lateral and ventral eye preparations maintained in constant light. In those experiments, the tissues were maintained in room light for at least 20 min prior to the addition of labelled phosphate. These latter results may indicate that in constant light the 46 kD protein is in a steady state between phosphorylated and nonphosphorylated forms.

The rate of dephosphorylation of the 46 kD protein differs depending on the conditions of its phosphorylation. When the 46 kD protein was phosphorylated by exposing dark-adapted tissues to a bright flash of light, the protein remained phosphorylated for at least 30 min after the flash. However, when light-adapted cells were transferred to the dark, the protein became dephosphorylated within 5-10 min. The reasons for these differences in the rate of dephosphorylation are not yet clear.

The identity of the 46 kD protein is presently unknown. It corresponds to a minor silver-stained band on SDS-PAGE in both the lateral eye and ventral eye P-fraction. It appears to be membrane bound since it is enriched in the 130,000 x g pellet.

The rate of phosphorylation of the 122 kD protein is slow compared to that of the 46 kD protein. Its phosphorylation in response to a 1 msec-1 sec burst of light required 1 to 3 min. The time course of its dephosphorylation is not yet clear. We presently believe that this light-stimulated 122 kD phosphoprotein is the same as that phosphorylated in response to the efferent neurotransmotter, octopamine. Thus this protein may be modulated in two ways - by light and by efferent innervation. (Supported by NEI Grant EY05724, NSF BNS 8607660, the Whitehall Foundation, and the Whitney Laboratory.)

386.5 EFFECTS OF FLUORIDE AND GUANOSINE 5'-O-[2-THIODIPHOSPHATE] ON THE EXCITATION OF LIMULUS PHOTORECEPTORS: EVIDENCE THAT R* ACTIVATION OF G-PROTEIN IS A LOW GAIN STEP IN INVERTEBRATE PHOTOTRANSDUCTION A. Kirkwood*, D.Weiner*, J. Lisman. Dept. Biol. Brandeis Univ. Waltham MA 02254.

The involvement of a G-protein in invertebrate phototransduction is supported by previous observations that G-protein activators, such as F^-, can induce quantum bumps in the dark, and that the G-protein blocker, Guanosine 5'-O-[2-thiodiphosphate] (GDP-ß-S), reduces the light response (Corson & Fein, 1983 J. Gen. Physiol 82, 639; Fein, 1986 Science 232, 1543). The bumps induced by F^- are only slightly smaller than the ones induced by light, indicating that F^- affects a very early step of phototransduction, before much of the gain occurs. This raises the possibility that F^- may act at the pigment level, possibly affecting metarhodopsin phosphorylation, the only known biochemical modification of the pigment. However, the results of our experiments in the Limulus median UV photoreceptor do not support this view. We found that the rate of F^- induced bumps is not dependent on the relative amount of rhodopsin and metarhodopsin. Thus, it is likely that F^- acts at a step subsequent to the pigment, probably at the G-protein level. To test this more directly, we injected the G-protein blocker, GDP-ß-S, into a ventral photoreceptor previously treated with F^-. The injection completely suppressed the F^- induced bumps. Since GDP-ß-S is known to block F^- activation of G-protein in the adenylate cyclase system (Eckstein et al., 1979 J. Biol. Chem. 254, 9829) our results strongly suggest that F^- bumps are produced by activation of G-protein. If a F^- activated G-protein induces a bump almost as large as a light induced bump, then it is likely that very few G-protein molecules are activated in the generation of a light induced bump. We further tested this hypothesis by studying the effect of G-protein blockage by GDP-ß-S on the light response. We found that GDP-ß-S injection caused a severe reduction in light sensitivity which was not due to a reduction in quantum bump size, but rather to a reduction in quantum efficiency (the probability that a photon evokes a quantum bump). These results can easily be accounted for with a model in which a single photoexcited rhodopsin normally activates only a few G-proteins. Thus, unlike vertebrates, where it is believed R* activates hundreds of G-proteins molecules, in invertebrates the gain of the first step of phototransduction may be close to one.

386.6 EFFECTS OF PROTEIN KINASE C ACTIVATORS ON PROTEIN PHOSPHORYLATION AND LIGHT-REGULATED CURRENT IN FROG ROD PHOTORECEPTORS. B.M. Binder, G.D. Nicol and M.D. Bownds. Lab. of Molecular Biology and Neurosciences Training Program, Univ. Wisc., Madison WI 53706.

The role of protein kinase C (PKC) activation in rod outer segments that retain their inner segment (OS-IS) was examined by correlating electrophysiological and biochemical measurements. Application of PKC activators, 1-oleoyl-2-acetyl glycerol (OAG, 100 uM) or dioctanoylglycerol (diC8, 10 uM), resulted in a 20% decrease in the light-regulated current after 2 min and a 50% decrease after 20 min. With 10 uM OAG a 20% decrease in the light-regulated current was observed after 20 min. Intensity-response curves showed no change in the light intensity required to half-suppress the maximal photoresponse, indicating no change in the rod's sensitivity to light.

To correlate the decrease in light-regulated current with phosphorylation of specific proteins by PKC, [γ-^{32}P]-ATP was added to suspensions of purified, electropermeabilized OS-IS. OAG enhanced, in a concentration- and time-dependent manner, the phosphorylation of a 55 kD protein and three proteins with molecular weights between 14 and 24 kD. Maximum phosphorylation of these proteins occured within 5 min after OAG addition. In some experiments, illumination caused enhanced phosphorylation of these proteins. These observations suggest that activators of PKC may lead to a reduced photoresponse through phosphorylation of proteins that influence channel closure or proteins that influence ion concentration gradients in the rod. This work was supported by NIH Grant EY-00463.

386.7 **PURKINJE SHIFT IN PHOTORECEPTORS: INTRACELLULAR RESPONSES TO CHANGES OF THE ROD AND CONE DOMINANCE.** Samuel M. Wu and Xiong-Li Yang.* Cullen Eye Institute, Baylor College of Medicine, Houston, Texas 77030.

Photoreceptors were recorded under visual control with intracellular microelectrodes in flat-mounted isolated retinas of the larval tiger salamander (Ambystoma tigrinum). About 10-20% of the rods (named rod_cs), identified by their morphology while recording, exhibited a mixed response waveform of the rod and the cone under dark-adapted condition: it repolarized immediately after the termination of the light step (like the cone) and it gave a long voltage tail afterwards (like the rod). In the presence of background illumination, rod_cs exhibited a response that closely resembled the waveform of the cone response, but with a smaller amplitude. Under dark-adapted conditions, the maximum spectral sensitivity of the rod_c was approximately 520 nm, which was very close to that of the rods. In the presence of background illumination, rod_c exhibited a spectral sensitivity that resembled that of the cone with a peak around 620 nm. This result demonstrates that the intracellular responses of the dark-adapted rod_c can exhibit Purkinje shift in response to steady background illumination. The strength of electrical coupling between the cones and the rods (or rod_cs) were measured by passing current pulses into the cone while recording the voltage response from the rod (or rod_c). To -1 nA current into an adjacent cone, the voltage response recorded from the rod_cs (9.4 $\pm$ 2.8 mV) is 3.4 times larger than that recorded from the rods (2.3 $\pm$ 1.7 mV). It is likely that the strong electrical synapses between the rod_cs and the cones mediate the mixture of the rod and cone responses in rod_c under dark-adapted conditions. These synapses also enable rod_cs to exhibit a cone response in the presence of background illumination when the rod response is suppressed.

386.8 GEOMETRICAL CONSIDERATIONS PREDICT THE RESPONSE OF BOTH VERTEBRATE RODS AND CONES FOLLOWING A SINGLE ISOMERIZATION. J.P. Raynauld*and S. Gagné* (SPON: F. Lepore). Centre de recherches en sciences neurologiques. Université de Montréal, Montréal, Québec, Canada. H3C 3J7.

An analysis of the fact that the disks of the cones are infoldings of the plasma membrane while the disks of the rods are isolated from the plasma membrane helps to predict the single quantum response of both rods and cones. For the cone, three dimentional analysis of the infolding of the plasma membrane leads to the conclusion that the interactions of an internal messenger are limited to the disk which captured the photon. Assuming that the action of the internal messenger is optimum in the sense that it closes all the open channels located on the disk, the percentage reduction in dark current should be equal to 1/n X 100, where n is the number of disks in the outer segment. For the turtle cone outer segment which contains 800 disks the current reduction should be 0.13%, experimentally the measured value is 0.16% (Baylor D.A. et al. J. Physiol. 242, 685, 1974). For the rods, the area of plasma membrane which contains the closed channels at the peak of the response following a single isomerization is equal to the area of one disk as if the effects of the internal messenger were exactly translocated from the disk to the plasma membrane. The occlusion length along the outer segment can be calculated to be equal to d/2 and the percent reduction in dark curent equal to (d/21) X 100, where d and l are respectively the diameter and the length of the rod outer segment. This formula predicts respectively the values of 6% and 4% for the reduction of dark current in the Bufo and monkey rods following a single isomerization. Theses values are in very good agreement with experimentally obtained values of 5% and 3-5% (Baylor D.A. et al. J. Physiol. 288, 613, 1979 and Baylor D.A. et al. J. Physiol. 3517, 575, 1984).

386.9 A MODEL FOR ADAPTATION IN VERTEBRATE RODS. K. N. Leibovic, Y. Y. Kim* and Z. H. Pan*. Dept. of Biophysics, SUNYAB, Buffalo, NY 14214.

It is now generally accepted that cGMP controls membrane conductance in photoreceptors and the transduction biochemistry is largely understood. There are remaining questions, especially concerning the response turn off; and the molecular basis of adaptation is unknown. Electrophysiology can provide guidance in this situation. Photoreceptor adaptation is driven by background light I_B and pigment bleaching B. We have shown by recording in Bufo rods that there is an equivalence $I_B \sim B$ with respect to the stationary parameters of threshold elevation and response compression. But this equivalence does not extend to the transient parameters, such as stimulus summation and recovery of sensitivity. To reconcile these and other data with the known biochemistry we propose that: (1) response compression is controlled by the steady state level of cGMP; (2) threshold elevation is controlled by the amounts of activated rhodopsin R^* and activated PDE^* entering the transduction cycle; (3) the processes (1) and (2) are coupled and this is the basis for the $I_B \sim B$ equivalence; (4) arrestin and localized Ca^{++} activity mediate (2) and (1) respectively; (5) response acceleration in the presence of I_B and the nonequivalence of the transient parameters argues for different mechanisms brought into play by I_B and B and the control they exert on R^*, PDE^* and cGMP via arrestin and Ca^{++}. We have modeled photoreceptor adaptation by computer simulation based on the above proposals.

386.10 CIRCADIAN CHANGES IN LIMULUS VENTRAL PHOTORECEPTOR RESPONSE. L. Kass*, Dept. of Zoology, Univ. Maine, Orono, ME, and G.H. Renninger, Biophysics Group, Univ. Guelph, Guelph, ON.

Photoreceptor cells in Limulus polyphemus receive efferent input from a circadian clock in the brain (1). Circadian rhythms have previously been observed in recordings from the lateral eyes and median ocelli (2). Here, we report that ventral photoreceptors also exhibit circadian rhythms in their responses to flashes of light.

The horseshoe crab was inverted, restrained, and maintained in darkness for several days and nights. The tip of a metal electrode was placed within the wart structure housing the ventral eye end-organ. Flashes of light (10 ms) directed onto the end-organ elicited ERG-like responses. The flashes were repeated at a rate of 0.35 Hz and the responses averaged at 4 different intensities of illumination. The average responses were larger at night than during the day for the 2 higher light intensities, but were not significantly different for the lower intensities.

It has been reported that: when the efferent nerve fibers are activated, octopamine is released in the photosensitive membrane region of both lateral and ventral photoreceptors (3); both ventral and lateral eye photoreceptors possess octopamine receptors which, when stimulated, increase intracellular cAMP levels (4); exogenous octopamine, or agents that increase cAMP levels, change fundamental characteristics of photoreceptor function in the lateral eye (5). We have also reported that the same pharmacological agents change ventral photoreceptor function in a similar fashion (6).

We conclude that ventral photoreceptors have circadian rhythms in their response to light which are mediated by biochemical machinery similar to that in lateral eye cells, and that understanding the functioning of ventral photoreceptors will require a delineation of the physiology and biochemistry of efferent neurotransmission in the Limulus visual system.

CHEMICAL SENSORY SYSTEMS II

387.1 Identification of a Monoclonal Antibody which Reacts with Neuronal Cells in the Rat CNS and Olfactory System Susan L. Warren* and Richard A. Akeson Division of Basic Research, Childrens Hospital Research Foundation, Cincinnati, Ohio,45229

Using the monoclonal antibody(Mab) 6B7, a cell surface component found in adult rat central nervous system membrane preparations and on the surfaces of many neurons in cultures of embryonic rat forebrain has been identified. This Mab was derived from mice immunized with a rat forebrain synaptic plasma membrane preparation. High levels of Mab 6B7 binding are observed with membrane preparations from rat forebrain and olfactory bulb but no detectable binding is observed with membranes from the non-neural adult rat tissues heart, kidney,liver, lung and testes. Binding to dorsal root ganglia preparations was 5 fold lower than to forebrain.In immunofluorescence analyses, Mab 6B7 binds to the surface of a significant proportion of neurons in cultures of embryonic day 14 rat forebrain. However it is absent from GFAP positive astrocytes and fibroblastic cells in rat neural cultures. The distribution of the 6B7 antigen in the olfactory epithelium was characterized in greater detail. In cryostat sections, 6B7 appears to react with a cell population of the basal layer of the adult rat epithelium but is absent from the more mature neuronal population which lies higher in the epithelium. This result suggests that within the olfactory epithelium Mab 6B7 may be useful as a marker for the proliferative basal cells which are the neuronal precursors in the epithelium.In summary the 6B7 antigen may be useful in identifying and analyzing cell subpopulations in both the rat central nervous system and olfactory epithelium. Supported by Grant PO1-NS23348 from the NIH.

387.2 TRANSNASAL TRANSNEURONAL TRANSPORT OF HERPES SIMPLEX VIRUS TYPE I INTO THE RAT BRAIN

J.H. McLean, M.T. Shipley. Dept. Anat./Cell Biol., Univ. Cincinnati Coll.Med., Cinti., OH. 45267-0521 and D.I. Bernstein*. The Gamble Institute, Cinti., OH.

The olfactory epithelium can incorporate macromolecules and transport them into the brain. This phenomenon has been established in the rat with the incorporation of WGA-HRP (Shipley, 1985; Baker and Spenser, 1986) and in the mouse with a virus (Tomlinson and Esiri, 1983). Thus, harmful or potentially beneficial substances may enter the brain via olfactory nerves. The purpose of this study was to determine where in the epithelium a virus is incorporated and whether the virus spreads transneuronally along defined anatomical circuits in the brain.

Live herpes simplex virus type 1 (HSV1)(McIntyre strain) was injected into the nose of anaesthetized adult rats (male, Sprague Dawley). Animals survived three to seven days before perfusion with 4% paraformaldehyde. Cryoprotected sections were cut at 30 um and reacted with an antisera to HSV1. Some additional animals were sacrificed and regions of the brain were cultured for HSV1.

Preliminary results indicate that virus placed in the nasal cavity enters the brain by at least two routes: the trigeminal nerve and the olfactory nerve. Here, we concentrate on olfactory pathways. The results are from animals that were sacrificed 5 days post-inoculation.

Scattered focal regions in the olfactory epithelium were infected with HSV1. The virus was transported to the olfactory bulb and to higher olfactory structures in a retrograde and possibly anterograde direction. In the olfactory bulb, labelled glomeruli and tufted, mitral and granule cells were often concentrated in discrete radial columns. These patterns suggest that the virus passed to successive neurons in local olfactory bulb circuits by a transynaptic mechanism. More distal olfactory-related structures were also labelled including the anterior olfactory nucleus (ipsi- and contralateral), taenia tecta, horizontal limb of diagonal band, nucleus of lateral olfactory tract, piriform cortex, endopiriform nucleus, raphe nucleus and locus coeruleus. These labelled neurons were predominantly ipsilateral to the infected nostral and were so densely stained that individual neurons had a Golgi-like appearance.

These results show that HSV1 can enter the rat brain through olfactory neurons, multiply and spread transneuronally along specific multi-neuronal circuits. Competition studies should be able to determine whether the virus binds to membrane sites similar to those recognized by WGA. We hypothesize that the virus spreads transneuronally in a manner similar to WGA. However, the viral labelling is very much greater than the lectin labelling because the virus multiplies in neurons at each stage of transneuronal transfer.

The nose may thus be an important site of entry for viral infection of the brain. Beyond pathological implications, these findings suggest transneuronal transport of viruses may be useful in delineating multisynaptic neural circuits in the brain. (Supported by BRSG SO7 RR5408-25, PHG AI 23482, NINCDS PO1 23348-01, NS 20643, NS 22053, and DAMD 17-86-C-6005).

387.3 ALL PARTS OF THE OLFACTORY EPITHELIUM RE-MAP INTO A MEDIAL BULB REMNANT. M.T. Shipley, J.H. McLean and W.T. Nickell, Univ. of Cincinnati College of Med., Cincinnati, OH 45267, B.M. Slotnick, American Univ., Wash., D.C. 20016

A central problem in olfactory research is the nature of the relationship between primary olfactory neurons (PONS) in the olfactory epithelium (OE) and their synaptic targets in the main olfactory bulb (MOB). One view is that the epithelium is a mosaic of intermingled, odor-specific PONS; PONS of similar specificity are thought to project to contiguous sites in MOB. This creates a chemotopic map in the bulb. At the other extreme PONS may be arranged to form chemotopic gradients; or the OE may have differential absorptive gradients so that it functions like a chromatograph; in either of these schemes specific sites in OE are selectively activated by different odorants.

Anatomical tracing studies provide evidence that is compatible with either the mosaic or gradient hypothesis; medial OE maps to medial MOB and lateral OE to lateral MOB. There is also some degree of circumferential and longitudinal organization in the OE-MOB projection but the microorganization of the OE-MOB projection is still poorly understood.

For the mosaic hypothesis, a remnant of the OE sheet would suffice to represent a wide range of odor qualities if specific PONS are randomly distributed. In the chemotopic schemes a large part of the OE sheet must be maintained in order to sort odorants along chemotopic gradients. Integrity of the OE sheet is, thus, a higher organizational priority for the chemotopic or gradient than for the mosaic hypotheses. The following results suggest that the OE-MOB projection strives to maintain the integrity of the OE sheet.

The lateral half and most of the dorsal and ventral parts of MOB were surgically ablated in 4-7 day old rats. Medial MOB and its connections with the medial septal OE were left intact. At 60-90 days of age multiple, large injections of WGA-HRP were made in the bulb remnant to retrogradely label PONS in the OE. Similar bulb loading was done either on the non-operated side or in non-operated litter mates. When these control bulb loadings were extensive, there was dense labelling of contigious PONS throughout the OE. Loading of bulb remnants consisting only of the medial part of the bulb produced a similar pattern of OE labelling. Some parts of the lateral OE were less heavily labeled than controls, but there were no major gaps in the labelling pattern. The labelling of the lateral turbinates in medial bulb remnant cases was in stark contrast to the absence of LT labelling in normal animals with injections restricted to medial MOB.

These observations indicate that the OE strives to re-map its entire representation into a drastically reduced bulb remnant. This implies that integrity of the OE sheet is an important organizing principle in the OE-MOB projection and is consistent with the possibility that chemotopic or chromatographic-like gradients are involved in olfactory processing. This suggests that animals with bulb remnants should be able to detect a normal range of different odors but animals with an OE remnant should be anosmic to some odors.

387.4 PROLONGED INHIBITION OF CONTRALATERAL AND POTENTIATION OF IPSILATERAL ASSOCIATION INPUTS TO THE OLFACTORY BULB BY STIMULATION OF THE DIAGONAL BAND. W.T.Nickell and M.T. Shipley (University of Cincinnati College of Medicine.)

The main olfactory bulb (MOB) receives afferent inputs from several sources: The two bulbs are connected by a large commissural system. There are also strong centrifugal inputs from ipsilateral cortical and subcortical olfactory structures. We report here that these afferent inputs are potently and selectively modulated by the centrifugal projection from the nucleus of the diagonal band (HDB).

Anaesthetized adult male rats were used. Stimulating electrodes were placed stereotaxically in the ipsilateral HDB, in the rostral wing of the contralateral anterior commissure (ACc), and in the ipsilateral piriform cortex (PCi). Stimulation of the ACc or PCi results in a negative field potential in gcl, which reflects an excitatory post-synaptic potential (epsp) in the granule cells. We previously described the field potential in MOB caused by HDB activation. Stimulation of HDB at 10 Hz for several seconds results in a large potentiation of the HDB field potential. We now report that this same HDB stimulation causes a powerful and long-lasting inhibition of the ACc response. After HDB potentiation, the ACc response is reduced to 15% or less of the control value and does not completely recover for more than 20 seconds. During this period of inhibition, a burst of shocks to ACc results in facilitation of response amplitude toward that of the control response.

In contrast to this potent inhibition of the commissural input, the same HDB stimulation potentiated the response to PCi. This potentiation was similar to the potentiation of the HDB field potential by HDB stimulation; it lasted 1-2 seconds and increased response amplitude and duration by factors of 2-3.

At least two mechanisms could account for the inhibition of ACc by HDB. (i) A postsynaptic increase in conductance of granule cells (postsynaptic inhibition) would shunt excitatory synaptic currents. Alternatively, (ii) presynaptic inhibition of ACc terminals synapsing onto granule cells would also inhibit the ACc response. The differential effect of HDB stimulation on the two inputs to the granule cells, and the ability of the ACc response to facilitate to nearly normal size during the inhibition, suggest that the inhibitory effect does not result from conductance changes in the granule cells; these would be non-specific and not reversible by presynaptic effects such as facilitation.

Exogenous application of acetylcholine in hippocampus causes presynaptic inhibition of both afferent inputs and intrinsic inhibitory interneurons. The HDB projection to the bulb contains a cholinergic component and the inhibition of ACc by HDB reported here may represent an analogous mechanism produced by synaptic release of acetylcholine. The potentiation of PCi may result from the same mechanism as the potentiation of the HDB field potential. (Supported by: NINCDS P01 23348-01, NS 20643-01, NS 22053,and DAMD 17-86-C-6005).

387.5 ELECTROPHYSIOLOGICAL AND ANATOMICAL EVIDENCE REVEAL PROJECTIONS FROM PREFRONTAL NEURONS TO THE MAIN OLFACTORY BULB (MOB) AND MEDIO DORSAL THALAMIC NUCLEUS (MD) IN THE RAT. A. R. Cinelli*, H. Ferreyra-Moyano, E. Barragán* and J.S. de Olmos*. Instituto de Investigación Médica M. y M. Ferreyra. C.C. 389. 5000 Córdoba, Argentina.

Although centrifugal projections from allocortical areas to the MOB have been demonstrated beyond doubt, only very limited evidence is available on projections from the frontal cortex (FC) to the MOB (Brutus et al. Brain Res. 1984; Neafsey et al. Brain Res. 1986). Due to the importance attached to FC in odor processing, we sought to explore this matter further. Under Urethane anesthesia, extracellular unit activity was recorded with stainless steel microelectrodes from agranular insular ventral (AIv), lateral orbital (LO) and ventrolateral orbital (VLO) regions. Twenty three neurons were antidromically invaded in these areas following stimulation of the ipsi (N=17; 74%) and contralateral (N=6; 26%) MOB; antidromic driving was confirmed in 47% of cells by collision. Antidromic latency and conduction velocity were 10±1.2 (X ± SE) and 0.47 ± 0.05 (X ± SE) for VLO neurons projecting to the ipsi lateral MOB. Stimulation of sulcal cortex in the dorsal lip of the rhinal fissure inhibited spontaneous discharges of mitral cells in the MOB. FC projections to the MOB were confirmed by anatomical studies. Unilateral injections of solid fluorescent retrograde tracers True Blue, Fast Blue and Nuclear Yellow were placed within the rostral tip of the MOB and in the MD. The MOB halo never encroached upon the AON and was restricted in most cases to the rostral half of the MOB. Following MOB injections, labelled neurons were found in the infralimbic (IL), VLO and AIv cortical regions, as well as in area 3 of the cingulate cortex (Cg3). The densest neuronal labelling occured in the transition cortical zone between the dorsal part of the AON and VLO. Most labelled neurons were found in the supragranular cortical layers with some of them located towards the transition zone of the infragranular layer. Some cells, in particular those in the VLO-AONd transition zone were double-labelled from MOB and MD injections. Tha majority of labelled cells in the opposite hemisphere were located in the IL cortex. These results suggest that prefrontal centrifugal neurons may provide a feed-back signal to the MOB operative in peripheral gating of afferent olfactory information.

387.6 OLFACTORY PATHWAY AND LOCUS COERULEUS INTERACTION AT MEDIODORSAL THALAMIC NUCLEUS. Luis Pastor Solano-Flores, Maria Olga Legoratti-Sánchez* and Rosalinda Guevara-Guzmán (SPON: H.U. Aguilar-Baturoni). Departamento de Fisiología, Facultad de Medicina, U.N.A.M. Apdo. Postal 70250, 04510 México, D.F.

The noradrenergic nucleus locus coeruleus (LC) projects fibers practically to the whole brain. It has been shown that LC is involved in a number of functions: sleep, stress, learning, aggression. LC also plays a modulatory role in sensory pathways, thus, the expected responses in neurons' firing rates and evoked activity in the visual and in somatosensory pathways are affected by LC stimulation. We have already shown that olfactory tubercle's neural activity is modulated by LC. Additionally, the inhibitory action of LC in the thalamic ventral nucleus has been shown. In the other hand, it is known that the activity of neurons in the mediodorsal thalamic nucleus is modified by olfactory bulb (OB) stimulation. Our laboratory and other researches have pointed out that the functional significance of LC activity upon sensorial pathways might be the modulation of the importance of the sensory information input to central levels in order to adequate the responses to the organism priorities. In order to search for a LC modulatory influence upon the processing of the olfactory input to central levels, this work was performed. In male Sprague Dawley rats, the firing rate of mediodorsal thalamic neurons was conventionally recorded. Stimulating electrodes were set in the LC and OB. Square pulses 0.2 msec, 0.1-0.8 mA, 15-30 Hz during 0.5-2.0 sec were applied to either of these structures. Generally the firing rates of thalamic units were enhanced notably after LC stimulation, this effect was abolished after an OB stimulation and this last effect was sistematically reversed after another LC stimulation. These results suggest that at thalamic levels, the olfactory information is modulated by LC.

387.7 RESPONSES TO TASTE STIMULI IN THE PARABRACHIAL PONS OF RATS WITH REVERSIBLE LESIONS OF THE GUSTATORY NEOCORTEX. Patricia M. DiLorenzo* (SPON: A. Yozawitz) Dept. of Psychology, SUNY at Binghamton, Binghamton, N.Y. 13901.

Because previous data have revealed differences in taste responses in the parabrachial nucleus of the pons (PbN) in decerebrate vs. intact rats, it is possible that descending forebrain influences play a functional role in the neural code for taste and/or palatability in this structure. This experiment was designed to study the influence of the gustatory neocortex (GN) on the neural code for gustation in the PbN.

Single unit responses to gustatory stimuli in the PbN were recorded in anesthetized rats before and after injections of procaine HCl (10% in saline, 1 µl) into the GN. Sapid solutions of NaCl (.1M), HCl (.01M), Sucrose (.5M), NaSaccharin (.004M) and Quinine HCl (.01M) were individually bathed over the tongue followed by a 20 sec rinse of distilled water.

Preliminary analysis of results suggest several consistent effects: 1) 17% of the taste-responsive PbN units showed significant reductions in spontaneous firing rate after procaine injection into the GN. This effect was accompanied by an attenuation of the responses to all taste stimuli, 2) 40% of the taste units showed attenuated responses to some or all of the taste stimuli without a reduction of spontaneous rate, 3) 35% of the PbN units showed an enhancement of response rate without changes in spontaneous firing rate. In some units responses were present after procaine injection in the GN that were not present before injection. In other units responses to some tastants were enhanced while the responses to others were attenuated, 4) 26% of the taste-responsive PbN units showed a response to the termination of the stimuli (OFF response) after procaine injection in the GN, but not before. This effect was not associated with changes in spontaneous rate. Recovery was observed for all of the affects noted above.

These results suggest that input from the GN to the PbN may be involved in the fine-tuning of the across-unit pattern of firing to gustatory stimuli. Furthermore the suppression of OFF responses in the PbN by the GN may be important for the modulation of the associative salience of gustatory stimuli by the GN.

387.8 CORRELATIONS BETWEEN MULTI-UNIT SPIKES AND EEG IN RAT OLFACTORY CORTEX. F. H. Eeckman and W.J. Freeman. Dept. of Physiology-Anatomy, U.C. Berkeley, Berkeley CA 94720

We performed simultaneous recordings of multi-unit activity and cortical EEG in the primary olfactory cortex of awake and motivated rats. No stimulation was used. Both the EEG and the spike trains were recorded with chronically implanted 100 micron stainless steel electrodes with sharpened tips. The electrodes were positioned at different depths so as to sample activity from all layers of the cortex.

The EEG trace was filtered at 10 and 300 Hz., and digitized at 1 msec. intervals. The unit signal was filtered at 300 and 3,000 Hz., and sent through a window discriminator. For every value within the window a standard 5 V, 1 msec. pulse was stored concurrently with the EEG.

Data were transferred to disk for off-line processing, using a Perkin-Elmer 3220 computer.

We used the two-dimensional conditional pulse probability table (Freeman, 1975) to find correlations between units and EEG.

Last year we reported data on spike-EEG correlations in the olfactory bulb of awake and motivated rats (Neurosci. poster # 370.5, 1986).

The following differences were found between the data obtained from studies in the olfactory bulb (OB) and data obtained in the present study on the olfactory cortex (OC). In the OB, units were found whose firing frequency correlated well with the dominant frequency of the EEG burst at 70- 80 Hz. In the OC, most unit firing is correlated with the 45- 55 Hz. frequency band. In the OB, the percentage of modulation was relatively high (60-90 % of the spikes); in the OC, this percentage is lower (55-75 %). In the OC, some traces were found (approx. 20%) where the spikes correlated with two frequency bands, that are not harmonics of one another. In these traces the pulses have a similar time-reference to the EEG.

In the OB, spikes lead the EEG maximum by approximately 1/4 cycle phaselead; in the OC, two types of unit traces were found: Group A, whose firing probability is in phase with the EEG maxima, and Group B, whose firing probability lags the EEG maximum by a 1/4 cycle (Freeman, 1968).

These data are explained in terms of a model for burst generation in the olfactory cortex (Freeman, 1975).

387.9 NONLINEAR SPATIO-TEMPORAL DYNAMICS OF OLFACTORY EEG IN BEHAVIOR. K. A. Grajski* and W. J. Freeman. Grad. Group in Biophysics, Dept. of Physiology. UC Berkeley. Berkeley, CA 94720.

Extended time series of EEG activity (3 seconds @ 1-2 msec. digitizing intervals) from rabbit and rat olfactory bulb and cortex were classified as basal, bursting or epileptiform. Corresponding simulations were generated by a model for olfactory EEG proposed by Freeman. Results of a qualitative analysis using phase portraits and Poincare sections and a quantitative analysis using power spectra and estimation of dimensionality and positive Lyapunov exponents show that low dimensional (3-4) chaotic attractors are manifested in basal, bursting and epileptiform EEG. The significance of these results is that complex activity generated by systems consisting of large numbers of interacting components, such as neurons in the olfactory system, is not random, rather, it is deterministic.

Spatial EEG was analyzed for correlates of behavior in waking rabbits. Habituation experiments demonstrated short- and long-term odor-specific habituation. An aversive differential conditioning procedure showed that subjects could associatively acquire differential response to odors. In all behavioral studies sniff magnitude and probability of sniff responding served as behavioral variables. Oscillatory bursts of 40-80Hz EEG activity (100 msec) were recorded using eight by eight electrode arrays chronically implanted epidurally on the lateral aspect of the olfactory bulb.

In habituation studies, results were found to be consistent with previous studies (Gray, et. al., 1986) in which infusion of norepinephrine into the bulb potentiated the transient spatial pattern change to novel odor stimulation. In the present study, the transient odor pattern averaged over the first four trials differed from that for the last four in the first twelve-trial session of unreinforced odor presentations. Both odor patterns differed from an essentially invariant air pattern. Across habituation sessions the air - odor pattern differences diminished and were statistically indistinguishable by the third twelve trial session. The odor specificity of habituation was revealed by introducing a single novel odor trial in the fifth habituation session. No odor-specific EEG spatial patterning was observed for either the habituated or novel odors.

In a differential conditioning experiment three subjects were presented with twelve reinforced (mild shock) trials of a CS+ odor for three sessions. Beginning with the fourth session, an additional set of twelve trials of an unreinforced odor CS- was introduced. By the sixth and continuing through the eighth session, subjects showed significant differential responding to the CS+ and not the CS- odor (two-sided paired t-test $\alpha \leq 0.04$). Consistent with previous studies (Grajski, et. al., 1986) with appetitive conditioning in rabbits, odor-specific patterns were seen to emerge, stabilize and persist as correlates of differential conditioning.

387.10 A COMPUTER SIMULATION OF A THREE-DIMENSIONAL MODEL OF PIRIFORM CORTEX WITH FUNCTIONAL IMPLICATIONS FOR STORAGE AND RECOGNITION OF SPATIAL AND TEMPORAL OLFACTORY PATTERNS. M. Wilson* and J. Bower (SPON: E. DeYoe). Division of Biology 216-76, California Institute of Technology, Pasadena, CA 91125.

Using parameters obtained from anatomical and physiological experiments (Haberly, Chem. Senses 1: 219, 1986), a computer model of piriform (olfactory) cortex has been developed that simulates physiological responses obtained using a variety of recording methods (Wilson et al., Soc. Neuroscience, 370.11, 1986). This one-dimensional model of 70 neurons has now been extended to a two-dimensional array of several thousand pyramidal cells interconnected by a highly divergent/convergent system of associational fibers. Excitatory input is now delivered to the cells along an afferent pathway containing multiple independent fibers. These fibers are capable of carrying complex spatial/temporal patterns with characteristics similar to the lateral olfactory tract projection to piriform cortex from the olfactory bulb. A more detailed dendritic model is now included which allows for spatial interaction of activity generated along different segments of the pyramidal cell dendrite. As in the original model, the two populations of interneurons included are each responsible for different forms of inhibition: a feedforward, long latency, long duration hyperpolarizing potential, which simulates the K^+ mediated potential observed in piriform cortex, and a feedback, short latency current shunting type inhibition simulating the well known Cl^- mediated process. The simulation incorporates the different propagation velocities of the separate fiber pathways, synaptic delays, refractory periods, time constant estimates for inhibitory and excitatory events, and spatial variations in the distribution of different excitatory and inhibitory influences. The previous model has been shown capable of simulating a variety of known intracellular and extracellular responses including odor-like oscillatory bursts, characteristic shock responses, and epileptiform activity. Simulation results have revealed the presence of propagating waves of activity across the cortex which are driven by afferent input and carried by both afferent and association pathways. The current model has been extended to explore the significance of these simulated cortical dynamics in the processing of olfactory information. Using connections consistent with the known circuitry of piriform cortex, and a learning rule which modifies synaptic strengths as a function of physiological variables the model can successfully store and recall spatially and temporally encoded patterns. Discrimination of such patterns is hypothesized to be the basis for olfactory processing in the cortex. Supported by Caltech Presidents Fund and Joseph Drown Foundation.

387.11 DIFFERENTIAL RESPIRATION DURING TRAINING IS NOT REQUIRED FOR EARLY OLFACTORY LEARNING IN INFANT RATS. Jacqueline T. Do*, Regina M. Sullivan* and Michael Leon, (Sponsor - G. Shaw), Department of Psychobiology, University of California at Irvine, 92717

Exposing neonatal rats to an odor while giving them reinforcing tactile stimulation (mimicking maternal contact) produces a behavioral preference and enhanced olfactory bulb focal 14C-2-deoxyglucose (2DG) uptake to that odor. One possible mechanism underlying the development of this neurobehavioral response is an enhanced activation of the olfactory system during odor training produced by a stimulation-induced increase in respiration. Tactile stimulation increases respiration rate in rat pups (Sullivan et al., Dev. Psychobiol, in press). The present experiments determined whether increased respiration during training is required for early olfactory learning, by pairing the odor with a stimulus that mimics an aspect of the dam-litter environment that does not modify pup respiration.

Neonatal Norway rats were assigned to one of the following treatment conditions from day 1-18 postnatal (PN): 1) ODOR-STROKE, 2) ODOR-HIGH HUMIDITY, 3) ODOR-ONLY, and 4) ODOR-STROKE-HIGH HUMIDITY. Additionally, respiration was monitored during training sessions on PN1, PN6, PN12 and PN18. On day 19, pups were either given a two-odor choice test (peppermint vs familiar pine shavings) or injected with 14C-2DG (200 uCi/kg) and given 45 min test exposure to peppermint. Autoradiographs were then developed and analyzed using standard techniques.

The results showed that, similarly to ODOR-STROKE training, ODOR-HIGH HUMIDITY training is sufficient to produce a learned odor preference and enhanced olfactory bulb glomerular focal 2DG uptake. Additionally, ODOR-STROKE-HIGH HUMIDITY pups, which exhibit enhanced respiration during training, do not exhibit the behavioral preference nor the enhanced 2-DG uptake at testing.

These results suggest that various kinds of moderate sensory stimulation, which mimic different aspects of maternal contact, can function to produce the behavioral and neural response modifications associated with early olfactory learning. Moreover, they indicate that enhanced respiration during training is neither necessary or sufficient for the acquisition of the behavioral preference and enhanced olfactory bulb 2-DG uptake.

387.12 NORADRENERGIC CONTROL OF NEURAL AND BEHAVIORAL CORRELATES OF EARLY OLFACTORY LEARNING. R.M. Sullivan*, D.A. Wilson, J. Do*, and M. Leon, (Sponsor - J. Leon), Dept. of Psychobiology, University of California at Irvine, 92717.

Norway rat pups learn to prefer odors paired with stimulation that mimicks maternal contact. This learned odor preference is associated with an enhanced olfactory bulb metabolic response (14C 2-deoxyglucose uptake) and modified olfactory bulb single unit response patterns to the odor in an odor-specific region of the bulb. This report examined the role of norepinephrine (NE) in the development of these learned behavioral and neural responses.

The olfactory training procedure lasted for 10 min/day from postnatal day 1 to 18, and consisted of either: 1) peppermint odor and vigorous stroking of the pup's body with a brush (Pepp-Stroked), 2) peppermint odor only, 3) stroking only, 4) neither stimulus. Within each training condition, pups were injected with either isoproterenol (NE agonist), or saline. On day 19, different groups of pups were: 1) given a two odor choice test (peppermint vs. a familiar pine odor), 2) injected with 14C-2-deoxyglucose (200 uCi/kg) and given a 45 min test exposure to peppermint, or 3) tested for mitral cell single unit responses to peppermint.

The results indicated that early odor experience paired with either stroking or isoproterenol produced a learned behavioral preference, enhanced focal 2-DG uptake and modified mitral cell response patterns to that odor. These results suggest that NE is sufficient for the acquisition of learned olfactory neural and behavioral responses early in life.

387.13 ENHANCED OLFACTORY BULB RESPONSE TO LEARNED ATTRACTIVE ODORS IN THE ABSENCE OF ALTERED RESPIRATORY RESPONSE. M. Kim*, D.A. Wilson, R.M. Sullivan*, and M. Leon, Dept. of Psychobiology, University of California at Irvine, 92717.

Norway rat pups learn to prefer odors paired with stimulation that mimics maternal contact. This learned odor preference is associated with an enhanced olfactory bulb metabolic response (14C 2-deoxyglucose uptake) to the odor in an odor-specific region of the bulb. Several mechanisms have been hypothesized to account for this enhanced focal 2-DG uptake to learned attractive odors: 1) structural or physiological changes within the olfactory bulb itself; 2) altered centrifugal input to the olfactory bulb from the rest of the brain; 3) enhanced input from the olfactory epithelium, for example due to altered respiration in response to the attractive odor. This report examined the role of modified respiration in the expression of the enhanced olfactory bulb response.

The olfactory training procedure consisted of 10 min/day from postnatal day 1 to 18 of either: 1) peppermint odor and vigorous stroking of the pup's body with a brush (Pepp-Stroked), 2) peppermint odor only, 3) stroking only, 4) neither stimulus. Experiment 1 - on day 19, pups were injected with 14C-2-deoxyglucose (200 uCi/kg) and given a 45 min test exposure to peppermint in an apparatus which recorded pup respiration patterns. Experiment 2 - on day 19, pups from all 4 groups were anesthetized with urethane and tracheotomized. Tubing was inserted into the trachea to the back of the nose and intermittent suction applied (200 ml/min, 200 ms duration, 2 Hz). The animals were then injected with 14C-2DG and exposed to peppermint odor for 45 min.

Results: Experiment 1 - Pepp-Stroked pups had enhanced focal 2-DG uptake in the glomerular layer, lateral and 1.5-2.2mm for the rostral pole of the bulb. No differences were found between groups in 1) total number of respirations, 2) respiration frequency distribution, 3) respiration rate during consecutive 12 sec monitoring periods. Experiment 2 - While pups in all groups had an equal rate and volume of inhaled peppermint odor during the artificial respiration, Pepp-Stroked pups had significantly enhanced glomerular layer focal 2-DG uptake compared to control pups.

Together, these results demonstrate that modified respiration is not required for the expression of a modified olfactory bulb response to learned attractive odors early in life.

387.14 POSTNATAL DEVELOPMENT OF NORADRENERGIC MODULATION OF OLFACTORY BULB EXCITABILITY IN THE RAT. D.A. Wilson and M. Leon, Department of Psychobiology, University of California at Irvine, 92717

Noradrenergic centrifugal inputs to the olfactory bulb terminate mainly on inhibitory interneurons, granule cells. In the mature bulb, norepinephrine suppresses granule cell activity, thus increasing the excitability of the primary output neurons of the bulb (Jahr & Nicoll, Nature, 1982, 297:227). However, since granule cells in the rat develop primarily postnatally, the effectiveness of noradrenergic inputs to the bulb during development is unclear. The present report describes the postnatal development of noradrenergic modulation of olfactory bulb function.

On postnatal day 5 (PN5), PN10 and PN20, Wistar rat pups were anesthetized with urethane. A microelectrode was placed in the granule cell layer of the olfactory bulb to record potentials evoked by stimulation of the lateral olfactory tract (LOT) via a bipolar stimulating electrode. A single conditioning pulse was applied to the LOT followed at 10 - 200 ms by an equal intensity test pulse. The amplitude of the response to the test pulse was depressed at 10ms compared to the conditioning response at all ages (Wilson & Leon, Dev Brain Res, 1987, in press). The effects of systemic injections or intra-bulbar infusions of the noradrenergic B-receptor antagonist dl-propranolol, and the B-receptor agonist isoproteronol, on this paired-pulse depressionn were then determined.

At PN10 and PN20, isoproteronol significantly decreased and propranolol significantly increased the magnitude of paired-pulse depression. No significant effects were seen at PN5, although there was a non-significant trend for isoproteronol to decrease and proranolol to increase inhibition at this age also. The results demonstrate that noradrenergic modulation of GABAergic inhibition in the rat olfactory bulb develops toward the end of the first postnatal week.

387.15 CARNOSINE AND INSULIN INCREASE OLFACTORY BULB GLYCOGEN SYSTHESIS. Robert Coopersmith* and Michael Leon (Spon: J. Conway). Department of Psychobiology, University of California, Irvine, CA 92717

Using histochemical techniques, we have recently shown that glycogen phosphorylase activity is extremely high in the glomerular layer of the rat olfactory bulb, possibly the highest level in the brain. The olfactory bulb also has the highest brain levels both of insulin receptors and the dipeptide carnosine. While the functions of carnosine and insulin in the bulb are uncertain, both substances can affect glycogen metabolism in other organs. We now report that insulin and carnosine increase the incorporation of glucose into glycogen in the olfactory bulb.

We adapted the in vitro tissue slice technique to the olfactory bulb to examine the effects of bioactive compounds and pharmacological agents on glycogen metabolism in this brain region. Briefly, 250 um bulb slices were incubated with tritiated glucose, followed by the addition of drug and further incubation. Following tissue homogenization and extraction procedures to remove glucose, proteins and amino acids, radioactivity corresponding to glycogen was counted. Without addition of drug, glucose incorporation into glycogen increased steadily for 30 minutes followed by a plateau phase. Insulin (1 mU/ml), added at the beginning of the incubation, increased the rate and total amount of incorporaton, with an almost 2-fold increase by 60 minutes. L-carnosine, added after 30 minutes of incubation, caused a 60% increase in glucose incorporation into glycogen at a 100 nM concentration, with smaller increases at both higher and lower concentrations. D-carnosine at the same concentration did not stimulate glycogen synthesis, causing a slight breakdown of glycogen.

It appears that at least part of the action of carnosine and insulin in the olfactory bulb involve modulation of glycogen metabolism. The localization of insulin receptors in the external plexiform layer and carnosine in the glomerular layer suggests that these systems may participate in separate glucose control mechanisms, possibly responding to different olfactory and centrifugal stimulus conditions. We will also report on the effects of other neuroactive substances on olfactory bulb glycogen metabolism.

387.16 OLFACTORY DEPRIVATION INCREASES [^{3}H] SPIROPERIDOL BINDING IN THE RAT OLFACTORY BULB. K. M. Guthrie, J. M. Pullara*, J. F. Marshall and M. Leon, Department of Psychobiology, University of California, Irvine CA 92717

Chemical or surgical afferent denervation of the rat main olfactory bulb decreases the levels of dopamine (DA) and tyrosine hydroxylase (TH) within an intrinsic population of dopaminergic juxtaglomerular cells. Reinervation is accompanied by a return to normal dopaminergic expression. Similarly, interruption of normal afferent stimulation during development by cauterization of the nares reduces bulb DA and TH.

In order to determine whether the effect of early olfactory deprivation on bulb dopamine expression is accompanied by changes in dopaminergic receptors, neonatal rats underwent unilateral naris closure or a sham procedure on postnatal Day 2. TH immunoreactivity and dopamine receptor binding were examined at Day 60. Quantitative autoradiography was used to determine the density of [^{3}H]spiroperidol binding sites in the bulbs of deprived rats and control littermates. Bulb sections were incubated in 0.7 nM [^{3}H]spiroperidol (77 Ci/mmol) in the presence of 40 nM ketanserin with or without 1 uM (+)-butaclamol. Tissue sections and standards were exposed to tritium sensitive film for 19 days. Autoradiographs were examined for [^{3}H]spiroperidol binding using computerized image analysis.

Early olfactory deprivation reduced TH immunoreactivity in the main olfactory bulb ipsilateral to the occluded naris (N=5). Staining of the contralateral bulb appeared similar to bulbs from control animals.

Deprived animals exhibited a 42% increase in [^{3}H]spiroperidol binding in the glomerular layer of the bulb ipsilateral to the lesion when compared to the contralateral bulb (N=5; $P < .01$). Binding in the non-deprived bulb did not differ significantly from that of control animals (N=5).

These results demonstrate that afferent sensory stimulation affects the olfactory bulb dopaminergic system at both the transmitter and receptor levels. The correspondence between the decrease in TH expression seen in deprived bulbs and the increase in [^{3}H]spiroperidol binding suggests that a reduction in DA results in an increase in glomerular D2 receptor density and/or affinity. Studies are now underway to determine the effects of deprivation on the distribution of D1 receptors and DA uptake sites in the olfactory bulb.

387.17 OLFACTORY DYSFUNCTION AND ODOR MEMORY IN ALZHEIMER'S DISEASE, HUNTINGTON'S DISEASE AND NORMAL AGING C. Murphy, B.R. Lasker* and D.P. Salmon. UCSD, San Diego State University, San Diego, CA 92182.

Neuroanatomical evidence for damage to olfactory areas in Alzheimer's Disease suggests the possibility of selective olfactory dysfunction in Alzheimer's Disease. Although deficits in olfactory-mediated tasks have been reported by Serby and his colleagues in 1985 and by Doty and his colleagues in 1986, such deficits could be ascribed to cognitive impairment and do not necessarily demonstrate selective olfactory deficits. The present study was designed to investigate the possibility of olfactory dysfunction in Alzheimer's Disease and in Huntington's Disease, a dementia in which there is no known selective olfactory involvement. We first investigated both olfactory threshold and memory for odors and visual stimuli in ten patients who met the NINCDS ARDA criteria and were thus diagnosed as either possible or probable Alzheimer's Disease by two different neurologists. Olfactory thresholds were determined on all subjects using a two-alternative, forced-choice, ascending series with butanol and using a criterion of four correct in a row. Results showed significantly higher olfactory thresholds for patients with Alzheimer's Disease relative to groups of elderly and young controls. Results of the threshold testing on the Huntington's patients will be compared to these results. Recognition memory was explored for three types of stimuli: common odors, faces of American presidents and vice-presidents, and electronic symbols. The Alzheimer's patients' performance was compared to that of young and elderly controls whose performance in the same task (with twice as many trials) has been reported (Cain and Murphy, ISOT, 1986). To control for differences in the subjects' criterion bias, ANOVA was conducted on the subjects' Az scores. Young subjects performed equally well with odors, faces, and symbols. The Alzheimer's patients scored significantly lower than the normal controls on all tasks and showed a greater decrement in odor memory than in visual memory. This impairment was distinguished by its severity from that seen for odor memory in normal elderly persons and for visual memory in Alzheimer's patients. The group of patients with Huntington's Disease were subjected to the same recognition memory testing and their results will be compared with those of the Alzheimer's patients. This study suggests significant impairment in both olfactory threshold and olfactory memory in Alzheimer's Disease. Since other primary sensory systems appear to be spared the early neuroanatomical damage and the sensory dysfunction seen in the olfactory system in Alzheimer's disease, selective olfactory dysfunction may serve as a marker for the disease. We suggest olfactory function be assessed to assist in the diagnosis of Probable Alzheimer's Disease.

Supported by NIH grant #AG04085 to C.M. We acknowledge the assistance of the Alzheimer's Disease Research Center at UCSD.

388.1 CYCLIC AMP CHEMORECEPTOR OF PARAMECIUM. J. L. Van Houten, J. Zhang, B. Cote, J. Baez, and J. M. Sasner. Dept. of Zoology, Univ. of Vermont, Burlington, Vt 05405

Cyclic AMP is an external attractant for Paramecium tetraurelia. Cells bind ^{3}H-cAMP specifically and saturably (Smith et al., Biochim. Biophys. Acta. in press, 1987) and cyclic AMP induces a hyperpolarization that is characteristic of attractant stimuli. 8-N_3-cAMP in ultraviolet light covalently binds to neighboring proteins and thereby affords a way to specifically label receptors and block chemoreceptor function. Cells treated with 8-N_3-cAMP in ultraviolet light lose attraction to cAMP but not to other attractant stimuli; no comparable loss occurs with photolysis of the parent compound cAMP. Therefore, a surface cAMP binding site, a chemoreceptor, appears to be involved in cAMP chemoresponse.

The cAMP chemoreceptor should be among the membrane proteins. The cell body membrane proteins of Paramecium include several cAMP binding proteins, but one prominent protein specifically elutes from cAMP-agarose affinity columns: A protein of 48,000 daltons (determined by SDS polyacrylamide electrophoresis) elutes from the column with cAMP or 5'AMP, but not with cGMP or 5'GMP. This correlates with the chemoresponse behavior, which is inhibited by 5'AMP, but by neither of the guanylate nucleotides. Binding of cAMP to whole cells likewise is inhibited by 5'AMP (Smith et al., 1987). This 48,000 d protein appears to be heterogeneous: KOAc, an unrealted attractant, does not elute any proteins from the column following the cAMP elution; however, KOAc does elute a 48,000 d protein when it precedes the cAMP elution, which then elutes off even more 48,000 d protein. A mutant, that is defective in its response to cAMP and does not bind cANP, does not appear to have this 48,000 d binding activity as defined by affinity chromatography.

Two dimensional electrophoresis, Affigel blue chromatography, ^{32}P-8-N_3-cAMP labeling, N terminal sequencing, and production of polyclonal antibodies comprise our current approaches to characterize this putative chemoreceptor.

Supported by NSF and Whitehall Foundation.

388.2 THE RESPONSE OF THE RAT GLOSSOPHARYNGEAL NERVE TO BITTER COMPOUNDS: MULTIPLE BITTER RECEPTORS? Pamela E. Scott and Joseph Farley. Program in Behavioral Neuroscience, Department of Psychology, Princeton University, Princeton, N. J. 08544.

Human psychophysical and animal behavioral studies suggest the presence of multiple subclasses of bitter perception (Fox, Proc.Nat.Acad.Sci. 18, 1932; McBurney et al., Per.& Psych., 11(3), 1972; Sugimoto and Sato, Comp.Biochem.Physiol. 69A, 1981; Herness and Pfaffman, Chem. Sens 11, 1986). These have been suggested to reflect multiple peripheral bitter receptor sites: a quinine site, a urea site, and a phenylthiocarbimide (PTC) site. We have attempted to obtain direct evidence for multiple bitter receptors by recording from the glossopharyngeal nerve of the rat, through the use of a cross-adaptation paradigm.

The glossopharyngeal nerve of adult male Sprague Dawley rats was prepared for whole-nerve multiple-unit recording as described by Frank (1965). The circumvallate papillae was stimulated. The control stimulus used was water; test stimuli were urea (0.01M, 0.03M, 0.1M 0.3M, 1M) and quinine hydrochloride (0.0001M, 0.0003M, 0.001M, 0.003M, 0.01M). In the initial experiments, the tongue was adapted with water (30 C) and was then stimulated with one of the two test stimuli. Concentration- response relationships were established for both test stimuli. Threshold concentrations were 0.0003M for QHCl and 0.1M for urea. In adaptation experiments, the tongue was adapted with QHCl (0.003M). The test solution used was urea (1M or 0.3M). After adaptation of the rat tongue to 0.003 QHCL, the response to 1M urea was attenuated but not completely abolished. The results can be interpreted in two ways: a) separate receptors for quinine or urea and b) one receptor site which is only partially adapted by quinine. Further experiments are needed.

388.3 AMILORIDE SENSITIVE SODIUM CHANNELS ARE REQUIRED FOR THE EXPRESSION OF SODIUM APPETITE IN THE RAT. C.J.Hennessy and I.L. Bernstein. Department of Psychology,University of Washington, Seattle, WA. 98195

Recent evidence indicates that the behavioral and electrophysiological response of the mammalian gustatory system to sodium chloride (NaCl) is dependent upon a Sodium (Na) transport system which is specifically blocked by the lingual application of the sodium transport blocker, amiloride. When rats are subjected to Na deficency they demonstrate avid ingestion of NaCl solutions, a response referred to as sodium appetite. Sodium appetite requires the recognition of solutions containing the sodium ion. The present study examined whether the expression of sodium appetite was dependent upon amiloride sensitive sodium channels in the rat.

Subjects were 8 male Long-Evans rats trained to drink from a spout by providing access to consecutive 2 minute presentations of water, 0.9% NaCl, and 10% sucrose under conditions of water deprivation until they reliably and consistently approached the tube and licked for the solutions presented. Individual licks were detected by photocell and recorded by microcomputer.

The effects of lingual amiloride on licking for 3% NaCl was first tested prior to induction of sodium appetite. Animals licked a 3% NaCl solution for 2 minutes after water or 100 uM amiloride hydrochloride exposure. Animals were then subjected to acute Na depletion by furosemide treatment (10 mg/Kg IP) along with maintenance on Na-free chow and distilled water and licking for 3% NaCl after either water or amiloride was again assessed.

The effects of exposure to amiloride on subsequent licking for 3% NaCl by rats were found to differ as a function of the animal's sodium balance. Licking for 3% NaCl was significantly increased in sodium replete and significantly decreased in sodium deplete rats by amiloride pretreatment. Expression of sodium appetite was virtually eliminated by pretreatment with amiloride. This suggests that the recognition of sodium solutions in animals with a sodium deficit is dependent on amiloride-sensitive sodium transport at the taste bud.

388.4 VOLTAGE-DEPENDENT AND CHEMICALLY-MODULATED IONIC CURRENTS IN ISOLATED TASTE RECEPTOR CELLS OF THE TIGER SALAMANDER. K. Sugimoto* and J.H. Teeter. Monell Chemical Senses Center and Department of Physiology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104.

In previous studies, we have shown that taste receptor cells isolated from larval tiger salamanders generate whole-cell currents exhibiting both inward and outward components in response to depolarizing voltage steps from a holding potential of -60 mV. Inward currents consisted of a transient component carried by Na^+ and, in some cells, a more slowly activating, persistent component, probably carried by Ca^{2+}. The outward currents were composed of at least two types of K^+ currents. In the present study, we have further characterized these voltage-dependent currents using single-channel recording techniques and examined the effects of taste stimuli on whole-cell currents and single-channel activity.

Taste receptor cells were dissociated from isolated pieces of lingual epithelium by treatment with a mixture of 0.5 mg/ml collagenase and 0.5 mg/ml hyaluronidase in low Ca^{2+} Ringer (20 min), followed by 4 min in Ca^{2+}-free Ringer containing 2 mM EGTA. Taste cells were collected in a pipette and plated on plastic culture dishes in Ringer containing (mM): 111 NaCl, 3 KCl, 5 $CaCl_2$, 3 HEPES and 2-glucose. The pipette solution contained (mM): 110 KCl, 2 $MgCl_2$, 1 $CaCl_2$, 2 EGTA, 10 HEPES and 2 ATP. Chemical stimuli were applied by pressure-ejection from micropipettes placed close to the cell or patch. In voltage-clamped taste cells, salts (500 mM NaCl, 120 mM KCl) and acids (1 mM acetic, 1 mM citric acid) elicited slow, inward currents which lasted as long as the stimulus was applied. The inward currents induced by NaCl were not suppressed by addition of 1 µM TTX to the stimulus solution and reversed at about + 20 mV. The inward currents evoked by KCl were not suppressed by 10 mM TEA and reversed at about 0 mV. The large voltage-dependent outward currents observed in most isolated taste cells were significantly reduced during stimulation with NaCl, KCl and acids. L-arginine and Na^+-glutamate (1-10 mM) both elicited small outward currents. In outside-out patches of taste cell membranes, voltage-dependent K^+-channels (blocked by 5 mM TEA and 5 mM $BaCl_2$ in the bath) were closed by application of 1 mM acetic acid.

These results suggest the presence of stimulus-activated cation channels in taste cell membranes and also indicate that some taste stimuli (e.g., acids and L-arginine) may modulate voltage-dependent channels. Further resolution of the ionic mechanisms involved in taste transduction will require selective stimulation of the apical (receptive) membranes of isolated cells.

388.5 CELL TYPES AND INTERCELLULAR CONNECTIVITY OF DYE-INJECTED TASTE CELLS OF NECTURUS MACULOUS R.J. Delay*, J. Yang*, and S. D. Roper Department of Anatomy, Colorado State University, Ft. Collins, CO 80523 and Rocky Mt. Taste & Smell Center, Denver, CO 80262.

Taste cells of Necturus are unusually large and thus are amenable to intracellular microelectrode studies. Yang and Roper (Soc. Neurosci. Abst. 12:1351,1986) found that 20% of the taste cells were elecrically-coupled, as revealed by dye couplings. However, there are several cell types within the mudpuppy taste bud and to date it has been extremely difficult to determine which cell types are electrically coupled. In addition, it has been difficult to correlate physiological responses with its taste cell type. To establish this correlation we impaled taste cells, recorded from them and then filled the cell with Lucifer Yellow.We have modifiated the technique described by Moranto (Science 217:952) to form an electon-dense reaction product visible at the electron microscope.

Lucifer Yellow was injected intracellularly into mudpuppy taste cells. Dye-filled single cells and coupled cells were then illuminated with UV light in the presence of diaminobenzidine (DAB) until a dark brown reaction product was formed. The tissues were then processed for electron microscopy. The reaction product formed an electron-dense product within the dye-injected cells that was visible in thin sections. The reaction product did not obscure the identifing granules of the Dark cells nor the smooth ER of the Light cells. It was possible to trace the torturous basal processes of dye-injected cells. Both Light and Dark cells reached the base of the taste bud and spines from the basal cells could be observed projecting into the cytoplasm of the injected cell. All the dye-coupled cells examined to date have been found to be Dark cells.

In the future this technique will allow us to determine more precisely the synaptic connectivity between taste cells, as well as between taste cells and nerve fibers more precisely and correlate ultrastructure with the physiological characteristics of the cells.

388.6 Characteriztion of a Taste-Stimulus Sensitive Adenylate Cyclase from the Gustatory Epithelium of the Channel Catfish, Ictalurus punctatus. D.L. Kalinoski, V. LaMorte* and J.G. Brand*. Monell Chemical Senses Center, Philadelphia, PA 19104, and Veterans Administration Medical Center, University of Pennsylvania, Philadelphia, PA 19104.

Adenylate cyclase activity has been reported in the gustatory systems of several species (Nomura, Olfaction and Taste, 7: 219, 1980) and has been suggested as a possible second messenger system for taste receptor transduction (Cagan, J. Neurosci. Res. 2: 363, 1976). Recently, the presence of GTP-binding regulatory proteins has been demonstrated in a purified plasma membrane fraction from catfish taste epithelium (Bruch and Kalinoski, J. Biol. Chem. 262: 2401, 1987), shown previously to contain receptors for taste stimuli (Cagan, Biochemistry of Taste and Olfaction, 175, 1981). With the present characterization of an adenylate cyclase system in catfish taste epithelia, the components of a G-protein mediated receptor-transduction process have been identified. We report here the initial characterization of adenylate cyclase activity in the sedimentable fraction (P2) from catfish taste epithelium. Taste epithelia exhibited low levels of adenylate cyclase activity, even in the presence of 1 mM isobutyl methyl xanthine, an inhibitor of cyclic nucleotide phosphodiesterase. Basal activity was stimulated approximately 3-fold by GTP, 8-fold by GppNHp and Forskolin and approximately 25-fold by GTP S. Sodium fluoride increased adenylate cyclase activity in a dose-dependent manner with 20 mM NaF yielding a maximal 10-fold stimulation of basal activity. Adenylate cyclase of Fraction P2 was sensitive to calcium ion. Addition of 0.63 mM $CaCl_2$ to the assay medium suppressed Forskolin activation of adenylate cyclase essentially to zero. Addition of 1 mM EGTA to Fraction P2 prepared in zero-calcium medium causes a 3-fold increase in unstimulated levels of cyclase activity. The taste stimulus L-alanine augmented adenylate cyclase activity in a dose-dependent manner. Stimulation of cyclase activity by low concentrations of L-alanine (0.5-4 uM) was more pronounced in the presence of GppNHp, suggesting a guanine nucleotide dependence for adenylate cyclase stimulation by amino acid taste stimuli. At all concentrations tested, GppNHp and L-alanine displayed a synergistic effect on cyclase activity. L-alanine stimulation of cyclase activity was affected by addition of EGTA or calcium ion. Addition of 1 mM EGTA increased basal and alanine-stimulated activity while addition of calcium ion inhibited amino acid stimulation. Thus, these data support a role for adenylate cyclase in the transduction pathway of the gustatory system and indicate that divalent cations act to regulate both basal and taste-stimulated adenylate cyclase activity.

388.7 RESPONSE PROPERTIES OF FACIAL LOBE SUBNUCLEI TO AMINO ACIDS IN THE CHANNEL CATFISH, ICTALURUS PUNCTATUS. T. Hayama and J. Caprio. Department of Zoology and Physiology, Louisiana State University, Baton Rouge, LA. 70803

The medullary facial lobes (FL) in freshwater channel catfish are the primary taste centers which receive facial nerve input in a somatotopical manner from taste and tactile neurons innervating the external body surface (1). The peripheral facial taste fibers respond best to either alanine or arginine among the amino acids tested (2). A preliminary report indicated that taste neurons in the FL of the same species also responded best to alanine or arginine (1). Previously, we reported that each FL of the channel catfish is divided into five subnuclei, each receiving input from one of the four barbels or the face-flank, respectively. We further showed that taste responses in three of the four barbel subnuclei are generally confined to dorsal areas, while tactile responses are observed throughout the subnuclei (3).

Presently we are examining the response specificity of taste neurons in the FL to amino acids and whether amino acid responses are differentially distributed. Single or multiunit activity in response to amino acid stimulation of three barbels (the medial and lateral mandibular, and the maxillary barbels) is recorded in the corresponding three subnuclei. Multiunit taste activity within the the three barbel subnuclei was greatest to alanine and/or arginine among the amino acids tested. Alanine and arginine responses were observed throughout the entire rostro-caudal extent of the dorsal part of the maxillary barbel subnucleus. The magnitude of the arginine responses ranged from ca. 0.5 to 1.5 times that of alanine responses. Some taste neurons showed suppressive responses to amino acid stimulation.

388.8 ULTRASTRUCTURE OF FACIAL NERVE TERMINALS WITHIN THE GUSTATORY LOBES OF THE CATFISH, ICTALURUS PUNCTATUS. M. Womble* and T.E. Finger (SPON: J. Kinnamon). Dept. Cellular & Structural Biol., U. Colo. Hlth. Sci. Ctr., Denver, CO 80262.

Previously (Finger & Womble, Abst. Soc. Neurosci., 1986), we demonstrated that two distinct types of primary afferent nerve terminals occur within the facial gustatory lobe of the channel catfish, Ictalurus punctatus. These terminal types include fine, vesicle-filled synaptic terminals and large (2-3 μm) bulbous processes replete with mitochondria, vesicles and accumulations of filaments. Since both trigeminal (general somatic) and facial (gustatory) nerve fibers are involved in innervating the barbels, and since both trigeminal and facial nerve fibers terminate within the facial lobe, each type of terminal, bulbous and fine, could have been associated uniquely, with one or the other cranial nerve. The present experiment was undertaken to test this hypothesis.

The body surface of catfish receives two types of innervation: general somatic, from the spinal nerves, and gustatory, from the facial nerve. The gustatory innervation to taste buds along the fish's flank is derived from the recurrent branch of the facial nerve. This branch is a pure facial nerve and contains no admixture of trigeminal or spinal components. Thus, we selected this nerve to fill peripherally with HRP. Following transganglionic transport of the enzyme, the brain was prepared for peroxidase EM-histochemistry. Both bulbous and fine terminal processes were labeled within the facial lobe. Thus, neither terminal type can uniquely be associated with trigeminal innervation of the barbels. Further, the general morphology of the recurrent nerve branch terminals was similar to that of terminals from the barbel nerves. Intriguingly, a common finding in these cases is the prevalence of specialized areas of contact between neighboring filled primary afferent fibers. These areas of contact involve relatively long (1-2 μm) regions of membrane specialization and often occur in association with the bulbous type ending. We have been unable to demonstrate an unequivocal synaptic contact, involving both presynaptic perimembrane vesicle accumulation, and postsynaptic membrane specialization, between two labeled processes. Many profiles, however, are suggestive of functional contact, e.g. presynaptic perimembrane vesicle accumulation, but details of the area of specialization are often obscured by the peroxidase reaction product. Thus, colloidal gold, immunocytochemical techniques will be used to identify labeled processes in future experiments.

388.9 ANATOMICAL AND ELECTROPHYSIOLOGICAL INVESTIGATION OF THE SUPERIOR SECONDARY GUSTATORY NUCLEUS OF THE JAPANESE SEA CATFISH. C. F. Lamb IV, T. Marui* and Y. Kasahara*. Dept. Oral Physiol., Kagoshima Univ. Dent. Sch., Kagoshima 890, Japan.

The superior secondary gustatory nucleus (nGS) of teleost fishes receives afferent fibers from the medullary taste centers, the facial (FL) and vagal (VL) lobes, and projects to the inferior lobe (LI) of the ventral diencephalon (Herrick, 1905). We used extracellular glass microelectrodes to study electrophysiological responses of nGS neurons of the Japanese sea catfish, Plotosus lineatus (=anguillaris), to mechanical and chemical stimulation of the external body surface and oropharyngeal cavity. HRP was iontophoretically injected into the nGS, as well as the FL, VL, and LI, to hodologically identify the connections of the nGS.

Responses of nGS neurons generally involved large receptive fields (RFs), including the whole body surface and oropharyngeal cavity. Restricted RFs were observed including only the ipsilateral barbels, but these neurons did not appear to be topographically arranged within the nGS. This is quite different from the FL of P. lineatus, where peripheral input is distinctly segregated into five somatotopically organized columns (Marui et al., submitted). Although mechanosensitive units were identifiable throughout the nGS, responses to amino acid solutions and to extracts of commercial feed were rarely encountered and were often unreproducible. This could result from the effects of capture and maintenance of the specimens, but the same recording techniques in the medullary taste centers produce readily identifiable, phasic chemoresponses. These results indicate a functional difference between the processing of information within the primary and secondary gustatory nuclei.

Results from HRP-labelling supported the electrophysiological results, showing overlapping bilateral termination within the nGS of FL and VL efferents. Restricted injections in the nGS typically retrogradely filled cell bodies in both the VL and several columns of the FL. HRP-labelled efferents from the nGS terminate ipsilaterally in the vicinity of the nucleus lobo-bulbaris (nLB), nucleus thalami posterioris (nTP), and nucleus diffusus lobi inferioris (nDLI). Reciprocal connections were found between the nLB/nTP and the VL, FL, and nGS. This provides an anatomical basis for a feedback system between the diencephalon and the primary and secondary gustatory nuclei.

388.10 GUSTATORY MODULATION OF OROMOTOR AND VISCEROMOTOR OUTPUTS IN THE CHANNEL CATFISH, ICTALURUS PUNCTATUS. J.S. Kanwal and T.E. Finger. Dept. of Cellular & Structural Biology, Univ. Colo. Hlth. Sci. Ctr., Denver, CO 80262.

Most animals utilize the gustatory sense to discriminate food from non-food prior to ingestion. Various behavioral and physiological responses to gustatory stimuli suggest the presence of relatively direct, sensorimotor interconnections between the gustatory system and the visceral motor systems within the medulla. We tested this hypothesis by recording from vagal motor neurons while applying taste and tactile stimuli to the oral and extra-oral epithelium of the channel catfish, Ictalurus punctatus. We observed gustatory-related changes in the electrophysiological activity of these motor neurons; this implies that taste and tactile information can modulate visceral functions.

Juvenile channel catfish, obtained locally, were paralysed by an intramuscular injection of Flaxedil and anaesthetized by local application of Xylocaine prior to surgery. Neural recordings from vagal motor neurons were obtained centrally with glass microelectrodes (impedance <1 Mohm; tip diameter, approx. 1 um) or peripherally by means of a silver wire hook electrode on which the central cut end of a branchial or coelomic branch of the vagus nerve was placed. The visceral motor column in ictalurid catfish is morphologically divisible into a lateral vagal motor column (LMC, = nucleus ambiguus of mammals) which innervates orobranchial musculature, and a medial vagal motor column (MMC, = dorsal motor nucleus X of mammals) which innervates coelomic viscera. Neurons in the LMC exhibited rhythmic patterns of activity which were only transiently excited or inhibited by taste and tactile stimulation of oral and peri-oral regions. Liver extract and high concentrations ($>10^{-2}$ M) of amino acid mixtures (alanine, arginine, and proline) were effective stimuli when applied to the oral and extra-oral surfaces, while responses to quinine ($>10^{-3}$ M) were obtained only for oral stimulation. Taste and touch sensitive neurons in the MMC responded differentially to stimulus application over separate areas extending bilaterally from the lips to the caudal flank. Response patterns similar to those of both populations of vagal motoneurons also were obtained from cells in the reticular formation at the level of the facial lobe. The present electrophysiological data, thus indicate medullary convergence of orofacial taste and tactile inputs onto neurons of the visceral motor column. Neuroanatomical tracing experiments, currently in progress, will elucidate further the gustatoreticular pathways mediating orovisceral changes observed at the behavioral and physiological levels.

388.11 AFFERENT CONNECTIONS OF THE CAUDOLATERAL ORBITOFRONTAL CORTEX TASTE AREA OF THE PRIMATE. Leslie L. Wiggins, Edmund T. Rolls and Gordon C. Baylis, University of Oxford, Department of Experimental Psychology, Oxford OX1 3UD, England

A cortical taste region has recently been identified in the caudo-lateral orbitofrontal cortex of the primate (Rolls, E.T., Yaxley, S., Sienkiewicz, Z.J. and Scott,T.R. (1985) Chemical Senses 10: 443.). In this area, single neurons are sharply tuned to gustatory stimuli, and are influenced by the motivational state of the monkey. In order to determine the afferents to this region of taste cortex, and to determine whether it is a primary, secondary, or tertiary region of cortical taste processing, injections of WGA-HRP for retrograde neuronal tracing were made into this region in three monkeys in which the exact location of this cortical taste region had been identified by recordings of the activity of single neurons. Labelled cell bodies were found in the frontal opercular taste cortex and in the insular taste cortex, both of which are primary taste cortices in that they receive from the thalamic taste nucleus, VPMpc. Further, the caudolateral orbitofrontal cortex taste area did not receive inputs from VPMpc, but instead received projections from the mediodorsal nucleus of the thalamus, the thalamic nucleus which projects to the prefrontal cortex. These results show that the caudolateral orbitofrontal taste cortex is a secondary taste cortical area, and that it receives gustatory inputs from the frontal opercular and insular taste cortices. Afferents were also shown to reach the caudolateral orbitofrontal taste cortex from the more ventral part of the rostral insular cortex, the amygdala, the substantia innominata, the rhinal sulcus, and from the surrounding orbitofrontal cortex. Through some of these pathways visceral information important in modulation of responsiveness by motivational state may reach the caudolateral orbitofrontal taste cortex.

388.12 PERIRECEPTOR EVENTS IN PURINERGIC CHEMORECEPTION BY THE SPINY LOBSTER. H. G. Trapido-Rosenthal, R. A. Gleeson* and W. E. S. Carr*. C. V. Whitney Lab. and Dept. of Zoology, University of Florida, St. Augustine, FL 32086.

Chemosensory transduction is initiated by the interaction of odorant molecules with receptors present on the plasma membranes of chemosensory neurons. Odorant molecules are affected by a variety of events that can directly influence their ability to interact with these receptors; such processes have been termed perireceptor events (Getchell et al., Prog. Neurobiol., 23:317, 1984). We describe here our studies of perireceptor events in purinergic chemoreception by the spiny lobster, Panulirus argus.

The olfactory organ of P. argus consists of a group of aesthetasc sensilla present on the antennule of this marine invertebrate. Each sensillum consists of a chitinous sheath, permeable to odorants, that encloses a volume of approximately 250 picoliters; within this sheath are densely packed dendrites of about 320 primary chemosensory neurons. Electrophysiological data indicate that many of the neurons are differentially excited by purine nucleotides (AMP, ADP, and ATP) when these compounds are present in seawater bathing the sensilla. Responses of the neurons sensitive to purine nucleotides are mediated by several classes of purinergic receptors with different ligand specificities. Adenosine (Ado) is only slightly stimulatory to these neurons.

Biochemical studies have shown that the aesthetasc sensilla contain ectonucleotidases that dephosphorylate the stimulatory purine nucleotides, generating the much less active nucleoside Ado; Ado is then specifically taken up into an intracellular compartment. The best characterized of these dephosphorylating enzymes is the 5'-ectonucleotidase which converts AMP to Ado; this enzyme has characteristics similar to those of ectonucleotidases on membrane surfaces of mammalian cells. It is characterized by a Km of 23 μM, and a Vmax of 89 pmoles/sensillum/second. It is inhibited by ADP and the poorly hydrolyzable ADP analog α,β-methylene ADP (AMPCP). The kinetics of this enzymatic activity are such that a micromolar concentration of AMP in a sensillum is reduced by a factor of 10 in 153 milliseconds. The electrophysiological response of AMP-sensitive chemosensory cells decays in a manner that is consistent with the hypothesis that signal molecules (AMP) are rapidly converted to non-signal molecules (Ado) by this enzymatic activity. The inhibition of 5'-ectonucleotidase activity by ADP or AMPCP can lead to a potentiation of the response of AMP-sensitive cells to this nucleotide. These results indicate that perireceptor events can make a direct and quantifiable contribution to the chemosensory process.

388.13 INTRACELLULAR STUDIES OF THE IONIC DEPENDENCY OF THE LOBSTER'S OLFACTORY RECEPTOR POTENTIAL. Ingrid Schmiedel-Jakob*, Peter A. V. Anderson and Barry W. Ache*. (SPON: J. Tautz). Whitney Lab. University of Florida, St. Augustine, FL 32086

The olfactory organ of the spiny lobster, Panulirus argus, consists of tufts of hair-like sensillae, which are innervated by bipolar neurons. The somata of the neurons are gathered in clusters at the base of each sensilla and their dendrites project into the lumen. Using the whole-cell configuration of the patch-clamp technique we have made intracellular, current clamp recordings from these receptor cells in situ. These cells have high input impedances, 4.87 (± 1.6 s.e.m.) Gohm, and long time constants (19.5 ± 5.7 ms).

Application of a chemical stimulus (individual and mixed amino acids, or extract of fish food) to the sensillae evoked a slow depolarization which reached peak amplitude in 60-300 ms. The amplitude of this depolarization was dose-dependent and linearly related to the log of stimulus concentration. With some cells chemically evoked depolarizations were associated with a decrease in conductance (up to 40%) while with others an initial increase in conductance was followed by a decrease. Depolarizations produced by current injection alone were associated only with a conductance increase.

To identify the ionic basis of this receptor potential the ionic composition of the medium surrounding the sensillae was changed. When external Na^+ was reduced from 480 mM to 48 mM by substitution with choline or TMA the receptor potential in some cells was eliminated or reduced. The effect was reversible and recovery occurred within 6 min. These Na^+-dependent receptor potentials were TTX-insensitive at concentrations where superimposed action potentials were blocked. Reducing $[K^+]_o$ from 13.4 mM to 1.4 mM led to the elimination or a reduction of the receptor potential in some cells. A similar effect was observed when $[Ca^{++}]_o$ was reduced. Both effects were reversible. On occasions, the receptor potential was reduced or eliminated by the presence of external Cs^+ ions, suggesting that voltage-sensitive K^+-currents may be involved in the transductory process.

The results suggest that at least three different ions, Na^+, K^+, and Ca^{++}, contribute to the generation of the receptor potential, and that the permeability changes evoked by chemical stimulation occur on the dendritic portion of the olfactory neurons.

Supported by NSF Grant BNS 85-11256 and a grant from the Whitehall Foundation

388.14 CATION-SELECTIVE ION CHANNELS FROM PRIMARY OLFACTORY RECEPTOR NEURONS OF THE SPINY LOBSTER. T. S. McClintock* and B. W. Ache*. (SPON: C. Leonard). C. V. Whitney Lab. and Depts. of Zoology and Neuroscience, University of Florida, St. Augustine, FL 32086.

Single-channel recording from the primary olfactory neurons of the lobster, Panulirus argus, reveals cation-selective channels on the neurons' somata. Because recent morphological evidence has suggested that the extreme length and small diameter of the branching dendritic process of this neuron might prohibit effective passive spread of a receptor potential (Grunert, U. and Ache, B. W., submitted to Cell Tiss. Res.), we are interested in possible alternative mechanisms of receptor potential propagation. These cation-selective channels have properties which would allow them to aid the spread of a receptor potential.

In inside-out patches, a 320 pS channel is observed which has a Na+/K+ permeability ratio of 1.28. Outward currents through this channel show a rapid, flickering block when 20 mM or 50 mM tetraethylammonium is applied to its intracellular side. The percent of time it spends in the open state is independent of bath calcium concentrations from 0.1 mM to 0.1 nM. The apparent gating chrge of 1.1 reflects the weak voltage dependency of this channel. At -60 mV holding potential, the channel appears to have a single open state with a mean open time of 4.9 msec.

Curiously, we never observe this 320 pS conductance in cell-attached patches. Many of these channels, however, are present in patches excised from cell-attached patches which contained 100 pS channels. This 100 pS channel is present with either KCl or NaCl solutions in the pipette and reversal potentials extrapolated from current-voltage relationships also suggest that it is cation-selective. It is characterized by short openings activated by steps from -60 mV to potentials of -40 mV or more. It inactivates only slowly, if at all, and appears to be weakly voltage dependent. We have never observed the 100 pS conductance in inside-out patches, allowing that both cation-selective conductances may be from the same channel.

We hypothesize that the role of this cation-selective channel, or channels, is to aid in the spread of the odor-stimulated receptor potential. The weak voltage dependency would be necessary to allow the graded nature of the receptor potential to be faithfully transmitted to the spike generating zone, presumably near the somatic-axonal junction.

388.15 NEURAL CODING OF QUALITY OF STIMULI BY THE OLFACTORY RECEPTOR CELLS IN THE SPINY LOBSTER: TOWARDS A UNIFIED MODEL. M.-N. Girardot and C.D. Derby. Department of Biology, Georgia State University, Atlanta, GA 30303.

Behavioral studies show that the spiny lobster, Panulirus argus, discriminates between food-related chemicals, whether of simple composition such as amino acids or nucleotides, or of a complex chemical nature (Daniel and Derby, Fine-Levy and Derby, AChemS Abstracts, 1987). The search for the physiological correlate of this discrimination using multivariate techniques provided evidence that the neural code is the pattern of responses generated by the entire population of chemoreceptors (ANP). This was true whether the stimuli used were of simple chemical nature, such as taurine, betaine, glutamate, glycine and adenosine-5'-monophosphate, or of highly complex composition (artificial mixtures based on the chemical composition of extracts of crab, mullet, oyster and shrimp, which varied only in terms of the relative quantitative contribution of the components). However, when the set of single components was used to stimulate the receptor cells, the resulting cell specificity was high (mean H values, index of breadth of responsiveness = .29), suggesting that the olfactory receptor cells are narrowly tuned and that quality discrimination among types of chemicals results from specific activity in well-defined groups, or types, of cells (Derby and Ache, 1984). While, when the chemicals used were the artificial mixtures, the cells were broadly tuned to the stimuli, revealing a lack of cell specificity (mean H value = .92), and the results failed to provide evidence that discrimination among chemicals results from the specific activation of well-defined types of cells with identical intertype across-stimuli pattern of responses. Various analytical techniques, including multidimensional scaling, will be used in an attempt to provide a unified model for chemodiscrimination by the olfactory receptor cells that will account for the findings resulting from the use of both simple and complex chemical stimuli.

388.16 SPATIAL-TEMPORAL FILTERING IN OLFACTORY CHEMORECEPTOR CELLS. R. Voigt* and J. Atema. (Boston University Marine Program, Marine Biological Laboratory, Woods Hole, MA 02543).

The lateral antennular flagellum of the American lobster functions as an olfactory organ, and is of critical importance for orientation in odor plumes. Intermittent sampling by flicking the antennules and the patchy nature of odor plumes make it likely that the receptor cells of this organ detect pulsed stimuli in a chemically noisy background. A major cell population of these receptors is narrowly tuned to taurine. We have started to characterize the time courses of adaptation and disadaptation of receptor cells using a series of standard 1s stimulus pulses with varying signal-to-noise ratios (SNR).

The temporal stimulus pulse profile was determined by measuring the change of conductivity of flowing deionized water (20 ml/min) after injection of 100 ul of 1M NaCl solution over 300 ms. The stimulus chamber allowed 5s interpulse intervals without interference from the previous stimulus. Single cells were identified electrophysiologically with 10^{-4}M taurine. A series of five pulses was applied in 10s intervals for one of several concentrations (10^{-3}-10^{-6}M) in different backgrounds (10^{-4}-10^{-7}M). Combinations of stimulus and noise background concentrations provided similar SNR at different absolute stimulus concentrations and vice versa.

The results suggest that regardless of the background noise levels the same SNR resulted in similar responses, including similar cumulative adaptation. Greater SNR caused stronger responses and showed greater cumulative adaptation while smaller SNR caused weaker responses and less adaptation. Thus, SNR ratios and not absolute stimulus levels were predictive of the responses of receptor cells in different backgrounds. This feature predisposes the receptor cells to extract information on spatio-temporal fine structure of odor plumes and not on the time-averaged concentration gradients.

388.17 RESPONSE SPECTRA OF MEDIAL ANTENNULAR CHEMORECEPTORS IN THE AMERICAN LOBSTER. Ann Jane Tierney, Rainer Voigt, Bruce R. Johnson and Jelle Atema. Boston Univ. Marine Program, Marine Biological Laboratory, Woods Hole, MA 02543.

The biramus antennules of decapod crustaceans are olfactory organs which mediate orientation to odor sources. Most physiological studies have focused on the lateral filament which bears chemoreceptive aesthetasc hairs. Cells from this filament are sensitive to low molecular weight compounds, particularly amino acids, and most are narrowly tuned to single compounds (Shepheard, P., Mar. Behav. Physiol., 2:261, 1974; Johnson, B.R. and Atema, J., Neurosci. Letts. 41:145, 1983). The medial filament is also chemosensory (Fuzessery, Z.M., Comp. Biochem. Physiol., 60:303, 1978). However, little is known about the response spectra or tuning properties of individual cells from this organ. In this study we determined the response specificity and sensitivity of medial antennular chemoreceptors to 15 compounds presented singly and within a mixture.

A suction electrode was used to record extracellular activity from small bundles of nerve in ablated medial antennular filaments. Chemosensitive cells were identified with a mixture of the following 15 compounds, all at an injected concentration of 10^{-4}: L-alanine, L-arginine, L-asparagine, L-aspartate, betaine, L-glutamate, L-glutamine, glycine, L-histidine, hydroxy-L-proline, L-leucine, L-lysine, ammonium chloride, L-proline and taurine. These compounds were then tested singly at 10^{-4} to determine the response spectra for individual cells. Injected concentrations were diluted to approximately $7x10^{-6}$ after introduction to the test chamber.

The best stimuli for the medial filament cells included taurine, hydroxyproline, betaine and ammonium chloride, which are also the most effective stimuli for lateral filament chemoreceptors. A significant population of arginine-best cells was also found. Most cells were narrowly tuned to single compounds, but some had a broader response spectrum. Broadly tuned cells which responded best to hydroxyproline, taurine, betaine or ammonium chloride were variably responsive to other compounds, with no consistent second best stimulus. In contrast, arginine-best cells consistently had leucine as the second best compound and lysine as the third best compound. As in lateral filament receptors, mixture suppression was common. In most cells responses to stimulatory compounds presented alone was clearly greater than responses to the same compounds presented in the mixture.

This work was supported by grants from NSF (BNS 85-12585) and the Whitehall Foundation.

388.18 MORPHOLOGICAL AND PHYSIOLOGICAL CHARACTERIZATION OF INDIVIDUAL OLFACTORY INTERNEURONS CONNECTING THE BRAIN AND MEDULLA TERMINALIS OF THE CRAYFISH. C.D. Derby and D. Blaustein*. Department of Biology, Georgia State University, Atlanta, Georgia 30303.

Toward understanding the functional organization of the crustacean olfactory system, we are using intracellular, dye-filled microelectrodes to correlate the structure and function of single, odorant-sensitive interneurons in the brain of the crayfish Procambarus clarkii. We report on a subset of interneurons that connect the brain proper with the medulla terminalis, a higher-order integrative center located in the eyestalk. All of the interneurons recorded in this study are assumed to be at least second-order olfactory interneurons, because they do not branch in the olfactory lobe, the neuropile to which primary olfactory receptor cells of the antennules project. The parolfactory lobe probably represents a low- or mid-order chemosensory or multimodal integrative center, since it contains chemosensory or multimodal interneurons that directly output to the medulla terminalis. Areas of the medulla terminalis shown definitively to be involved in integrating olfactory or multimodal (including olfactory) information are neuropile regions III, VI, and XII, and soma clusters D and E). The medullae terminales are connected directly to the nerve cord by chemosensitive interneurons. Morphologically complex interneurons (defined by laterality of branching) were more likely to have complex response characteristics (defined by modal sensitivity). For example, bilateral interneurons were all found to be multimodal (odorants, touch, chemicals), while unilateral interneurons could be either uni-, bi-, or multimodal. Higher-order olfactory interneurons (with soma in the medulla terminalis) showed the most complex response profiles, being multimodally sensitive and having "mixed" responses (e.g., excited by odorants but inhibited by touch and/or light). This correlation indicates that such higher-order interneurons may function in multimodal processing and feature detection in a manner qualitatively different than do lower-order interneurons. The diversity of structural and functional classes of interneurons in the eyestalk nerve indicates that chemosensory and other information is transmitted and processed at this level by parallel arrays of neurons.

388PO EFFECTS OF UNILATERAL NARIS CLOSURE ON THE OLFACTORY EPITHELIA OF ADULT MICE. J.A. Maruniak* and P.J. Lin.* (SPON: W.S. Stark). Biological Sciences, University of Missouri, Columbia, MO 65211.

This study investigated the effects of unilateral naris closure in adult mice on the histology of the bilateral olfactory epithelia, turnover rates of their receptor neurons, and production of olfactory marker protein (OMP). Adult mice at least 6 months old had either their right or left naris closed by cautery and apposition of the burned areas with 7-0 suture. Controls were untreated. Groups had their nares closed for 1, 3, 6, 8, or 12 weeks.

Our general procedure was to assess: 1) turnover rates, using on-the-slide autoradiography of the sectioned epithelia of mice that had been injected with tritiated thymidine; 2) histology, using H &E stained paraffin sections; and 3) presence and maturational state of the olfactory receptor neurons, using immunohistochemistry for OMP.

In the control group and 3 groups with unilateral closure for 6 weeks or less, no differences could be detected between the 2 sides of the nose in any of the histological or immunohistochemical parameters. In mice with naris closure for 8 or 12 weeks, there were time-dependent differences in both the histology and immunohistochemistry of the 2 sides. The olfactory epithelia on the closed sides displayed no detectable abnormalities compared to controls, but the open sides showed varying degrees of degenerative changes. Beginning after 8 weeks of closure, losses of olfactory receptor neurons could be observed on the open side in most of the mice. Particularly within the 12 week group, there was a range of responses such that in about half of the mice there were minor to almost no losses of receptor neurons on the open side while in the other half there were moderate to virtually complete losses of olfactory receptor neurons.

Data from the tritiated thymidine studies of turnover rates indicated no significant differences in turnover between the 2 sides. This suggested that losses of cells on the open sides were caused by the inability of a more or less constant rate of turnover to compensate for a greater than normal rate of receptor neuron loss.

389.1 IMMUNOCHEMICAL DETECTION OF CAPSAICIN CONGENERS
J.N. Wood, I.F. James, K.J. Masdin*, C. Walpole*, A. Dray and P.R. Coote*. Sandoz Institute for Medical Research, 5 Gower Place, London WC1E 6BN.

Capsaicin (8-methyl N-vanillyl 6-noneamide) is a pungent component of red peppers, which exerts excitatory and toxic actions on a subset of sensory neurones. The strict cellular specificity of capsaicin, together with the well defined structural requirements for activity revealed by an analysis of a series of capsaicin congeners (Szolscanyi and Jancso-Gabor, Arz-Forsch, 25, 1877, 1975) are consistent with the existence of a specific capsaicin receptor. No direct evidence for such a receptor or an endogenous capsaicin-like ligand exists. To help define the putative capsaicin receptor and endogenous capsaicin-like ligands, specific anti-capsaicin antisera have been used to;

1) screen for endogenous capsaicin-like immunoreactive material
2) produce anti-idiotypic antisera which may define a capsaicin receptor
3) detect capsaicin-like photoaffinity probes coupled to proteins and lipids.

8-amino-octylvanillylamine was covalently coupled to thyroglobulin with glutaraldehyde, emulsified with Freunds adjuvant and used to immunise rabbits. Experiments described here were all carried out with a single serum sample from one rabbit. The specificity of the serum was assessed in a competition radioimmunoassay using reductively tritiated dihydrocapsaicin (specific activity 60 Ci/mMol, Amersham). The structural requirements for recognition by the serum lay in the vanillylamine ring and amide bond region with a less stringent requirement for an aliphatic side chain. The serum was highly specific, failing to recognise molecules such as vanillylamine and 3-methoxytyramine which are structurally similar to capsaicin. The detection limit of the assay was 1pmol of capsaicin-like immunoreactive material.

Analysis of inflammed and normal rat and mouse tissue extracts failed to reveal the presence of endogenous capsaicin-like immunoreactive material.

Affinity purified $F(ab)_2$ anti-capsaicin antibodies have been used to generate rabbit anti-idiotypic antisera, which are weak antagonists in a capsaicin-stimulated calcium accumulation assay in rat DRG neurones in culture. Proteins labelled with the photoaffinity probe N-(4-hydroxy, 3 methoxy benzyl)-4'azidophenyl-propionamide, which shows capsaicin-like activity on rat DRG neurones in culture, could be detected with the antiserum on dot blots with a sensitivity limit of 10fmol. A Western and TLC immunoblot analysis of photaffinity labelled rat DRG neurones in culture reveals a number of immunoreactive molecules.

389.2 SENSORY CHARACTERISTICS OF HISTAMINE-INDUCED EXPERIMENTAL ITCH.
A. C. Brown and S. T. Denman*. Oregon Health Sciences University, Portland, Oregon, 97201.

The purpose of this work was to examine the sensory response to controlled patterns of histamine application to skin in normal young adult human volunteers. An area of approximately 0.4 sq cm was lightly stripped by repeated application of adhesive film. Histamine phosphate (HP) dissolved in buffered physiological saline, pH 7.30, was applied to the stripped region using a special perfusion chamber and control system ("pruritometer") which permitted application of any desired concentration pattern. Subjects reported verbally itch intensity at 10 second intervals using a numerical 0-10 analog scale, with 0 = no sensation, and 10 = most intense itch imaginable. Using a ramp concentration pattern, itch threshold averaged 0.159 ± 0.041 mM HP over all subjects tested. Itch intensity increased with increasing HP concentration; at the highest concentration used here, approximately twice threshold, the maximum response was "5". Upon application of a suprathreshold step function stimulus, the typical response pattern was a 40 second delay before the subject reported any sensation, an increase in sensation intensity to maximum over the next 30 seconds, followed by spontaneous adaptation to a lower itch intensity during the following 100 seconds even though HP concentration was held constant. Subsequent perfusion with control solution followed several minutes later by reapplication of HP demonstrated that histamine sensitivity remained low. Sensory evaluation of the test patch immediately following the experiment indicated that subjects retained normal sensitivity to sharp prick (pain), but often had reduced sensitivity to touch-pressure, compared to surrounding control skin. We conclude the following: (1) The "pruritometer" is a useful instrument for investigation of the psychophysics of itch; (2) HP-induced experimental itch differs from natural itch, since the former is characterized by adaptation while the latter is not. (3) Our finding that cutaneous HP application results in eventual reduction of itch sensitivity while pain sensitivity remains normal is surprising, since pain and itch are assumed to be closely related. (Supported by NIH grant NS 22594.)

389.3 STIMULATION OF NASAL TRIGEMINAL RECEPTORS WITH NICOTINE AND TOLUENE.
W.L. Silver and D.B. Walker*. Dept. of Biology, Wake Forest University, Winston-Salem, NC 27109.

Trigeminal receptors in the nasal cavity respond to a variety of chemical stimuli. Although some of these stimuli appear to be non-irritating, trigeminal chemoreception is often considered a part of the common chemical sense whose primary function is to elicit protective reflexes when stimulated with irritating compounds. Compared to olfaction, however, there is still relatively little quantitative information available about the kinds and concentrations of chemical compounds which are effective trigeminal stimuli. In the present experiment we examined the effectiveness of two potential environmental irritants, nicotine (NI) and toluene (TO) as trigeminal stimuli. Multiunit activity was obtained from the ethmoid branch of the rat trigeminal nerve. Respiration was monitored via a thermistor wire placed into a tracheal cannula. Stimuli were delivered in the vapor phase via a microprocessor controlled, air-dilution olfactometer. Dilution ratios were controlled by electronic mass flow controllers. Concentration-response curves and thresholds (defined as the concentration which first elicited a response discernible from baseline) were obtained from 8 rats. The response to NI differed from responses to TO (and other compounds) in that it only gradually returned to baseline. Thresholds for NI and TO were approximately 4 and 2400 ppm, respectively. Respiration was affected at concentrations as low as 7 ppm for NI and 2400 ppm for TO. These results demonstrate that NI and TO are effective in eliciting neural responses from the rat trigeminal nerve. Whether or not they function as sensory irritants in the environment obviously depends on their concentration in the environment and the sensitivity of the organism.

389.4 AN *IN VITRO* NEURAL NETWORK MODEL OF THE OLFACTORY SYSTEM.
S.P. Fracek, Jr., G.W. Gross and R. Schafer, North Texas State University, Denton, TX 76203.

Mouse embyronic olfactory tissues are being used to to develop an *in vitro* model of information processing. Our goal is to create a tissue culture-based system that responds to natural stimuli and processes stimulus information. The olfactory system offers certain advantages. Both the olfactory neuroepithelium (which detects odors) and the olfactory bulb (where information processing occurs) are anatomically distinct and can easily be removed and cultured. Unlike other neurons, the olfactory receptor cells constantly develop from basal cells, mature, and become functional when their axons form synapses with mitral cells of the olfactory bulb. Thus, it is potentially possible to construct an "artificial nose" consisting of tissue explants of olfactory epithelium, whose axons synapse with mitral cells from cultured disassociated olfactory bulbs. Although the three dimensional structure of the olfactory epithelium and bulb is lost along with most of the normal inputs and outputs of the system, it is hoped that this system will mimic in some respects the natural process. This "artificial nose" can be used to examine the processes of information processing and storage; chemical, electrophysiological, pharmacological, and morphological manipulations are possible. A functional system will allow testing of mathematical models of information processing, such as the Hopfield model.

Several concurrent projects involving microelectronic technology and computer hardware and software will permit full analysis of the "artificial nose." Tissues are currently being cultured on multimicroelectrode plates (MMEPs). MMEPs have 36 or 64 photoetched transparent indium-tin oxide electrodes in a 6X6 or 8X8 array. The surface of the MMEP has been modified to allow cell adhesion and growth. We are designing a recording chamber that maintains sterility, pH, osmolarity, and temperature during recording as well as the introduction of pharmacological agents and odorants. A multichannel amplifier system allows us to simultaneously examine all the channels for activity. We are developing a data analysis system that will allow simultaneous recording and data analysis of 32 channels (generally not all of the electrodes are active) on a MassComp 5700.

The project is divided into two phases. Phase one is the analysis of the olfactory bulb cultures. The data indicate that olfactory bulb neurons form active neural networks in culture with single- and multiunits having tonic and phasic activity. This type of activity including rhythemic bursting is also seen in cultured spinal cord cell networks, although, in general, the activity of olfactory bulb cultures is higher than spinal cord cultures. Although we have yet to fully characterize the olfactory bulb neural network, we have embarked on phase two, which is the addition of tissue explants of olfactory neuroepithelium to a functioning olfactory bulb neural network.

389.5 CONSTRUCTION OF A RAT OLFACTORY NEURONAL CELL LINE. P. Hen,*[1] J. Dodd,[2] C. Cepko*[3] and R. Axel*[1] (SPON: P. Bovolenta). [1]Howard Hughes Medical Institute and [2]Department of Physiology, Columbia University College of Physicians and Surgeons, New York, NY 10032; [3]Department of Genetics, Harvard Medical School, Cambridge, MA 02115.

Olfaction in vertebrates is thought to be mediated by specific odorant receptors located on sensory neurons within the olfactory epithelium. The population of olfactory neurons is renewed throughout life by the differentiation of continually dividing basal cells. In order to study the cellular and molecular events underlying the transduction of olfactory information, we wish to obtain immortal cell lines capable of differentiating into mature olfactory neurons in cell culture. To this end, partially dissociated olfactory epithelia of young rats were exposed to recombinant retrovirus containing the immortalizing oncogene E1A of adenovirus 2, together with the neo R gene which confers resistance to the antibiotic G418. Transformed olfactory epithelial cells resistant to antibiotic were then examined for the expression of olfactory neuron markers. One clone, 13S.1, contained a subset of cells exhibiting a bipolar morphology and reactive with a number of antibodies which label carbohydrate determinants selectively expressed by olfactory neurons in vivo.

When 13S.1 cells were grown on a monolayer of cerebral cortex primary astrocytes, most of the cells extended long bipolar processes and over 50% of these cells expressed olfactory marker protein (OMP), a cytoplasmic protein found exclusively in mature olfactory neurons. These studies suggest that we have constructed an immortal olfactory neuroblast cell line which, upon exposure to astrocytes, undergoes differentiation to express a variety of properties characteristic of a mature olfactory sensory neuron. We are currently examining the response of these cells to odorants. The expression of odorant receptors by 13S.1 cells would support the use of this line as a homogeneous in vitro system with which to examine the molecular and cellular mechanisms of olfaction.

389.6 **A BOVINE OLFACTORY CILIA PREPARATION: SPECIFIC TRANSMEMBRANE GLYCOPROTEINS AND PHOSPHOPROTEINS.** **Rita Kropf*†, Doron Lancet, and Daniel Lazard*. Dept. of Membrane Research, the Weizmann Institute, Rehovot, Israel; †now at Dept. of Chemistry, Amherst College, Amherst MA 01002, USA.**

We have obtained cilia preparations from cow olfactory and respiratory epithelia, using the calcium shock technique previously used for rat and frog. The bovine preparation is advantageous because relatively large amounts of starting material are available, and because it allows one to make a clear distinction between olfactory and control nasal respiratory epithelia. The SDS polyacrylamide gel electrophoresis polypeptide patterns show a remarkable similarity between olfactory and respiratory cilia preparations. The glycoprotein pattern visualized by ^{125}I-Concanavalin A overlays is also very similar for both, including a common 85 kDalton glycoprotein previously thought to be homologous to frog gp95 (Chen et al., J. Biol. Chem. 261:1299, 1986). A notable exception is a prominent glycoprotein at 56 kDalton (gp56) which is found in olfactory, but not in respiratory cilia. gp56 behaves as a transmembrane glycoprotein in Triton X-114 and pH 11.3 extractions. A polypeptide with almost identical properties is also seen in a rat olfactory cilia preparation. Protein gp56 is thus an interesting mammalian olfactory receptor candidate, similar to the frog ciliary glycoprotein gp95. Efforts are now under way to purify it and study its possible function.

The olfactory cilia preparation in cow has a relatively low specific activity of adenylate cyclase, compared to that in rat and frog. Thus the background level of cAMP-dependent protein kinase (PK-A) activity is diminished, and the study of specific substrates for this enzyme is facilitated. We have identified cAMP-regulated phosphoproteins at 24, 40, 52 and 57 kDalton. For phosphoprotein 57 (pp57) [^{32}P]-phosphate incorporation decreased with added cAMP, and this polypeptide is tentatively identified as type 2 regulatory subunit of PK-A. The phosphorylation of the other three polypeptides markedly increased with cAMP addition. Phosphoprotein 52 (pp52) was notable in being both olfactory cilia-specific (compared with control respiratory cilia and deciliated olfactory epithelial membranes), and in behaving as a transmembrane protein in Triton X-114 extraction. Phosphoprotein 40 (pp40) is near to but does not comigrate with rat olfactory G_s α chain. Phosphoprotein 24 (pp24) may be akin to a similar cAMP-regulated phosphoprotein in frog (Heldman et al., J. Neurochem. 47:1527, 1986) and rat olfactory cilia. The role of these phosphoproteins in olfactory adaptation is being investigated (Pace et al., Neurosci. Soc. Abst. 13:000, 1987).

389.7 DEVELOPMENTALLY REGULATED EXPRESSION IN OLFACTORY STRUCTURES OF REACTIVITY TO A MONOCLONAL ANTIBODY AGAINST FETAL OLFACTORY EPITHELIA. V.McM.Carr and A.I.Farbman.Dept. of Neurobiol. & Physiol., Northwestern Univ., Evanston, IL 60201.

The Mab 1 A-6 was initially raised in mice against fetal rat olfactory epithelia. 1 A-6 reactivity was examined in embryonic and neonatal rats using immunohistological techniques at light and electron microscopic levels. In the olfactory epithelia (OE) 1 A-6 reactivity appeared at the luminal surface of the nasal cavity. The intensity of this reactivity increased to a peak at E19 and then declined. Its initial appearance was quite early, at embryonic day 14 (E14). This luminal reactivity occurred on the surface membranes, microvilli, and cilia of olfactory dendritic knobs and supporting cells. Reactivity was also present in the respiratory epithelia (RE), as a punctate staining of some cell surfaces and the basal membrane. In both the OE and RE reactivity through at least E19 was noticeably greater on the medial than on the lateral walls of the nasal cavity.

In the olfactory bulb (OB) 1 A-6 reactivity also first appeared at E14. This initial OB reactivity was confined to the ventrolateral wall of the rostral cerebral vesicles, the site of the developing OBs. Little or no reactivity was present in the medial or dorsal walls. The most intense staining in the lateral wall was associated with radial processes that traverse the entire thickness of the wall. By the following day (E15), however, these reactive processes disappeared, and only short lengths of randomly oriented fibers showed reactivity. The lateral and medial walls were similar in appearance. As the OB assumed a more adult organization, reactivity subjacent to the olfactory nerve layer declined. Olfactory glomeruli showed reduced reactivity relative to the neighboring olfactory nerve fibers.

389.8 ION CHANNEL MODULATION BY CAMP AND PROTEIN KINASE INHIBITOR.
V.Vodyanov* and I.Vodyanov*. (SPON.C.Gorenstein). Dept. of Physiol. and Biophys., Univ. of Calif. Irvine, CA 92717.

We reported (Soc. Neurosci. Abstr., Vol.12, Part 2, p.1353, 1986; Neurosci. Lett., 73, 253, 1987) a model system to study the initial electrochemical membrane events in chemoreception by the mammalian olfactory epithelium: membrane from rat olfactory epithelial homogenates (ROH) incorporated into planar bimolecular lipid membranes (BLM's). The steady-state conductance of BLM modified with ROH became sensitive to very low concentrations of odorant in the presence of adenosine triphosphate (ATP) and guanosine triphosphate (GTP). Adenosine 3',5'monophosphate (cAMP) mimicked the effect of the odorant. It was not known if changed levels of cAMP in our reconstituted system activated a protein kinase which phosphorylates the ion channel to modulate its activity or whether the cAMP directly gates the channel.

In this work we study the electrochemical properties of bilayers treated with ROH by the tip-dipping method. The bare BLM was first formed by the successive transfer of two phospholipid monolayers upon a tip of a patch pipet (about 1 u), and then the ROH was added to the *cis*-side of the membrane. The membrane unitary currents were measured with Yale Mk V Patch-clamp system. The signal from the clamp was filtered at low pass 3 kHz and recorded with PCM/VCR DASS System (Unitrade, Inc).

Analysis of single channel fluctuations indicate the existence of an ion channel of about 70 pS in 30 mM KCl, 30 mM NaCl, 2 mM $CaCl_2$, pH 7.4, activated by addition of cAMP (no ATP, GTP). The mean open time is about 1 sec. Subsequent addition of ATP to the *cis*-compartment of the system does not change the unitary amplitude, but causes a significant decrease of the mean open time to 6 msec. This activity was completely antagonized by protein kinase inhibitor. A change in the mean open time of single channel events in response to the presence of odorants was previously demonstrated (Vodyanoy and Murphy, Science, 220, 717, 1983). We believe that phosphorylation does not mediate the opening and closing of the channel, but is likely to modulate the mean open time in our reconstituted system. This suggests that cAMP regulates this channel activity in two ways: (a) directly, (b) *via* protein kinase system. These data are consistent with the hypothesis that cAMP is a second messenger in the initial steps of olfaction and a protein kinase can be involved in the ion channel modulation.

389.9 OPTICAL RECORDING OF ELECTRICAL ACTIVITY IN SLICES OF MAMMALIAN OLFACTORY STRUCTURES: EXTRINSIC SIGNALS FROM OLFACTORY BULB AND PYRIFORM AND SULCAL CORTICES OF THE MOUSE. A.R. Cinelli* and B.M. Salzberg. Dept of Physiol., Univ. of Penn., Phila., PA, 19104.

Optical methods provide an opportunity to study the spread of activity in large numbers of neurons. Sagital or tranverse slices from the mouse brain were stained with a pyrazo-oxonol voltage sensitive dye (RH155 or RH482), and a system for multiple site optical recording of transmembrane voltage (MSORTV) was used to monitor changes in the light absorbance following focal electrical stimulation (1 to 3 mAmp, 300-500 usec) of the slice. All the brain structures exhibited both fast and slow depolarizing optical responses, whose relative magnitudes depended on the site of recording. The two dye signals had characteristic wavelength dependencies and disappeared in high KCL. No significant intrinsic signal was observed.

The fast component of the signal recorded from the olfactory bulb appeared to arise from action potentials propagating in the lateral olfactory tract and the mitral cells. Increased stimulus intensity resulted in the spread of the fast signal in the glomerular and external plexiform layer, and may indicate the genesis of action potentials in the dendritic tufts of the mitral or granule cells. Stimulation of the pyriform cortical slice ellicited fast and slow components in the sulcal region. Observation of the fast signal suggests a direct projection between these two cortical regions.

Both the slow component and the field potential recorded from the olfactory bulb were partially suppressed when tested by paired volleys or trials delivered at 1 Hz. The magnitude and spread of the fast and slow components evoked orthodromically and antidromically depended on temperature in a complex fashion. Cd^{++} and low Ca^{++}-high Mg^{++} solutions substantially reduced the size of the slow component. GABA (1 mM) reduced the magnitude of the slow component ellicited by orthodromic or antidromic stimulation. Bicuculine (10 uM) reversed the effect of GABA.

The slow component of the optical signal may derive from several sources: synaptic activity and/or electrotonic spread of action potentials in dendrites; and/or glial cell depolarization secondary to K^{+}-efflux.

389.10 *IMPROVED VISUALIZATION OF THE SALAMANDER OLFACTORY BULB FOR OPTICAL RECORDING.*

D.M. Senseman, C.L. Garcia* and M.J. Wayner.

Brain Research Laboratory, Division of Life Sciences, The University of Texas at San Antonio, San Antonio, Texas 78285.

Recently, Kauer, Senseman and Cohen (Brain Res., *in press*) demonstrated the ability of potentiometric probes to optically monitor changes in neuronal activity in 124 anatomical regions of the salamander olfactory bulb in response to odor stimulation of the olfactory mucosa. For these experiments, Kauer *et al.* viewed the bulb, *in situ*, from its dorsal aspect. Since the laminae of the salamander olfactory bulb are arranged as a series of plates stacked along the rostral-caudal axis, they could readily observe differences in odor-evoked activity between bulbar layers but not regional differences across the laminar faces.

Since spatial differences in intra-laminar activation might be important for encoding odor quality information, we have developed a minimum preparation of the salamander olfactory system that provides improved visualization of the olfactory bulb for optical recording. The *in vitro* preparation consists simply of the anterior 2/3's of a single cerebral hemisphere attached via the olfactory nerve to its ipsilateral olfactory mucosal chamber. The transected hemisphere is mounted vertically in the recording chamber, parallel to the optical axis of the microscope, so that the bulb is viewed along its rostral-caudal axis. Mounting is accomplished by slipping the cut rostral end of the hemisphere over a vertical 1mm dia clad quartz rod that fits within the large cerebral ventricle. The olfactory bulb itself rests on top of the clad rod which also serves as a light guide for illumination.

We are currently using this preparation to map the central projections of the primary olfactory receptors to their post-synaptic bulbar targets. A miniature concentric bipolar electrode is being used to electrically activate small patches of primary olfactory receptor neurons within various regions of the dorsal and ventral olfactory mucosa while optically monitoring evoked responses in the olfactory bulb with a 124-element photodiode array. In accord with earlier histological investigations, our initial studies show that focal electrical stimulation of the receptor mucosa evokes relatively widespread, but not spatially uniform, activity in the olfactory bulb. Moreover, the widespread distribution of post-synaptic responses is not significantly altered by a 100-fold change in stimulating voltage. This suggests that our electrode current is, in fact , restricted to a small patch of mucosa membrane so that the widespread effects observed in the olfactory bulb are not likely the result of activating nerve fasicles passing through the stimulated mucosal region.

389.11 COMPARISON OF MITRAL/TUFTED CELL RESPONSES TO ODOR AND ELECTRICAL STIMULATION IN THE OLFACTORY BULB OF THE TIGER SALAMANDER. K.A. Hamilton and J.S. Kauer. Depts. of Neurosurgery, Anatomy and Cell Biology, Tufts- New England Medical Center, Boston MA 02111.

When a defined odor pulse is applied to the olfactory mucosa of the tiger salamander, the action potential activity generated in mitral and/or tufted (M/T) cells in the olfactory bulb often can be classified as an excitatory (E) or suppressive (S) response type. Using intracellular recording techniques, we have previously shown that periods of depolarization and hyperpolarization underlie the E- and S-type odor response patterns (Hamilton, K.A and J.S. Kauer, Brain Research, 338:181, 1985). In the present study, the contributions of synaptic connections to the generation of response patterns in 47 M/T cells were investigated, by examining the responses both to odors and to electrical stimulation of the olfactory nerve and olfactory tract.

Most odor responses began with hyperpolarization. In E-type responses, this initial hyperpolarization was followed by a period of excitation, which in turn was followed by a prolonged period of hyperpolarization and suppression of spontaneous action potentials. The latencies of hyperpolaration and excitation decreased with increases in odor concentration. Action potentials evoked in E-type responses tended to occur earlier, however, than any action potentials evoked in S-type responses. In response to high odor concentration, action potentials preceded the onset of hyperpolarization in E-type responses, but not in S-type responses.

In response to electrical stimulation, any evoked excitation preceded hyperpolarization, unlike most odor responses. As in the odor responses, latencies of depolarizing and hyperpolarizing components of the responses decreased with increases in stimulus intensity. The peak amplitude and duration of hyperpolarization also changed. An analysis of response components indicated that increases in intensity affected responses to stimulation of the olfactory nerve and medial or lateral tracts somewhat differently.

Together with results of tests conducted while hyperpolarizing cells with anodal current and using paired stimuli, these results indicate that the distribution of excitatory and inhibitory synapses on the M/T cell dendrites and soma in the tiger salamander is comparable to the distribution which appears to exist in other vertebrate species. The results further suggest that these synapses are activated differently by orthodromic and antidromic electrical stimulation, and also in E-type and S-type responses to odors. The patterns of activation evoked by odor stimulation generally do not appear to resemble the patterns evoked by electrical stimulation in the salamander olfactory bulb.

Supported by NIH Grants NS-22035 (KAH) and NS-20003 (JSK), and the Department of Neurosurgery.

389.12 ODOR INDUCED RESPONSES OF MORPHOLOGICALLY IDENTIFIED RAT OLFACTORY BULB NEURONS David P. Wellis and John W. Scott. Department of Anatomy and Cell Biology, Emory University School of Medicine, Atlanta, GA 30322.

While the basic circuitry of the rat olfactory bulb has been established, how this circuitry participates in sensory coding of odorant information remains to be determined. Extracellular electrophysiological techniques fail to identify all olfactory bulb cell types during studies of odor responsiveness. Therefore, we are using intracellular recording and marking to study sensory processing in the olfactory bulb.

Recordings were made with KCl-horseradish peroxidase (HRP) filled microelectrodes bevelled to resistances of 60-130 MOhms. Ten cells have been recorded for periods of 15 minutes to over 4 1/2 hours with membrane potentials of -40 to -75 mV. Antidromic activation of output neurons from the lateral olfactory tract, olfactory tubercle and posterior piriform cortex defined projection patterns. Responses to electrical stimulation of the olfactory nerve layer were observed and compared with odor induced responses. Odors were presented in random series of 6 concentrations spanning 2 log units.

Several output cells (mitral and tufted cells) as well as interneurons (a superficial granule cell and a superficial short axon cell) exhibited odor responses and were filled with HRP. All output cells exhibited complex temporal patterns to different odors over a range of concentration. These responses were stable over time and were systematically correlated with odorant concentration by our measure (Harrison and Scott, J. Neurophysiol. 56:1571, 1986). Previously, cells not antidromically activated were presumed to be interneurons. The two interneurons we have filled so far in this study unequivocally show that certain interneurons do respond to odor and in fact exhibit steeper stimulus-response functions than output neurons in this study. In one middle tufted cell, the response pattern changed with hyperpolarization but without disrupting its graded nature across odorant concentration. This suggests that tonic inhibition by olfactory bulb local circuits has significant effects on olfactory coding.

Supported by NIH grant NS-12400.

389.13 OLFACTORY BULB REMOVAL IN THE RAT RESULTS IN INCREASED BASAL CELL MITOTIC ACTIVITY. M.A. Schwartz*, D.M. Chikaraishi and J.S. Kauer. Neuroscience Program, Tufts-NEMC, Boston, MA 02111.

The olfactory system has the unique ability to regenerate receptor cells from undifferentiated stem cells in adult animals. Biochemical and morphological evidence for regeneration of the olfactory neurons following axotomy or bulbectomy is well established, with regenerating axons reestablishing synapses with their target site, the olfactory bulb (OB) (Graziadei, P.P.C. Br. Res. (1980)186:289-300). In both normal turnover and experimentally induced regeneration, the replacement elements are the basal cells residing in the olfactory epithelium (OE). In the present study, it has been shown that removal of the olfactory bulb in adult rats gives rise to a significant increase in the level of mitotic activity in the ipsilateral basal cell layer of the OE.

Right olfactory bulbs of adult (2-3 months) male, Sprague-Dawley rats were removed by aspiration. The left side served as an intact control. Four days after bulbectomy, each animal received an injection of ^{3}H-Thymidine (^{3}H-TdR) for one hour, was deeply anesthetized with ketamine, and was perfused. The OE and OB were sectioned at 8um and 10um, and prepared for autoradiography. Histological sections through the OB confirmed a complete right bulbectomy. The OE on the bulbectomized side was half the thickness of the control side, due to a marked decrease in the receptor cell layer as assessed using morphological characteristics. Counts of ^{3}H-TdR labelled basal cells revealed a significant increase ($p<.01$) in the mitotic activity on the bulbectomized side compared to the control side. In each animal counts were taken from representative homologous regions of epithelium along the septum, 500um in rostral/caudal extent. In this area, a range of 45-100% increase of mitotic activity over the control side was observed. Counts of labelled cells on the control side of bulbectomized rats gave a basal level of turnover not significantly different from age-matched, unoperated control animals. On the experimental side, the cells that incorporated the radioactive label were not randomly distributed, but were grouped in patches. Mitotically active contiguous cells, separated by at least 60um, constituted a patch. The size of the patches varied along the septum and contained as few as 3 or as many as 10 labelled cells.

These results demonstrate that removal of the olfactory bulb results in an increase in ^{3}H-Thymidine incorporation by the basal cells over that found in control regions. These observations suggest that the patches of active mitosis may represent groups of functionally related cells.

389.14 THE MORPHOLOGY AND DEVELOPMENT OF DENDRITIC SPINES MEDIATING RECIPROCAL DENDRODENDRITIC SYNAPSES. Charles A. Greer. Sec. Neurosurgery and Neuroanatomy, Yale Univ. Sch. Med., New Haven, CT 06510.

Reciprocal dendrodendritic synapses occur between the output neurons of the olfactory bulb, mitral and tufted cells, and a population of interneurons, granule cells. As part of an ongoing effort directed at elucidating the properties of these dendritic microcircuits, the present study was undertaken to examine the morphological features of the granule cell dendritic spines. In general, postsynaptic spines exhibit a wide range of shapes and sizes which in turn, influence the extent to which an individual spine attenuates the effectiveness of apposed synapses. The current study sought, in part, to establish if comparable morphological variation occurs in the functionally more complex spines involved in reciprocal synapses.

Granule cell spine morphology was initially studied in Sprague-Dawley rats with a developmental series of Golgi stained material processed for light microscopy (LM). In subsequent studies Golgi-EM material was gold-toned and processed for either conventional transmission electronmicroscopy (TEM) of thin (70nm) sections or high voltage electronmicroscopy (HVEM) of thick (1 - 4um) sections.

The LM and EM analyses revealed the presence of both sessile and pedunculated spines although the latter were predominant. Morphometric analyses demonstrated that spine dimensions increased between 3 and 21 days postnatal. The largest increase (27%) was in the length of the neck while smaller increases were found for the major and minor axes of the spine head (14% and 12%, respectively). By 21 days postnatal spine necks had a mean length of 1.96um (±0.1), but often exceeded 4um. The HVEM analyses demonstrated that spine necks often followed tortuous courses parallel to the parent dendrite. Of particular interest, the HVEM analyses also revealed complex spinous appendages in which the spine neck bifurcated 1 or more times. Serial reconstructions of the TEM material provided a further confirmation that the asymmetrical afferent synapse and symmetrical efferent synapse of the spines occur as reciprocal pairs. The TEM analyses also show that a single spine can sustain more than 1 topologically segregated reciprocal pair.

The data reveal a complexity of granule cell dendritic spines not previously recognized. Morphometric analyses suggest that their biophysical properties may change significantly during postnatal development, possibly reflecting postnatal increases in olfactory acuity previously documented. In addition, the data suggest that some spines may be effectively isolated from the parent dendrite and thus may function as segregated units.

389.15 THE CHANGES IN THE TRIPARTITE OLFACTORY SYSTEM OF XENOPUS LAEVIS (ANURA, AMPHIBIA) DURING METAMORPHOSIS: AN ELECTRON MICROSCOPICAL AND TRACT TRACING STUDY

G. J. Weiss* (SPON: L. Selzer), Dept. of Zoology, University of Regensburg, 8400 Regensburg, Federal Republic of Germany

The olfactory organ of the South African clawed frog, Xenopus laevis, was studied in late larval and postmetamorphic stages by means of electron microscopy.

The olfactory organs consist of three parts: the medial diverticulum (MD), the lateral diverticulum (LD) and the vomeronasal organ (VNO). Sensory epithelia occur in all three parts. Receptor cells are lacking in the LD of terrestrial anurans. Their presence in the aquatic Xenopus is regarded as an adaption for smelling underwater.

The ultrastructure of the sensory epithelia corresponds to the general vertebrate scheme. However, the sensory epithelia show specialisations depending upon the medium above (air or water). Their receptor cells have either cilia or microvilli, and their supporting cells either secretory granules or motile cilia. The presence or absence of intraepithelial glands is another characteristic feature.

No substantial changes occur in the sensory epithelia of the LD and the VNO during metamorphosis. In the MD, however, the larval water-flooded epithelium changes to a postmetamorphic air-flooded epithelium.

In tadpoles and postmetamorphic animals the olfactory bulb consists of two parts: the main olfactory bulb (MOB) and the accessory olfactory bulb (AOB). As in terrestrial anurans, the MOBs of the left and right side are fused in the midsagittal line.

The termination of the axons of the receptor cells within the glomerular layer of the olfactory bulb was studied by injections of horseradish peroxidase into the sensory epithelia. Clear topographical relationships were observed. In larval stages, the axons of sensory cells of the MD project to all regions of the MOB; those of the LD run to the ventrolateral region of the MOB, and those of the VNO terminate exclusively in the AOB. In postmetamorphic stages, however, the axons of the sensory cells of the MD project to the medial, dorsolateral and dorsal regions of the MOB, those of the LD again terminate in the ventrolateral region of the MOB.

A neurogenesis of receptor cells is proposed as a mechanism to segregate fibers of the MD and LD in the glomerular layer of the MOB during metamorphosis.

390.1 ELECTROPHORETIC CHARACTERIZATION OF CARBON-14 BOUND TO MOUSE BRAIN TISSUE AFTER THE IN VIVO ADMINISTRATION OF [^{14}C]L-DEPRENYL. S. L. Dewey, A. P. Wolf*, R. R. MacGregor* and J. S. Fowler* Chemistry Department, Brookhaven National Laboratory, Upton, NY 11973

Recently, we reported that carbon-11 labeled clorgyline and L-deprenyl and positron emission tomography could be used to map the distribution of monoamine oxidase A and B in living human brain (Science 235: 481-485, 1987). For both tracers the binding of carbon-11 was significantly reduced by prior inhibition with an MAO inhibitor and for [^{11}C]L-deprenyl the binding was shown to be stereoselective. Since PET is a non-invasive procedure which does not involve the direct sampling and analysis of tissue, we have designed a series of experiments to more fully characterize the binding of L-deprenyl to brain tissue. In the present study, we have used [^{14}C]L-deprenyl and SDS polyacrylamide gel electrophoresis to identify the proteins which are labeled with carbon-14 after its in vivo administration in adult mice.

N-[^{14}C-Methyl]L-deprenyl was injected into a lateral tail vein of adult female mice (30-35g). Following a 30 minute survival period, brains were excised and homogenized in 10.0 vols. of 0.25 M sucrose (4°C). Mitochondria were isolated according to Laduron, et al., J. Neurochem. 41: 83-94, 1983. Pellets were washed by resuspension in 7.0 ml, 50 mM Tris-HCl, pH 7.5 and centrifuged. The final pellet was resuspended in 50 µl of a solution containing 3% SDS, 0.15M sucrose, 7.0% 2-mercaptoethanol, 0.05% bromophenol blue and 0.03M Tris-HCl, pH 7.5. Electrophoresis was carried out in 10% polyacrylamide slab gels in the presence of SDS. Gel slices (2.5 mm) were incubated overnight at 25°C in 5 ml of a mixture containing Aquasol and 4% Protosol (NEN) (Edwards and Pak, Biochem. Biophys. Res. Comm. 86: 350-357, 1979). One band of radioactivity was detected by this method. It had a molecular weight of 58,000 daltons, as estimated in linear 10% gels by the migration of known molecular weight proteins. This is consistent with the molecular weight of MAO as determined using [^{3}H]pargyline (Costa and Breakfield, Mol. Pharm. 16: 242-249, 1979).

In summary, the results of this study show that [^{14}C]-L-deprenyl can be used to specifically identify MAO B from crude mitochondrial preparations on SDS-polyacrylamide gels and support the use of [^{11}C]-L-deprenyl and positron emission tomography to determine the regional distribution of MAO B in human and primate brain.

390.2 ^{14}C-DEOXYGLUCOSE MAPPING OF COTURNIX QUAIL BRAIN: RESPONSE TO VARIOUS PHOTOPERIODS. M. M. Beck and K. E. Borg*, Dept. of Animal Science, Univ. of Nebraska; B. D. Schambacher*, USMARC, Clay Center, NE; and K. M. Eskridge*, Biometrics and Information Center, Univ. of Nebraska, Lincoln, NE 68583-0908.

Male Japanese quail, raised on an 8L:16D photoperiod, were separated into 3 groups at 10 wks of age: longdays (16L:8D), shortdays (8L:16D), or skeleton longdays (8L:4.5D:2L:9.5D). Additional treatments within photoperiod were pinealectomy, sham-pinealectomy, antimelatonin, control serum, or no treatment. Testicular weights and serum testosterone were used as markers of reproductive response. In all responses, longday photoperiod had significant effects (P<.05), with shortday responses always less, and skeleton longday responses intermediate. Autoradiographic analysis, using Kodak SB-5 x-ray film, and the Bio-Quant microdensitometry system, showed both tectofugal and thalamofugal visual pathways labeled by the deoxyglucose. Photoperiod did not stimulate either pathway preferentially, but longday brains had densest labeling (highest metabolic activity), with shortday brains least (lowest activity), and skeleton longday brains intermediate. At 6 mos of age, an additional 12 quail, maintained on 16L:8D, were divided, with one group receiving 8L:16D and the rest remaining on longdays. Testicular weights and cloacal gland atrophy were used as indicators that shortday photoperiod had reversed reproductive condition. Analysis of autoradiographs of the 2 groups, 10 days after initiation of photoperiod, showed that metabolic activity of visual nuclei was significantly reduced by shortday exposure. The consistent lack of treatment effects within photoperiod confirms earlier research that the pineal does not mediate stimulatory photoperiod response in the quail. Residual extra-pineal melatonin apparently is also not involved in the response. In no birds was the SCN stimulated metabolically.

390.3 CEREBRAL GLUCOSE UTILIZATION AFTER REPEATED STRESS AND DURING CONDITIONED FEAR IN THE RAT. R.A.W. Lehman and R.M. Bryan. Departments of Surgery (Neurosurgery) and Physiology, The M.S. Hershey Medical Center of The Pennsylvania State University, Hershey, PA 17033.

Regional cerebral glucose utilization (rCMRglu) was studied in rats after repeated stress and during conditioned fear. Four groups of rats were studied. Two groups of rats were aversely conditioned by placing them in a shock chamber (conditioned stimulus) where they received random footshocks. The two remaining groups were placed in the shock chamber but not conditioned. Regional CMRglu and systemic parameters (heart rate, blood pressure, blood gases and pH, plasma catecholamines, and plasma glucose) were measured in unconditioned and conditioned rats in the presence and in the absence of the conditioned stimulus. The changes in rCMRglu described below appeared to be global and not limited to specific regions. Results are as follows: (1) Transferring unconditioned rats to the shock chamber had no significant effect on rCMRglu even though the systemic parameters indicated a stress response. It appears that stress capable of inducing changes in heart rate, MABP, and plasma catecholamines is not necessarily accompanied by increases in cerebral glucose utilization. (2) Conditioned rats not exposed to the shock chamber at the time rCMRglu was measured had decreased rates of rCMRglu compared to rats that were not conditioned. Except for plasma epinephrine, which increased after conditioning, systemic parameters were not affected. (3) Conditioned fear, elicited by transferring conditioned rats to the shock chamber, increased rCMRglu when compared to a control group that was conditioned to footshock using the same paradigm but not exposed to the shock chamber at the time rCMRglu was measured. The systemic parameters indicated a stress response in conditioned rats transferred to the shock chamber. We conclude that past experience of shock can manifest itself by altering cerebral glucose utilization. Aversive conditioning acted to suppress basal rCMRgl and the conditioned fear paradigm was associated with an increase in rCMRgl superimposed on the suppressed basal rate. 390.4 CEREBRAL METABOLISM AND EEG: RELATIONS TO COGNITIVE TASK. J. T. Metz, N. J.Yasillo*, and M. Cooper*. PET Center, University of Chicago, and Illinois State Psychiatric Institute, Chicago, IL 60637.

EEG alpha activity has long been known to decrease as a subject's attention to a task increases. Cerebral metabolism has also been presumed to change as the neuronal processes mediating cognition change. The relationships between these physiological measures, however, have not been directly examined in a behaviorally controlled experiment. In this study, we simultaneously recorded regional cerebral metabolism and multi-channel EEG while varying complexity of a cognitive task.

Six normal males, aged 20-28, were studied on two occasions each. Metabolic rates during 40 minutes of performing each of two tasks were determined with ^{18}fluoro-2-deoxyglucose and a PETT VI tomograph. EEG during task performance was recorded on analog tape from 16 leads referred to the forehead. Both tasks were presented on a computer screen. The computer also measured accuracy of response and reaction time to each stimulus. The complex cognitive task was a variation of the Wisconsin Card Sorting Test (WCST), a task which involves memory and the ability to adapt to changing conditions. Lesion studies have shown that this task requires functioning of the frontal cortex. The control condition was a simple match-to-sample task which had sensory, motor, and instructional demands similar to the WCST. Half of the subjects received the control task first, half received the WCST first.

A researcher who was blind to the task condition identified 44 regions of interest from three PET slices parallel to the orbital-meatal plane (the slice through the plane of the basal ganglia and the slices immediately above and below the basal ganglia). Metabolic rates in these regions were averaged and z-score normalized for each session. The EEG from each channel was digitized (200 hz) in 2.56 second epochs. Ten artifact-free epochs per subject, sampled during the first 10 minutes of each task, were transformed by the fast Fourier technique and averaged to provide quantification of power in five spectral bands.

The average time to respond to stimuli was significantly longer on the WCST than on the control task (1942 vs. 989 milliseconds), confirming that the WCST was a more demanding task. Average metabolic rate across all regions was significantly higher when the subjects were performing the WCST (mean of 7.69 vs. 5.95 mg/100 grams/minute, $t = 3.86$, $p < 0.02$). The change in average metabolism between the control task and the WCST was significantly correlated with change in alpha power ($r = -0.90$, $p < .05$).

None of the normalized regional metabolic values showed a statistically significant difference between the two tasks. The decrease in alpha power was found in all areas, but was most prominent in temporal and parietal leads. Across subjects and within each task condition, no EEG parameter was strongly related to metabolism.

These results demonstrate that as the complexity of a cognitive task increases, reaction time increases, average cerebral metabolic activity increases and average alpha power decreases. Alpha power was found to be strongly reflective of changes in cerebral metabolism. We were not able to demonstrate that specific brain areas were uniquely involved in the performance of either task.

390.5 POSSIBLE EVIDENCE OF A FUNCTIONAL DISCONNECTION BETWEEN ORBITAL CORTEX AND CAUDATE NUCLEUS IN UNIPOLAR DEPRESSION USING PET. J.M. Schwartz*, L.R. Baxter, Jr., *, M.E. Phelps, J.C. Mazziotta, B.H. Guze*, C.E. Selin* (SPON: D.X. Freedman). Depts. of Psychiatry, Neurology and Div. of Nuclear Medicine and Biophysics, UCLA School of Medicine, Los Angeles, CA 90024.

A substantial body of evidence demonstrates a close functional connection between prefrontal cortex (PFC) and the head of the caudate nucleus (Cd) (e.g. I. Divac, in Functions of the Basal Ganglia, Ciba Fdn. Symp. 107, Pitman Pr, 1984, pp201-215). Previous work by our group (Baxter, et al, Arch Gen Psychiat 42:441-447, 1985), using PET, has shown a decrease in local cerebral metabolic rates for glucose (LCMRGlc) in the Cd relative to the ipsilateral hemisphere in patients with unipolar depression, mainly accounted for by a decrease in LCMRGlc of the Cd with respect to PFC (Schwartz, et al, JAMA, in press).

We extended this work, looking at PFC-Cd relationships in a group of age and sex matched normal controls (NC, n=14,31.6+4.5 yrs), unipolar depressed (UD, n=10, 36.0+11.0) and bipolar depressed (BD, n=10, 38.4+14.0) subjects. Depressed patients were carefully diagnosed and showed comparable scores on the 21-item Hamilton Rating Scale for Depression (UD=22.1+4.9; BD=25.0+5.8). We calculated correlation coefficients and performed linear regression analyses between LCMRGlcs for each Cd and the ipsilateral middle frontal gyrus (MFG), inferior frontal gyrus (IFG) and orbital gyrus (OG) for each group.

As expected, NC showed high correlation coefficients between LCMRGlcs for each of these prefrontal regions and the Cd, with all rs>.9 ($p<10^{-5}$). Coefficients of determination ranged from .81 to .88. Furthermore, the BD group also showed high correlations on these measures: all r >.9 (p<.0005) and coeff of deter >.82, except for the right OG and Cd where they were .84 (p<.002) and .70, respectively. In the UD group, there was a marked discrepancy in the lack of any significant correlations between LCMRGlcs for OG and Cd: on the left r=.49 (p=.15), coeff of deter =.24; on the right r=.42 (p=.22) coeff of deter = .18. In contrast the MFG and IFG showed high correlations with Cd activity, with all r>.85 (p<.002) and all coeff of deter >.72. These data may indicate a loss of functional interaction between the OG and Cd in unipolar depression.

This work was supported in part by contract AM03-76 SF00012 from the Department of Energy; grant MH 37916-02 from the National Institute of Mental Health; donations from the Jennifer Jones Simon Foundation; and the Judson Braun Chair in Psychiatry.

390.6 LOCAL INJECTION OF TETRODOTOXIN DECREASES METABOLIC ACTIVITY IN DISCRETE BRAIN REGIONS: A 2-DEOXYGLUCOSE AUTORADIOGRAPHY ANALYSIS L.Cahill, R.M.Coopersmith, M.Leon, and J.L.McGaugh. Center for the Neurobiology of Learning and Memory and Department of Psychobiology, University of California, Irvine, CA 92717

The production of reversible brain "lesions," with local injections of drugs such as tetrodotoxin or procaine, is a powerful method of analyzing brain function. With such procedures, however, the extent and duration of the treatment is often unknown. In this study we have used 14C-2-deoxyglucose autoradiography (2DG) and the Fink-Heimer stain for degenerating axons to determine the effects of an intra-cranial injection of tetrodotoxin (TTX).

Male Sprague-Dawley rats were implanted bilaterally with guide cannulae terminating just above the amygdaloid complex. After recovery from surgery, the rats received an injection of TTX in one amygdala and vehicle in the other, allowing for within rat comparisons of the TTX effects. In the first phase of the experiment, rats received 0.1, 0.4, or 1.0 μl of a 10 ng/μl TTX solution, followed five minutes later by an intravenous injection of 2DG (150 μC/kg). Forty-five minutes later, the rats were decapitated and the brains frozen in freon. After cryostat sectioning (20 μm), the tissue was exposed for 10 days and the autoradiographs analyzed with a computer-based digital image processor. In the second phase, delays of 2, 4, 8, and 12 hours were placed between the TTX and 2DG injections. Finally, the brains of some rats receiving unilateral TTX (but no 2DG) were stained for degenerating axons by the Fink-Heimer method.

The results show that: 1) Intra-amygdala TTX injections produce significant reductions in 2DG uptake in specific regions, with the largest and most consistent effects seen in the basolateral amygdala; 2) This effect was not seen with 2DG injections delayed 8 and 12 hours after TTX; 3) No degeneration is seen in areas receiving TTX compared to those receiving vehicle. It is concluded that TTX reversibly slows metabolic activity in discrete regions following local injection, and produces no neuronal death.

ACKNOWLEDGEMENTS: We thank Dr. Ricardo Miledi and Dr. Chris Gall for technical advice.

390.7 DIFFERENTIAL SENSITIVITY TO COCAINE IN LEWIS AND FISCHER-344 RATS AS INDICATED BY LOCAL CEREBRAL GLUCOSE UTILIZATION. G. Wilkerson*, S.R. Goldberg*, M. Risner, and E.D. London (SPON: B.E. Hackley). Neuropharm. Lab., NIDA Addiction Res. Ctr., Baltimore, MD 21224.

It is well-established that cocaine is a reinforcer with a high abuse potential in humans. However, little is known about genetic factors which may contribute to cocaine sensitivity and, perhaps thereby, to susceptibility for cocaine abuse. We therefore assessed the sensitivity to cocaine, as indicated by rates of local cerebral glucose utilization (LCGU), in two commonly available inbred strains of albino rats.

Rates of LCGU were measured in partially restrained, 4-6-month-old, male rats of the Lewis (L) and Fischer-344 (F) strains, which were treated acutely with cocaine HCl (1, 10, or 30 mg/kg, i.p.) or saline (control) 5 min before the i.v. injection of the radiotracer (100-125 μCi/kg 2-deoxy-D-[1-^{14}C]glucose, DG). Timed arterial blood samples were obtained, and LCGU was determined autoradiographically in fifty-nine brain regions, as described by L. Sokoloff et al. (J. Neurochem. 28:897, 1977).

F rats showed no overt behavioral effects or LCGU alterations with 1 mg/kg cocaine. The 10 mg/kg dose produced stereotypies (head weaving, sniffing) in 17% of the animals and decreased LCGU in the lateral habenula. At 30 mg/kg cocaine, 80% of the rats showed stereotypies and LCGU stimulation in several components of the extrapyramidal motor system (caudate-putamen, globus pallidus, substantia nigra reticulata, subthalamic nucleus (n.), cerebellar vermis), but reduced in the lateral habenula. No significant effects in several limbic areas implicated in drug-induced reward (e.g., accumbens n., ventral tegmental area) were noted.

L rats showed a greater cocaine sensitivity, indicated by a tendency for LCGU stimulation by 1 mg/kg cocaine in several areas, including the ventral tegmental area, accumbens n., and several neocortical areas. At 10 mg/kg, 75% of the rats showed stereotypies. Also at this dose, extrapyramidal areas affected only at 30 mg/kg cocaine in F rats showed stimulation, and LCGU was decreased in the lateral habenula. All L rats treated with 30 mg/kg cocaine showed marked stereotypies and a suppression of LCGU in many areas.

The greater sensitivity of L as compared to F rats to cerebral metabolic effects of cocaine is consistent with a previous report that L rats are more responsive to open field activating effects of cocaine (George, F. R. et al., Fed. Proc. 46:402, 1987). Taken together, these findings support the view that there are genetic differences in the sensitivity to cocaine, which may be related to susceptibility to cocaine abuse. Further studies are indicated to determine whether the observed strain differences in response to cocaine reflect genetic differences in metabolism or CNS sensitivity.

390.8 BRAIN SLICE GLUCOSE UTILIZATION USING ^{14}C-2-DEOXYGLUCOSE. G.C. Newman, F.E. Hospod and P. Wu. Department of Neurology, SUNY, Stony Brook, New York 11794.

Measurement of glucose utilization using the 2-deoxyglucose tracer kinetic model of Sokoloff et al[1] is one of the fundamental means of assessing brain activity in vivo. The ability to measure actual glucose utilization in vitro, especially in brain slices, would facilitate a wide variety of experiments including pharmacological studies, determination of physiological events associated with glucose utilization and studies of brain slice preservation. Most importantly, the ability to measure glucose utilization in vitro would permit the direct comparison of in vitro and in vivo results. To calculate in vitro glucose utilization, it is necessary to modify the equation for glucose utilization and to remeasure the kinetics constants that apply, including the lumped constant.

We have performed the necessary modifications, remeasured the constants and tested the model using the hypothalamic brain slice containing suprachiasmatic nucleus (SCN). Since SCN has a spontaneous cycle of metabolic activity in vivo that is not dependent upon neural input and that persists in vitro,[2] this slice is well-suited to developing methods. The kinetics constants were remeasured for whole hypothalamic slices by incubation with ^{14}C-2-deoxyglucose (^{2}DG), separation of 2DG from 2-deoxyglucose-6-phosphate (2DG6P) by anion exchange chromatography and rinse times were used to study influx or efflux process. The lumped constant was estimated by using the hexokinase Michaelis-Menton constants for 2DG and glucose, assuming small glucose-6 phosphatase activity and measuring the volumes of distribution for 2DG and ^{14}C-glucose in the brain slice. The in vitro system permits phosphatase activity to be measured directly from long term efflux experiments and the small phosphatase activity can thus be confirmed.

Using these constants and the modified equation, we have measured glucose utilization in the SCN and adjacent anterior hypothalamic area during subjective daytime and nighttime. SCN glucose utilization reaches a high of 68 and a low of 48 umole glucose/g tissue/min throughout the day while AHA remains uniformly low at about 30 umole glucose/g tissue/min. These results are entirely consistent with prior in vivo measurements.[3,4] Studies with hippocampus, cerebral cortex and thalamus are in progress.

We have demonstrated the feasibility of measuring actual glucose utilization in vitro using the ^{14}C-2-deoxyglucose method with modifications for in vitro incubations and anticipate wide application for this method in brain slice research.

390.9 MCPP, a central serotonin agonist: its effects on cerebral metabolism, in relation to behavior and neuroendocrine response in the rat.

G.L. Ricchieri *, K.M. Wozniak *, C.S. Aulakh *, D.L. Murphy and S.I. Rapoport (Sponsor: B. Horwitz).
Laboratory of Neurosciences, National Institute on Aging, and Laboratory of Clinical Science, National Institute of Mental Health, NIH, Bethesda, MD 20892.

1-(m-chlorophenyl) piperazine (MCPP) is a metabolite of trazodone, a drug used clinically as an antidepressant, and a potent 5-HT agonist in the central nervous system. Its metabolic formation from trazodone has been suggested to account for the antidepressant activity of trazodone.

We measured local cerebral glucose utilization (LCGU), using the quantitative [14C]-2-deoxy-D-glucose method, in awake 3 mo old male Fischer-344 rats at 5, 15, 30 or 60 min after MCPP 2.5 mg/kg or saline i.p. Behavior was evaluated at fixed time intervals after MCPP administration.

The drug produced behavioral and neuroendocrine changes. Sedation, with a decrease of spontaneous locomotor activity and hunched posture, increases in plasma prolactin and corticosterone levels, and a decline in growth hormone concentration, were observed in the animals. These effects were evident within 5-10 min after administration and peaked at about 15 min, thereafter decreasing to reach pre-treatment levels after 1 h. LCGU was decreased significantly ($p<0.05$) at 15 min after MCPP in 24% of the 71 brain regions examined, with a 20% decline of mean cerebral metabolism, as compared to controls. At 1 h after injection of MCPP, LCGU values were similar to pre-treatment values. Cerebral metabolism declined in most neocortical areas (layer IV), the olfactory system, basal ganglia, thalamic and hypothalamic nuclei and hippocampus.

The topography of changes in LCGU after MCPP suggests a preferential action of the drug in areas where 5-HT receptors are present in high density. The peak decline of cerebral metabolism, coupled temporally with hypomotility and peak neuroendocrine effects, is consistent with the role of 5-HT in these functions. The effect of MCPP in some brain regions which have been reported to be involved in the mediation of anxiety (Lader, 1983) also is consistent with the reported anxiolytic properties of trazodone in the clinical use.

390.10 EFFECTS OF ADENOSINE ON ATP AND TOTAL ADENYLATE CONTENT OF RAT HIPPOCAMPAL SLICES.

E. Warman*, J.C. LaManna, and T.S. Whittingham, Departments of Biomedical Engineering, Neurology, Physiology/Biophysics and Division of Neurological Surgery, Case Western Reserve University School of Medicine, Cleveland, Ohio 44106.

Previous results have shown that a 3 hr exposure of hippocampal slices to 25 mM creatine in the incubation medium greatly increased the phosphocreatine content of those slices and also significantly prolonged their ability to maintain electrical function during transient anoxia. The creatine effect may be attributed to increased neuronal energy reserves at the onset of the anoxic insult, or by increased hydrogen ion buffering afforded by the creatine kinase system. If creatine exposure is prolonging synaptic transmission during anoxia by maintaining local ATP levels, then a similar protective effect should be provided by directly increasing slice ATP content.

Hippocampal slices (500 µm) were prepared and incubated in standard bicarbonate medium (125 mM NaCl, 3.0 mM KCl, 1.4 mM KH_2PO_4, 1.3 mM $MgSO_4$, 2.24 mM $CaCl_2$, 26 mM $NaHCO_3$, 10 mM glucose, and equilibrated with 95% O_2/5% CO_2 to adjust pH to 7.4) in a heated shaker bath.

The addition of 8 mM adenosine, an adenylate precursor, following a 1 hr pre-incubation in standard medium, increased hippocampal slice ATP and total adenylate (ATP+ADP+AMP) levels over a period of 5 hr. ATP levels rose from about 10 nmol/mg protein to 50 nmol/mg protein, and total adenylates from 15 to 19.5 nmol/mg protein during these incubations. Slice energy charge increased slightly (from 0.782 to 0.851) in both control and adenosine-treated slices during a 5 hr incubation, indicating that the slices maintained a normal distribution of the adenylate pool in the presence of adenosine. The increase in the adenylate pool was time-dependent, and the presence of adenosine during slice preparation and the initial hour of incubation did not appear to significantly enhance the metabolic effects. Initial results indicate that the enhanced adenylate pool remained elevated after removal of adenosine from the incubation medium, though some loss appears to occur over two hours in normal medium. Recent experiments also suggest that phosphocreatine and total creatine levels may be decreased by the adenosine incubation. This would tend to minimize the energetic benefits of accumulated ATP.

The apparent gain of ATP and loss of phosphocreatine may make it possible to delineate between the energetic and pH effects by which creatine incubation may have acted to provide functional protection during transient anoxia.

390.11 PALMITATE INCORPORATION FOLLOWING HYPOGLOSSAL AXOTOMY IN ADULT FISCHER 344 RATS.

S.Yamazaki*, J.M.Gnaedinger, J.M.Bell* and S.I.Rapoport. Laboratory of Neuroscience, National Institute on Aging, NIH, Bethesda, MD 20892.

The effects of axonal regeneration and degeneration on palmitate incorporation into the hypoglossal nucleus were studied using autoradiography applying the method of Kimes et al(1983). Three mo. old male Fischer-344 rats were axotomized on the left side using one of two operations. The 'R'-operation was to transect the hypoglossal nerve and remove a 3 mm fragment. The "D"-operation was to pack the transected proximal end in silicone glue after removing a 1.0 cm segment of nerve. One to 84 days after axotomy, [U-14C]palmitate (450 µCi/kg) was injected i.v in awake animals. Animals were killed after 4 hrs, and brains were sectioned into 20 um at -20 C. Sections were exposed against Kodak SB5 film for 5 weeks. Optical densities of 5 regions, including the hypoglossal nucleus, were determined and the percent differences between operated and unoperated sides were calculated. In the "R"-operation group, palmitate incorporation into axotomized hypoglossal nucleus showed increases of 6%, 9% and 21% against the unaxotomized side ($p < 0.01$) on days 4, 12, and 24 days, respectively, after axotomy. The difference declined gradually thereafter, disappearing on day 70. In the "D"-operation group, at 24 and 35 days after axotomy, there was a 7% and 7.5% decrease ($p < 0.01$) respectively on the axotomized side. Reestablishment of nerve connections was examined histologically using horseradish peroxidase, which was injected into the tongue and whose appearance in the hypoglossal nucleus indicated whether axonal connections were intact. Among animals in the "R"-operation group, axonal regeneration was first demonstrated 20 days after axotomy. After then, axonal connectivity was shown consistantly. No axonal connectivity was shown in the group after the "D"-operation. After axonal injuries, disappearance of synaptic junctions, disintegration of organelles and proliferation of neuroglia occur in the hypoglossal nucleus. These degenerative changes can disappear following return of the functional connections between muscle and neuron cell bodies. If the axons are prevented from regenerating, these phenomena remain and result in the atrophy of the nucleus. The results in the "D"-operation group are attributed only to degenerative changes, as they also show only decreased palmitate incorporation into the region. In the "R"-operation group, the increase in palmitate incorporation from 4 to 24 days after axotomy is ascribed to the regeneration of axolemma, and from 24 to 49 days after axotomy to the reconstitution of organelles and synaptic junctions. Those results indicate that the palmitate method(Kimes et al, 1983) can be used to examine plastic degenerative and regenerative neuronal changes following axotomy.

390.12 METABOLIC EVIDENCE FOR A RED AND WHITE BRAIN.

I. L. Wagman* and R. C. Collins; Depts. of Neurology and Neurological Surgery, and the McDonnell Center for the Study of Higher Brain Function, Washington Univ. Sch. Of Med, St. Louis, MO 63110

In previous studies we have found that capillary density in rat brain does not correlate with mitochondrial density [quantitative cytochrome oxidase (CO) histochemistry] as it does in muscle (Wagman and Collins, submitted). Furthermore, we found no correlation between the distribution of regional rates of glucose utilization [quantitative [^{14}C] deoxyglucose (DG) autoradiography] and regional rates of CO activity. The regional density of capillaries did, however, correlate well with regional rates of glucose utilization ($r = 0.78$). These studies suggest that the separation of aspects of oxidative and glycolytic metabolism in brain may follow some of the principles governing the separation of these activities in muscle.

To explore this idea further we have used lactate dehydrogenase (LDH) histochemical staining and quantitative microdensitometric analysis to compare regional differences in glycolytic and oxidative enzyme activities . Ten um brain sections were cut in a cryostat and stained for LDH by a modification of the technique of Jacobsen (Histochemie, 20:250, 1969). An intermediate electron carrier, phenazine methosulfate, was used to bypass the endogenous NADH tetrazolium reductase. The reaction was found to be linear with time. Sections stained without lactate or without NAD showed only a trace of reaction. Regional optical densities were measured in 19 gray and 4 white matter areas for 4 rats. The highest activities of LDH among gray areas were found in stratum radiatum and oriens of the hippocampus. The lowest activities were in the spinal nucleus V, red nucleus and white matter. There was a 2 fold range of values for gray areas. When the regional distribution of LDH was compared against the regional distribution of CO, [^{14}C]DG and capillary density among these areas, no statistically pleasing relationship was found.

When the pattern of enzyme activity was examined in greater detail in the hippocampus, a striking hodological reciprocity was found between LDH and CO. Terminal zones of the perforant path from the entorhinal cortex showed high levels of CO but low levels of LDH. Terminal zones of the commissural and associational fibers showed high levels of LDH but low levels of CO. These findings suggest that afferent input may control levels of certain enzymes of energy metabolism within brain as within muscle. We are testing this hypothesis.

390.13 METHOD FOR MEASURING SDH ACTIVITY IN SINGLE NEURONS
G.R. Chalmers and V.R. Edgerton.Dept. of Kinesiology and Brain Research Institute,UCLA,Los Angeles,CA 90024

A histochemical technique for quantifying succinate dehydrogenase activity(SDH) in single motoneurons has been developed. Previous measures of enzymatic activities of single neurons(1,2,3) have been based on the optical density(OD) of a region of cytoplasm after a specific period of staining in an incubation medium containing the appropriate substrate, sometimes(3) using fixed tissue. In these assays reaction product not specific to the substrate of interest is included in the OD measurements (1,2,3,). In the present study SDH rates were measured using a video camera interfaced with a light microscope. The camera was calibrated in absolute OD units divided into 256 grey levels for each pixel (480x640). The data were processed using a PDP11-34 computer. The rate of change in OD was determined from video scans repeated every 30s. In 10um fresh-frozen sections of cat lumbar spinal cord placed in an incubating medium with succinate a linear rate of change in OD was observed for 1.5 min followed by a slower, but linear, rate for 6 min. The rate was then reduced and non-linear. Placement of the tissue in an incubation medium without substrate resulted in a high rate of product formation for 2 min subsequently reaching zero. Therefore, the 1.5 min slope with succinate substrate reflects a combination of SDH specific activity and non-specific staining. The subsequent 6 min slope represents the substrate specific activity. Due to the magnitude of the nonspecific staining the endpoint OD was poorly correlated with SDH activity. The OD of tissue sections reacted in the incubation medium with succinate was linearly related to tissue thicknesses ranging between 6 and 20um. Two repeated measures on the same cell(n=45) resulted in a mean difference in the measures of 14.4%. Within one 10u section neighboring regions exhibited as much as an 8.5% variability in SDH activity. This intracellular variability is consistent with the intracellular heterogeneity of cytochrome oxidase observed using electron microscopy(3).

390.14 ETHANOL EFFECT ON MOLECULAR AGREGATION STATE OF ALCOHOL-NAD-OXIDOREDUCTASE (ADH EC 1.1.1.1) AND ALDEHYDE-NAD-OXIDOREDUCTASE (ALDH EC 1.2.1.3) IN RAT CNS: A COMPARATIVE STUDY BETWEEN NORMAL AND "A.G. RATS".
E. Egaña, P. Grez* &**J. Aldunate*. University of Chile - Faculty of Medicine - Institute of Experimental Medicine - Laboratory of Neurochemistry and **Department of Biochemistry the same University & Faculty - Santiago 7 - Chile.

In previous work communicated by our Institute it was found that the molecular agregation state of CNS ADH and ALDH of rat drinking ethanol 12% v/v as unique fluid intake (permanent and generational "A.G./12"), was different from normal CNS. Based on this result and others such as the increased in CNS enzymic activity in drinking rats (acute and chronic experiments), we were interested knowing the exact molecular agregation state of these enzymes as also the relationship between the different enzymic activity in both experimental groups (Normal and "A.G./12" rats)

Adult albino Wistar rats ♂ & ♀ by separate. Normal (control) and "A.G./12" drinking exclusively a 12% v/v ethanol solution (86 generations). 4 CNS' areas: brain cortex, hypothalamus, cerebellum and midbrain. Electrophoresis was run in 20.000 x g supernatant of the above mentioned areas. Molecular subunits weight were estimated by calibrating the gels against bovine serum albumin dimer and monomer (mol. wt. 132,000 and 66,000 respectively), carbonic anhydrase (mol. wt. 29,000), ∝-Lacto albumin (mol. wt. 14,200) and ovalbumin (mol. wt. 45,000) standards. The enzymic activity was detected in poliacrylamide gels of different concentrations by McRobbie et al. method (1985).

Differences in molecular agregations state of both enzymes were found, which could explain the increase in enzymic activity of alcoholic rat's brain demostrated by some authors in other models of experimental alcoholism (acute and/or chronic) run in one single generation. In "A.G. rat" the enzymatic change through genetic mechanism is supposed to be involved (enzymic mutation).

390.15 THE BRAIN PI POOL INVOLVED IN DEACYLATION-REACYLATION MECHANISM IS INACCESSIBLE TO PHOSPHOLIPASE C.
Meena Navidi* and Grace Y. Sun (SPON:F.S. Vomsaal). Biochemistry Dept. and Sinclair Research Farm, University of Missouri, Columbia, MO 65203.

Although phosphatidylinositol (PI) in brain is a minor phospholipid constituting only 4% of the total lipid phosphorus, it is metabolically active and is involved in the cyclic event related to receptor-mediated turnover of the poly-phosphoinositides. Besides synthesis by the de novo pathway, PI is also actively engaged in an deacylation-reacylation mechanism which is highly selective for turnover of arachidonoyl group. Using [^{14}C]-arachidonic acid and in the presence of Mg^{2+}ATP, CoA, and lyso-PI, the label is actively incorporated into PI and phosphatidylcholine (PC) of somal plasma membranes and synaptosomes of rat cerebral cortex. The washed-prelabeled membranes were further incubated in the presence of Ca^{2+} and/or deoxycholate in order to observe phospholipase A_2 and PI-phospholipase C activities in the prelabeled membranes. Under this condition, Ca^{2+} modulated some decrease in labeled PI and PC with concomitant increase in labeled free fatty acids, suggestive of phospholipase A_2 activity. However no labeled diacylglycerol was released, indicating the absence of phospholipase activity towards the prelabeld PI in the membrane. Phospholipase C activity specifically towards PI was only observed when prelabeled membranes were incubated in the presence of Ca^{2+} and deoxycholate. In another experiment in which [^{14}C]-arachidonoyl-PI was used for incubation with the same membrane fractions, both labeled diacylglycerols and free fatty acids were released as a result of incubation in the presence of Ca^{2+} (1 mM). EGTA (2 mM) blocked the diacylglycerol release completely, but only partially inhibited labeled free fatty acids formed. Deoxycholate further enhanced PI-phospholipase C activity but partially inhibited the free fatty acid release. Results thus indicate that the PI pool in brain subcellular membranes that is involved in the deacylation-reacylation mechanism is inaccessible to reaction by phospholipase C. 390.16 IN VITRO ACYLATION OF ENDOGENOUS PROTEOLIPID PROTEIN IN MYELIN SUBFRACTIONS DURING DEVELOPMENT.
Oscar A. Bizzozero*, James F. McGarry*, and Marjorie B. Lees. Biochemistry Dept., E.K. Shriver Center, Waltham, MA.

Myelin proteolipid protein (PLP) contains covalently bound fatty acids. We have been studying the mechanism of the acylation reaction and have recently shown that incubation of isolated myelin membranes with fatty acid-CoA leads to PLP acylation. Thus, the protein pool available for acylation and the acyl transferase activity are both present in myelin. These observations are consistent with an autoacylation process. The present study was designed to examine the acylation reaction in myelin subfractions during development. Rat brain myelin subfractions obtained from animals of 10, 15, 17, 20, 25, 34, and 90 days of age, were incubated with [^{3}H] palmitoyl-CoA for 15 and 30 min. Proteins were analyzed by SDS-PAGE and radioactivity was determined by fluorography. At all ages and in all subfractions, PLP and DM-20 were the only proteins labelled. Treatment with hydroxylamine showed that the fatty acid was attached to the protein by an ester linkage. Pulse-chase experiments showed that the acylation reaction was a net addition of fatty acids. In vitro acylation of endogenous myelin PLP was observed as early as 10 days and increased with age. However, the amount of label was always proportional to the amount of PLP in the fraction and, therefore, no differences were obtained in the relative specific radioactivities. Similarly, acylation of PLP in different myelin subfractions was proportional to the amount of PLP in each fraction. These results indicate that PLP acylation is a dynamic process that is occurring actively at all ages, regardless of the expression of the protein which is maximal at 17-20 days of age. The findings are in agreement with in vivo experiments showing that acylation occurs in adult animals and in all myelin subfractions. They also provide further support of our hypothesis that PLP acylation is an autocatalytic process. Supported by NIH grants HD05515 and NS 13645.

390.17 THE STRUCTURE AND ANTIGENICITY OF METALLOTHIONEIN-LIKE PROTEIN IN RAT BRAIN. M. Ebadi, D. Babin,*† and S. Swanson*. Dept. of Pharmacol., Univ. of Neb. Coll. of Med., and Dept. of Biochem.†, Creighton Univ. Sch. of Med., Omaha, NE 68105.

We have identified a metallothionein-like protein in the rat brain with an elution volume (ve/vo) of 2.06 and an Mr of <10000 daltons. The synthesis of this protein is stimulated following intracerebroventricular (icv, 0.20 μmol zinc/μl/h, 48 h), but not intraperitoneal (ip), administration of $ZnSO_4$. Furthermore, chronic ip administration of $ZnSO_4$ (5.0 mg/kg/d/10 d) does not alter the level of the metallothionein-like protein in the brain. However, the hepatic metallothionein is induced following icv administration of $ZnSO_4$ (see Ebadi, Biol. Trace Ele. Res. 11:111-127, 1987). The chromatofocusing of metallothionein-like protein isolated by gel permeation chromatography on Sephadex G-75 exhibits three zinc-binding peaks, which focus at pH 6.8, 6.2, and 5.3, respectively. It is expected that the protein peak focusing at pH 5.3 is a metallothionein-like protein. Purification of the zinc-stimulated metallothionein-like protein on ion exchange chromatography on DEAE-Sephadex A-25 columns, using a linear gradient elution procedure, produces two isoforms, eluting at 75 and 137 mM of Tris-acetate buffer, pH 7.5, respectively. The comparative high performance liquid chromatographic (HPLC) profiles of the zinc-induced hepatic metallothionein isoforms I and II (retention times 17.39 and 18.73 min) and those of the zinc-stimulated metallothionein-like protein isoforms I and II (retention times 17.32 and 18.64 min) are very similar. The amino acid compositions of metallothionein-like protein isoforms I and II, which resemble those of the hepatic metallothionein, are:

AMINO ACIDS	ISOFORM I		ISOFORM II	
	Residues	%Total	Residues	%Total
Aspartic Acid	5	8.4	4	6.5
Threonine	3	5.0	3	4.9
Serine	8	13.3	9	14.8
Glutamic Acid	3	5.0	4	6.6
Proline	2	3.3	2	3.3
Glycine	7	11.7	5	8.2
Alanine	4	6.7	5	8.2
Valine	2	3.3	1	1.6
Cysteine	17	28.3	18	29.5
Methionine	1	1.7	1	1.6
Isoleucine	-	-	-	-
Lysine	8	13.3	9	14.8

These two isoforms are devoid of histidine, arginine, leucine, tyrosine, and phenylalanine. A preliminary study completed by Professor J. Garvey (Dept. of Biol., Syracuse Univ.), using as a reference rat hepatic metallothionein isoforms I and II with ^{125}I label on isoform I, is indicative of a complete cross reactivity between the metallothionein-like protein in the brain and the hepatic metallothionein. The function(s) of the metallothionein-like protein isoforms in the brain remains to be elucidated (supported by a grant from USPHS ES 03949).

SPECIFICITY OF SYNAPTIC CONNECTIONS I

391.1 THE PERIPHERAL NERVOUS SYSTEM-CENTRAL NERVOUS SYSTEM INTERFACE: GANGLION CELL ARRANGEMENT AND AFFERENT FASCICULATION IN THE ELECTRORECEPTIVE SYSTEM OF APTERONOTUS LEPTORHYNCHUS (GYMNOTIFORMES). M.J. Lannoo*, L. Maler, and B. Tinner*. Dept. of Anatomy, Univ. of Ottawa, Ottawa, Ont. K1H 8M5 (SPON: W. Staines).

To understand the organizational principles underlying the peripheral electrosensory nervous system of weakly electric gymnotiform teleosts we labelled each of the four afferent nerves to the lateral line ganglion with HRP. We determined the position of labelled cell bodies within the ganglion and followed anterograde fibers to their termination sites in one of the four topographic maps in the electroreceptive lateral line lobe (ELL). Within the ganglion, cell bodies exhibit a general topography based on afferent nerve position: trunk electroreceptors have their cell bodies located in the caudal ganglion, cell bodies to head receptors are rostral. Cell bodies to the head exhibit a rough dorsal-ventral polarity: supraorbital nerve ganglion cells are located in the dorsal ganglion, infraorbital centrally, and mandibular ventrally. Despite this general ordering there was substantial overlap of cell bodies within the region of any particular nerve. There was no rostro-caudal polarity obvious within regions of the ganglion representing the head. There was also no clustering of cell bodies based on receptor function: ampullary and tuberous electroreceptor soma are randomly distributed. Peripherally, axons from the cell bodies fasciculate to form afferent nerves. However, within an afferent nerve there does not appear to be any topographic arrangement. Centrally, axons from the cell bodies to the ELL retain the position of their cell body until they reach the distal border of the deep fiber layer (DFL). Fibers in the DFL are fasciculated and reorganize themselves mediolaterally and rostrocaudally prior to terminating in one of the lateral three segments (tuberous organs) or the medial segment (ampullary organs). Thus the axons from ampullary receptors form a distinct fascicle separate from the axons innervating tuberous organs. Fibers in the DFL run horizontally then turn vertically to terminate in appropriate topographic order; there are few oblique fibers. Horizontal DFL fibers from dorsal receptors seem to run ventrally and vice versa. Developmentally, we view the portion of the peripheral electrosensory system outside the ELL as organized in terms of afferent nerve position, perhaps as a result of axonal guidance involving embryonic lateral line placodal migration. Centrally, the electrosensory system is organized in terms of both receptor function and topographic position. We view fiber reorganization in the DFL as a problem of selective fasciculation and target selection, perhaps mediated by chemical cues.

Supported by MRC, Canada.

391.2 COMBINATORIAL RULES IN SYNAPTIC ORGANIZATION. A. Fröhlich, Mt. St. Vincent University, Halifax, N.S., Canada, B3H 2J6.

The rules determining the combination of postsynaptic elements at a multiple-contact synapse have been studied under conditions where one of the neurons normally postsynaptic is missing.

In the first optic neuropile of the fly's visual system photoreceptor terminals form divergent tetrad synapses at which four postsynaptic elements cluster. Normally a receptor terminal synapses upon two monopolar cells, L1 and L2, which are always situated side by side in the so-called medial positions of the tetrad, flanking which are two other postsynaptic elements in the polar positions. These polar elements are most often both alpha-processes of amacrine cells or both glial cell processes. Alternatively, processes of either an amacrine cell or a glial cell may pair with a process of a third monopolar neuron, L3.

The combination of postsynaptic elements and their geometric arrangement at the synaptic site were analyzed under conditions where one of the normally obligatory postsynaptic contributors, L1, was missing. Under these conditions various findings might be expected: (a) synapses might not be found at all, (b) the synapses formed might lack postsynaptic elements, (c) the elements normally postsynaptic at the photoreceptor tetrad synapse might contribute more than their usual share of postsynaptic processes at any one synapse, (d) a cell not normally contributing to the synapse might become postsynaptic.

(a) Synapses exist despite the absence of L1. Analysis of 140 such synapses identified in consecutive electron micrographs shows: (b) in addition to the tetrads, synapses are found with three (triads) and two (dyads) postsynaptic elements. (c) The monopolar L2 still always provides one but never more than one postsynaptic element at each synapse. At synapses where L3 is a postsynaptic element it never contributes more than once, as in normal synapses. Up to three amacrine processes may be found at a synaptic site instead of the normal maximum of two. Amacrine processes may be postsynaptic together with glial processes at the same synapse, a condition normally not found. (d) In addition, beta-processes of T1 cells may occasionally contribute to a synapse. These have been suspected to contribute to "normal" synapses only rarely. This beta process or any of the other processes normally taking up a polar position may be found in the medial position otherwise occupied by the missing L1.

Further analysis should allow predictions as to the role of differential cell recognition during synaptogenesis.

391.3 REFINEMENT OF THE GOLDFISH RETINOTECTAL PROJECTION IN THE ABSENCE OF ACTIVITY AND IN THE DARK. M.D. Olson and R.L. Meyer, Developmental and Cell Biology, Developmental Biology Center, University of California, Irvine, California 92717

During optic nerve regeneration in goldfish, retinal fibers initially form a roughly ordered tectal projection which subsequently becomes more refined. Tetrodotoxin (TTX) impulse blockade has been shown to inhibit the refinement of this topographic projection. Whether any refinement can occur under impulse blockade is unknown because of the limitations of previously used mapping techniques. To address this question we have utilized spot injections of wheat germ aggulutinin conjugated to horseradish peroxidase (WGA-HRP) into the retina to reveal the tectal projection of a small area of retina.

In a previous study it was found that these spot injections in normal animals produced a sharply defined patch of product 200-300um wide in the appropriate tectal region. During optic nerve regeneration the product is initially dispersed over about one third of the tectum. This widely dispersed product subsequently becomes condensed into two or more distinct patches separated by an unlabeled interdigitating space resembling ocular dominance columns.

In the present study the optic nerve was crushed and activity was blocked by periodic injections of TTX into the vitreous. At selected time points between 30 and 120 days after nerve crush, a spot injection of WGA-HRP was made into the dorsal and ventral peripheral retina. After 18 hours the fish were perfused, the tectum serially sectioned and the WGA-HRP was visualized with tetramethyl benzidine (TMB) histochemistry.

Animals treated with TTX did not exhibit the normal sequence of projection refinement. The label remained widely dispersed in a large continuous patch for as long as 120 days of regeneration. The projection, however, did not remain as widely distributed as it was at 30 days of regeneration. A progressive topographic refinement was observed in which the label gradually condensed over the appropriate tectal region. Thus substantial topographic refinement occurs without activity but the formation of discrete clumps appears to be activity dependent. In other fish TTX activity blockade was stopped after 60 or 125 days and the fish were allowed to recover for 74 to 130 days. Normal refinement and the formation of clumps was found, indicating the TTX effect was reversible.

We also examined animals kept in total darkness during optic nerve regeneration since there has been contradictory claims of whether this disrupts refinement. These animals exhibited the normal refinement and clumping, though it may have been delayed by about two weeks.

391.4 INHIBITION OF OCULAR DOMINANCE PATCH FORMATION IN GOLDFISH OPTIC TECTUM BY INTRAOCULAR COLCHICINE. R. E. Davis, Neurosci. Lab., Univ. of Michigan, Ann Arbor, MI 48104-1687.

To examine whether their formation of functional synapses with optic tectum neurons inhibits regenerating optic axons from forming ocular dominance patches (Meyer, R.L., Brain Res. 155:213, 1978), goldfish (8-10 cm) kept at 30°C were administered right optic tectum ablation followed by io injection of colchicine (Sigma; 0.1 or 0.5) in the right eye at 2 wks postaxotomy WPA. The extent of patch formation was measured at 8, 10 and 12 WPA using autoradiography to trace the projections of the foreign axons (Schlumpf, B.E. and Davis, R.E., Brain Res. 386:305, 1986). Normally, following the tectum ablation, regenerating axons from the left eye grow into the optic layers of the ipsilateral tectum and their terminal arbors are distributed among the intact resident optic axons in a crude retinotopic map within 4 weeks (Easter, S.S. and Schmidt, J.J., J. Neurophys. 40:1245, 1977). At ca. 6-7 weeks postaxotomy (WPA) the endings of the foreign and resident optic axons variously segregate forming eye-specific patches of innervation. Patch formation appears to be complete at ca. 12 WPA (Springer, A.A. and Cohen, S.M., Brain Res. 224:23, 1981). The formation of distinct ocular patches, as demonstrated by autoradiographic localization of [^{3}H]-labeled foreign or resident axons, preceeds or accompanies synaptogenesis in the foreign optic axons, based on EM results (Airhart, M.J. and Norden, J.J., Brain Res. 325:307, 1985) and the recovery of visual function which occurs between 7-15 WPA (Davis, R.E., Schlumpf, B.E. and Klinger, P.D., Behav. Brain Res. 13:287, 1984). This suggests that optic axons may aggregate in patches prior to establishing terminals on tectum targets. The aggregation of unconnected axon endings is proposed as an alternative to the synaptic stabilization theory of patch formation (Boss, V.C. and Schmidt, J.T., J. Neurosci. 4:2891, 1984). Intoxicating the resident axons by io colchicine facilitates recovery of visual function in the foreign axons; vision with the left eye is restored within 3-5 WPA and prior to patch formation. The colchicine was found to inhibit fast axonal transport of [^{3}H]-labeled retinal protein to the tectum. In the present experiments, fish given the io colchicine treatment showed decreased patch formation up to 12 WPA. Lumicolchicine, which does not inhibit axonal transport, had no significant effect on patch formation. These results suggest that patch formation is a result of forces of axon aggregation and exclusion and the tendency of optic axons to synapse with suitable, available targets. Both connected and unconnected axons exert exclusionary forces. Aggregation forces are seen to operate only on unconnected axons. Colchicine could decrease patch formation by inhibiting axon exclusionary forces in the residents thereby enabling foreign axons to become connected before being greatly affected by the forces of axon aggregation.

391.5 RESTORATION OF VISUOTOPIC MAPS IN THE GOLDFISH TECTUM AND TORUS LONGITUDINALIS AFTER OPTIC NERVE CRUSH. D.P.M.Northmore. Dept. of Psychology & Institute for Neuroscience, University of Delaware, Newark, DE 19716.

Following crush of the goldfish optic nerve and its subsequent regeneration, the first visual multiunit receptive fields (MURFs) that can be recorded electrophysiologically in tectum are abnormally diffuse. Presumably, such MURF characteristics reflect the widespread branching of regenerating optic fibers, but not necessarily the pattern of retinotectal connections. If connectivity were more specific than tectal MURFs imply, receptive fields with relatively normal properties might be found in the torus longitudinalis (TL) which receives a topographic synaptic input from the adjacent tectal lobe.

At various times after intraorbital crush of one optic nerve, the projections of both visual fields to tectum and TL were mapped electrophysiologically using objective methods. The eyes were corrected for vision in air by contact lenses. Two-dimensional maps giving tectal MURF size, shape and strength were obtained by recording multiunit activity to red LEDs flashed in a grid pattern. Because TL responds with sustained activity only to dark objects in the contralateral field, it was mapped one-dimensionally by recording activity profiles during horizontal rotation of a vertical black stripe. The same method was also useful for mapping newly regenerated retinotectal projections.

In the normal visual system, two-dimensional mapping of tectum yielded nearly circular MURFs, 5-10° across. One-dimensional mapping of tectum typically gave double-peaked response profiles indicating the nasal and temporal limits of the MURF, while TL gave bell-shaped profiles 30-40° wide.

In the regenerating system, the earliest visual responses that were recorded in tectum around 21 days post crush (24 °C) were weak multiunit bursts to moving black objects. Flashing LEDs evoked no consistent responses. In both tectum and TL, one-dimensional mapping revealed broad, low amplitude profiles (60-90° across), often with multiple peaks, but roughly normal topography. After about 30 days, tectal responses to LEDs reappeared but MURFs were abnormally large, irregular and weak. Although these abnormalities declined over time, they were still noticeable at 200 - 250 days post crush. Meanwhile, TL response profiles returned to a normal unimodal shape.

Conclusions: The first recordable tectal MURFs are excited by dimming, and are closely related in time and space to the dimming responses of TL, suggesting that the initial diffuse retinotectal MURFs represent a similarly diffuse connectivity with the tectal cells that project to TL. (Supported by NIH grant EY2697).

391.6 NAVIGATION AND TARGET RECOGNITION OF REGENERATING RETINAL AXONS IN LONG-TERM DENERVATED TECTA IN GOLDFISH. U. Busse* and C.A.O. Stuermer (SPON: W. Harris). Friedrich-Miescher-Lab., Max-Planck-Institute, D-7400 Tuebingen, FRG.

To test whether the re-establishment of the retinotopic projection is governed by "tectal cues" induced by retinal fibers (Schmidt 1978) or by markers inherent to tectum (Meyer 1987), we pursued the path of regenerating axons in long-term denervated tecta.

The right optic tectum was deprived from retinal afferents by enucleation of the left eye. Axons from the right eye were induced to regenerate into the denervated ipsilateral right tectum by removal of the left tectum (T-rem) 0, 1, 2, 3, 4 or 5 months after eye enucleation. 20 - 150 d post-T-rem small populations of axons were labeled by intraretinal application of HRP to dorso (D)temporal (-nasal) or ventro(V)temporal (-nasal) retina and viewed in tectal whole mounts.

Despite T-rem, axons grow contralaterally and only 10 - 20 % reach the ipsilateral tectum. To evaluate whether ipsilaterally projecting (IP) axons show a preference for retinotopically appropriate regions, labeled axons were counted at the brachial bifurcation of the ipsilateral optic tract and at rostral, mid-tectal and caudal levels in the tectum (N=39). With similar label sites in retina, the relative fiber distribution over the regions examined varied little after different denervation periods so that the data were pooled.

At the brachial bifurcation of the optic tract normal axons from D and V retina segregate almost completely. IP-axons make pathway mistakes, but 78 % of D(V) axons pass through the retinotopically appropriate V(D) brachium. In tectum 82.5 % of temporal axons were found rostrally, 17 % at midtectal levels and 0.5 % caudally. In contrast, the distribution of nasal axons over rostral and midtectal regions was 53.1 % and 41.6 % resp. and 5.3 % caudally. Thus, in tecta denervated for up to 5 mo - very similar to axons regenerating immediately into contralateral tecta (Stuermer 1987) -, temporal axons show a strong preference for rostral and nasal axons for their more appropriate caudal tectum. Likewise, IP-fibers in incorrect tectal regions correct their routes and form terminal arbors 30 - 50 d after their arrival in tectum at retinotopic sites.

In tecta denervated for several months, IP-fibers still grow preferentially to the correct hemitectum and terminate retinotopically. These findings are consistent with the idea that axons are guided by long-lasting positional markers intrinsic to tectum.

391.7 TECTAL PATHWAYS OF REGENERATING GOLDFISH OPTIC AXONS AFTER HALF-NASAL OR HALF-TEMPORAL RETINAL REMOVAL. M.F. Humphrey* and C.A.O. Stuermer (SPON: J. Bolz). Max-Planck-Institut für Hirnforschung, D-6000 Frankfurt, FRG (M.F.H.) and Friedrich-Miescher-Lab., Max-Planck-Institute, D-7400 Tuebingen, FRG (C.A.O.S.).

The pathways of regenerating goldfish optic axons through the tectum are abnormal but not random. 65 % of temporal (temp) axons course through rostral tectum, 31 % in midtectal and 4 % in caudal tectal regions, whereas nasal (nas) axons proceed into caudal tectum (Stuermer et al '86). In this study we tested whether temp axons were confined to rostral tectum by the presence of nas axons in caudal tectum or whether they preferentially course within rostral tectum regardless of other axons. We similarly tested whether nas axons would grow preferentially into caudal tectum in the absence of temp axons.

Either the nasal or temporal half retina was removed at the time of optic nerve section (ONS). At 35 and 70 days after ONS regenerating optic axons were labeled with HRP and their pathways and distribution determined in DAB reacted tectal whole mounts.

In the absence of nas axons the relative density of temp axons in rostral, mid and caudal tectum was 70 %, 28 % and 2 %, respectively. The corresponding values for nasal axons were 30 %, 40 % and 30 %, respectively.

In the Stratum opticum both nas and temp axons formed fascicles similar to those of whole retinal regenerates (Stuermer et al '86). Most nas axons exited from fascicles in caudal tectum and branched preferentially there in the synaptic layer. Those which had entered the synaptic layer in rostral tectum coursed in caudally oriented routes.

The majority of temp axons exited from fascicles in rostral tectum where they branched in the synaptic layer. Near the boundary between rostral and caudal tectum, temp axons made bends to avoid entering caudal tectum. In the absence of nas axons, temp axons formed numerous mediolaterally oriented fascicles which crossed the tectal equator in the synaptic layer. Axons misrouted into the incorrect dorsal or ventral hemitectum often take such pathways (Stuermer et al '86).

Thus, nas and temp axons obviously discriminate between rostral and caudal tectum despite pathway disorganization and absence of axons from the other hemiretina. This is consistent with axonal growth being under the influence of positional markers in tectum.

391.8 MINOR REORGANIZATION OF THALAMOCORTICAL PROJECTIONS FOLLOWING LARGE NEONATAL THALAMIC LESION IN THE GOLDEN HAMSTER B.Miller*, M. S. Windrem*, L. Anllo-Vento* and B. L. Finlay. Department of Psychology, Cornell University, Ithaca, New York 14853

Previous studies on developing thalamocortical connections have demonstrated that thalamic fibers make initial contact with the developing cortex in the same tangential pattern as seen in the adult (Crandall and Caviness, 1984). This specificity is in contrast to corticofugal (callosal, intracortical and subcortical) systems which make transient initial projections to multiple targets. These corticofugal systems demonstrate considerable reorganization after early damage (see review by Fish, Mooney & Rhoades, 1985). This experiment addresses the question of whether the thalamocortical system,with its more specific patterns of early connectivity, can also reorganize its connections after early thalamic lesion.

Golden hamster pups were given electrolytic lesions on the day of birth in posterior thalamus, damaging principally either the ventrobasal (VB) or the dorsal lateral geniculate (LGd) thalamic nucleus, but also the posteromedial (Pom), lateral posterior (LP) and lateral (L) nuclei. At 30 days of age, horseradish peroxidase was implanted in either the somatosensory or visual cortex matching the area of implant with the intended thalamic lesion. The thalamus was reconstructed to determine remaining nuclei and the distribution of retrogradely labeled cells was plotted. These animals were compared to a group of normal adult animals which established which thalamic nuclei normally project to somatosensory and visual cortex.

Animals with lesions to the primary visual nuclei (LGd, LP, L) showed some retrogradely labeled cells in anomalous nuclei: Medial dorsal (MD), submedial (S), anterodorsal (AD), anteroventral (AV) and medial geniculate (MG). The projections from these nuclei were weak, however,with only a few cells per nucleus sending projections to the deafferented visual cortex. One experimental animal with a lesion of the ventrobasal nucleus had anomalously labeled cells in MD and AD, with a substantial fraction of the AD cells projecting to the deafferented somatosensory cortex.

In summary, thalamocortical projections show very limited reor ganization after early thalamic lesions.

391.9 THE ULTRASTRUCTURAL ORGANIZATION OF SEROTONIN AXONS IN ADULT RAT HYPOTHALAMUS AND SUBTHALAMUS AFTER 5,7-DIHYDROXYTRYPTAMINE-AXOTOMY INDUCED REGENERATION. M. Frankfurt and A. Beaudet. Lab. of Neuroanatomy, Montreal Neurological Institute, Montreal, Quebec H3A 2B4.

It has been shown, at the light microscopic level, that serotonin (5-HT) axons reinnervate the adult rat hypothalamus following 5,7-dihydroxytryptamine (5,7-DHT)-induced axotomy (Frankfurt and Azmitia, Brain Res., 298, 273, 1984). In the present study, the ultrastructural organization of regenerated 5-HT axons was examined in the dorsomedial hypothalamic area (DMH) and medial zona incerta (ZI), 30 (DMH) and 50 (DMH and ZI) days, after unilateral injection of 5,7-DHT or vehicle solution into the dorsolateral hypothalamus. 5-HT terminals were identified by electron microscopic (EM) radioautography following prolonged intraventricular infusion of (^{3}H)5-HT. For studies of the ZI, tyrosine hydroxylase (TH)-immunoreactive neurons were visualized in the same sections using peroxidase anti-peroxidase immunocytochemistry.

In the DMH of sham rats, (^{3}H)5-HT-labeled axon terminals were small, contained many small clear vesicles (30-50 nm), one or more large, granular vesicles (70-90 nm) and showed very few synaptic specializations. Both 30 and 50 days after 5,7-DHT injection, the internal organization and microenvironment of (^{3}H)5-HT-labeled profiles in 5,7-DHT-treated rats resembled that of sham-treated rats. However, a slight increase in synaptic frequency was found for (^{3}H)5-HT-labeled terminals in the 5,7-DHT treated group fifty days post-lesion as compared to sham. Also, at both time points there was an increase in the number of perikarya contacted by (^{3}H)5-HT-labeled terminals.

In the ZI of both sham and 5,7-DHT-treated rats, (^{3}H)5-HT-labeled axon terminals resembled those in the DMH and were observed abutting TH-positive dendrites, dendritic spines and occasionally TH-positive perikarya. Our results also indicate that, 50 days after 5,7-DHT treatment, (^{3}H)5-HT-labeled terminals in 5,7-DHT-treated rats may establish synaptic relationships with TH-positive elements as they occasionally do in both sham-treated and normal (Bosler et al., Neurosci. Lett., 48, 279, 1984) rats. These results indicate that 5-HT fibers, which have regenerated following 5,7-DHT induced axotomy, reoccupy a cellular environment comparable to that observed normally. Furthermore, some of the targets of regenerated 5-HT axons are chemically identical to those observed normally. Taken together these observations suggest that regeneration of 5-HT axons occurs with a great deal of cellular specificity and could, therefore, provide a morphological substrate for functional restoration.

Supported by the NIH and MRC.

391.10 FUNCTIONAL SIGNIFICANCE OF THE HYPERINNERVATION OF STRIATUM BY SEROTONIN NEURONS AFTER NEONATAL 6-HYDROXYDOPAMINE (6-OHDA) LESIONS. H.A. Tilson, K.P. Nanry*, S.J. Li, J.-S. Hong and M.K. Stachowiak. Lab. Behav. Neurol. Toxicol., NIEHS, Research Triangle Park, NC 27709.

Neonatal lesions of the nigrostriatal bundle (NSB) result in the ingrowth of serotonergic neurons into the striatum (Stachowiak et al., Brain Res. 291: 164, 1984). The purpose of the following experiment was to determine whether or not hyperinnervating serotonin terminals could substitute for dopamine in the control of striatal substance-P (SP) and enkephalin (EK)-containing cells. Three-day old male rats were injected with 6-OHDA (150 ug, ivt.) or vehicle. To protect noradrenergic neurons, rats were pretreated with desmethylimipramine (DMI, 25 mg/kg). When rats were sacrificed at 45 days of age, striatal DA and DOPAC contents were reduced by more than 95%. As previously reported, striatal serotonin levels were increased 2.5 fold. Changes in monoamine levels were accompanied by 50% increase in [Met^5]-enkephalin-like immunoreactivity (ME-LI) and 40-50% decreases in SP-like immunoreactivity (SP-LI). To examine the role of serotonin in the control of striatal peptides, rats treated neonatally with 6-OHDA were given bilateral injections of 5,7-dihydroxytryptamine (5,7-DHT, 16 ug/side, 30 min after pretreatment with 25 mg/kg DMI) at 30 days of age. Neurochemical measurements performed two weeks later found that 5,7-DHT decreased striatal serotonin by 50-80%. 6-OHDA did not alter the striatal ME-LI in the neonatal vehicle group, but produced an additional 50% increase of ME-LI in the 6-OHDA treated group. In contrast, 6-OHDA-induced decrease in the striatal level of SP-LI was not affected by 5,7-DHT treatment. These data are consistent with the hypothesis that heterotypic serotonergic sprouting may lead to establishment of new functional contacts between serotonin terminals and striatal EK neurons.

391.11 MONOCLONAL ANTIBODY G8 IDENTIFIES AN ANTIGEN PRESENT ON A SUBSET OF DENDRITES IN THE RAT CNS. J.M. Gossels and V.M. Ingram. Dept. of Biology, Mass. Institute of Technology, Cambridge, MA 02139.

The specificities of synapses in the CNS are ultimately determined by the protein and chemical compositions of both pre- and postsynaptic extensions. An investigation of proteins present in a subset of axons or dendrites, therefore, might help to identify or explain similarities between these synapses and possible relationships in neuronal function. A monoclonal antibody, G8, has been isolated which identifies an antigen present on a subset of dendrites in the adult rat CNS. This antibody has been used to characterize its antigen both anatomically and biochemically.

Immunohistochemistry was performed on 30 um floating cryostat sections of paraformaldehyde fixed rat brains of various ages. In the adult, G8 stains pyramidal cell cytoplasm and dendrites in the hippocampus. Staining is somewhat stronger in CA1 than in CA3. Dentate gyrus granule cell somas and dendrites also stain darkly. The G8 antigen is present in a subset of Purkinje cell bodies and their dendrites. The stained Purkinje cells are clustered and are usually localized on the dorsal region of each folium. In P1 and P5 rat brain sections G8 recognizes processes almost exclusively. The antigen is prominent in processes in the cortex, deep cerebellar nuclei, olfactory bulb, and regions of the brainstem. Staining is also evident in the hippocampus. At embryonic ages there is very little antigen present. Preliminary results in tissue culture suggest immunofluorescent staining of filaments in extensions and somas of a subset of P1 cerebellar and cortical cells.

On immunoblots of SDS PAGE G8 recognizes a single somewhat diffuse band of M.W. 52,000. This protein is more prominent in adult than newborn brain homogenates. In a comparison of brain, heart, kidney, and liver homogenates, G8 recognizes a band only in brain. The antigen recognized by G8 does not comigrate with GFAP or vimentin. The G8 antigen is actually enriched in the supernatant of a 100,000x g spin, indicating that it is a soluble component of the cytoplasm.

We are continuing to characterize the protein recognized by G8. The localization of the protein to diverse regions of the brain suggests that cells in these areas share a common function, perhaps involving a second messenger system.

391.12 MONOCLONAL ANTIBODIES DIRECTED AT THE SURFACES OF EMBRYONIC BRAIN CELLS. H. Rayburn*, H.M. Wu*, D. Stainier*, E. Bennett*, and W. Gilbert. Cellular and Developmental Biology, Harvard University, Cambridge, MA 02138.

In a search to identify antigens expressed on the surface of localized groups of cells in the embryonic CNS, monoclonal antibodies were raised to cell suspensions of rat E15 mid and hind brain. Antibodies were screened on cultures of E15 cells. Hybridomas that yielded antibodies that stained rare cells (1 in 1000 or fewer) of neuronal morphology were cloned. Six antibodies will be described. Group I consists of two antibodies which stain patches on and between cells in culture. The stain is not reduced by neuramidase treatment. Group II consists of four antibodies that stain cell surfaces and processes solidly and brightly in culture, and is neuramidase sensitive. The localization of these antibodies is being studied on 15 micron frozen sections taken from day E15 through birth. At E15 all antibodies stain cells of the germinal layers, radial fibers, and patches on the pial surface of the brain. Group I antibodies, however, are expressed primarily in small regions of the prosencephalon, whereas Group II antibodies are localized in discrete patches of cells throughout the embryonic brain. Later in development, the antibodies are expressed in fewer places. The characterization of the antibodies and the chemistry of the antigens will be presented.

391.13 MONOCLONAL CELL SURFACE ANTIBODIES DEFINING MESENCEPHALIC NUCLEI. D. Stainier*, H.M. Wu*, H. Rayburn*, E. Bennett*, and W. Gilbert (SPON: M. Livingstone).
Cellular and Developmental Biology, Harvard University, Cambridge, MA 02138.

Monoclonal antibodies (mAbs) were generated against surface antigens of brain cells. Cell suspensions from embryonic rat or mouse brains, whole or partial, were injected up to four times into the peritoneum of Balb-c mice. Hybridomas were screened via immunofluorescence on fresh mouse brain, either on small chunks in squashes or on 150 micron vibratome sections. Those showing a localized pattern of surface staining were cloned by limiting dilution. Double immunofluorescence in conjunction with a mAb against a neurofilament protein indicated the neuronal nature of the antigens recognized.

Of the mAbs isolated this way, two, B30 and B53, have been studied extensively. Around birth, they outline the neurons and the axons of what corresponds to the location and description of the deep mesencephalic and the mesencephalic trigeminal nuclei. The stained neurons include both small and large (35μ) globular or oval pseudounipolar cells and variably sized multipolar cells. Axons can be seen projecting to the cerebellum, where small cells in the granule cell layer are prominently stained. Fibers from the caudalmost part of the mesencephalic trigeminal nucleus proceed caudally to reach the ipsilateral spinal trigeminal nuclei which are also stained.

On renatured immunoblots of SDS gels, mAb B53 reacts with a 40,000 MW band which has been enriched by appropriate dissection.

391.14 IMMUNOHISTOCHEMICAL VISUALIZATION OF GABAERGIC SYNAPSES IN FROG SPINAL CORD. S.L. Stewart*, D.L. Glanzman, S.A. Hoffman and A. Narendran*. Depts. of Psychology and Microbiology, Arizona State University, Tempe, AZ 85287.

Immunohistochemical techniques were employed to visualize axo-axonal synapses within the lumbosacral region of frog spinal cord (Rana pipiens). Application of anti-GABA (gamma-aminobutyric acid) antibodies allowed detection of synapses formed by GABAergic interneurons upon terminal elements of descending lateral column (LC) fibers.

Production of anti-GABA antibodies utilized a protocol in which GABA was conjugated to a series of protein carrier molecules. This circumvented the haptenic limitation afforded by small molecules (such as amino acids) and also increased the magnitude of the specific antibody response to the common immunogenic constituent (i.e., GABA)(Seguela, P., M. Geffard, R.M. Buijs and M. Le Moal, Proc. Natl. Acad. Sci. USA, 81:3888, 1984). Rabbits were sequentially immunized with antigens prepared by glutaraldehyde-induced conjugation of GABA to bovine serum albumin (BSA), to ovalbumin, and to poly(L-lysine); subsequent reduction of immunoreactive double bonds with sodium borohydride increased the specificity of the antibodies thus produced. Standard enzyme-linked immunosorbent assay (ELISA) provided quantitative and qualitative characterization of these anti-GABA antibodies.

Positive identification of LC fibers and terminals was achieved by transection of the lateral funiculus at the level of spinal segments 5-6 approximately 7-10 days prior to sacrifice. Alternate horizontal sections of spinal cord were then stained with 1) reduced silver procedure to clearly visualize axonal and terminal degeneration, or 2) rabbit anti-GABA antisera, using a conventional indirect immunoenzymatic assay, with peroxidase conjugated goat anti-rabbit IgG antisera as the secondary antibody. Direct comparison of adjacent tissue sections provided an estimation of the association between GABAergic interneurons and LC terminals.

392.1 BIOPHYSICAL AND IMMUNOLOGICAL STUDY OF GAP JUNCTIONS IN NORMAL AND REGENERATING GIANT AXONS IN *Lumbricus terrestris*. A.W. Lyckman and G.D. Bittner. Department of Zoology, University of Texas, Austin, TX, 78712.

We are studying the cellular and molecular mechanisms in *Lumbricus terrestris* which contribute to the regeneration of cell-specific connections between uniquely identifiable neurons, the medial and lateral giant axons (MGA and LGA). The MGA and LGA are segmental interneurons which form two anatomicaly and functionally distinct giant fiber systems, the MGF's and LGF's, respectively. Septa between the giant axons of one fiber contain gap junctions. Regenerating neurites sprout from the cut ends of transected giant axons and rapidly reestablish bidirectionally transmitting connections between appropriate giant axons (Balter et al., *J. Exp. Zool.* **211**:395, 1980; Birse and Bittner, *J. Neurophysiol.* **45**:724, 1981). Injection of Lucifer yellow CH (LYCH) into regenerating giant axons has demonstrated that transected giant axons become appropriately dye-coupled across the lesion (Lyckman and Bittner, *Soc. Neurosci. Abs.*, 1986). Thus, regenerating giant axons can reform appropriate electrotonic connections.

Intracellular injection of LYCH into normal giant axons followed by epiflourescent examination showed that LYCH diffuses more rapidly and completely through the LGF than through the MGF. LGA septa, but not MGA septa, are detectably permeable to Lucifier yellow 37. In collaboration with Dr. P.R. Brink (SUNY at Stonybrook), septal permeability coefficients (P_s) were determined by intracellular injection of carboxyflourescein (CFL). Dye spread in axoplasm and across septa was measured flourometrically and analyzed by computer modelling (Brink and Ramanan, *Biophys. J.* **48**:299, 1985). P_s is 8.5×10^{-6} cm/s for the LGF and 8.6×10^{-7}cm/s for the MGF, i.e., CFL permeance is approximately ten-fold greater for the LGF than for the MGF. The difference in CFL permeance is not attributable to differences in the axoplasmic or plasma membrane diffusion coefficients, which were equal for both giant fibers. MGF and LGF septal resistances were determined by measuring trans-septal currents under double voltage clamp conditions (Verselis and Brink, *Biophys. J.* **45**:147, 1984). Septal resistance is 50kΩ for the MGF and 15kΩ for the LGF. We conclude that the LGF septa are more permeable and have a higher conductance than the MGF septa. This macroscopic conclusion has two microscopic explanations: 1) LGF septa have more gap junctions than MGF septa, and/or 2) the gap junctions of the LGF have greater single channel conductance and permeability than MGF gap junctions. In the latter case, the LGF and MGF channels might differ in protein structure.

To decide which of these two microscopic parameters may account for our macroscopic observations, we are determining the density of gap junction channels and single channel conductances in the MGF and LGF by patch-clamping septal membranes. In addition, we are determining if MGF and LGF gap junctions differ structurally by measuring differences between affinities of monoclonal antibodies to MGF vs. LGF gap junctions. It is possible that the specificity of giant fiber regeneration occurs because MGA's and LGA's are incapable of forming functional electrotonic junctions with each other because of differing and incompatible molecular specificities in their respective gap junction proteins.

Supported by grants NS 19764 and TATRP 14-9700 to GDB.

392.2 THE FORMATION OF TERMINAL FIELDS BY IDENTIFIED MOTONEURONS IN THE ZEBRAFISH. Dennis W. Liu and Monte Westerfield, Institute of Neuroscience, University of Oregon, Eugene, OR 97403.

In some parts of the nervous system, individual neurons innervate many postsynaptic cells. The size and shape of these fields appear to be precisely regulated, although the underlying mechanisms are unknown. To learn how the terminal fields of motoneurons are established, we examined the growth of individual axonal branches of two identified motoneurons in the zebrafish that innervate adjacent territories.

In adult zebrafish, muscle fibers on each side of every body segment are innervated by three motoneurons which can be identified on the basis of their cell body positions within the spinal cord. One of these motoneurons, CaP, innervates muscle fibers in the most ventral part of its body segment while the RoP motoneuron innervates fibers just dorsal of this region in the central part of the segment. There is an abrupt boundary between the terminal fields of these two motoneurons with no obvious overlap between their adjacent territories.

To understand how this boundary is established, we made direct observations of single, labeled motoneurons in live embryos throughout the first few days of development. We found that during initial development, the CaP growth cone, which pioneers the peripheral nerve, extends from the spinal cord and grows straight to the ventral part of the segment, the region that it will ultimately innervate. Consistently (13 of 16 neurons examined), however, we found that the CaP axon subsequently formed varicosities and small side branches along its proximal trunk in the region that would be innervated subsequently by the RoP motoneuron. We followed the fates of these proximal side branches on individual CaP motoneurons and found that they stopped growing during the second day of development and usually were retracted even though more distal branches located in the ventral part of the segment continued to grow.

These results suggest that the terminal fields of CaP motoneurons are established by two processes: exuberant axonal growth within the appropriate territory and selective pruning of side branches located in inappropriate regions. Supported by NS21132.

392.3 THE PROBABILITY OF QUANTAL SECRETION ALONG TERMINAL BRANCHES OF COMPETING AMPHIBIAN NERVE TERMINALS DURING SYNAPSE ELIMINATION. Nickolas A. Lavidis* and Max R. Bennett, Neurobiology Research Centre, University of Sydney, Sydney, Australia, 2006.

At amphibian motor endplates most mature and juvenile terminal branches possess a high level of quantal secretion for release sites near the branch origins; this declines exponentially for release sites further along the branch (Bennett, M.R. and Lavidis, N.A. Dev. Brain Res. 5: 1-9, 1982; Bennett, M.R., Jones, P. and Lavidis, N.A. J. Physiol. 279: 157-174, 1986). About 20% of muscle fibers in the amphibian glutaeus muscle receive a dual innervation from segmental nerves 8 (N8) and 9 (N9), (Bennett, M.R. and Lavidis N.A. J. Physiol. 375: 303-325, 1986; Malik, R. and Bennett, M.R. Dev. Brain Res. in press) during post metamorphic development, A comparison is made of the probability of quantal secretion along simple primary nerve terminal branches belonging to N8 and N9 nerve terminals on single and dually innervated muscle fibers.

On muscle fibers innervated either by N8 or N9 the total quantal content (mi) per 100μm of terminal length decreased exponentially with an increase in the total length of the terminal; the length constant for N8 was 400μm (correlation coefficient 0.79) and for N9 it was 430μm (0.81). The release of quanta along individual terminal branches measured with an extracellular electrode (me) decreased exponentially with distance from the point of branch origin for 62% of N8 terminal branches and 64% of N9 terminal branches (n=25); the remaining short branches in each case did not show a decline in release. (Table 1)

TABLE 1. Quantal release from terminals for single and dually innervated muscle fibers.

Innervation	mi/100μm of terminal length ±SD	Terminal Size (μm)	me along the length of terminal branches
Single N8	1.00±0.18	375-800	62% decreased exponentially
Dual N8	0.88±0.24	375-800	100% decreased exponentially
Single N9	2.35±0.80	50-250	64% decreased exponentially
Dual N9	0.28±0.12	50-250	100% uniformly low

There is a decrease in mi per 100μm of terminal length, as the terminals increase in length, for fibers singly innervated by N8 or N9 and for N8 on dually innervated fibers. This occurs as a result of the decline in the probability of secretion of release sites (me) added to the distal parts of terminal branches. N9 terminals on dually innervated fibers show a significantly low mi per 100μm of terminal length when compared to the larger N8 terminals. The probability of secretion at release sites of N9 terminals is suppressed by the larger N8 terminals on dually innervated muscle fibers prior to their possible elimination.

392.4 THE POSSIBLE ROLE OF ALPHA-MELANOCYTE STIMULATING HORMONE IN THE REGULATION OF SYNAPSE ELIMINATION IN THE FROG. N. Oren,* P.E. Micevych, and M.S. Letinsky. Depts. of Physiology and Anatomy, Ahmanson Laboratory of Neurobiology, University of California, Los Angeles, California 90024.

Motor nerve terminals in the frog cutaneous pectoris (CP) muscle have been shown to contain α-MSH-like immunoreactivity (Soc. Neurosci Abstr. 12:547, 1986) and to respond to in vitro α-MSH by increasing transmitter release (Johnson et al., Science 220:1071, 1983). Since the augmented release outlasted the presence of the peptide, it is possible that α-MSH modulated the nerve terminals' functional state. In order to determine whether α-MSH can modulate synaptic function in vivo we tested the effect of a potent and long lasting analogue [Nle^4, D-Phe^7]- α-MSH on synapse elimination in the frog. Tadpoles and postmetamorphic bullfrogs (Rana catesbeiana) were injected twice weekly with 0.1 ml of 10^{-6} mM analogue in 0.1% BSA-NFR or vehicle solution. Animals received injections throughout the period of rapid synapse elimination for the CP muscle beginning at premetamorphic stage XXII until the end of the second week postmetamorphosis. Motor nerve terminals were stained with nitroblue tetrazolium salts and the amount of polyneuronal innervation and synaptic organization determined for various development stages (Letinsky and Morrison-Graham, J. Neurocytol. 9:321, 1980). Administration of [Nle^4, D-Phe^7]- α-MSH, significantly accelerated the appearance of single innervation. This was especially apparent at premetamorphic stages where analogue injected tadpoles had 30-35% single innervation compared to the 12-23% found in the vehicle injected animals. With further development the amount of single innervation increased in both groups, but the [Nle^4, D-Phe^7]- α-MSH treated muscle had 57-59% single innervation compared with 41-42% in the control. Terminals innervated by overgrown branches from terminals or neighboring muscle fibers (serial-innervation) were the first to be eliminated (Morrison-Graham, Develop. Biol. 99:298, 1983). α-MSH analogue treatment also accelerated this process. The number of serially-innervated nerve terminals/muscle was significantly decreased during metamorphosis in analogue (56-61%) compared to vehicle (79-82%) treated muscles. These results suggest that α-MSH may be a factor involved in the regulation of innervation and synaptic organization in the frog. These experiments were supported by USPHS grants NS13470 (ML) and NS23468(PM).

392.5 **DIFFERENTIAL LOSS OF NEUROMUSCULAR CONNECTIONS ACCORDING TO SPINAL POSITION OF MAMMALIAN SKELETAL MOTOR NEURONS.** E.M. Callaway and D.C. Van Essen. Div. of Biol., Caltech, Pasadena, CA 91125.

We have examined the distribution of motor unit sizes as a function of spinal position in soleus muscles of rabbits at different postnatal ages. Motor unit twitch tensions and rise times were measured *in vitro*. The majority of the soleus motor axons (about 65) exit through the S1 root, while a minority (mean of 4-6 per root) leave through the L7 and/or S2 roots. Units were separated into fast and slow groups based on rise times, and twitch tensions were normalized to the median fast or slow value (as appropriate) from the S1 population for that animal to elucidate differences in size between L7/S2 and S1 root motor units. Motor unit sizes were measured from animals in 3 age groups: 4-5 days, when the rabbit soleus is heavily polyinnervated (seven animals); 8-9 days, when elimination is about half completed (six animals); and 11-15 days, when the soleus muscle is singly innervated (nine animals).

Results from 4-5 day animals indicate that when polyinnervation is substantial, L7/S2 neurons on average innervate at least as many muscle fibers as S1 neurons. For the slow population, L7/S2 units were larger than S1 units (129 ± 9 % of median, mean $\pm$ S.E.M., versus $106 \pm 5, p < 0.05$, Mann-Whitney U-test); for the fast population there was no significant difference (108 ± 7 versus $105 \pm 3, p > 0.5$). However, by 8-9 days L7/S2 units were significantly smaller than S1 units for both the slow population (84 ± 6 versus $109 \pm 5, p < 0.001$) and the fast population (79 ± 5 versus $108 \pm 4, p < 0.001$). This difference persisted in 11-15 day animals where L7/S2 motor units were smaller than S1 units for the slow population (86 ± 7 versus $107 \pm 4, p < 0.05$) and for the fast population (84 ± 7 versus $103 \pm 4, p < 0.05$). No significant differences were observed between motor units from L7 versus S2 extremes at any age, confirming the absence of a rostro-caudal bias reported by Gordon & Van Essen (*J. Physiol.* **339**, 591-597).

We conclude that motor neurons from extreme positions in the rabbit's soleus motor pool lose significantly more synapses than those from the middle. The differential loss of synapses appears to occur primarily during the earlier stages of synapse elimination, day 4 to day 9, when the rate of loss by extreme neurons is 50-80% faster than for middle neurons.

Bennett and Lavidis have shown that a differential loss of synapses by rostral versus caudal motor neurons contributes to topographic ordering of inputs within the the lateral gastrocnemius of the rat (*J. Neurosci.* **4**, 2204-2212). No topography has been demonstrated for the soleus muscle. It will be of interest whether our result is observed in other muscles or species since previous work has not made comparisons among extreme versus middle populations of motor neurons.

392.6 **REINNERVATION OF NEONATAL RABBIT SOLEUS LACKS SPECIFICITY BY FIBER TYPE.** J. M. Soha, E. M. Callaway and D. C. Van Essen, Division of Biology, Caltech, Pasadena, CA 91125.

Neonatal rabbit soleus muscle contains both fast-contracting and slow-contracting muscle fibers, in about a 2:1 ratio. Previous physiological and anatomical studies have suggested a pattern of innervation which is highly specific by muscle fiber type, even while polyinnervation remains widespread. Chemospecific recognition of appropriate muscle fibers by motor neurons during synaptogenesis is one possible mechanism by which this specificity could be established. To study this possibility, we have looked for specificity during the reinnervation which follows experimental crush of the muscle nerve in neonatal rabbits, using the distribution of single motor unit twitch tension rise times in an *in vitro* assay.

Soleus nerves of rabbits were crushed just proximal to their insertion into the muscle at postnatal day 4 (N=7, 162 units) or 1 (N=3, 72 units). To minimize the opportunity for conversion of muscle fiber contractile type, muscles were analyzed *in vitro* 6 days after nerve crush, within 1-2 days of the start of reinnervation and when reinnervation averaged only about 30% complete. Single motor units were isolated by graded stimulation of teased ventral root filaments, and twitch tension traces recorded at room temperature. Histograms of twitch tension rise times in normal muscles were broad and bimodal. In contrast, histograms of twitch tension rise times in all 10 reinnervated muscles were narrow ($\sigma = 36$ ms vs. $\sigma = 76$ ms for normal units) and unimodal, suggesting that all motor units were composed of a similar combination of fast and slow contracting fibers. Rise times for reinnervated units were intermediate to those of normal control fast and slow motor units, indicating that the unimodal distribution did not arise from specific reinnervation by only one population of motor neurons.

To control for a possible dedifferentiation of muscle fiber contractile properties during the interval of denervation, a second set of muscles was analyzed following a transmission blockade for an equal interval induced by botulinum toxin poisoning. Following bath application of 4-aminopyridine to restore synaptic transmission, motor units from toxin treated muscles exhibited a distinctly bimodal distribution of twitch rise times. Hence, short-term inactivity did not markedly affect muscle contractile properties.

From these experiments, we conclude that there is little if any specificity by fiber type during reinnervation of early postnatal rabbit soleus. Our findings do not rule out chemospecific recognition during initial synaptogenesis. Differences in our results and those of Soileau and Thompson (Soc. Neurosci. Abstr. 11:101, 1985), who reported evidence of fiber-specific reinnervation of neonatal rat soleus, remain to be reconciled.

392.7 TOPOGRAPHICALLY SELECTIVE REINNERVATION OF ADULT MAMMALIAN MUSCLES. M.B. Laskowski[1] and J.R. Sanes[2]. [1]Department of Physiology, St. Louis University School of Medicine, St. Louis, MO 63104; and [2]Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

In two rat muscles, serratus anterior and diaphragm, the rostrocaudal axis of the motor pool is systematically mapped onto the rostrocaudal axis of the muscle's surface (Laskowski and Sanes, J. Neurosci. 7: 252, 1987). One explanation for this orderly topography is that motor axons and muscle fibers might bear positionally varying labels that bias synapse formation between positionally matched partners. To test for the existence of such labels, we asked whether axons would selectively reinnervate topographically appropriate portions of the muscles following nerve transection in the adult.

Motor nerves supplying diaphragm or serratus anterior were cut near the muscle's edge; proximal and distal stumps were separated to avoid passive guidance of axons by their endoneurial sheaths. Four to 11 weeks later, following reinnervation, topography was assessed by recording intracellularly from muscle fibers while stimulating motor axons in individual ventral roots or rootlets. In both muscles, axons from the rostral portion of the motor pool reinnervated more fibers in the rostral half of the muscle than in the caudal half, while caudally-derived axons selectively reinnervated the caudal half of the muscle. Thus, while several previous studies have reported nonselective reinnervation of adult mammalian muscle (Landmesser, Ann. Rev. Neurosci. 3: 279, 1980), selectivity is demonstrable when rostrocaudal position is evaluated.

In a separate series of experiments, the serratus anterior was denervated in neonates (1 day postnatal), and reinnervation assessed 1-2 months later as above. Reinnervation was somewhat more topographically selective following neonatal than following adult denervation, although in neither case was the normal adult map faithfully reproduced. Thus, positional cues can be expressed after injury in motor neurons and muscle fibers of neonates as well as of adults. Together with previous evidence that preganglionic sympathetic axons from various levels of the spinal cord preferentially reinnervate intercostal muscles from matching segments (Wigston and Sanes, J. Neurosci. 5: 1208, 1985), the present results argue for the existence of a system of positional cues that play a role in organizing neuromuscular topography. (Supported by NIH and MDA.)

392.8 ABSENCE OF COMPETITIVE INTERACTIONS AMONG REGENERATING AXON TERMINALS OF MOTOR NEURONS. J.L. Denburg, B.F. Murphy Jr.*, S.L. Powell*. Biology Department, Univ. of Iowa, Iowa City, IA 52242.

The formation of patterns of connections between neurons and their targets often proceeds through a transient stage of multiple innervation in which the targets form synapses with both appropriate and inappropriate neurons. The elimination of the inappropriate connections is usually taken as an indication of competitive interactions among the axon terminals. In adult cockroaches, Periplaneta americana, axotomized motor neurons regenerate axons and eventually reform synapses only with the leg muscles to which they were originally connected. However, the reformation of this innervation pattern is preceded by the functional innervation of the muscles by excess motor neurons. This is followed by the elimination of the inappropriate synapses. The experiments reported here indicate that this process occurs without competitive interactions occurring among the axon terminals.

Leg muscle 178 is normally innervated only by the identified motor neuron, D_f. When the nerve containing the axon of D_f is crushed, this neuron and 30 other motor neurons are axotomized. At early stages of regeneration all of these motor neurons send axon terminals into muscle 178, as detected by the retrograde transport of wheat germ agglutinin conjugated with horseradish peroxidase (WGA-HRP). During the interval of 40 - 60 days after nerve crush the inappropriate axon terminals are eliminated and only those of the appropriate neuron, D_f, remain.

In order to test for competitive interactions among the axon terminals this experiment was repeated in insects in which D_f had been killed by intracellular injection of pronase. The destruction of this motor neuron was confirmed by the disappearance of its cell body in toluidine blue stained whole mounts of the ganglion. The destruction of D_f's axon terminals was confirmed by the loss of uptake and retrograde transport of WGA-HRP, absence of binding of a monoclonal antibody specific for axon terminals and the loss of synaptic junction potentials evoked in the muscle by nerve stimulation. All these changes occurred by 5 days after injection of D_f and at this time the nerve was crushed. Inappropriate axon terminals grew into muscle 178 and were eliminated with an identical time course as during axonal regeneration when D_f was present.

These results indicate that competition does not play a role in the reformation of the original innervation pattern. A specific cell-cell recognition is required such that each motor neuron eliminates its inappropriate axon terminals only after it synapses with its original target muscle. (Funded by NIH grant 14295).

393.1 SELECTIVE LOSS OF NON-SYNAPTIC AND CLUSTERING OF SYNAPTIC 5- HT RECEPTORS DURING INNERVATION OF AN IDENTIFIED LEECH NEURON IN VITRO. P. Drapeau and S. Sanchez-Armass*, Neurosciences Unit, Montreal General Hospital Research Institute and McGill University, Montreal, Canada, H3G 1A4.

Identified Retzius neurons reform an inhibitory serotoninergic (5-HT) synapse with pressure-sensitive (P) neurons when the somas are removed from the leech and placed in tissue culture. We have shown previously (Biophys. J. 51:63a; manuscript submitted) that single P cells in culture have both Na channels (gNa) and Cl channels (gCl) that are activated by 5-HT. When a P cell is innervated by a Retzius cell, only gCl is activated by synaptic 5-HT release. These results are consistent with previously reported observations of differences in synaptic and somal responses to 5-HT for P cells in vivo. We have measured, using the voltage clamp, the pre- and postsynaptic ionic currents induced by 5- HT in order to examine the redistribution of receptors during synapse formation in this model culture system.

Application of saturating (>100 μM) 5-HT onto single P cells elicited a gCl of 27 +/- 4 nS (n=12). Synaptic release or application of 5-HT onto innervated P cells induced a gCl= 12 +/- 3 nS (n=22) and 3.6 +/-0.4 nS (n=5), respectively. A previous electron microscopic study (J. Comp. Neurol. 256:515-527,1987) demonstrated that the area of synaptic contacts is <0.1% of the total P cell surface area. This suggests a >400 fold increase in postsynaptic gCl density.

Synaptic release of 5-HT failed to activate gNa in P cells; 5- HT application resulted in a much lower gNa (3.5 +/- 1.2 nS; n=5) than was observed in single P cells (14 +/- 3 nS;n=18). gNa was reduced in P cells paired with Retzius cells prior to synapse formation (3.0 +/- 0.7 nS; n=19) whereas gCl was unaffected (23 +/- 4 nS; n=12).

gCl and gNa were observed in presynaptic Retzius cells but were unaffected by pairing with a P cell.

It is concluded that synapse formation is preceeded by the selective loss of counter-effective gNa and results in clustering of gCl specifically in the postsynaptic neuron.

393.2 THE DEVELOPMENT OF EVOKED TRANSMITTER RELEASE AND THE PRESYNAPTIC CALCIUM CURRENT IS INDEPENDENT OF INTERNEURONAL COMMUNICATION. P.G. Haydon, E.M. Cawley*, and R.G. Wong. Dept of Zoology, Iowa State University, Ames, IA 50011, and Dept. of Biology, Carleton College, Northfield, MN 55057.

We previously reported that pairs of isolated identified neuronal somata of Helisoma reliably form a cholinergic chemical synapse in cell culture in the absence of neurite extension(Haydon, P.G. Neurosci. Abst.12: 188). Since both the pre and postsynaptic elements of the synapse are large spherical somata (100 um diameter) which are devoid of neurites, this system permits direct electrophysiological access to the synaptic terminal.

We now report that the initial development of synaptic transmission is independent of interneuronal communication. Using the somata of neurons B5 (presynaptic) and B19 (postsynaptic) we have determined whether maintained contact between B5 and B19 is required i) to gain the ability to release neurotransmitter, and ii) for the development of a specific calcium current of the presynaptic membrane.

Single identified neurons were isolated from adult specimens of the pond snail Helisoma and cultured alone in 1% hemolymph in defined medium for upto 3 days. To detect transmitter release from B5, this neuron was transferred to a recording chamber and the soma of B19 was manipulated into contact with B5 to act as a bioassay for released acetylcholine. On days 1-3 the spontaneous release of transmitter from B5 was reliably detected in the form of transient depolarizing potentials in B19. Action potential evoked release of neurotransmitter was readily detected only after a culture period of 3 days; at earlier times (days 0-1) evoked release was rarely present. Thus, maintained contact with a postsynaptic cell is not required to develop the ability to release neurotransmitter.

Given the importance of an influx of Ca^{++} in the transmitter release process, we determined the characteristics of the presynaptic calcium current when evoked transmitter release was reliably detected. A voltage clamp study of neuron B5 was performed using patch pipettes in the whole-cell mode of recording. Calcium currents were selectively detected using a combination of standard ion-substitution and pharmacological manipulations. The membrane of B5 contains at least 2 pharmacologically separable calcium currents on day 0-1 of culture. However, by day 3, when action potentials in B5 can evoke transmitter release, only one calcium current was present. This voltage-dependent current is characterized by its slow rate of decay, activation threshold of -20 mV, is blocked by cadmium, and barium readily replaces calcium as a charge carrier. Furthermore, the appearence of this specific calcium current occurs irrespective of whether the presynaptic cell (B5) contacts the postsynaptic neuron (B19). Thus, interneuronal communication is not required for the initial development of the presynaptic calcium current nor is maintained contact required to develop the ability for action potentials to evoke transmitter release

393.3 DEVELOPMENT OF PROPERTIES OF TRANSMITTER RELEASE DURING INITIAL STAGES OF SYNAPTOGENESIS. I.Chow, S.H.Young, J.Cheng* and A.D. Grinnell. Jerry Lewis Neuromuscular Res. Ctr. and Dept. of Physiol. University of California, Los Angeles, CA 90024.

Previous studies have shown that after a muscle cell is manipulated into contact with an isolated cholinergic neuron MEPP-like depolarizations can be recorded from the muscle cell within a few minutes (Chow & Poo, J.Neurosci.5:1076, 1985). We have investigated the possibility that this acetylcholine (ACh) release is specific to muscle contact and that it may be a result of cell-cell surface interaction rather than that of a secreted factor. Whether such a manipulated muscle contact will also cause changes in the neuron, such as increase in the number and preferential localization of presynaptic ACh vesicles was also investigated. In addition, experiments testing the presence of an excitation-transmitter release mechanism at the manipulated soma-myoball contacts were carried out. Both intracellular microelectrode and patch electrode recording techniques were carried out on 1-day old Xenopus nerve-muscle co-cultures. The presence of presynaptic vesicles was detected by using monoclonal antibodies to vesicle membrane proteins labelled with peroxidase-anti-peroxidase (Ab-PAP).

Excised outside-out muscle membrane patches were used to detect the extent of ACh release from growth cones of isolated neurons,and after masses of "freshly killed" muscle cells or neurons were pressed into cotnact with the region of neurite just proxinal to the growth cone. Within minutes of muscle mass contact bursts of ACh channel activity were detected, whereas no or only slight increase in single ACh channel activity was detected after neuron mass contact. Since the cell masses consisted of membranes of cells stabbed successively, these results suggest that the triggering molecules for ACh release are found on the muscle cell membrane surface.

After 5-6 hours of manipulated contact between myoball and soma Ab-PAP reaction product was found in 80% of the somata and 100% of the neurites when contact was made between muscle and neurite. In isolated uncontacted neurons about 55% of the somata and 27% of the neurites had the reaction product.

Using the tight seal patch clamp technique, which allows the detection of action currents (see Cohan & Kater, Science 232: 1638, 1986), we stimulated the soma manipulated into contact (up to 1hr) with a myoball from which continuous recording with an intracellular microelectrode was maintained. No evoked EPPs were detected even when action currents were induced in the soma, while MEPP-like depolarizations continued to be present. This suggests that, at least during the initial stages of nerve-muscle contact, ACh release cannot be easily evoked by depolariaing the somatal membrane, and that some "maturation" process takes place for development of the excitation-tansmitter release machinery.

393.4 MORPHOLOGY OF DEVELOPING NEUROMUSCULAR JUNCTION DURING THE FIRST FEW HOURS OF FUNCTIONAL CONTACT. J. Buchanan*, Y-a. Sun, and M-m. Poo. Section of Molecular Neurobiology, Yale University School of Medicine, New Haven, Ct 06510.

The structure and function of early synaptic contacts between Xenopus spinal neurons and myotomal muscle cells were studied in cell cultures. Isolated spherical muscle cells (myoballs) were manipulated into contact with the growth cone of the co-cultured neuron at a defined time and the development of synaptic transmission was monitored by tight-seal whole-cell recording of the nerve-evoked and spontaneous synaptic currents in the muscle cell. In the majority of cases, functional neuromuscular transmission was established within the first minute of contact. To assess changes in synaptic function, two separate recordings (each about 3 min duration) were made at the beginning and the end of the contact period (ranging from 20 min to 6 hrs) and immediately prior to fixation. These functional cell pairs were then fixed and processed for thin-section transmission electron microscopy.

The morphology of isolated (non-contacting) nerve and muscle cells and that of naturally-occurring neuromuscular synapses in 2-3 day cultures were used as the basis for comparing synaptic specialization in the manipulated contacts. We found that during the first few hours of contact, when functional transmission had already become highly reliable, few specializations that characterize mature synapses were detectable. Some nerve processes in contact with the muscle cells showed clear and dense-core vesicles in a distribution similar to non-contacting growth cones. Coated pits and vesicles were frequently observed in both nerve and muscle cells. Interestingly, the intercellular spacing between the nerve and muscle membranes, or cleft, at the contact sites was quite narrow (less than 20 nm) and sometimes absent. Little basal lamina-like material was seen on the cell surface or in the cleft. The earliest specialization (observed in 20 min contacts) was a fuzzy appearance of the muscle membrane at the contact sites. Thickening of muscle membrane at the contact sites was also observed in some cases (as early as 3 hrs). Out of 18 cell pairs, for which serial sections have been examined, only in one case (40 min contact) did we find aggregations of clear vesicles in a configuration similar to that of the active zone. We concluded that early functional neuromuscular contacts are in general morphologically undifferentiated and the first sign of specialization appears to be an accumulation of undefined muscle membrane associated substance at the site of contact. The narrow cleft between the nerve and muscle membranes during the first few hours of contact may allow direct interactions of cell surface molecules. Supported in part by NIH grant NS-22764.

393.5 ELEVATED POTASSIUM INCREASES SYNAPSE FORMATION IN SPINAL CORD - MUSCLE COCULTURES. J.M. Thompson and S. Ruch*. Department of Anatomical Sciences, School of Life Sciences and College of Medicine, University of Illinois, Urbana, IL 61801

One force which has been implicated in stimulating the formation and stabilization of synapses is activity of either the presynaptic and/or the postsynaptic cell. As a model of increased activity, in tissue culture the application of depolarizing agents such as increased extracellular KCl will produce a chronic depolarization of neural and muscle cells which mimics constant activation of the cells. Thus, cultures of spinal cord neurons and muscle cells were grown in 5.4 mM, 13 mM and 38 mM KCl (osmolarity balanced by reducing NaCl, normal KCl concentration of medium is 5.4 mM). To assure that the components of the culture medium do not change, the medium was changed every other day. After 1 and 5 days of coculture in these conditions, one hour prior to recording, the culture medium is removed and replaced with fresh medium at the normal extracellular potassium concentration (5.4 mM KCl). The cultures were then examined for the presence of nerve-muscle synapses by intracellular recording of the muscle cells. Previous studies have demonstrated that spinal cord - muscle synapses are formed within the first 48 hr of coculture.

We observed an increase in the percentage of muscle cells innervated by spinal cord neurons with increasing concentration of KCl at both 1 and 5 days in vitro as shown in the following table:

	5.4 mM KCl	13 mM KCl	38 mM KCl
	(Percent of muscle cells innervated)		
1-Day in Vitro	26 ± 4.0 (5)	39 ± 7.5 (5)	47 ± 13.3 (5)
5-Days in Vitro	16 ± 4.0 (5)	58 ± 6.5 (6)	78 ± 8.0 (5)

The frequency of spontaneous muscle responses also increased with potassium concentration. There was not a selective increase in the survival of neurons in the higher potassium conditions, nor was there a selective increase in neurite outgrowth from the spinal cord neurons. Addition of cytosine arabinoside, a mitotic inhibitor, to the high potassium medium did not inhibit the increase in synapse number seen at 5 days. Addition of d-tubocurarine (100 uM) partially reversed the increase in synapse number produced by the high potassium medium. These results indicate that chronic depolarization by increased extracellular potassium stimulates the number of spinal cord - muscle synapses.

393.6 AN ACETYLCHOLINE RECEPTOR INDUCING FACTOR FROM CHICK BRAIN INCREASES THE LEVEL OF mRNA ENCODING THE RECEPTOR α-SUBUNIT. D.A. Harris, D.L. Falls, and G.D. Fischbach. Dept. of Anatomy and Neurobiology, Washington Univ. School of Med., St. Louis, MO 63110.

We have recently purified a glycoprotein from chick brain that stimulates the rate of insertion of acetylcholine receptors (AChRs) into the surface of cultured chick myotubes (Usdin and Fischbach, J. Cell Biol. 103:493-507, 1986). This protein, called 42kD ARIA (for AChR inducing activity), may play a role in the nerve-induced accumulation of AChRs at developing neuromuscular synapses. The increased rate of insertion of AChRs produced by ARIA might result from enhanced synthesis of receptor subunits, or from more efficient post-translational processing. We report here that ARIA increases the level of α-subunit mRNA, and thus may increase insertion by stimulating subunit biosynthesis.

The preparation of 42kD ARIA used in our experiments consisted of the most active fraction from a Vydac C_{18} column eluted with an acetonitrile gradient in heptafluorobutyric acid. The material used is purified more than 40,000 fold compared to a saline extract of chick brain. ARIA was assayed in 35mm plates that had been seeded 5 days earlier with $1.5x10^6$ mononucleated muscle cells. The rate of new receptor insertion was measured with ^{125}I-α-bungarotoxin after blocking all preexisting receptors with unlabeled toxin. The amount of α-subunit mRNA was quantitated in the same cultures by a nuclease protection assay. ^{32}P-labeled anti-sense RNA was synthesized using a template constructed from px2, a genomic clone which contains exon 7 of the chick α-subunit (kindly provided by M. Ballivet, Universite de Geneve). Total cellular RNA (2-10 ug/plate) was hybridized in solution with the probe and then digested with RNase and analyzed on urea-polyacrylamide gels. Northern blots demonstrated that α-mRNA is approximately 3kb in both control and ARIA-treated cultures.

We have found that 42kD ARIA produces a dose-dependent increase in the amount of α-subunit mRNA, which parallels the increase in the rate of AChR insertion. A 1.5-fold stimulation can be produced by as little as 5ng/ml of the partially purified preparation, and the maximal effect was approximately 3-fold at 110ng/ml. A 3-fold increase in α-subunit mRNA levels and in AChR insertion rate was also produced by treating muscle cultures for 24 hrs with 1uM tetrodotoxin. ARIA does not alter the amount of mRNA encoding β-cytoplasmic actin.

Experiments are in progress to assess the effect of ARIA on the mRNAs encoding the γ and δ subunits of the AChR, and to determine the time course over which the factor acts.

393.7 ELIMINATION OF DISTRIBUTED SYNAPTIC ACETYLCHOLINE RECEPTOR CLUSTERS FROM DEVELOPING AVIAN FAST-TWITCH MUSCLE FIBERS ACCOMPANIES LOSS OF POLYNEURONAL INNERVATION. William D. Phillips* and Max R. Bennett, (SPON: J. Stone). Neurobiology Research Centre, University of Sydney, Sydney, Australia, 2006.

In the adult chicken, the fast-twitch fibers such as those of the posterior latissimus dorsi (PLD) muscle are each innervated at a single (focal) synaptic site. Depolarization of the fiber depends upon the propagated action potential. However nerve evoked contraction of the muscle is underway by embryonic day 6-8 (E6-E8) several days before the development of the action potential mechanism. In order to investigate the distribution of synaptic acetylcholine receptor clusters (AChR-C) on developing fast-twitch fibers, embryonic muscles were ultrasonically dissociated into single fiber fragments and were stained with fluoresceine conjugated α-bungarotoxin. Presumptive fast-twitch fibers were distinguished from the minority of slow-type fibers in the PLD by immunofluorescence using an antibody against slow-type myosin. Whereas mature PLD muscle fibers are focally innervated, at embryonic day 11 (E11) many of the fast-type fiber fragments from the PLD (44 ± 6% mean ± SEM, n = 7 embryos, mean fragment lengths 500-600 μm) displayed two or more large (longer than 2 μm) AChR-C. Double labelling with anti-neurofilament antibody suggested that most of these AChR-C (82 ± 2%) were associated with neuromuscular contacts. There was a progressive decline in the number of large AChR-C per 1000 μm of fiber from 3.2 ± 0.5 at E11 to 0.4 ± 0.1 at E18. By E18 fiber fragments with more than one large AChR-C were rare (1 ± 1%). Primary generation muscle cells identified at E11 and E16 by tritiated thymidine labelling showed a decline in the number of large AChR-C per 1000 μm proportional to that seen in the fiber population as a whole, suggesting that distributed synaptic AChR-C are eliminated from individual fibers as they mature. Thus it would seem that establishment of the mature pattern of innervation on avian fast-twitch fibers involves the elimination of distributed synaptic sites as well as the loss of multiple axon terminals at those sites which remain. Both processes occur during the period E11 to E18. Partial paralysis of embryos with d-tubocurarine starting at E6 prevented the loss of distributed AChR-C from fast-type PLD fibers between E11 and E14, suggesting that the activity of the motoneurones may play an important role in establishing the focal synaptic site AChR-C.

393.8 INVOLVEMENT OF CALCIUM CHANNELS IN THE NEUROTROPHIC REGULATION OF ACETYLCHOLINESTERASE IN MUSCLE CELLS. N. Rosenberg*, A. Yaron*, B. Attali*, F. Rieger, L. Garcia*, A.M. Tassin* and Z. Vogel. Depts. of Neurobiology and Biophysics, Weizmann Institute of Science, Rehovot, 76100, Israel, and Dev. Biol. Pathol. Neuromuscul., INSERM U153, 75005, Paris, France.

Muscle electrical activity as well as neurotrophic factors have been reported to play a role in acetylcholinesterase (AChE) accumulation in muscle. In addition, Ca^{2+} ions have been implicated in regulation of AChE in muscle cells in culture.

The high speed supernatant of extract prepared from one-month old rat brains stimulated the accumulation of AChE in C_2 cultured mouse muscle cells. We have purified the stimulatory activity by various HPLC procedures. A purification of more than 20-fold was obtained by gel filtration on TSK-G 3000SW column. This neurotrophic factor (NTF) preparation increased AChE accumulation in a dose dependent manner (1- to 4-fold). NTF is of a low molecular weight (<3000 daltons) and its $t_{1/2}$ at 100°C is 30 min. Incubation for 48 hr with NTF increased all AChE molecular forms in the muscle cultured cells. However, the increase of the 16S form was relatively more pronounced reaching 7-fold, compared with the lighter forms which increased by 2-fold. In addition, treatment with NTF changed the cellular distribution of AChE and increased the number of membrane patches containing high concentrations of enzyme. Increasing Ca^{2+} concentration in the culture medium synergistically increased the effect of NTF on AChE accumulation, while Ca^{2+} by itself had only a marginal effect. The voltage dependent Ca^{2+} channel blocker, nitrendipine, markedly inhibited the effects of NTF on the accumulation of AChE (by more than 60%). It also reduced the amount of AChE in the untreated cells although to a somewhat lesser extent (ca. 30%). Nitrendipine also sharply inhibited the clustering of AChE seen in NTF-treated cells. Moreover, preincubation of C_2 cells with the factor increased the $^{45}Ca^{2+}$ rate of influx into the cells by 50 to 80% compared with control cells.

In summary, our results suggest that NTF increases the uptake of Ca^{2+} into the cells, possibly through nitrendipine sensitive sites. This uptake of Ca^{2+} plays a role in the regulation of AChE in the cells.

Supported by grants to Z.V. form the Muscular Dystrophy Association, the U.S.-Israel Binational Science Foundation and the Minerva Foundation, Munich, Germany, and by a short term EMBO fellowship to N.R.

393.9 DELAYED EXPRESSION OF 200 KILODALTON NEUROFILAMENT PROTEIN AT THE NEUROMUSCULAR JUNCTION. S.P. Donahue*, A.W. English, and J. WOOD*. Dept. of Anatomy and Cell Biology. Emory University School of Medicine. Atlanta, GA 30322 (SPON: Barbara L. Brown).

The 200kD neurofilament protein (200kD NFP) is thought to stabilize axons in the adult CNS. We tested the hypothesis that the 200kD NFP stabilizes PNS axons by observing immunoreactivity to the 200kD NFP during neuromuscular synapse elimination, a postnatal process whereby polyinnervated muscle fibers lose innervation from all but one axon. If 200kD NFP selectively stabilizes axons, its appearance in a presynaptic axon might favor connections made by that axon. Axons lacking the 200kD NFP would be eliminated because of their inherent instability.

Fisher rats of postnatal ages zero to 19 days were deeply anesthetized and perfused through the heart with 4% paraformaldehyde and 0.1% glutaraldehyde. The triceps surae muscles were sectioned in a cryostat, reacted to demonstrate 200kD NFP immunoreactivity, and processed to localize acetylcholinesterase (AChE) at endplate sites. Animals five days and older show immunoreactivity to the phosphorylated 200kD NFP as far distally as preterminal axons. Animals younger than three days of age show immunoreactivity in axons, but not in presynaptic axons within AChE-stained endplates. Immunoreactivity appears in preterminal axons on the third postnatal day, after which time several immunoreactive axons can be observed at many endplates.

The number of axons observed to contact each fiber is comparable to that obtained by intracellular recording from muscle fibers (see also Bennett et al., J. Physiol 381:351-376, 1986), suggesting that the 200kD NFP appears in each axon that makes a functional synapse.

Some evidence suggests that the 200kD NFP becomes phosphorylated after it has been transported down the axon. Since our antibody recognizes a phosphorylated epitope, it is possible that a non-phosphorylated 200kD NFP is present during the perinatal period. To test this idea, we reacted sections from triceps surae muscles with an antibody to non-phosphorylated 200kD NFP. The results are similar to those described above, suggesting that post-translational modification of the 200kD NFP does not account for the delayed appearance we observed.

We conclude that selective appearance of the 200kD NFP does not determine which axons survive. We are unable to rule out the possibility that the subsequent selective loss of the 200kD NFP in some axons might trigger their demise. Manipulating synapse elimination by varying activity may determine if 200kD NFP expression is related to the process of synapse elimination or proceeds independently. 393.10 ULTRASTRUCTURAL CHARACTERIZATION OF SYNAPTIC BOUTONS IN THE CARDIAC GANGLIA OF POSTMETAMORPHIC AND ADULT *XENOPUS LAEVIS*. L. C. Streichert*[1,2], C. Magill[1] and P. B. Sargent[2]. (SPON: M. A. Baker). [1]Neurosciences Program, Stanford University, Stanford, CA 94305, and [2]Division of Biomedical Sciences, University of California, Riverside, CA 92521.

During postmetamorphic growth parasympathetic neurons in the frog cardiac ganglion undergo a dramatic increase in cell body size. Previous work from this lab has demonstrated that during growth there is a direct correlation between the surface area of a cell body and the number of synaptic boutons which terminate upon it. The overall density of boutons and the average size of individual boutons as seen in the light microscope remain constant. Therefore, the increase in synaptic contact which accompanies cell enlargement is regulated by increasing the *number* of synaptic boutons.

The preceding result suggests that synaptic boutons are the structural units of synaptic growth. If so, then the fine structure of boutons should appear similar in animals of different sizes and stages of postmetamorphic development. To examine this further, serial section electron micrographs of synaptic boutons from the cardiac ganglia of frogs which have just completed metamorphosis (stage 66) were analyzed and compared with those from adults.

Synaptic boutons appear as axonal swellings which contain synaptic vesicles. Active zones were defined by the presence of synaptic vesicles in proximity to electron-dense pre- and postsynaptic membrane specializations. At both stage 66 and in the adult the area of bouton-soma contact, the number of active zones per bouton, the area of active zone contact and the fraction of bouton area which is occupied by active zone were measured.

Synaptic boutons in adults usually have one active zone but may have as many as five. Larger boutons tend to have more active zones. The area of bouton-soma contact in adults varies over a 6-fold range, and the area of active zone contact varies over an 8-fold range. A similar degree of variability is observed for boutons at stage 66. No significant differences are observed for any of the parameters measured in stage 66 and adult animals, indicating that boutons at the two stages are morphologically similar. The only observed difference between synapses at the two stages is the number of boutons on the somatic surface. This result supports the hypothesis that boutons are the structural units of synaptic growth.

393.11 FORMATION OF SYNAPSES BY SYMPATHETIC PREGANGLIONIC NEURONS. R.I. Hume and M.G. Honig. Dept. of Biology, Univ. of Michigan, Ann Arbor, MI 48109.

The only synapse for which a detailed timetable of the development of synaptic function is known is the skeletal neuromuscular junction. One wonders whether the schedule of events might be different at other synapses. To address this issue we have examined the properties of developing synapses between sympathetic preganglionic neurons and their normal target neurons from sympathetic ganglia.

All experiments were performed on neurons in dissociated cell culture. Cells were labelled prior to co-culture with long-lasting fluorescent carbocyanine dyes so that we could determine the identity of each cell type (Honig and Hume, J. Cell Biol. 103:171). Our culture methods were similar to those previously described except that we found that the incidence of synaptic connections was higher when collagenase rather than trypsin was used to dissociate the cells of the spinal cord. Preganglionic neurons from stage 30-32 chick embryos were added to cultures of sympathetic ganglion neurons (from stage 33-35 embryos) that had been established 1-20 days previously.

The earliest we detected synaptic potentials was at 3 days of co-culture. The frequency with which we detected connected pairs of cells increased until about day 6 of co-culture. At 3 days synaptic function usually ceased after only a few stimuli, but by 4 days we could typically record hundreds of sequential synaptic potentials. The physiological properties of connected pairs studied between 4 and 10 days seemed quite similar. The EPSPs ranged in size from 2-30 mV and fluctuated between discrete levels (typically of 1-2 mV spacing), even when the calcium level was high (5 mM) and the stimulation rate was low (.2 Hz). At higher stimulus rates (.5-5 Hz), EPSP amplitude rapidly declined with repetitive stimulation, though the spacing between steps did not seem to change. These results suggest that release is quantal and that the number of release sites might be quite small. To test this possibility, we injected pairs of synaptically connected neurons with intracellular markers (Lucifer yellow or horseradish peroxidase). An individual ganglion cell received from 2 to 40 boutons from the preganglionic neuron that innervated it. These boutons were typically located on some, but not all, of the dendrites of the ganglion cell, and often on its cell body as well.

These results indicate that several properties of mature synapses develop relatively rapidly.

393.12 CHRONIC STIMULATION ALTERS SYNAPTIC CONNECTIVITY IN A COMPARTMENTAL TISSUE CULTURE SYSTEM. E.A. Neale, C. Yu*, L.M. Bowers*, S.C. Fitzgerald*, and P.G. Nelson. Lab. of Develop. Neurobiol., NICHD, NIH, Bethesda, MD 20892

Synapse elimination and stabilization are important phenomena during development of neuromuscular and neuro-neuronal synaptic connections. In an effort to understand the cellular mechanisms involved in these processes, we have undertaken a study of the effect of electrical stimulation on synaptic interactions occurring in multicompartment culture chambers (Campenot, R.B., PNAS, 74:4516, 1977).

Cells dissected from the ventral horn (VH) of the embryonic mouse spinal cord are plated on a layer of non-neuronal feeder cells in the central compartment of the chamber. A week later, dorsal root ganglion (DRG) cells are plated in the side compartments. Within several days, DRG neurites grow under a grease barrier into the central compartment and form synaptic contacts with the VH neurons.

Platinum coil electrodes attached to the culture dish lids are used for chronic stimulation across the chamber barriers. Intracellular recordings from DRG neurons in the side chambers are obtained in dishes connected in parallel with chronically stimulated dishes to ensure adequacy of stimulation. Stimulus parameters used in the chronic experiments are: five bipolar 100-200 μsec pulses, 1-2 msec separation, delivered at 10-20 Hz every 1-1.5 sec. Stimulus intensity is about 4X threshold.

Intracellular recordings are obtained from VH neurons in the central compartment to assess synaptic connectivity. The number of separate synaptic inputs to individual neurons is determined using graded stimulation across each barrier. (Occasional apparent antidromic activation of VH neurons is seen). VH neurons in the central compartment, but close to one of the barriers, have more inputs from DRG neurites crossing under that barrier from the adjacent side compartment than from DRG neurons in the opposite side compartment. After four days of chronic stimulation, the relative connectivity between chronically activated DRG neurons and VH neurons near the opposite barrier is increased. Preliminary data from control cultures indicate that the ratio of inputs from the adjacent as compared to the opposite side is 1.9 (n=41; SD=0.6). In chronically stimulated cultures, this ratio for VH neurons near the unstimulated barrier is 1.2 (n=29; SD=0.5). This difference is significant at $p<0.05$.

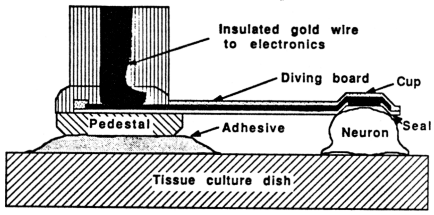
393.13 EFFECTS OF ALTERATIONS IN THE LEVEL OF SPONTANEOUS BIO-ELECTRIC ACTIVITY ON THE DEVELOPMENT OF FIRING PATTERNS IN CULTURES OF DISSOCIATED RAT CEREBRAL CORTEX. Ger J.A. Ramakers* and Michael A. Corner. Netherlands Institute for Brain Research, 1105AZ Amsterdam, The Netherlands.

Synaptogenesis in cultures of dissociated cerebral cortex of fetal rats has been found to be lowered when spontaneous bio-electric activity (SBA) is chronically suppressed with tetrodotoxin (TTX), and accelerated during treatment with the GABA-antagonist picrotoxin (PTX). Spontaneously active single neurons in normally grown cultures show a development from highly stereotyped burst activity, with overall high interval dependency and a low variability in the burst period (i.e. the interval between the onset of two successive bursts) at around 10 days in vitro (DIV), to firing patterns having a low interval dependence and high variability in the burst period by 21 DIV.

To see if TTX and PTX also affect the development of the firing patterns, cultures were grown in medium containing 0.1 uM TTX or 1 uM PTX. In control cultures (recorded at around 14, 21 and 42 DIV) the overall interval depence decreased with age. In TTX-grown cultures, when recorded in control medium, interval dependence remained as strong as at the early ages. Conversely, the PTX cultures (which were only recorded at 21 DIV) tended towards higher interval dependence than in the controls. At 21 DIV variability in the burst period was significantly lower in TTX cultures and higher in PTX cultures. These results suggest that the amount of SBA during development in vitro affects the rate of development of firing patterns, parallel to effects on synaptogenesis.

393.14 A CHRONIC *IN VITRO* MICRODEVICE-NEURON CONNECTION. W. G. Regehr*†, S. B. Kater‡, and J. Pine† (SPON: D. C. Van Essen). †Departments of Physics and Applied Physics, California Institute of Technology, Pasadena, CA 91125. ‡ Program in Neuronal Growth and Development, Colorado State University, Fort Collins, CO 80523.

A new method for long term recording from, and stimulation of cultured neurons has been developed. Silicon-based microelectrodes have been fabricated using integrated circuit technology. The figure below is a schematic of such an electrode with its silicon pedestal glued to the bottom of a tissue culture dish and in electrical contact with a neuron. Attached to this pedestal is an insulated gold wire to make contact to the electronics, and a long "diving board" structure that consists of a gold lead sandwiched between two insulating layers. This gold lead is exposed only at the bottom of a cup structure that makes a seal to the cell in much the same way as a conventional glass patch electrode.



These electrodes have been used to stimulate and record from identified *Helisoma* neurons 5 and 19. To understand device operation two electrode experiments were performed, with a diving board electrode sealed to the top of a cell, and an intracellular electrode in the same cell. With the routinely attained seals of the order of 1MΩ it is possible to record action potentials. It is also possible to stimulate a neuron with a diving board electrode and to record the resulting action potential with the same electrode. Preliminary results indicate that it will be possible to noninvasively stimulate and record from neurons for several days. Using such a long term *in vitro* connection it will be possible to answer questions about development and plasticity that are difficult or impossible to answer using conventional techniques.

393.15 NONINVASIVE TECHNIQUES FOR MEASUREMENT AND LONG-TERM MONITORING OF SYNAPTIC CONNECTIVITY IN MICROCULTURES OF SYMPATHETIC NEURONS. C.-B. Chien*, W. D. Crank*, and J. Pine. Division of Biology, California Institute of Technology, Pasadena, CA 91125

We are trying to gain insight into the cellular mechanisms of learning and memory by studying simple neuronal cultures, containing two to ten neurons each, whose connectivity we can map completely. To this end, we have developed noninvasive techniques which allow us to stimulate any selected cell(s) in one of these microcultures, and record from all the cells simultaneously. These techniques will allow us to measure all the synaptic strengths of a culture and observe their development over time. Further, we will be able to observe the effects of specific patterns of chronic stimulation (applied for days) on this development.

We have chosen cultures of principal neurons from the rat superior cervical ganglion as a simple, well-characterized system. These neurons grow reliably in long-term microculture on a substrate of extracellular matrix produced by bovine endothelial corneal cells, and form excitatory cholinergic synapses.

We apply extracellular stimulation using electrodes built into the bottom of the culture dish.[1] These electrode dishes, made with standard integrated-circuit technology, have a hexagonal array of 61 electrodes spaced such that any cell on the array may be stimulated. The electrode tips are platinized for low impedance; the electrode leads are made of indium tin oxide, a transparent conductor, to avoid obscuring the cells during optical recording.

For noninvasive recording, we stain cells with the voltage-sensitive fluorescent dye RH423.[2,3] An array of 256 optical detectors records the fluorescence signals, allowing simultaneous recording from each cell in the microculture. This dye gives a 1% fluorescence change during an action potential, which is detectable without any signal averaging; subthreshold EPSPs are detectable with averaging. Preliminary data indicate that photodynamic damage caused by the dye is not significant under the conditions we will use. Recording from all the cells in a culture while stimulating each cell in succession gives the physiological strengths of all the synapses in the culture.

Initial measurements of synaptic connectivity using these techniques will be presented.

394.1 IMMUNOCYTOCHEMICAL CHARACTERIZATION OF A DORSAL ROOT GANGLION CULTURE SYSTEM DERIVED FROM TWO-DAY OLD RATS. J.J. Lah* and R.W. Burry (SPON: J.S. King). Dept. of Anatomy, The Ohio State Univ., Columbus, OH 43210.

Study of early events in the formation of synapses is often complicated by the presence of previously formed synapses. Dorsal root ganglion (DRG) cells do not form synapses on each other in culture. A culture system of DRG neurons could therefore be used advantageously in the study of early molecular events involved in synapse formation.

Dorsal root ganglia from 2-day old rats were pooled and incubated with collagenase and DNAse at 37°C. After 1 hr., the ganglia were mechanically dissociated, and neurons were grown on a collagen substrate with medium containing NGF at 20 ng/ml. Cultures were treated with cytosine arabinoside from 12 hrs. to 6 days in culture. This procedure yields DRG neuronal cultures contaminated by very few non-neuronal cells. Morphometric analysis has shown that the culturing procedure selects for neurons with maximum cell diameters ranging between 8um-56um (mean=22um). Cell counts of cultures have shown that there is approximately 30% neuronal cell survival at 14 days in culture.

Using immunocytochemical techniques, we have begun more detailed characterization of the expression and localization of several antigens in this culture system. Monoclonal antibodies directed against MAP-2 and Tau protein (courtesy of Dr. Lester Binder) were employed for initial characterization of processes formed by DRG neurons in culture. At 7 days in culture, staining for MAP-2 was largely restricted to the cell body. In contrast, all processes appeared to stain positively for Tau protein. Cultures were also probed for the expression of synapse-specific antigens using antibodies directed against SVP-65 (courtesy of Dr. William Matthews) and Synapsin-1 (courtesy of Dr. Pietro de Camilli). When followed for 14 days in culture, SVP-65 staining could be detected through the entire period. The pattern of staining, however, showed variable intensity in individual cell bodies and processes. Synapsin-1 immunoreactivity could also be followed through 14 days in culture, and, like SVP-65, there was variability in the intensity of staining of cell bodies. However, most processes appeared to be positive for Synapsin-1.

From the data described, we can draw several conclusions: 1) Viable, long-term DRG neuronal cultures can be conveniently established from 2-day old rats. 2) These cultures contain neurons with a wide range of cell diameters. 3) Processes produced by these neurons in culture stain for Tau protein but not MAP-2, indicating that they are axons. 4) In the absence of synapse formation, cultured DRG neurons show positive immunoreactivity for the synapse-specific proteins Synapsin-1 and SVP-65; it is not yet clear whether or not this is related to formation of synapses prior to removal of DRG neurons for culturing.

394.2 PROTEINS ISOLATED FROM POLYLYSINE-COATED BEADS INCUBATED WITH NEURONALLY ENRICHED CEREBELLAR CULTURES Richard W. Burry and Diane M. Hayes*, Department of Anatomy, and the Neuroscience Research Laboratory, The Ohio State University, Columbus, Ohio. 43210-1239

The mechanisms for control of synapse formation are not known, but proteins are probably involved as receptors for signals between cells and/or as the signals themselves (Burry, 1985, Brain Res. 344:109-119). In an attempt to identify developmental synaptic proteins, we have isolated proteins from fractions of neuronally enriched cell cultures. An enriched population of neurons was obtained from mixed glial and neuronal cultures after antimitotic drug treatment. The presynaptic elements were further purified by isolating polylysine-coated beads from the cell cultures after presynaptic elements had formed on the surface of the bead.

Cerebella from 3 day rats were mechanically dissociated, plated at 2.5×10^4 per cm^2, and treated at 2 days with cytosine arabinoside. At 11 days in culture, an average of 77,500 neurons per cm^2 (31% cells plated) and 650 non-neuronal cells per cm^2 (0.3% cells plated) were seen. Thus, at 11 days in vitro, neurons represent 99.3% of the cells in culture.

The proteins present in these neuronal cultures were examined with NEPHGE after incubation of the culture in ^{35}S methionine. With autoradiography over 60 different proteins were detected. Most of the proteins were under 120 kd and only a dozen were basic proteins. To determine if the cultures were enriched with some proteins, the pattern seen in the cultures was compared to a silver stain of NEPHGE gels from 7- to 10- day rat cerebellum. While many of the proteins seen in cultures were detected in animals, the cultures showed numerous different proteins not detected in the animal

To further investigate the synaptic proteins, polylysine coated-beads were isolated from enriched neuronal cultures. Presynaptic elements which form on the surface of the bead (Burry, 1982, Brain Res. 247:1-16) were isolated from the cultures by centrifugation through a PBS Percoll gradient. Microscopic analysis showed that neuronal aggregates were separated at the top of the gradient. The pellet contained no neuronal aggregates and greater than half of the beads. Scintilation counts of the beads showed that between 3% and 10% of the counts from the neuronal culture were isolated with the beads. As a control, cultures were incubated for a few minutes with beads and had less than 1% of the counts. NEPHGE of the isolated bead proteins showed good correlation with the proteins from the whole culture. Enrichment for several proteins and reductions in other proteins was seen.

It is concluded that the enriched cerebellar culture system is an excellent source of neuronal proteins for studies of development and synaptogenesis.

394.3 EXPRESSION OF A UNIQUE NERVE TERMINAL PROTEIN DURING SPINAL CORD DEVELOPMENT. L.M. Cabalka*, T.C. Ritchie, M.A. Thomas* and J.D. Coulter. Dept. of Anatomy, The University of Iowa, Iowa City, IA 52242.

The S-7B8 monoclonal antibody binds to a membrane protein associated with select nerve terminals in rat central nervous system. In spinal cord, laminae I and II display the highest density of nerve terminals containing S-7B8 antigen, with a moderate density extending through lamina V. Primary sensory afferents contribute the majority of S-7B8 immunoreactive terminals. No S-7B8 immunoreactivity is present in cell bodies or most fiber tracts, in the adult. However, immunocytochemical studies on developing rat spinal cord indicate that S-7B8 antibody strongly stains growing nerve fibers. Staining becomes concentrated in nerve terminals during and after synaptogenesis. Primary afferent fibers in the spinal cord first exhibit S-7B8 immunoreactivity between embryonic day 15 and 17. Staining first appears in deeper laminae of the dorsal horn by postnatal day 2 (P2) and expands dorsally between P4-P6. Staining also occurs along the superficial margin of the dorsal horn at this developmental stage. By P7, S-7B8 immunoreactivity extends throughout the superficial laminae. Thereafter, staining in laminae I and II increases and achieves the characteristic adult pattern in the third postnatal week. Axons in the developing corticospinal tract (CT) also exhibited S-7B8 immunoreactivity. By P2, staining appears in the brainstem, and at P7 the stained CT was clearly discernible in lumbar spinal cord. The staining density peaked at P15, then diminished. The development of the S-7B8 staining pattern in the spinal cord dorsal horn confirms previous studies of the synaptic development of the primary afferent and corticospinal systems.

The adult ventral horn contains only sparsely distributed S-7B8 immunoreactive nerve terminals, but transient staining was evident between P0 and P15, with peak density between P7 and P9. Loss of this staining in later development may indicate developmental regulation of S-7B8 antigen production or a pruning back of nerve endings containing the antigen. A dot-immunobinding assay was used to compare the amount of S-7B8 antigen in particulate fractions of developing and adult spinal cord. The specific activity of the S-7B8 antigen peaks during the second postnatal week, correlating well with the wide distribution of S-7B8 immunoreactivity in the spinal grey matter at this developmental stage.

In summary, the results suggest that the S-7B8 antibody is a useful probe for studying the development of synaptic connections in the spinal cord. Supported by NS23783.

394.4 EXPRESSION OF A SELECTIVELY DISTRIBUTED NERVE TERMINAL PROTEIN IN CEREBELLAR CORTEX. D.J. Wright, T.C. Ritchie, and J.D. Coulter. Dept. of Anatomy, University of Iowa, Iowa City, IA 52242.

The monoclonal antibody S-7B8 recognizes an antigen localized to a subset of nerve terminals in rat brain. The antigen is an integral membrane protein and may be associated with synaptic vesicles. This report describes the distribution and developmental expression of the S-7B8 antigen within the rat cerebellum. In the adult rat, positive immunocytochemical labeling with the S-7B8 antibody is concentrated within the cerebellar molecular layer, although there is some sparse punctate labeling of the neuropil within the granule cell layer. No cell bodies were found to stain. Colchicine application to the cerebellum prior to processing for immunocytochemical staining did, however, cause the build up of the antigen within certain neuronal cell bodies. After 24 hours exposure to colchicine, numerous medium sized neurons identified as Golgi cells were labeled within the most superficial part of the granule cell layer. After 48 hours of exposure to colchicine, most of the granule cells also appear to contain diffuse S-7B8 positive staining. Hence the antigen recognized by the S-7B8 monoclonal antibody is localized to neurons that utilize different neurotransmitters, since Golgi cells and granule cells are believed to use GABA and glutamate respectively.

The developmental expression of the nerve terminal protein recognized by the S-7B8 antibody has been studied in vivo and in vitro. At a postnatal (P) age of 10 days, S-7B8 positive labeling is first discernible within the deeper half of the developing cerebellar molecular layer. The width of the S-7B8 positive zone broadens to the most superficial part of the molecular layer by P21. The time of appearance of the antigen recognized by the S-7B8 antibody corresponds to the formation of synapses by the parallel fibers of the granule cells, suggesting an important function for this protein within the newly forming parallel fiber synapses. Cultured neurons of dissociated P7 rat cerebellum plated onto poly-l-lysine coated glass coverslips express the S-7B8 antigen after three days in vitro. The S-7B8 positive labeling first appears within neuronal cell bodies, and subsequently becomes localized to growing neurites. Within 7 days in vitro the staining is punctate, and is presumably localized to presynaptic nerve terminals.

In conclusion, within the cerebellum, the antigen recognized by the S-7B8 monoclonal antibody is expressed by neuronal populations of apparently unrelated neurotransmitter content and is expressed by neurons at the time of synapse formation.

Supported by NIH grant NS23783.

394.5 ENDOGENOUS OPIOIDS REGULATE NEURONAL DEVELOPMENT AND SYNAPSE FORMATION IN THE RAT CEREBELLUM: ULTRASTRUCTURAL OBSERVATIONS. K.F. Hauser, P.J. McLaughlin and I.S. Zagon. Dept. of Anatomy, The M.S. Hershey Medical Center, The Pennsylvania State Univ., Hershey, PA 17033.

Utilizing Golgi-impregnations at the light microscopic level, we have previously demonstrated that endogenous opioid systems (i.e., endogenous opioids and opioid receptors) regulate Purkinje cell dendrite growth and spine formation (Hauser et al., 1987, Brain Res., in press). In these studies, continuous blockade of endogenous opioid-opioid receptor interactions (e.g., daily s.c. injections of 50 mg/kg naltrexone (NTX)) was used to accelerate growth, whereas intermittent (4-6 hour) blockade (e.g., 1 mg/kg NTX per day), which results in increased opioid-opioid receptor interactions, was utilized to inhibit growth. In the present experiment, the above opioid antagonist paradigm was used to examine the ultrastructural consequences of manipulating endogenous opioid systems on cerebellar development during the preweaning period. Sprague-Dawley rats were treated with sterile water (controls), 1 mg/kg NTX, or 50 mg/kg NTX from birth until sacrifice at day 10. Cerebellar lobules 7 and 8 were processed for electron microscopy, and Purkinje and granule cells were examined in detail, including quantitative analysis of molecular layer synapses.

Purkinje cells in rats receiving continuous opioid receptor blockade had more mature cytoplasmic features and synaptic development. Moreover, granule cell development was correspondingly accelerated by complete receptor blockade. Counts of molecular layer synapses/100 um^2 demonstrated that there were up to 2 fold more synapses following continuous opioid receptor blockade compared to controls. In contrast, with intermittent blockade, the degree of Purkinje cell maturation, as well as synaptic density, were comparable to controls. These results indicate that endogenous opioid systems regulate synapse formation, as well as cytologic differentiation, by functioning as an inhibitory influence. When findings from previous Golgi studies are considered, a direct correlation between Purkinje cell maturation and the density of afferent synapses is apparent. Because Purkinje cell development is highly dependent on the amount and type of presynaptic input, this suggests that opioid-dependent alterations in afferent cell populations are likely to be a significant mechanism by which these neuropeptides regulate Purkinje cell maturation.

Supported by NIH grant NS-20500.

394.6 PURKINJE CELL DENDRITIC SPINE MORPHOLOGY IN LEAD TREATED KITTENS: AN ELECTRON MICROSCOPIC STUDY. George W. Patrick and Douglas L. Franke*, Department of Anatomy, Indiana University School of Medicine, Fort Wayne, Indiana 46805.

Lead poisoning is known to cause neurological problems in children. Among these neurological disorders are hyperactivity, slowed learning rates, mental retardation and loss of fine motor coordination. Studies in rodents have shown that lead exposure causes a decrease in the dendritic arbor and number of synapses on cerebellar Purkinje cells. In previous studies of lead treated kittens using Golgi-Cox staining, we found changes in dendritic spine numbers and branching patterns of Purkinje cells. This study was designed to describe the ultrastructural consequences of lead on Purkinje cell synaptic spines. Kittens were obtained at birth from the colony at the Fort Wayne Center. Beginning the day after birth and continued daily, the kittens were given 20 mg/kg body weight lead acetate solution by esophageal intubation, with one kitten maintained as a control receiving sodium acetate solution (20 mg/kg). Kittens were killed at weekly intervals to determine the time course and sensitive period of lead induced pathology. The animals were anesthesized with 70 mg/kg pentobarbital and perfused by a transcardiac cannula with 0.9% saline followed by cold 6% glutaraldehyde in phosphate buffer. The brain was removed and a piece of cerebellum posterior to the central fissure (simple lobule) was excised. This was postfixed in glutaraldehyde and then osmium, and embedded in epon. Thin sections were obtained and electromicrographs of dendritic spines were developed. Synaptic spine counts and areal measurements were taken with a digitizer and WiCat computer. Students T-test and ANOVA were used for statistical analysis. No statistical differences were seen in spine area or number of synapses at any age. Preliminary data analysis indicates that control animals may have more short stubby and long thin shaped spines, while lead animals have greater numbers of short thin, pedunculated and polymorphic shaped spines. Differences in spine shape have been shown to represent alterations in functional status of the synapse. These results suggest that despite the increased density of dendritic spines seen in Golgi-Cox stained neurons, the brain of lead-treated animals is capable of sufficient plasticity to compensate at the synaptic level. However, this compensation does not preclude effects on the temporal and spatial properties of incoming electrical signals, thereby disrupting fine motor coordination without affecting the gross functioning of the cerebellum.

394.7 ULTRASTRUCTURAL LOCALIZATION OF A GROWTH-RELATED ANTIGEN (5B4) AND ITS RELATIONSHIP TO IMMUNOCYTOCHEMICALLY IDENTIFIED NEURONS IN THE OLFACTORY BULB OF THE ADULT RAT. Thomas J. Mahalik, K.H. Pfenninger, and Thomas E. Finger. Dept. of Cellular and Structural Biology, University of Colorado Medical School, Denver, Colorado.

The ultrastructural distribution of the growth-regulated antigen, 5B4, was examined in the olfactory bulb of adult rat. Previous light microscopic studies (Ellis et al. J. Cell Biol. 101: 1977:85) have shown that the 5B4 antibody labels the growth cones of fetal neurons and a subpopulation of olfactory axons of the adult rat.

Rat olfactory bulbs were prepared for immunocytochemistry. 5B4 immunoreactivity was detected with either the immunoperoxidase or immunogold methods. To determine whether 5B4 immunoreactivity was expressed in identified olfactory neurons, an antiserum against tyrosine hydroxylase (TH) was used as a marker for dopaminergic periglomerular cells; in these experiments 5B4 and TH immunoreactivities were detected simultaneously by combining the immunogold and immunoperoxidase methods.

By light microscopy, 5B4 immunoreactivity was present within the olfactory nerve and periglomerular layers of the olfactory bulb. TH-like immunoreactivity was present in cell bodies adjacent to each of the olfactory glomeruli. By contrast, significant amounts of 5B4 immunoreactivity were present in only a subset of olfactory glomeruli.

Ultrastructurally, 5B4 was present in clusters of axons of the olfactory nerve layer. 5B4 immunoreactivity was present on cytoplasmic membrane faces in axons of the olfactory nerve layer, and in axon terminals in the periglomerular layer; within labeled terminals, reaction product was present on the outer surface of round vesicles. 5B4 immunoreactivity also was observed in discrete patches along the plasmalemma (cytoplasmic face) of periglomerular cells, and of dendrites of the periglomerular layer. In some cases 5B4 immunoreactivity was co-localized with tyrosine hydroxylase-like immunoreactivity. If the 5B4 antigen is a marker for neuronal growth as the earlier data suggest, then our new findings suggest that the turnover of the olfactory axons is associated with remodeling of post-synaptic elements in the olfactory bulb.

394.8 INCREASES IN MESSENGER RNA FOR ACTIN AND TUBULIN WITHIN THE DENERVATED NEUROPIL OF THE DENTATE GYRUS DURING LESION-INDUCED SYNAPTOGENESIS. L.L. Phillips, D.M. Chikaraishi*, and O. Steward. Departments of Neuroscience and Neurosurgery, Univ. of Va. Sch. of Med., Charlottesville, VA 22908, and Neurosciences Program, Tufts Univ., Boston, MA 02111.

Following the denervation of the dentate gyrus there is an increase in the proportion of dendritic spines with underlying polyribosomes (Steward, O., J. Neurosci., 3:177, 1983) and an increase in protein synthesis within the dendritic laminae (Fass, B. and Steward, O., Neurosci. 9:653, 1983). These increases are maximal during the period of lesioned-induced synaptogenesis. We have been interested in identifying the protein(s) which are produced at these sites of local synthesis. Our initial biochemical analysis of dissected samples of the neuropil layer showed that polypeptides of molecular weights 43, 52 and 56 kD contain the highest levels of radioactivity following a ^{3}H-leucine pulse (Phillips, et al., Soc. Neurosci. Abstr. 18:1019, 1984). These molecular weights correspond approximately to actin and tubulin, suggesting that actin and tubulin might be amongst the proteins that are synthesized in the denervated neuropil. In the present study we utilize in situ hybridization to evaluate this question, employing high specific activity riboprobes for the messenger RNAs (mRNAs) of beta-actin and beta-tubulin in order to determine the cellular localization of the respective mRNAs.

Adult male albino rats were sacrificed by vascular perfusion of mixed aldehyde fixative at 6 days after unilateral destruction of the entorhinal cortex. Vibratome sections were hybridized with ^{3}H-labeled riboprobes (Melton, D.A., et al., Nuc. Acid Res. 12:7055, 1984) prepared from either chick beta-actin or chick beta-tubulin mRNA and processed for light microscopic autoradiography. Qualitative analysis of autoradiograms at 6 days after lesion showed a clear increase in mRNA for beta-actin within the denervated neuropil when compared to the intact dentate gyrus on the contralateral side. High grain density was visible over the outer two-thirds of the molecular layer which contains the denervated dendrites of the dentate granule neurons. There was also an increase in labeling over the same zone using the riboprobe for beta-tubulin mRNA.

The present results suggest that local protein synthesis within the denervated neuropil of the dentate gyrus involves, in part, an increase in the production of cytoskeletal proteins. These proteins could play a role in the activity of neurons or glial cells, or both during the degeneration/regeneration cycle induced by lesion. Supported by NIH grant NS 12333 to O.S.

394.9 USE OF IN SITU HYBRIDIZATION AND IMMUNOCYTOCHEMISTRY TO EXAMINE THE DISTRIBUTION OF ACTIN AND TUBULIN AND THEIR MESSENGER RNA IN CNS NEURONS. P.A. Trimmer, L.L. Phillips, and O. Steward. Depts. of Neuroscience and Neurosurgery, Univ. of Virginia. School of Medicine, Charlottesville, VA 22908.

During early development, neurons elaborate different processes (axons and dendrites) which are structurally and functionally distinct, and which differ in molecular composition. How differences in the molecular composition of axons and dendrites occur is currently unknown, but one possibility is that the synthesis of certain proteins may be localized in particular regions of the cell. Lawrence and Singer (Cell, 45:407-415, 1986) detected localized concentrations of messenger RNAs (mRNA) for actin and tubulin in the cytoplasm of fibroblasts. The focus of this study is to determine if there is a similar compartmentalization of mRNAs in neurons and if their distribution correlates with the expression of their respective proteins. We addressed this question by examining the distibution of actin and tubulin and their mRNAs in cultures of neurons from the dentate gyrus using immunocytochemistry in combination with in situ hybridization.

Coverslip cultures of isolated neurons were hybridized with 3H-labeled riboprobes for actin and tubulin mRNA prepared from chick beta-actin and beta-tubulin by D. M. Chikaraishi according to the method of Melton, D. A. et al. (Nucl. Acid Res. 12:7035-7056, 1984). Parallel coverslip cultures were hybridized with a cDNA probe complementary to ribosomal RNA to determine the overall distribution of protein synthetic machinery. The cultures were subsequently immunostained with antibodies to actin, beta-tubulin or cell specific markers such as GFAP and MAP2 using indirect immunofluorescence. The coverslips were then processed for autoradiography.

The mRNAs for actin and tubulin appeared to be distributed throughout the cytoplasm of the cell soma, with no evidence of accumulations at poles of the cell giving rise to either axons or dendrites. These data suggest that actin and tubulin synthesis may not be regionally localized in these neurons. Immunocytochemical staining for actin and beta-tubulin was also distributed throughout the cytoplasm of these neurons. In future studies we plan to evaluate whether molecules that are differentially distributed in neurons (i.e., MAP2 and Tau) are synthesized in distinct intracellular locations. Supported by NIH grant NS12333 to O.S. P.T. is supported by training grant NS 07199.

394.10 A NOVEL SUBTYPE OF AXOSPINOUS SYNAPSES DISTINGUISHED BY A SEGMENTED POSTSYNAPTIC DENSITY. Y. Geinisman, F. Morrell and L. de Toledo-Morrell. Dept. of Cell Biol. & Anat., Northwestern Univ. Med. Sch. and Depts. of Neurol. Sci. and Psychol., Rush Med. Coll., Chicago, IL 60611.

The so-called perforated axospinous synapses, which are characterized by a discontinuous postsynaptic density (PSD), have been proposed to represent structural intermediates in the processes of synapse turnover or division (Nieto-Sampedro, M. et al., Proc. Natl. Acad. Sci. USA, 79:5718, 1982; Carlin, P.K. & Siekevitz, P., Ibid., 80:3517, 1983; Dyson, S.E. & Jones, D.G., Dev. Brain Res., 13:125, 1984). These hypotheses have postulated the existence of axospinous synapses with the PSD consisting of separate segments: the segmented PSD develops through the stages of perforated and U-shaped PSDs as a step of splitting of a large synapse into smaller ones. However, axospinous synapses with segmented PSD had not been directly observed so far. We now present direct evidence for the existence of such synaptic contacts.

Axospinous synapses were examined in the molecular layer of the rat dentate gyrus. Serial section analysis of synapses, which exhibited a PSD discontinuity, was performed. Reconstruction of each discontinuous PSD was made in a plane perpendicular to that of serial sections. The results obtained indicate that some profiles of perforated synapses visualized in random sections of osmicated tissue are produced by sectioning of synapses with perforated or U-shaped PSDs. This observation confirms the conclusions of earlier serial section studies (Peters, A. & Kaiserman-Abramof, I.R., Z. Zellforsch., 100:487, 1969; Cohen, R. & Siekevitz, P., J. Cell Biol., 78:36, 1978; Nieto-Sampedro, M. et al., 1982; Calverley, R. K.S. & Jones, D.G., Cell Tiss. Res., 247:565, 1987). Additionally, it has been found in this study that another synaptic subtype, namely synapses with segmented PSD, contributes to the number of profiles of perforated synapses. Synaptic contacts with segmented PSD are distinguished by the presence of 2-5 discrete PSD segments at the interface between a presynaptic axon terminal and a postsynaptic dendritic spine.

The demonstration of axospinous synapses with segmented PSD is consistent with the hypotheses of synapse turnover and division. However, the hypothesized final splitting of synapses may not be necessary. Conceivably, the segmented PSD may evolve from perforated and U-shaped PSDs to form a specialized synaptic contact of an unusually high efficacy. Each PSD segment is a component of a separate synaptic complex comparable to that of a small axospinous synapse with a continuous PSD. A concerted activation of several synaptic complexes within a single synaptic junction may provide a mechanism for an amplification of synaptic transmission.

394.11 SYNAPSES ON DENDRITIC SHAFTS EXHIBIT A PERFORATED POSTSYNAPTIC DENSITY. D.L. Scholz*, Y. Geinisman, F. Morrell and L. de Toledo-Morrell. Dept. of Cell Biol. & Anat., Northwestern Univ. Med. Sch. and Depts. of Neurol. Sci. and Psychol., Rush Med. Coll., Chicago, IL 60611.

A postsynaptic density (PSD), which contains a perforation(s), has been hypothesized to underlie an augmentation of synaptic efficacy or to be a structural intermediate in the processes of synapse turnover or division (Peters, A. & Kaiserman-Abramof, I.R., Z. Zellforsch., 100:487, 1969; Greenough, W.T. et al., Science, 202:1096, 1978; Nieto-Sampedro, M. et al., Proc. Natl. Acad. Sci. USA, 79:5718, 1982; Carlin, P.K. & Siekevitz, P., Ibid., 80:3517, 1983). If any of these hypotheses is correct, then the presence of PSD perforations reflects a fundamental property of synapses, and different synaptic types should incorporate a proportion of junctions characterized by a perforated PSD. However, only the category of synapses on dendritic spines had been demonstrated to include synaptic contacts with a perforated PSD (Peters, A. & Kaiserman-Abramoff, I.R., 1969; Cohen, R.C. & Siekevitz, P., J. Cell Biol., 78:36, 1978; Nieto-Sampedro, M. et al., 1982; Calverley, R.K.C. & Jones, D.G., Cell Tiss. Res., 247:565, 1987; Geinisman, Y. et al., Soc. Neurosci. Abstr., 1987). To elucidate whether synaptic types other than axospinous junctions also include synapses with a perforated PSD, we undertook a serial section study of synapses on dendritic shafts.

The tissue was processed for electron microscopy by means of perfusion fixation with aldehydes, osmication, Araldite embedding and section staining with uranyl acetate and lead citrate. Asymmetrical synapses on dendritic shafts were examined in electron micrographs of serial sections obtained from the molecular layer of the rat dentate gyrus. Some of these synapses were found to exhibit profiles of a discontinuous PSD. PSD reconstructions from serial sections showed that profiles of discontinuous PSDs observed in random sections of dendritic shaft synapses were generated by sectioning of PSD plates that contained 1-3 perforations.

The demonstration of dendritic shaft synapses distinguished by a perforated PSD complements the results of serial section studies cited above, which document the existence of axospinous synapses with a perforated PSD. Moreover, some axosomatic synapses may also have a perforated PSD, since PSD discontinuities have been noticed in their random sections (Peters, A. et al., The Fine Structure of the Nervous System, Saunders, Philadelphia, 1976: 147). These data, taken together, indicate that the presence of PSD perforations is a general phenomenon common to subpopulations of different synaptic types. Such a phenomenon may, therefore, represent a structural correlate of a basic synaptic function.

394.12 DEVELOPMENT OF HIPPOCAMPAL SYNAPSES, SPINES AND LTP. K.M. Harris, F.E. Jensen, and B. Tsao. Dept. Neurosci., Children's Hospital, Boston, MA 02115

In an earlier study it was shown that the magnitude of hippocampal longterm potentiation (LTP) produced at postnatal day 15 (P15) in stratum radiatum of area CA1 is 3-4 times greater than the magnitude observed in hippocampal slices from adult rats (Harris KM. and Teyler TJ., 1984, J. Physiol. 346:27-48). We hypothesized that this peak and falloff in LTP during development could be mediated by a population of plastic synapses which are consolidated by maturation-related experience so that in the adult fewer of the total synapses are available for tetanus-induced potentiation.

The goal of the present study is to test whether changes in synapse or spine morphology could distinguish 'plastic' from 'consolidated' synapses at P15 and Adult ages. An accurate and relatively quick method for surveying the neuropil was developed. To determine the density of each synaptic type located in s. radiatum, a randomly-selected field (150-200 um^2) located 200-250 um from the pyramidal cell body layer is photographed and viewed through adjacent serial sections. Then to distinguish changes in synaptic density from changes in synaptic size, shape, or orientation with respect to the plane of sectioning, the total area of each synapse with a portion found on the middle section of the series is measured through serial sections using a computer-assisted reconstruction system. Synaptic densities were corrected for changes in the probability of observing synapses on the analyis section by subtracting the percent mean change in the total number of sections required to contain the synaptic area from the total area of the neuropil analyzed. Table I illustrates preliminary analyses from 2 fields at each of ages P15 and adult:

TABLE I: COMPARISON OF SYNAPSES AT P15 AND ADULT.

SYN LOCATION	SYN DENSITY/100um^2		SYN AREA (um^2, mean±sd)	
	P15	ADULT	P15	ADULT
Stubby Spine	6	2	0.16±0.10	0.08±0.03
Mushroom Spine	4	8	0.16±0.10	0.35±0.20
Thin Spine	4	27	0.07±0.05	0.06±0.04
Asymmetric Shaft	3	2	0.24±0.10	0.21±0.27
Symmetric Shaft	1.5	2	0.16±0.12	0.14±0.09

Dendritic spines were classified 'stubby' when the neck diameter $\geq$ neck length; 'mushroom' when the neck diameter <<<< head diameter; 'thin' when the neck diameter <<<< neck length and neck diameter $\leq$ head diameter. The decrease in stubby spine density was exactly matched by the increase in mushroom spine density between P15 and adult. Synapses on adult mushroom spines were on average 2 times larger than synapses on P15 stubby or mushroom spines. The density of thin spines increased dramatically between these two ages, though the size of synapses on thin spines did not change. Shaft synapse density and size did not change significantly.

Changes in individual thin spine synapses are not likely to be involved in tetanus-induced LTP as many more of them are present in the adult than at P15 when LTP is maximal. Similarly changes in shaft synapses do not parallel the development of LTP.

Stubby spines at P15 have many ultrastructural features of more mature mushroom spines, showing relatively large, often perforated synapses and abundent amounts of smooth endoplasmic reticulum. Perhaps the stubby become mushroom spines whose synapses are 'plastic', and age-related experience or tetanic stimulation induces an enlargement of the spine and area of synapses on the spine up to a maximum. In the adult, proportionately more of the synapses have reached that maximum ('consolidated' synapses) and therefore are unavailable for further enlargement from tetanus-induced LTP.

394.13 DENDRITIC PROLIFERATION AS A MECHANISM OF SPARING AND RECOVERY OF FUNCTION IN THE RAT. B. Kolb and R. Gibb*. Dept. of Psychology, Univ. of Lethbridge, Lethbridge, Canada, T1K 3M4.

We have demonstrated in previous work that the developing brain is especially vulnerable to the effects of cortical injury until cell migration in the cortex is completed, around 7-10 days of age in the rat. Thus, damage before 7 days produces more severe behavioral consequences than similar damage in adulthood, whereas damage around 10 days allows almost complete sparing of function. In adulthood, recovery of function following cortical lesions is quite limited but sometimes can be attenuated by serial lesions, enriched experience, or certain drug treatments. The goal of the current experiments was to examine the possibility that dendritic arborization might correlate with the presence or absence of behavioral sparing or recovery. Rats were given a) bilateral or unilateral lesions of the frontal cortex at 1, 10 or 90 days of age; b) two-stage lesions of the same tissue at 1 and 10 or 90 and 120 days, or c) hemidecortication at 1 or 90 days. Animals were raised in standard laboratory conditions or in "enriched environments" and given a battery of behavioral tests before the brains were stained with Golgi-Cox. Layer II/III pyramidal cells were drawn and the apical and basal dendrites quantified in several regions.

The results showed that the behavioral outcome was correlated with the extent of dendritic arborization. 1) Rats with 1-day frontal lesions showed no behavioral sparing and showed stunting of dendrites throughout the cortex. 2) Rats with 10-day lesions showed good sparing of function and an expansion of dendritic arborization, especially in the parietal, visual and temporal cortex. 3) Serial lesions in infancy allowed partial sparing of function along with stunted growth on the 1-day side and expanded growth on the 10-day side. 4) Hemidecortication produced increased arborization in the forepaw area, consistent with their partial recovery of motor function.

The results are interpreted as showing an anatomical basis of sparing and recovery of function in the rat cortex.

394.14 THE POSTNATAL DISTRIBUTIONAL CHANGES AND SYNAPTOGENESIS OF CORTICOSPINAL TRACT NEURONS IN THE CEREBRAL CORTEX OF THE RAT WITH HRP-LABELING MEHTOD. R. Ohtani*, T. Shirai* & H. Kato* (SPON:J.Yamada). Department of Anatomy and Physiology*, Yamagata University, School of Medicine, Zaoiida, Yamagata 990-23, Japan

We studied the establishment of the distributional pattern and the synaptic formation of corticospinal tract (CST) neurons in the postnatal rat.

By injecting HRP into cervical cords, CST neurons were labeled at various ages. CST neurons of neonatal rats were distributed in layer V as one continuous band from the medial region to the lateral one of the frontal and parietal areas. By the end of the second postnatal week, CST neurons became localized into two narrow bands. These two bands consisted of a dorsomedial band in the frontal and the anterior parietal cortices and a relatively smaller band in the lateral parietal cortex, and no labeled neurons appeared between these two bands. This distributional pattern of CST neurons was maintained to adult rats.

Subsequently, the HRP-labeled cells in the motor cortex were observed with the electron microscope to study the postnatal development of the synapses on the soma of the CST neuron. Synapses were found neither on the soma nor at the proximal region of dendrites of CST neurons on day 1, but appeared in both areas by day 7 and increased rapidly in number by day 14. The average number of synapses per 1mm CLS(circumferential length of the soma) was 0, 41±20, 93±35, 111±30, 115±35, on day 1, 7, 14, 28 and in adult rats, respectively. These studies indicate that the distributional reorganization of CST neurons and the synaptic formation on their somata and proximal dendrites were almost completed by the end of the second postnatal week.

Furthermore, the synaptic organization on distal dendrites and their spines of CST neurons were investigated using intracellular HRP-injection in the slice preparation of motor cortices of various ages. Together with these findings, we would show the synaptogesesis on the whole CST neuron.

This work was supported by the Grant-in-Aid for Encouragement of Young Scientist (60770054, 61770036) from the Ministry of Education, Science and Culture of Japan.

396 SYMPOSIUM: NEURONAL SEROTONIN RECEPTORS. J.M. Palacios, Sandoz Ltd. Basle (Chairperson); M. Hamon*, INSERM U.288 Paris; P. Hartig, Johns Hopkins Univ.; S. Maayani, Mount Sinai Med. Ctr.; G.K. Aghajanian, Yale Univ.; B.P. Richardson*, Sandoz Ltd., Basle

Selective new drugs permit the pharmacological classification of serotonin (5-hydroxytryptamine, 5HT) receptors into three categories: $5HT_1$, $5HT_2$ and $5HT_3$. Although $5HT_2$ receptors are homogenous, subtypes of $5HT_1$ and $5HT_3$ receptors clearly exist. All serotonin receptor subtypes occur in the CNS or PNS and this symposium will review the considerable progress made in their pharmacology, biochemistry, distribution and function.

Michel Hamon shows how radioligand studies have permitted identification of different $5HT_1$ receptor subtypes in rat brain membranes. Of these, both $5HT_{1A}$ and $5HT_{1B}$ receptors are located mainly postsynaptically, but with differing regional distributions. Photoaffinity labelling has demonstrated the $5HT_{1A}$ binding subunit to be a 63 kD protein functionally coupled to adenylate cyclase.

Paul Hartig demonstrates that the $5HT_{1C}$ receptor is present at high density in the choroid plexus and at low density in several other brain regions. It is located on the apical face of the choroid plexus epithelium, and is activated by serotonin in the CSF. Recently the $5HT_{1C}$ receptor has been cloned.

Saul Maayani explains how radioligand binding studies originally permitted the identification of $5HT_2$ sites in the CNS. Both biochemical (phosphatidylinositide hydrolysis) and behavioural correlates for these binding sites now exist. The density of $5HT_2$ binding sites, which is not uniform throughout animal and human brain, can be modulated in vivo by psychoactive drugs.

Brian Richardson shows $5HT_3$ receptors are widely distributed throughout the PNS, where they mediate exclusively excitatory actions of 5HT. Recently three subtypes of $5HT_3$ receptor have been identified using selective pharmacological tools. Evidence for the existence of $5HT_3$ receptors in the CNS will also be presented.

George Aghajanian presents electrophysiological studies showing that $5HT_{1A}$ ligands are full agonists in the dorsal raphé, mimicking 5HT inhibition of serotonergic neurones, whereas in the hippocampus they are only weak, partial agonists. In both regions, 5HT inhibition is mediated by a pertussis toxin-sensitive G-protein. Hallucinogenic indolamine and phenethylamines act as $5HT_2$ agonists.

José Palacios explains how binding and autoradiographic techniques have shown the human brain to contain $5HT_{1A}$, $5HT_{1C}$, $5HT_{1D}$ and $5HT_2$ sites but no $5HT_{1B}$ sites. $5HT_{1A}$ and $5HT_{1D}$ sites are enriched in limbic areas and the basal ganglia respectively, while $5HT_2$ sites occur predominantly in the cerebral cortex. Altered densities of $5HT_{1A}$ and $5HT_2$ sites occur in senile dementia.

397 WORKSHOP. NEW DIRECTIONS IN MAMMALIAN CNS *IN VITRO*: BEYOND THE SLICE. K. Walton, New York Univ. Med. Sch. (Chairperson); J. Feldman, Univ. Calif. Los Angeles ; P. Getting, Univ. of Iowa; L. Renaud, Montreal Gen. Hosp. and McGill Univ.; R. Llinás, New York Univ. Med. Sch.

The advantages of studying the electrophysiology of mammalian CNS *in vitro* have been elegantly demonstrated over the last decade where, in brain slices, many new ionic conductances have been characterized. However, in the slice many essential features of brain organization, such as the integrity of neuronal circuits, are lost. In order to combine the advantages of *in vitro* recording with complete circuitry, several mammalian CNS *en bloc* preparations have been introduced. This workshop will explore recent advances in the development and use of these preparations and consider the place of such preparations in the Neuroscience armamentarium.

Kerry Walton is using an SC-brainstem-cerebellum preparation isolated from neonatal rat to study the role of neuronal activity in the development of the motor system. She will discuss the contribution of motoneuron membrane properties and spinal circuit elements in the generation of rhythmic activity and the importance of such oscillations in SC development.

Jack Feldman and Jeff Smith are using an isolated neonatal rat SC-brainstem preparation (with/without ribcage) to study the motor control system for respiration. Jack's talk will focus on (1) the necessary role of inhibition in generating respiratory patterns and (2) the class of neuromessenger (possibly an excitatory amino acid or related peptide) transmitting respiratory drive from the brainstem to respiratory motoneurons.

Peter Getting and George Richardson have developed a perfused *in situ* adult guinea pig brain preparation. Their procedure uses non-pulsatile flow of perfluorocarbon artificial blood. Peter will discuss its usefulnesss in studies of neural network function and evaluate the effects of peripheral and central afferent systems on the neural control of respiration.

Leo Renaud has been studying neurosecretory neurons in the supraoptic nucleus in arterially perfused hypothalamic explants from adult rat. He will discuss the properties of local circuits transmitting cardiovascular input to neurosecretory cells and evaluate the membrane actions and hormone release capacities of neurotransmitters and modulators in the neurohypophyseal axis.

Rodolfo Llinás has developed an isolated adult guinea pig whole brain preparation. He will discuss recent experiments concerning the olivo-cerebellar system, pontocerebellar system and the interaction between mossy and climbing fiber inputs to Purkinje cells.

398.1 RELATIONSHIPS BETWEEN BRAIN VOLUME LOSS, INTELLIGENCE, AND POSTINJURY INTELLECTUAL DEFICITS. E. Irle*§, B. Wowra*§§, V. Sturm*§§ and St. Kunze* (Head)§§ (SPON: G. Raisman). Dept. of Psychology§ and Dept. of Neurosurgery§§, Univ. of Heidelberg, D-6900 Heidelberg,FRG

Forty-six patients sustaining surgery for tumors of the brain and 12 patients sustaining surgery of the spine were investigated. All subjects were inpatients of the neurosurgical division of the University Clinic of Heidelberg. The tumor patients were chosen on the basis of having a tumor restricted to cortical tissue of the frontal, temporal, or parietal lobes; the control subjects were matched for age and education to the tumor group. Pre- and postoperatively, all subjects were tested in a variety of cognitive and mnemonic tasks, e.g. a shortened version of the WAIS, Benton test, tests of endurance and psychomotor speed, and a paired associate learning task using lists with semantically related words. If the performance of a subject on one of these tests was impaired because of paresis, or neglect, or aphasia, these data were excluded from the statistical analysis. The tumor location and tumor volume were determined with quantitative computed tomographic analysis of both pre- and postoperative scans.

The volumes of the tumors varied between 1 and 87 cm^3. As the sizes of the tumors and the surrounding edemas were correlated ($r=.52$, $p<.01$) only the tumor volume was considered for further analysis. The tumors were not separated for different types as analyses of variance revealed no effects of groups for the tumor volume as well as for the general IQ measured preoperatively ($p's>.1$). Compared to their controls, the tumor patients performed significantly worse in the WAIS and the paired associate learning (t-tests, $p's<.05$). A preliminary correlation analysis revealed that the age of the tumor patients was not related to the preoperatively measured IQ ($r=-.06$, $p<.5$). However, the premorbid intelligence (estimated by age, gender, education and occupation) predicted the preoperatively measured IQ, and the performance in the paired associate learning (IQ: $r=.4$, $p<.01$; paired associate learning: $r=.32$, $p<.05$). Furthermore, the volume of the tumor was positively correlated with the preoperative IQ ($r=.2$, $p<.2$), that is, patients with larger tumors had higher IQ's. The same is true for the paired associate learning ($r=.17$, $p<.3$). However, the premorbid IQ not only correlated with the preoperative IQ, but also with the tumor volume, in that way, that larger IQ's were related to larger tumors ($r=.24$, $p<.1$). Thus, it may be suggested that subjects with higher intelligence tolerate a growing tumor for a longer time, until neurological or psychological deficits appear. More important, it may be true that the likeliness of functional compensation increases with the lesion extent and thus the necessity of the brain to fulfill plastic changes.

We thank S. Gauggel, J. Keller, S. Kubath, M. Peper, C. Ramrath and J. Werner for the testing of the patients.
Supported by grant Ir 15/3 of the Deutsche Forschungsgemeinschaft.

398.2 COGNITIVE ABNORMALITIES AND RATE OF PROGRESSION IN ALZHEIMER'S DISEASE. J.T. BECKER, F.J. HUFF, R.D. NEBES*, A. HOLLAND*, F. BOLLER, Alz. Dis. Res. Centr., Univ. Pittsburgh, Pittsburgh, PA, USA

The relationship between the pattern of cognitive deficits in Alzheimer's Disease (AD) and the progression of the dementia may reveal important clues to the pathophysiology of the disorder. Previous studies have suggested that the age at which clinical symptoms first appear may be an important predictor of both clinical presentation and disease progression. Younger individuals (i.e., <=65 yrs) may have more pronounced language deficits, and a more rapid decline of function.

The performance of 92 normal elderly controls (NC) and 87 AD patients was examined on tests of language and visuoconstructional abilities as part of a longitudinal study of dementia. A principal components analysis of the patient data revealed two components: one of visuoconstructional skill (VC) and the other of access to lexical/semantic knowledge (LS). Composite scores were created, and each subject's score was adjusted for age, education and sex. Fiften patients were identified with relatively "focal" patterns of impairment: 11 with LS defects and 4 with prominent VC impairments. There were no differences between the non-focal patients and those with LS or VC defects in terms of education, global measures of dementia, or duration of illness. However, the mean age at onset of illness among the LS patients (71.2 yrs) was greater than that of the non-focal (64.1 yrs) and VC patients (62.0 yrs).

One year later, seven of the patients had died, all of whom were in the "non-focal" group. Of the seven patients who had been institutionalized, all but two were in the non-focal group. The rate of decline in function, whether measured by change with repeated testing using the two composite variables or the Mini-Mental State Exam, did not differ as a function of patient group. Measures of expressive language, both written and oral, also failed to predict more rapid rates of disease progression.

These results confirm previous reports which identified VC and LS components of the cognitive deficit in AD, and specifically a similar component structure by Martin, et al. (1986). The predicted relationships between the pattern of presentation and disease progression, however, were not found. A longer follow-up interval may be necessary to differentiate among the groups of patients. Our finding that the LS impaired patients were the older ones in our group is also contrary to expectation. This result suggests that differences between young and old AD patients with regard to pattern of cognitive abnormalities may not be as consistent as was previously thought (supported by: AG03705, AG05133, MH30915).

398.3 THE ROLE OF THE FRONTAL CORTEX IN THE USE OF ADVANCE INFORMATION. B. Alivisatos* (SPON: B. Milner). Montreal Neurological Institute and Hospital, McGill University, Montreal, Quebec, Canada, H3A 2B4.

The present study explored the ability of patients with unilateral frontal or temporal-lobe excisions to use advance information in a choice reaction-time paradigm requiring the discrimination of alpha-numeric characters on the basis of their form of presentation, normal or mirror-image. The target stimuli were presented in various angular orientations, and the subject had to respond by pressing one key with one hand when the letters or numbers were normal and another key with the other hand when they were mirror-image. In the No-Information (NI) condition, a warning signal appeared for 1500ms, followed by the target, which remained on until the subject responded. In the Advance-Information (AI) condition, an informative cue was provided for 1500ms, followed for another 1500ms by the same warning signal as in the NI condition and finally being replaced by the target. In this AI condition, the cue conveyed the target's identity and orientation and always appeared in its normal form.

A total of 66 patients and 18 normal control subjects were tested assigned to the following groups: (1) left frontal (n=9); (2) right frontal (n=12); (3) left temporal (n=22); (4) right temporal (n=23). In accordance with findings for normal subjects (Cooper, L.A. and Shepard, R.N., Memory and Cognition, 1:246, 1973), in the NI condition, reaction time for all groups increased as a function of the target's angular departure from the standard upright orientation. In the AI condition, reaction time remained constant across changes of orientation for all subject groups, except the group with right frontal-lobe lesions. These results suggest that patients with right frontal-lobe removals did not use the cues to the same extent as normal control subjects but, instead, continued mentally rotating the target to the upright position before responding. The deficits found in the right frontal-lobe group cannot be attributed to a simple inability to make 'Same-Different' judgments, because these same patients performed normally in a control condition requiring the comparison of letters or numbers presented sequentially.

Previous findings in a visuospatial reaction-time study (Alivisatos, B. and Milner, B., Proc. Eastern Psychol. Assoc., 56:19, 1985) showed that patients with frontal-lobe removals were impaired in making use of directional cues, which indicated the spatial location where a target was about to appear. The present study supports and extends further the notion that the frontal cortex is involved in making use of cues to anticipate an event and prepare for a specific response.

398.4 A DOPAMINE DEFICIENCY SYNDROME OF DEMENTIA. N. Wolfe, D.I. Katz*, M.L. Albert*, M.C. Smith*, R. Durso*, L. Volicer, A. Almozlino*. Boston University School of Medicine, Boston, MA 02130

Preliminary findings from the first 12 patients entered in a study of dopaminergic function and dementia reveal a distinctive pattern of neuropsychological test results in a subset of demented patients with low cerebrospinal fluid homovanillic acid (CSF HVA). We hypothesized that such a dopaminergic deficiency syndrome may cut across traditional diagnostic categories, and thus included subjects with: Alzheimer's disease (n=4), Parkinson's disease (n=4) and Major Depression (n=4). Subjects were excluded from study if they had a Hachinski Ischemia Score > 4 (suggesting multi-infarct dementia), structural lesion on CT scan, evidence of central nervous system infection or chronic seizure disorder.

Cerebrospinal fluid HVA was measured using high pressure liquid chromatography with electrochemical detection. Neuropsychological testing emphasized patterns of cognitive decline which have been associated in the past with dopamine deficiency (slowness in rate of information processing, impairment in memory, and impaired manipulation of acquired knowledge). We identified two groups of demented subjects based on CSF HVA level. The mean HVA level in the low HVA group (11.7 ± 2.7 ng/ml)(n=3) was significantly lower than the mean HVA in the high HVA group (21.9 ± 7.1 ng/ml)(n=9) (Mann-Whitney $U=2$, $p<.016$, one-tailed). The low HVA group included 2 patients with Alzheimer's disease and 1 with Major Depression.

The low and high HVA groups also differed significantly in two specific neuropsychological measurements. First, speed of processing, assessed using a revised Paced Auditory Serial Addition Test (PASAT-r) was significantly slower in the low HVA group ($U=4$, $p<.045$ one-tailed). Second, it has been observed that patients with fronto-subcortical dysfunction perform better on cognitive tasks when provided with more structure. Consequently, we used the verbal fluency test (Controlled Oral Word Association Test, F.A.S.) to assess performance under greater structure (semantic categories: animals,fruits and vegetables) and lesser structure (phonemic categories: words beginning with F,A and S). Patients in the low HVA group showed significantly greater benefit from structure on the verbal fluency task, compared to those in the high HVA group ($U=1$, $p<.008$). The correlation between dopamine measurement (HVA level) and benefit from structure (FAS score) across all 12 patients was significant (Spearman $r=-.59$, $p<.025$, one-tailed).

These neuropsychologic differences: decreased speed of processing and greater benefit from structure on a verbal fluency task, can NOT be explained simply as a decrease in overall cognitive abilities, since the two groups did not differ significantly on the Mini Mental State Test (Folstein, M.F. et al., J Psychiatr Res., 12:189, 1975).

398.5 SINGLE-PULSE SENTENCE CONSTRUCTION WITHIN LAYERED, HEBBIAN, NEURAL NETWORKS. R. Martin. Department of Chemistry, Brooklyn College, Brooklyn, NY 11210.

The simulations to be reported illustrate how a "blank" network of nerve cells, linked together by connections of uniform strength, can develop the capacity to respond to questions like "What do lions do during the night?" and "Where do tigers live?" with logical and grammatically correct answers such as: "During the night lions hunt" and "Tigers live in India". Each of the sentences produced by the network is planned or constructed as a consequence of a single pulse of discharge from cells within a central "speech center". Apparently no additional time is required for determination of correct conceptual and semantic responses and selection of an appropriate grammatical structure for the answer. Connection patterns that develop within the net are able to select novel combinations of words when novel statements are required. These connection patterns also specify which word combinations are appropriate and which are not, so that under ordinary circumstances illogical statements like "Tigers hunt during India" will not be produced even if they conform to formal rules of grammar. The network learns quite rapidly if connection values are adjusted in large increments. As little as one "training example" involving a new word enables the word to be used correctly within all of the sentence structures previously learned by the network. And as few as two illustrations of a novel sentence structure are sufficient for the network to learn how to construct variations on this structure that include any appropriate combination of previously encountered words. As outlined previously (1-3) word selection proceeds within limits determined by many thousands of behavioral constraints which govern the use of concept hierarchies.

398.6 EFFECTS OF A BENZODIAZEPINE RECEPTOR ANTAGONIST IN PATIENTS WITH PANIC DISORDER. S.W. Woods, D.S. Charney, J.M. Silver* and G.R. Heninger. Clinical Neuroscience Research Unit, Dept. of Psychiatry, Yale University School of Medicine, New Haven, CT 06508 and the Hoffmann-LaRoche Co., Nutley, NJ 07110.

To evaluate the hypothesis that abnormal regulation of benzodiazepine receptor function may relate to the pathophysiology of panic disorder, the benzodiazepine receptor antagonist flumazenil (RO 15-1788) was administered to panic disorder patients and healthy subjects.

METHODS: Eleven patients (age 37±7 yrs) drug-free for four weeks and five healthy subjects (age 24±4 yrs) participated after giving informed consent. All 11 patients received flumazenil 600 mg, ten received flumazenil 200 mg, and eight received matching placebo orally in random sequence on separate test days seven days apart. Too few healthy subjects were recruited to permit statistical analysis because of premature termination of the study due to unexplained EKG changes in two subjects. Subjective visual analog scale (100 mm) mood ratings, heart rate, blood pressure, and plasma cortisol and 3-methoxy-4-hydroxyphenylglycol (MHPG) measurements were obtained 30 minutes and immediately preceding and 30, 60, 90, 120, 150, 180, 210, 240, 270, and 300 minutes following drug administration.

RESULTS: On placebo days, ratings of anxiety decreased from baseline by 11±14 mm ($p<.10$) at 30 minutes and by 29 to 40 mm at each time point ($p<.05$) thereafter. On 200 mg days, anxiety ratings increased by 19±39 mm ($p<.05$ vs. placebo) at 30 minutes and then fell below baseline by 5 to 23 mm at later time points (all N.S. vs. placebo). On 600 mg days, anxiety ratings decreased from baseline by 3±18 mm at 30 minutes (N.S.) and to levels similar to those on placebo days at later time points. Neither dose of flumazenil significantly altered heart rate, blood pressure, or plasma cortisol or MHPG in comparison to placebo.

DISCUSSION: Flumazenil was not anxiolytic at these doses in panic disorder patients. The 200mg dose produced a significant anxiogenic effect. These results suggest that flumazenil at these doses does not antagonize an increased interaction of benzodiazepine receptors with an endogenous benzodiazepine receptor inverse agonist in panic disorder patients. The data do not exclude an intrinsic inverse agonist or partial agonist effect of flumazenil at these doses or the existence of a hypofunctioning endogenous benzodiazepine agonist system in panic disorder.

398.7 BRAIN ELECTRICAL ACTIVITY MAPPING IN PARANOID SCHIZOPHRENIA AND RELATED DISORDERS. J.D. Raese, K.D. Pool*, R.G. Paulman*, T. Finitzo*, C.R. Judd*, R.R. Gregory*, and J. Steinberg, Schizophrenia Research Center, Dallas VA Medical Ctr., and Dallas Neuroscience Associates, Dallas, TX 75216.

This study examined the similarities and differences of electrocortical activity as well as their topography in psychotic disorders. Brain electrical activity mapping, consisting of twenty five channel conventional and quantitative EEG, and auditory, visual and somatosensory evoked potentials were used to evaluate electrocortical function in twenty-two psychotic male patients between the ages of 21 and 47 years. Thirteen were diagnosed (by DSM III Criteria) as paranoid schizophrenics, four as nonparanoid schizophrenics and five as atypical psychosis. Patterns of electrocortical activity were examined in relationship to diagnostic category and neuropsychological measures obtained from the Luria Nebraska and/or Halstead-Reitan Neuropsychological Batteries. These data were compared to 95 age-matched control subjects who by history and examination were free of neurological and psychiatric illness. Statistical analyses were done as t-tests corrected for small sample size. A serial binomial exclusion was employed to correct for multiple measures-effects. The alpha level for T-determination was a two-tailed T measure set at $p<0.01$.

Changes in EEG spectra in all psychotic patients were mild. More robust and persistent changes were seen with sensory activation. Analysis of spectral data with rigorous attention to eye movement artifact did not confirm the increase in frontal delta activity previously described by Morihisa et al. (Arch. Gen. Psych., 40:719, 1983). We confirmed, however, the decrease in higher frequency beta activity in psychotic patients compared to controls. In paranoid schizophrenics the reduction in beta activity was seen over the left paramedian parietal territory extending over the occipital head regions. In nonparanoid patients this finding was more prominent and less focal.

Evoked potential mapping showed characteristic deficits common to all three diagnostic groups. The major finding consisted of a reduction in vertex potentials in response to auditory and visual stimuli. For the AER and VER this occurred both in the normally seen N100 and P200 waves. Paranoid schizophrenics additionally showed focal abnormalities particularly in the left hemisphere. Patients showing neuropsychological deficits in the right posterior quadrant differed in their somatosensory mappings over right temporal, posterior temporal and occipital regions. These results confirm that electrocortical activity in psychotic patients differs significantly from normal controls. Moreover, electrocortical changes appear to have neurobehavioral correlates.

398.8 SHIFTS IN SPATIAL ATTENTION AND EVENT-RELATED POTENTIALS (ERPs). M. R. Harter. Psychology, Univ. N. C. at Greensboro, Greensboro, N.C. 27412.

ERPs were recorded over the left and right hemisphere of twenty-eight 6-7 year old children. Two processes associated with a shift of spatial attention from the central to either the right or left visual field were investigated: those associated with a cue (an arrow) which shifts attention and which presumably causes contalateral hemispheric activation; and those associated with the differential processing of targets depending on whether or not they are in the relevant (cued by the arrow) visual field.

The arrow was presented for 1000 msec and pointed randomly either to the right or left. The direction of the arrow determined the relevant visual field. 600 msec after arrow onset, a small target was flashed 10 degrees randomly to the right or left visual field. The subjects were required to give a finger-lift reaction-time response to targets only if in the relevant (cued) visual field. ERPs (O1, O2, P3, P4, C3, C4, F3, and F4) and EOGs were measured for 1000 msec following the onset of the arrow.

A switch in attention influenced the amplitude of a slow negativity (termed switch in attention negativity or SAN) which started at approximately 300 msec following arrow onset. The direction of the shift influenced SAN differently depending on the electrode position: a) Frontal SAN was generally larger when attention was switched to the right than left visual field. This effect was symmetrical over the left and right hemispheres and peaked at about 450 msec after the shift. Reaction times were faster to right (437 msec) than left (464 msec) visual field stimuli which suggests that frontal SAN may reflect an excitatory process. The direction of an attention shift had little influence on central SAN. Occipital and parietal SAN were larger over the hemisphere ipsilateral to the direction of the attention shift--they were greater over the right hemisphere when attention was shifted to the right and greater over left hemisphere when attention was shifted to the left. This ipsilateral effect peaked at about 650 msec after a shift, just after the presentation of the target at 600 msec. Given the ipsilateral occipital hemisphere is the projection area for the irrelevant (ignored) visual field, occipital SAN most likely reflects some inhibitory process. This interpretation is supported by the effects of field relevance on ERPs to the targets.

The P1 and N1 ERP component to targets were greatest a) over the occipital and parietal regions, b) to targets in the relevant visual field, and c) over the hemisphere contralateral to the relevant visual field. The larger the SAN prior to the target, the smaller the P1 and N1 to the target.

398.9 PARALLEL COMPUTATIONAL MODEL OF VISUAL ERRORS IN ACQUIRED DYSLEXIA. B. Gordon and J.M. Sieracki*. Cognitive Neurology Div., Dept. of Neurology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Acquired dyslexia has typically been explained in terms of disruptions to or disconnections between processing components. Yet the specific operations performed by these components have been left underspecified at best. Recently, detailed models of processing in neural networks have been offered as examples of how these operations might be accomplished. Testing these models has been difficult because of the complexity of the reading process in normal individuals. We now describe a detailed computational model applied to the specific pattern of reading performance in a patient with a left hemisphere lesion, in whom the lesion and specialized testing allowed data to be obtained from relatively early stages of visual word recognition.

This patient makes frequent (7-37%, depending upon word frequency) visual errors in reading single words aloud (e.g., misreading MIDST as "MAST"). These errors can be shown to be visually-mediated rather than phonologically-mediated, to arise relatively early in the direct lexical access route (at or before the visually-based word store, the orthographic lexicon), and to be highly reproducible (Gordon, Goodman-Schulman, & Caramazza, submitted). Both normal reading and this patient's specific errors could be simulated by a two-stage computational model similar to several recently proposed ones (e.g., McClelland, 1986). In the model, a letter perceptual stage is connected in parallel to an orthographic lexical stage, with feedback. Letters in the stimulus activate many possible candidates in the lexical stage; the most strongly activated one is normally the correct one. This patient's cerebral damage is assumed to make the correct orthographic representation less available, permitting a lexical representation that would not normally be activated enough by the stimulus to be produced as a visual error (cf. Gordon et al., submitted).

While this simulation was necessarily post hoc, it does provide a plausible fit of much more detailed data than is typically considered in constructing accounts of acquired dyslexia. More importantly, independent estimates of some of the model's critical parameters should be possible in other patients, permitting a more rigorous, a priori, test. The visual word recognition process and its disruption may therefore provide a useful means for testing computational models of reading and for understanding the effects of cerebral damage on these higher-level functions.

398.10 SUPPLEMENTARY MOTOR AND PREMOTOR RESPONSES TO ACTUAL AND IMAGINED HAND MOVEMENTS WITH POSITRON EMISSION TOMOGRAPHY. P.T. Fox, J.V. Pardo, S.E. Petersen*, M.E. Raichle. Washington Univ. Medical School, St. Louis MO 63110.

Imagined performance of a motor task has been reported to selectively activate brain regions performing "motor programming". Initial studies of imagined movement indicated exclusive but bilateral activation of the supplementary motor area (SMA) (Roland et al., J. Neurophysiol 43:118). Pursuant to these earlier observations, we measured brain blood flow in normal human volunteers with positron emission tomography during: 1) repetitive (1 Hz) opening and closing of the hand, 2) imagined performance of task 1, 3) vibratory finger stimulation, 4) eyes-closed rest. Responses were identified by a maximum-detection algorithm applied to subtraction images (task state minus control) after stereotactic inter-subject image averaging to enhance signal:noise.

SMA was activated equally by all 3 tasks (7%) increase), passive tactile input being as potent as overt or covert movement. SMA responses were unilateral, contralateral to the engaged hand. Posterior, inferior premotor cortex (PIP, in or near Brodman area 44), however, was more active during imagined (6%) than actual (4%) movement, was not activated by tactile stimulation, and was lateralized toward the dominant hemisphere. Both overt movement and tactile stimulation activated rolandic sensorimotor cortex and cerebellum; covert movement activated neither. We suggest that the PIP, being preferentially activated by motor planning, independent of sensory feedback, and lateralized to the dominant hemisphere, is upstream to SMA. SMA would then be construed as allowing lateralized application of the abstract motor plan (created in PIP) to primary motor cortex and cerebellum within the context of ongoing sensory feedback.

398.11 A COMPARISON OF AUDITORY AND VISUAL PROCESSING OF SINGLE WORDS USING AVERAGED IMAGES OF CEREBRAL BLOOD FLOW CHANGE. S.E. Petersen*, P.T. Fox, M.I. Posner, M.E. Raichle. Depts. of Neurology, Neurological Surgery and Radiology, and the McDonnell Center for Studies of Higher Brain Function, Washington University School of Medicine, St. Louis, Missouri, USA.

Brain areas activated during the processing of single words (lexical processing) were identified as changes in local blood flow during a stepwise progression of tasks in 12 right-handed normals. Condition 1 was simply to fixate on a "+" synbol presented on a video monitor. Fixation was a component of all tasks. For Condition 2, single nouns were presented at 1 Hz either auditorily or visually. The 2nd level tasks were expected to produce passive sensory processing, and possibly earlier lexical processing. Vocal repetition of the presented words (Condition 3) added rate-controlled motor output. Higher level processing was added at the final level (Condition 4): a verb appropriate to the presented noun was said aloud (e.g. cake...eat). Both auditory and visual presentations were tested during a single session. Focal blood flow changes induced by the different level tasks were identified by subtractions of pairs of blood flow images.

"Passive" observation (2 minus 1) activated primary visual (for visual presentation) and primary auditory (for auditory presentation) cortical areas bilaterally. Lateral, extra-striate, occipital cortex was also bilaterally activated by visual nouns; left supramarginal gyrus was activated by auditory nouns. These extraprimary responses could be related to early lexical processing. Vocalization (3 minus 2) recruited several areas not active in Task 2, areas that are consistent with the word production demands of this comparison. These included: rolandic cortex (sensorimotor mouth, L = R), supplementary motor area, inferior frontal cortex (Broca's area) (L > R), and medial superior cerebellum. Verb generation (4 minus 3) gave strong activation of anterior cingulate gyrus, right inferior lateral cerebellum, and left inferior anterior frontal cortex (at or near area 45). Further studies, using a task during which subjects monitor lists for target words in a semantic category, activated a region of inferior anterior frontal cortex in a location similar to that in the verb generation task. This converging evidence implicates frontal area 45 in semantic processing.

The use of image averaging and stepwise task design has allowed us to identify brain areas related to different levels of cognitive activity. Further experiments are aimed at determining the specific functions related to these areas.

398.12 PREOPERATIVE ASSESSMENT OF CEREBRAL DOMINANCE FOR LANGUAGE USING POSITRON EMISSION TOMOGRAPHIC MEASURMENTS OF BRAIN BLOOD FLOW. J.V. Pardo, P.T. Fox, S. Goldring, M.E. Raichle. Washington University Medical School, St. Louis Mo, 63110

Preoperative assessment of cerebral dominance for language requires selective carotid catheterization and anesthesia of each cerebral hemisphere (Wada test), a highly invasive procedure. Regional brain activation lateralizing to the left cerebral hemisphere and right cerebellar hemisphere in right-handed normal volunteers has been reported by this laboratory (Soc. Neurosci Abst.12:1161) using PET measurements of brain blood flow. While this study reported averaged data, responses often were seen in individual images, suggesting PET as a noninvasive test for language laterality.

Based on our work in normals, 3 conditions and 4 response zones were tested in 9 candidates for surgical treatment of partial complex epilepsy. Tasks were: 1) repetition aloud of visually presented words (nouns), 2) generation aloud of verbs semantically related to visually presented nouns, 3) eyes-closed rest (control state). Response zones assessed were: 1) sensorimotor mouth areas (rolandic; repeat vs rest); 2) posterior, inferior frontal cortex (Broca's area; repeat vs rest); 3) anterior, inferior frontal cortex (generate vs repeat); 4) inferior, lateral cerebellum (generate vs. repeat). Areas of task-induced neuronal activation were identified as focal increases in the distribution of oxygen-15 labeled water, a blood flow tracer,and required only an intravenous catheter. Wada testing indicated left-hemishere dominance in 8 subjects and was indeterminate in 1 subject.

Anterior, inferior frontal responses were both robust and strongly lateralized to the left hemisphere in 7/9 patients. Sensorimotor (rolandic) responses were robust (7/9 pts), but bilateral with weak lateralization (L>R 4/9 pts). Posterior, inferior frontal responses were present in 7/9 pts, lateralized L>R in 4/9 pts, and bilateral in 2/9. Inferior cerebellum was seen only sporadically (3/9 pts), perhaps due to poor sampling of this area, but was strongly lateralized to the right. Only one case activated a region (Broca R>L) inconsistent with the Wada results.

PET measurement of brain blood flow during language performance has considerable potential as a preoperative technique for assessing cerebral dominance for language with minimal invasiveness.

399.1 SEGREGATION OF FUNCTIONALLY DISTINCT OPTIC AXONS IN THE OPTIC TRACT OF OLD WORLD MONKEYS. B.E. Reese* and A. Cowey*. (SPON: R.W. Guillery) University of Oxford, Departments of Human Anatomy and Experimental Psychology, Oxford OX1 3QX, U.K.

The optic tract of old world monkeys displays a partial segregation of its optic axons according to diameter: coarse axons are most abundant superficially, near the tract's pial surface, while at progressively deeper locations in the tract, only fine calibre axons are present (Reese & Guillery, J. Comp. Neurol. in press). We have interpreted this segregation by size as a segregation of functionally distinct ganglion cell axons, but an alternative interpretation, consistent with classical neuro-ophthalmologic descriptions of the optic tract, is also available, namely, that this size segregation reflects a centro-peripheral retinal gradient. In order to test between these two alternatives, implants of HRP have been surgically inserted into one optic tract at varying deep-to-superficial locations in five rhesus or cynomolgous monkeys. Following a 48-72 hour survival, monkeys were perfused with saline followed by 2% paraformaldehyde. Eyes were then removed, retinae were dissected out and reacted for HRP histochemistry, and wholemounts were prepared. The perfusion was continued with 1.25% paraformaldehyde + 2.5% glutaraldehyde. Brains were then cut frozen at 50µm, and sections were processed for HRP histochemistry.

Implants of HRP deep in the optic tract retrogradely labelled a population of retinal ganglion cells with small somas, the majority of which possessed the morphological appearance of the primate's P_β cell. Cellular labelling was densest centrally, near the fovea, but labelled cells extended to the retinal periphery. These implants produced anterograde labelling that was mainly confined to the parvocellular laminae of the lateral geniculate nucleus. Implants placed at more superficial positions labelled a population of retinal ganglion cells many of which had substantially larger somas and a dendritic morphology characteristic of the primate's P_α cell. Density of cellular labelling showed little variation across retinal eccentricity, but measurements of density near the fovea and at the retinal periphery indicated that even these superficial implants labelled more central than peripheral retinal ganglion cells. Anterograde labelling after such superficial implants was found primarily in the magnocellular laminae of the lateral geniculate nucleus.

The present results indicate that the deep-to-superficial axis of the monkey's optic tract does not simply contain a single representation of the foveo-peripheral radial dimension. Rather, this axis contains a partial segregation of axons arising from morphologically distinct retinal ganglion cell classes, each population having its own, independent, visual field representation.

399.2 POSSIBLE NEUROTRANSMITTERS IN THE MONKEY RETINOGENICULATE PATHWAYS. Ricardo Molinar-Rode and Pedro Pasik. Neurobiol, Grad. Prog., Depts. Neurol. & Anat., Mount Sinai Sch. Med., CUNY, New York, N.Y. 10029.

The retinogeniculate pathways in the monkey offer the possibility of analyzing the two major retinal ganglion cell subsystems which remain segregated within the magnocellular and parvocellular laminae of the dorsal lateral geniculate nucleus (LGNd). Current electrophysiologic, pharmacologic and biochemical findings suggest an acidic substance with glutamate-like properties as one neurotransmitter in these pathways. Glutamate (GLU), aspartate (ASP) and acidic dipeptides rich in these amino acids (AA), such as N-acetyl-aspartylglutamate (NAAG) have been considered putative candidates.

We investigated this hypothesis by measuring the concentration of these substances in the two segments of both LGNd, in 5 adolescent monkeys (M. fascicularis), 7 days after transection of the right optic tract, just behind the optic chiasm (histologically verified). Additional information was obtained from the distal portions of the optic tracts (OT). The animals were sacrificed with an overdose of barbiturates, and the brain removed in the cold within 10 sec of death. Blocks containing the structures distal to the lesion were frozen within additional 5 min. Cryostat sections, 256 µm thick, were mounted on glass, kept frozen and microdissected with a 22-gauge punch on a freezing stage. Approximately 40 discs were collected from each structure separately. AA and NAAG were extracted by homogenization in 0.4N perchloric acid, and analyzed by HPLC.

Of the 40 AA studied only ASP and GLU showed important decreases on the lesion side as compared to the intact side. In the LGNd, there were no significant differences between magnocellular and parvocellular laminae on either side so that values were combined for further analyses. ASP and GLU decreased 22% and 16%, respectively ($N=5$, $p < 0.05$). A greater reduction, 39%, was noted in the levels of NAAG ($N=4$, $p < 0.05$). Preliminary results in the OT showed even more marked drops, amounting to 71%, 67% and 80% in ASP, GLU and NAAG, respectively. The latter data reached significance in ASP, and only approached it in GLU and NAAG, probably due to the small sample ($N=3$).

The findings are consistent with the hypothesis that ASP, GLU, and NAAG are putative neurotransmitters in the retinogeniculate pathway. The lack of significant differences between the two segments of the LGNd, may indicate that the same neuroactive substances are used by both retinal ganglion cell subsystems. The more prominent decreases obtained in the OT probably reflect the more uniform population of elements present in this structure, since in the LGNd, ASP, GLU and NAAG may also be contained in geniculate neurons and/or afferents from sources other than the retina.

Aided by NIH Grants # NS 18657, NS 11631 and EY 01867.

399.3 **MORPHOLOGY OF CORTICOGENICULATE AXON ARBORS IN A PRIMATE.** E.A. Lachica*, J.B. Hutchins and V.A. Casagrande. Depts. Cell Biology and Psychology, Vanderbilt Univ., Nashville, TN 37232

While it is clear that a feedback circuit exists between visual cortex and the lateral geniculate nucleus (LGN), its function remains obscure. One way to address this question is to examine the arborization patterns of cortical axons that project to the LGN. Iontophoretic injections of horseradish peroxidase into the optic radiations near the LGN have allowed us to reconstruct putative corticogeniculate axons in *Galago crassicaudatus*, a prosimian primate. In galago, physiologically-distinct cell classes are segregated within magno- (Y-like), parvo- (X-like) and koniocellular (W-like) LGN layers. Hence, in the LGN we can examine (1) how corticogeniculate arbors interact with LGN laminae that receive input from different eyes, and (2) how these arbors interact with laminae that contain different physiological cell classes.

Our results suggest that there may be three types of axons that enter the LGN from the optic radiations. The first type gives off 2-3 collaterals that ramify within a single line of projection in several laminae and interlaminar zones; it then turns orthogonal to its original course and issues 2-3 more collaterals within a single layer over more than one projection column. The terminal arbors of these axons are composed of short side branches which possess strings of *boutons en passant* as well as *boutons terminaux*, and resemble the Type I corticogeniculate axons described in cats by Guillery ('66,'67) and Robson ('83).

Additionally, we find two other axonal arbor classes. For convenience, we refer to these as types II and III. (Since type III arbors were only seen in cases in which the main injection was made close to the LGN, we cannot be certain that they originate in cortex. However, in all cases, parent axons were traced into the optic radiations.) Type II axons have richly-branched terminal fields, restricted to individual LGN layers. They are oriented parallel to a line of projection and have *boutons en passant* in strings. Type III arbors also follow a course that is roughly parallel to a line of projection, giving off clusters in functionally matched pairs of layers. Like type II axon arbors, the rich terminal branches of type III arbors are of fine caliber and possess strings of *boutons en passant* as well as *boutons terminaux*. So far, we have identified terminals of type III axons within the magno- or koniocellular layers, but not in the parvocellular layers. If all three axon types are indeed of cortical origin, then our results suggest that the cortex can modulate LGN activity through at least three channels. Type I axons are in a position to influence several layers within one retinotopic region as well as across a broad retinotopic zone in one layer. In contrast, types II and III axons restrict their influence retinotopically and relate either to just one monocularly-innervated layer (type II) or two layers of the same functional type (type III). Supported by NIH EY01778 and the University Research Council (VAC).

399.4 MORPHOLOGY OF IDENTIFIED FERRET LGN NEURONS CHARACTERIZED IN VIVO AND IN VITRO. M. Esguerra*, A. W. Roe* and M. Sur. (SPON: J. Arezzo). Dept. of Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139.

The ferret lateral geniculate nucleus (LGN) contains the W, X and Y functional cell classes as initially described in the cat. In the present study, we describe the morphology and laminar distribution of ferret LGN neurons identified physiologically as X or Y cells in vivo and as relay cells in vitro.

In vivo, we characterized cells as X or Y based on a battery of tests and injected them intracellularly with horseradish peroxidase (HRP). To date, we have recovered 6 Y cells and 2 X cells. For these cells, we have identified sublaminar locations, measured soma sizes and estimated dendritic arbor extents. The somata of ON center X and Y cells lie in the inner leaflets, and those of OFF center cells in the outer leaflets of laminae A and A1, reflecting the physiological division of these laminae into ON and OFF leaflets (Stryker and Zahs, J. Neurosci. 3:1943, 1983). Y cell somata are found in laminae A, A1, C, and interlaminar zones, and have somal areas that range from 163-580 um2. Their dendritic arbors arise from 5-9 primary dendrites and freely cross laminar and sublaminar borders, extending up to 800 um parallel and 600 um orthogonal to laminar borders. These sizes are similar to those of retinogeniculate Y axon terminal arbors (Roe et al., Soc. Neurosci. Abst. 12:9, 1986). One X cell (soma size, 237 um2) has 6 primary dendrites, with a dendritic arbor that is confined to a narrow region perpendicular to laminar borders and spans the entire inner leaflet of lamina A. Retinogeniculate X axons have arbors of similar size and shape. The other X cell (soma size, 574 um2) has 10 primary dendrites. Its soma is situated in the interlaminar zone between laminae A and A1 as are most of its dendrites; its dendritic extent, predominantly parallel to laminar borders, is at least 400 um.

We have also begun in vitro intracellular recording and injection of cells in the ferret LGN, as a prelude to studies of transmitter-induced conductances in identified cells. Rhodamine-latex microspheres are injected into areas 17 and 18 of visual cortex in adult ferrets to retrogradely label relay cell somata in the LGN (Katz, J. Neurosci. 7:1223, 1987). Rhodamine-labeled cells are identified in slices of thalamus 300 um thick and injected with Lucifer Yellow to reveal their dendritic morphology. Initial observations with this preparation suggest that area 18 receives projections from large LGN cells with morphology similar to that of HRP-filled Y-cells, while a heterogeneous population of cells projects to area 17.

399.5 INNERVATION OF THE CAT'S LATERAL GENICULATE NUCLEUS BY INDIVIDUAL CELLS OF THE PERIGENICULATE NUCLEUS.

D.J. Uhlrich, J.B. Cucchiaro, and S.M. Sherman. Department of Neurobiology and Behavior, SUNY, Stony Brook, NY 11794.

The cat's perigeniculate nucleus (PGN) consists of a thin layer of GABAergic cells lying just dorsal to the lateral geniculate nucleus (LGN); the PGN may be part of the thalamic reticular nucleus. PGN cells are innervated by the LGN, by the visual cortex, and by several ascending brainstem pathways. PGN cells in turn provide a dense, apparently inhibitory innervation to the LGN that strongly modulates geniculate cell activity. To reveal the morphology of the pathway from the PGN to the LGN, we intracellularly labeled individual PGN cells with HRP after recording from them electrophysiologically.

Visual responsiveness of each of our labeled sample of PGN cells was strongly dominated by one or the other eye; PGN cells driven equally by both eyes have not yet been labeled and recovered. Each labeled PGN cell has 5 or 6 primary dendrites that branch and produce beaded secondary and tertiary dendrites. The dendritic arbor extends horizontally for roughly 1mm. Each axon generally originates from a proximal dendrite, and it branches several times within 500um of the soma. One branch usually arborizes within the dendritic arbor, and two sets of branches descend into the LGN A-laminae to form terminal arbors that are mediolaterally separated by 150-300um. Of these, the more lateral arbor, which contains many more boutons, is 500-600um wide and is confined either to lamina A if the contralateral eye dominated PGN cell responses or to lamina A1 if the ipsilateral eye dominated. The more medial arbor, which contains relatively few boutons, innervates laminae A and A1; the innervation is via boutons en passant or several small clusters of boutons (20-150um wide) on short collateral branches. Our prior electron microscopic analysis (Cucchiaro et al., Neurosci. Abstr. 11:231, 1985) suggests a different pattern of contacts between the medial and lateral arbors of these PGN axons. We have as yet observed no projection of PGN axons to the C-laminae or medial interlaminar nucleus. Finally, some PGN cells project an axon branch caudo-medially towards a presently unknown destination, possibly in the midbrain. We are currently labeling a limited number of PGN cells with discrete extracellular injections of the anterograde tracer Phaseolus vulgaris leucoagglutinin to confirm and extend these observations.

399.6 CONVERGENCE OF CORTICAL AND RETINAL W-CELL INPUT TO CELLS OF CAT SUPERIOR COLLICULUS.

D.M. Berson. Sect. Neurobiology, Div. Biol. & Med., Brown Univ., Providence, RI 02912

The superficial layers of the cat's superior colliculus receive input from retinal Y- and W-cells and from the visual cortex. Many collicular neurons ("W-direct cells") appear to receive direct retinal input exclusively from W-cells. Corticotectal afferents densely innervate the upper half of the superficial gray where W-direct cells predominate, but it is not certain that cortical input reaches W-direct cells. For example, some collicular cells exhibit a polysynaptic Y-cell influence mediated by corticotectal input, but this "Y-indirect" influence is not seen in W-direct cells (Hoffmann, J. Neurophys. 36: 1973).

To determine whether W-direct cells receive cortical input, responses of collicular neurons to intracortical stimulation of area 17 were tested in barbiturate-anesthetized cats. W-direct cells were identified on the basis of the slow conduction velocity of their retinal afferents (<13 m/s), as determined from differences in their minimal latencies of activation from the optic disk, chiasm and tract. W-direct cells were common in the superficial layers, making up 94% (44/47) of cells whose afferent conduction velocities could be estimated with confidence. Nearly three-fourths of these W-direct cells (32/44; 73%) could be driven from area 17, a proportion comparable to that among superficial-layer cells overall (106/133; 80%). The fraction of W-direct cells receiving excitatory cortical influence is probably even higher, since retinotopic alignment of stimulus and recording sites was only approximate in this study. Latencies of cortical activation of W-direct cells ($\bar{X}$ = 6.5 $\pm$ 3.1 ms; range: 2.6 - 16.5; n = 32) were similar to those of superficial-layer cells overall ($\bar{X}$ = 5.3 $\pm$ 2.7 ms; range: 0.5 - 16.5; n = 112).

Convergence of W-cell and corticotectal input to collicular neurons is perhaps not surprising, in view of the overlapping terminal distributions of these projections to the superficial gray. Further, most W-direct cells are binocular and direction-selective (Hoffmann, 1973), properties thought to depend largely on corticotectal influence. It is unclear why W-direct cells fail to exhibit the polysynaptic "Y-indirect" influence seen in other collicular cells with cortical input. One possibility is that functionally distinct sets of corticotectal neurons influence the two collicular cell types. In support of this view, preliminary results suggest that cells with Y-indirect input exhibit shorter latencies of activation from the cortex and lie deeper in the superficial layers than do W-direct cells.

399.7 TOPOGRAPHICAL ORGANIZATION OF THE CONNECTIONS FROM THE DIENCEPHALON TO THE SUPERIOR COLLICULUS IN THE CAT.

J.M. Giménez-Amaya*, A. Tortelly* and F. Reinoso-Suárez (SPON: C. Avendaño) . Dpto. Morfología, Fac. Medicina, Univ. Autónoma, 28029-Madrid, Spain.

In the last years several authors have proposed that the superior colliculus (SC) plays an important role in the regulation of eye and head orientation movements, being involved in the transfer of locational and behavioral information to the motor system. On the basis of retrograde HRP studies Tortelly and Reinoso-Suárez (Neurosci. Lett., 18: 257, 1980) described projections from several diencephalic formations to the SC, which could serve as a morphological substrate for such a role. With the aim of confirming and understanding more thoroughly these connections we have analyzed the topographical organization of the diencephalo-collicular projections by using the HRP and HRP-WGA retrograde and anterograde tracing techniques. In 29 adult cats, three groups of HRP injections (Sigma VI) were placed in the SC: massive injections, injections above the stratum opticum (SO) and small injections in the strati grisei intermedium (SGI) and profundum (SGP). Fourteen additional animals received HRP-WGA injections (Sigma VI) in different parts of the diencephalon in order to examine the anterograde labeling in the SC. The SC receives billateral projections (mainly from the ipsilateral side) from the dorsal (DHA), lateral, posterior and anterior hypothalamic areas, zona incerta (ZI), the fields of Forel, reticular thalamic nucleus (RT), ventral lateral geniculate nucleus (GLV), ventromedial hypothalamic nucleus and other hypothalamic structures. Almost all these projections end in the deep collicular layers of the SC, although those arising in GLV, which also extend above the SO. Every portion of the SGI and SGP of the SC receives projections from large areas of the diencephalon. However we have verified a certain segregation in the distribution of the connections to the SC from different diencephalic formations. The medial part of the SGI and SGP is the one receiving most abundant and consistent projections from the hypothalamus and the lateral zone of the SC receives connections principally from the lateral and caudal hypothalamic formations. The central (mediolaterally) part of the SC receives few hypothalamic projections, which mainly originate in the lateral part of the anterior hypothalamic area and ventral hypothalamus. The DHA projects widely to the deep collicular layers. The major output from the ZI reaches the rostral and lateral part of the deep collicular layers and the RT projects to the whole extension of the SC, although we have observed a rostrocaudal and mediolateral segregation in these projections. Finally, we have found that the GLV also projects to the entire extension of the SC with a reversed mediolateral topography.

399.8 CORTICOTECTAL CELLS IN CAT ARE GLUTAMATE IMMUNOREACTIVE: A DOUBLE LABEL STUDY USING WGA RETROGRADE TRANSPORT AND TRANSMITTER IMMUNOCYTOCHEMISTRY.

R.R. Mize,[1] M.R. Gurski*,[1] A.J. Beitz,[2] and J.E. Madl*[2]. [1]Dept. Anatomy and Neurobiology, Univ. Tennessee, Memphis, TN 38163 and [2]Dept. Veterinary Biology, Univ. Minnesota, St. Paul, MN 55018.

The corticotectal pathway in cat arises primarily from layer V pyramidal cells and is thought to be excitatory. Evidence for which neurotransmitter mediates this excitation is contradictory. Removal of visual cortex reduces glutamate levels in the superior colliculus (SC), but few or no corticotectal cells are retrogradely labeled by ^{3}H-D-aspartate, a substance thought to be transported by glutamate neurons. We have used an antibody raised directly against a glutamate conjugate to determine if corticotectal cells in cat contain this excitatory amino acid neurotransmitter.

Either ^{3}H-n-acetylated wheat germ agglutinin (WGA) or HRP conjugated WGA were injected into SC in order to retrogradely label corticotectal cells. ^{3}H-WGA was localized by autoradiography, WGA-HRP by cobalt intensified diaminobenzidine histochemistry. Cells in visual cortex which were labeled by the glutamate antibody were stained using the avidin-biotin (ABC) technique. Preabsorption of the antibody with 4 mM L-gamma-glutamic acid dramatically reduced specific antibody staining. By contrast, preabsorption with 4 mM GABA had no effect on specific staining. The antibody therefore appears specific to neurons containing glutamate but not GABA.

Anti-glutamate positive cells were found throughout visual cortex. Pyramidal cells in layers II,III, and V were especially heavily labeled. The apical and basilar dendrites of these cells were also well-labeled. Many retrogradely labeled corticotectal cells were also found in visual cortex. These cells were found only in layer V. After large injections involving both the superficial and deep layers of SC, retrogradely labeled corticotectal cells were found in areas 17, 18, 19, and several regions of lateral suprasylvian cortex (LS). Smaller injections resulted in labeling of corticotectal cells in more restricted regions.

Approximately 92% of the retrogradely labeled corticotectal cells were double labeled by the glutamate antibody. Thus, all but a small fraction of neurons projecting to SC contain glutamate. Double-labeled corticotectal cells were all pyramidal neurons, most with prominently labeled apical dendrites. These cells varied in size and were widely stratified within layer V.

Our double-label technique demonstrates that the vast majority of all cortical neurons projecting to the cat superior colliculus contain glutamate, regardless of the visual cortical area in which the cells are located. Glutamate is therefore a likely neurotransmitter candidate of the corticotectal system in cat. This conclusion is also supported by evidence that 1) laminae of SC which are known to receive cortical input are densely stained by the glutamate antibody; and 2) visual cortical lesions reduce glutamate levels in SC.

399.9 RETINAL AND CORTICAL PROJECTIONS TO THE NUCLEUS OF THE OPTIC TRACT AND DORSAL TERMINAL NUCLEUS IN MACAQUE MONKEYS. K.-P. Hoffmann, R. Erickson* and C. Distler*. Allg. Zoologie und Neurobiologie, Ruhr Universitaet Bochum, Postfach 102148, 4630 Bochum, FRG

The nucleus of the optic tract (NOT) in the pretectum and the dorsal terminal nucleus (DTN) of the accessory optic tract in vertebrates are essential for slow horizontal eye movements stabilizing the image on the retina (Optokinetic Reflex OKR). Comparative neuroanatomical studies of mammals have shown that with increasing 'corticalization' of the visual system the midbrain receives an increasing proportion of its input from cortical areas as opposed to the well established direct retinal projection.

To extend this comparative study towards the primate visual system we investigated the relative strength of retinal and cortical projections to the NOT and DTN in the macaque monkey. Electrical stimulation was applied to the optic tract (OT), striate cortex (V1), and different cortical areas in the superior temporal sulcus (STS) while recording extracellularly from single neurons in the NOT and DTN of anaesthetized paralyzed animals. NOT-DTN cells were identified by their antidromic spike following electrical stimulation of their axons projecting to the inferior olive and by their high degree of movement and direction selectivity. All NOT-DTN cells on the left side of the brain prefer leftward movement of visual stimuli in the visual field and vice versa. The receptive fields always include the fovea and mostly extend far into both the contralateral and ipsilateral hemifields. NOT-DTN neurons respond to stimulus velocities from less than 0.1°/s up to several hundred degrees per second. The mean peak sensitivity of the whole population occurs at 20-30°/s.

Only about half of the NOT-DTN cells could be activated by OT-stimulation. The low conduction velocity of the retinal axons to the NOT and DTN (4-9m/s) implies that they originate from so called 'rarely encountered' ganglion cells with special receptive field properties (Schiller,P.H., Malpeli, J.G., (1977), J. Neurophysiol. 40, 428-445). Electrical stimulation in V1 as well as STS activated all cells recorded in the NOT-DTN with average latencies of 3.2 ±0.7 and 2.1 ±0.5ms, respectively. Anatomical studies confirm our physiological results by showing direct projections from both V1 and STS to NOT and DTN.

A comparison of retinal and cortical input to the NOT and DTN in different mammals shows that the strongest preponderance of cortical influence exists in monkeys. This could explain why in monkeys all NOT-DTN neurons can be activated from either eye and why monocularly tested horizontal OKR is completely symmetrical. In humans the cortical input to NOT and DTN may be so important that in patients with cortical blindness the retinal input alone cannot maintain the OKR.

399.10 TREE SHREW PULVINAR NUCLEUS: DIFFERENTIAL PROJECTIONS TO ACHE-RICH AND -POOR ZONES FROM THE SUPERIOR COLLICULUS BASED ON CELL SIZES, DEPTH AND MORPHOLOGY. R.G. Carey. Div. of Neurobiol., Barrow Neurol. Inst., St. Joseph's Hosp. & Med. Ctr., Phoenix, AZ 85013.

We recently showed that in the tree shrew two distinct pathways exist from the superior colliculus (SC) to the pulvinar nucleus (Pul) (Carey et. al., 1985). The first is bilateral and projects diffusely to widespread regions of the AChE-rich portions of the Pul, while the second is strictly ipsilateral and projects topographically to specific discrete regions of the AChE-poor Pul. The present investigation examined the distribution of HRP-labeled cells in the SC following small electrophoretic tracer injections (WGA/HRP or cholera toxin/HRP) into restricted portions of the pulvinar nucleus in anesthetized tree shrews. Each of these tracers, when reacted properly, result in Golgi-like visualization of the labeled cells for use in the morphological analyses.

Following injections restricted to AChE-rich Pul, labeled cells were located bilaterally within the deep part of the lower stratum griseum superficiale (SGS) and the most superficial portion of the stratum opticum (SO) with a mean depth of 375um (S.D.=55um). Labeled cells ipsilateral to the injection consistently were found throughout widespread regions of the SC and often covered the entire rostral-caudal extent of the colliculus. These cells were typically medium to large horizontally or vertically oriented fusiform, multipolar or triangular cells with cross-sectional areas ranging from 100 to 500um^2 ($\bar{X}$=215um, S.D.=70um), but were skewed heavily towards the larger cells. The various classes appeared to occur with no particular order, except that the cells were generally larger at the deeper depths. Contralateral cells, while basically similar, were less variable in depth and size.

Following injections of the AChE-poor Pul, a different pattern of labeled cells emerged. These labeled cells were strictly ipsilateral and occurred only within limited areas of the SC; their position varied with the placement of the injection in the Pul. Further, they principally were located in the mid to deep part of the lower SGS with fewer cells occurring in SO, but with a number of cells occurring in the lower part of the upper SGS with a mean depth = 335um (S.D=60um). These labeled cells characteristically were small to medium spherical and flat fusiform cells, with a cross-sectional area of their cell bodies ranging from 30-250um^2 ($\bar{X}$=109um, S.D.= 38um) and reflecting a fairly normal distribution slightly skewed towards smaller cells.

Thus, in the tree shrew two distinct projection pathways exist between SC and Pul that are distinguished not only by termination pattern within the Pul, but by cellular characteristics as well. These paths may represent separate "Y" and "W" channels to Pul and eventually to extrastriate cortex, analogous to that occuring in the retinogeniculate pathways.

399.11 SPATIO-TEMPORAL RESPONSE PROPERTIES OF NEURONS WITHIN THE FERRET VISUAL CLAUSTRUM. K.M. Horn and R.G. Carey. Division of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013.

Quantitative examination of visual response characteristics of over 100 neurons within the claustrum of paralyzed, anesthetized ferrets (Mustela putorius furo) has revealed three major spatio-temporal response properties. (1) Even though the receptive fields of claustral cells are relatively long (mean=24°), only a few cells (<20%) demonstrate length summation. In fact, the majority of the claustral neurons (>60%) exhibit peak responses to stimuli that are less than 50% of the receptive field length. These neurons can be classified as a form of special complex cell since their responses are either 'tuned' to a particular slit length and exhibit either response decrements to longer slits or show no further summation to longer length slits. A major subgroup of these cells prefers stimuli that are less than 5% of the receptive field length. (2) Claustral cells prefer moving stimuli and concomitantly are less responsive to stationary stimuli. Over 50% of the claustral neurons prefer fast moving stimuli (>100°/sec) and can be categorized as velocity-high pass cells since they respond poorly to slow moving slits and have responses of over 70% of maximum when tested at 1000°/sec. Velocity-broad band (22%) and velocity-tuned (20%) cells constitute the remaining claustral neurons. The only decrements in response activity in velocity-broad neurons are found at either slow (<25°/sec) or very fast (>500°/sec) velocities, while velocity-tuned cells exhibit response decrements when the velocity of the stimulus is either less than or greater than a narrow range of velocities (usually less than 75°/sec in width). No cells in the claustrum have been sampled that respond exclusively to slow moving stimuli (<25°/sec). (3) Directional preferences to moving stimuli are shown in many cells (>30%). The majority of these cells continue to exhibit directionality when tested at nonpreferred or fast velocities. The remaining neurons exhibit either a directional bias (30%), pan-directionality (20%), or bi-directionality (16%). Finally, we have noted interactions between the spatio-temporal characteristics of stimulus length, velocity and direction.

The dorsal claustrum has extensive reciprocal connections with visual cortices (striate, adjacent extrastriate, and lateral suprasylvian) and thalamus (lateral posterior and intralaminar nuclei). These anatomical connections in conjunction with the spatio-temporal properties of the majority of ferret claustral cells provide preliminary evidence that these cells are involved in either providing 'attentional tonus/gating' or fast saccade processing information to multiple visual cortices.

400.1 Double-labelling Retrograde Transport in the Mouse Thymus and adjacent tissue. K. Bulloch and L. Tollefson. Neuroimmune Physiology Laboratory, Helicon Foundation, San Diego, CA 92109.

In view of the close anatomical positions of the esophagus, neck musculature, and intercostal regions to the thymus gland in the mouse, and the reported labelling of these areas of the spinal cord and by the vagal complex of the brain stem, it is possible that early retrograde transport studies might have produced ambiguous results. Therefore we have undertaken the re-examination of the innervation patterns of the thymus gland and the aforementioned tissues using a double-labelled retrograde transport technique.

To determine the best procedure for peripheral double-labelled retrograde transport, several different substances and protocols were developed and tested. Retrograde transport from peripheral tissue to the central nervous system using Rhodamine beads (Luma-Fluor) proved to be ineffective as a transporting agent but did serve as an excellent marker in later experiments for varifying the specificity of the injection sites. There were some drawbacks with the use of Rhodamine in the periphery. These beads initiate a massive migration of phagocytic cells to the injection site which may be responsible for the failure of this agent to be taken up by autonomic nerves. The most effective combination of double-labelled retrograde transport markers were found to be Horseradish peroxidase(HRP) (Sigma Type VI) and Fluoro-gold (Fluorochrome, Inc.). Fluoro-gold proved to be even a more sensitive label than HRP and thus could be injected in very small quantities.

To determine the pattern of innervation of the various aforementioned tissues and organs, HRP and Fluoro-gold were simultaneously injected into mice anesthesized with Ketamine and Rompun. Neck muscles, pectoral muscles or the areas of the esophagus adjacent to the thymus received multiple injections of a 30% HRP (1-3 ul) whereas the thymus received injections of 0.5-1.0 ul of 2.5% Fluoro-gold. Many different variations of the aforementioned protocol were used in these experiments. The results clearly show Fluoro-gold injections into the thymus when compared to HRP injections into the other tissue produce very few double-labelled neurons in the brain stem and the spinal cord. The presence of double-labelled neurons may reflect diffusion of one or both of the substances onto the adjacent areas in question or onto other tissue (heart, lung, thoracic duct, etc...) that receives vagal innervation. Supported by ONR grant #N00014-85k-0528.

400.2 SIGMA RECEPTORS IN HUMAN PERIPHERAL BLOOD LEUKOCYTES (HPBL) AND RAT SPLEEN: IDENTIFICATION, CHARACTERIZATION AND AUTORADIOGRAPHIC LOCALIZATION. S.A. Wolfe, Jr.*, C. Kulsakdinun* and E.B. De Souza. (SPON: K. Dismukes) Neuroscience Branch, NIDA Addiction Research Center, Baltimore, MD 21224.

Phencyclidine (PCP) and sigma opioids have been shown to produce psychotomimetic effects in humans and associated behavioral effects in animals through actions on specific receptors in brain. In addition, PCP has been reported to cause immunosuppression in vitro. The aim of the present study was to identify, characterize and localize the sites of PCP action (sigma and/or PCP receptors) in immune tissues. Sigma receptors were labeled in homogenates of rat cerebellum, rat spleen and HPBL, and in slide-mounted sections of rat brain and spleen with ^{3}H-haloperidol in the presence of 25 nM spiperone. PCP receptors were labeled with ^{3}H-(1-[1-(2-thienylcyclohexyl)]piperidine) (^{3}H-TCP). Nonspecific binding was defined as ^{3}H-haloperidol or ^{3}H-TCP bound in the presence of 30 μM (-)butaclamol or 20 μM PCP, respectively. ^{3}H-Haloperidol binding in rat spleen, rat cerebellum and HPBL was saturable and of high affinity, with comparable K_D values (mean $\pm$ S.E.M.; n = 3) of 1.07 $\pm$ 0.16, 0.74 $\pm$ 0.12, and 0.63 $\pm$ 0.09 nM, respectively. In competition studies, the pharmacological profiles were virtually identical in all three tissues; the rank order of potency was haloperidol >> (-)butaclamol = pentazocine > [3-hydroxyphenyl]-N-(1-propyl)piperidine (3-PPP) > (+)SKF 10,047 = (+)butaclamol > ethylketocyclazocine = PCP = (-)SKF 10,047 = levallorphan > TCP. The highest density of ^{3}H-haloperidol-labeled sigma receptors (B_{max}, fmol/mg protein,) was found in spleen (1198 $\pm$ 105, n = 4), with comparable but significantly lower densities present in HPBL (884 $\pm$ 143, n = 3) and rat cerebellum (753 $\pm$ 26, n = 4). Autoradiographic studies carried out in slide-mounted sections of rat spleen demonstrated that ^{3}H-haloperidol-labeled sigma receptors were localized primarily in the white pulp areas, which contain a high density of lymphocytes. In contrast, there was a notable absence of ^{3}H-TCP-labeled PCP receptors in rat spleen and HPBL using either homogenate binding or autoradiographic methods. In summary, these results demonstrating high concentration of sigma receptors and the virtual absence of PCP receptors in immune tissues suggest that PCP exerts its immunomodulatory influence via sigma receptors. Furthermore, the data suggest that endogenous "sigma" ligands may play a role in immune regulation, either directly or by lymphokine or monokine induction. Studies of the effects of PCP and sigma agonists on immune function are presently underway in our laboratory. The sigma receptor in HPBL may also be a useful peripheral marker for assessing the role of sigma receptors in human brain.

400.3 EFFECTS OF MORPHINE ON THE PHENOTYPIC EXPRESSION OF T-LYMPHOCYTE CELL SURFACE MARKERS IN THE MOUSE. A.S. Kimes, W.J. Smith*, C.P. Jaffe* and E.D. London. Neuropharm. Lab., NIDA Addiction Research Center, Baltimore, MD 21224.

Intravenous drug abusers are at a high risk for infection by the acquired immune deficiency syndrome (AIDS) virus. Therefore, it was of interest to study the effect of opioids, the drug class most often abused by self-injection, on immune cells which are attacked by the AIDS virus, HIV. Peripheral blood lymphocytes (PBL) were obtained from blood of pathogen-free male C57/BL6J mice. While under halothane anesthesia, each mouse received a subcutaneous placebo (P) pellet, a low dose morphine (M) pellet (6.7 mg M sulfate), or a high dose M pellet (75 mg M sulfate) (n = 8-10 per group). Three days later, the mice were anesthetized with halothane again, and blood was obtained by cardiac puncture. Numbers of white blood cells (WBC), lymphocytes, total T-cells, T-helpers and T-cytotoxic/suppressors were measured in each sample using flow cytometry and monoclonal antibodies to cell surface antigens specific for T-cells, T-helpers and T-cytotoxic/suppressors (Thy-1, L3T4, and Lyt2, respectively). Spleen/body weight ratios also were calculated for each mouse.

All of the aforementioned measures were significantly lower in M-treated mice, showing a dose-response relation. In vitro incubation of PBL with naloxone (100 nM) partially reversed the M effect on Thy-1 expression but had no effect on Thy-1 expression in PBL from P-treated mice. The M effect (6.7 mg) on spleen-body weight ratios, number of lymphocytes and WBC count was blocked by naltrexone (40 mg/kg, s.c., twice daily).

Studies on PBL of parenteral M and heroin drug abusers have failed to demonstrate lower levels of T-cell markers compared to normal controls. It seemed reasonable that this failure might be due to antigenic stimulation found in drug abusers because of their needle sharing practices. In order to test the effect of antigenic stimulation on detectability of an opioid effect on immune markers, we gave mice injections of sheep red blood cells. Spleen/body weight ratios of P- and M-pelleted mice which received these injections were higher than those of vehicle-treated controls, demonstrating that M-treated mice could respond to an antigenic stimulus, and suggesting that such a response might obscure a reduction of T-cell numbers and a suppression of T-cell markers in human addicts. We detected no differences in ^{3}H-thymidine incorporation into splenocytes in the presence of mitogenic agents (concanavalin A, phytohemagglutinin, and pokeweed) comparing M- (75 mg) and P-pelleted mice.

We conclude that M may affect the phenotypic expression of cell surface markers and possibly number of T-cells. Inasmuch as mitogen assays reflect the immunological competency of T-cells, the present findings do not suggest a functional impairment.

400.4 CENTRAL OPIOID SYSTEMS ARE DIFFERENTIALLY AFFECTED BY PRODUCTS OF THE IMMUNE RESPONSE. P.M. Dougherty* and N. Dafny (SPON: F. Yatsu). Dept. of Neurobiology and Anatomy, The Univ. of Texas Med. Sch. at Houston, P. O. Box 20708, Houston, TX 77225.

The present study compares the effects induced by muramyl dipeptide (MDP), the smallest biologically active fragment of bacterial endotoxin (lipopolysaccharide), and interferon-alpha (IFN), the most rapidly produced defense against viral infection, upon various central opioid behavioral and electrophysiological activities. Forty-eight male Sprague Dawley rats were used to study the dose-response characteristics of MDP and IFN upon naloxone-precipitated withdrawal in morphine-dependent animals following both intracerebroventricular (i.c.v.) and systemic (i.p.) administration in the first half of this study. In the second half, the relationship of the similarities as well as differences in the actions of these two immune-response products upon the baseline and post-narcotic electrophysiological sensory-evoked responses of four brain regions essential for the in vivo manifestation of various opioid activities is investigated. Electrical activity from 24 male Sprague-Dawley rats previously implanted with permanent semi-microelectrodes in the hypothalamus, septum, mesencephalon and cortex was recorded prior to and following either MDP or IFN, and later following morphine and naloxone. The results obtained demonstrate that: 1) MDP attenuates withdrawal severity in a typical linear dose-related fashion, while IFN attenuates withdrawal severity in a U-shaped pattern 2) The cortex, mesencephalon and septum were modified differently following MDP versus IFN treatment; however, the responses obtained from the hypothalamus were the same for both agents. 3) In addition, MDP and IFN have differing effects upon the actions of morphine and naloxone in the cortex, septum and mesencephalon; but, again, these agents exhibit the same effects upon morphine activity in the hypothalamus. These results indicate that the shared effects of these two agents upon the behavioral expression of opiate withdrawal may be due to a common activity upon the physiologic sequelae of opioids in the hypothalamus. In addition, since each peptide also has unique dose-response characteristics as well as unique effects upon the electrophysiologic activities of other subcortical and cortical structures, these results support the conclusion that central opioid systems may provide a target for the perception and differentiation of sensory immunologic information by the brain.

400.5 CORTICOTROPIN RELEASING FACTOR STIMULATES PROLIFERATION OF RAT LYMPHOCYTES IN VITRO. J. P. McGillis, A. Park*, M. Dallman*, and D. G. Payan*. Dept. of Medicine and Physiology, and Howard Hughes Medical Institute, Universisty of California, San Francisco, San Francisco, CA 94143

An immunoregulatory role for neuropeptides is supported by evidence from functional studies, by the presence of specific neuropeptide receptors on lymphocytes, and by the ability of immunological tissues to produce neuropeptides. Production of immunoreactive (ir) ACTH and ß endorphin peptides, and POMC mRNA by lymphocytes suggests that immunological tissues utilize these peptides in a manner similar to the neuroendocrine system. This analogy is consistant with the observation that CRF can induce the production of irACTH and ß endorphin in lymphocytes in vitro.

In these studies a functional effect of CRF on lymphocytes was identified by demonstrating that CRF stimulates lymphocyte proliferation. Rat splenocyte suspensions were prepared from male rats and were cultered at 10^6 cells/ml in 96 well microtiter plates. The cells were treated with CRF (n=6) at doses ranging from 10^{-12} to 10^{-6} M. After 48 hrs 1 µCi of ^{3}H-thymidine (Tdr) was added and the cells were harvested 8 hrs later. Proliferation was quantified by determining the amount of ^{3}H-Tdr incorporated into cellular DNA. Both ovine and rat CRF caused a dose dependent cellular proliferation which peaked at 10^{-8} M CRF. A significant response was usually seen at doses as low as 10^{-10} M and the ED_{50} was about 2 x 10^{-9} M. The maximal response to 10^{-8} M CRF varied between 250 and 500 % of unstimulated controls. This effect of CRF appears to be pharmacologically distinct in that the antagonist αhCRF (9-41) acts as an equipotent agonist in inducing lymphocyte proliferation. This suggests that the 8 N-terminal amino acids of CRF are not required for lymphocyte stimulation. Further studies are being done with other fragments of CRF to localize the biological activity.

The response of lymphocytes from different lymphoid tissues and different subsets of lymphocytes were also studied. Lymphocytes were isolated from mesenteric lymph nodes (MLN), Peyer's Patches (PP), Inguinal lymph nodes (ILN), spleen, and thymus and were stimulated with CRF. The greatest response to CRF induced lymphocyte proliferation was seen in gut associated lymphoid tissue, MLN and PP (> 350 % unstim. control) followed by ILN and spleen (200-250 %). Thymocytes did not proliferate following CRF treatment. When enriched populations of T-cells, B-cells, and macrophages were treated with CRF, only B-cells responded by proliferating. The ability of CRF to stimulate B-cell proliferation supports the hypothesis that CRF has an immunoregulatory role in addition to its role in integrating autonomic and neuroendocrine stress responses.

400.6 NOREPINEPHRINE INHIBITION OF G-IFN INDUCED Ia EXPRESSION ON CULTURED ASTROCYTES SEEMS TO WORK THROUGH A BETA-2 RECEPTOR MECHANISM THAT INVOLVES ELEVATIONS IN INTRACELLULAR cAMP. E.M. Frohman, B. Vayuvegula, S. Gupta, and S. van den Noort. Departments of Neurology and Immunology, University of California at Irvine, Irvine, CA 92717

Recent studies show that astrocytes serve as mediators of intracerebral immune responses. Astrocytes do not normally express the MHC class II antigens (Ia in mouse and DR in man) that are necessary for the initiation of such responses, but instead must be induced to do so. A potent inducer of Ia expression is gamma-interferon (G-IFN). Despite the presence of this lymphokine in the CNS, there is a paucity of Ia (DR) expression in normal brain. Due to this apparent paradox, we sought to determine whether there are intracerebral modulators that prevent G-IFN induced Ia expression on astrocytes. For this purpose, enriched astrocyte cultures were made from brains of newborn Balb-C mice. When cultures were treated with 2 units/ml of G-IFN, 37%, 50.2% and 51.5% of cells were Ia+ at 24, 48, and 72 hours when analyzed by flow cytometry. When cultures were co-treated with 2 units/ml of G-IFN and varying concentrations of NE (10^{-7} to 10^{-3}M) the percent inhibition of Ia expression ranged from 18.4% to 86.2% at 24 hours; 0 to 89% at 48 hours; and 0 to 94.2% at 72 hours. To determine the mechanism by which such an inhibitory effect occurs, we co-treated cultures with 2 units/ml of G-IFN and varying doses of isoproterenol (10^{-8} to 10^{-4}M), a beta-2 adrenergic agonist. Results showed that this drug in a dose dependent fashion, inhibited G-IFN induced Ia expression on cultured astrocytes. Further, we have demonstrated that propranolol, a beta-adrenergic antagonist, but not atenolol (a beta-1 antagonist) or alpha antagonists, attenuated the NE inhibitory effect on G-IFN induced Ia expression. Since prostaglandin E, an inhbitory modulator of Ia expression, causes an increase in intracellular cAMP, NE may act through a similar mechanism. To test this hypothesis, we treated cultures with 2 units/ml of G-IFN and varying doses of dipyridimole (10^{-7} to 10^{-4}M), a phosphodiesterase inhibitor, and observed a significant inhibition of Ia expression (11.4% to 83.0% respectively). These findings suggest that NE inhibition of Ia expression acts via beta-2 adrenergic receptor transduction pathways, which are known to involve the activation of adenylate cyclase (PKA) and a rise in cAMP. This contrasts with Ia inducing signals such as G-IFN, that are believed to work through activation of protein kinase C (PKC).

400.7 Autonomic Nervous System Receptors as a Marker for T-Cell Differentiation and Function. T. Radojcic (1), M. Gersten (2), S.J. Divis (2), D. Darko (3), H. Moltusky (3), D. Smith (3), M. Cohn (2), and K. Bulloch (1). (T. Melnechuk, sponsor). Neuroimmune Physiology Laboratory, Helicon Foundation, San Diego, Cal. 92109 (1), Salk Institute, San Diego, Cal. 92138 (2), Univ. of Cal. San Diego, 92093 (3).

Recently, studies have indicated complex interaction between the nervous system and the immune system. Furthermore, it is becoming increasingly evident that the nervous system may play a significant role in the maturation of functional lymphocyte subtypes. In this study, murine-derived cloned cell lines in log phase of growth, representative of the ontogeny of the immunocompetent T-cell, have been investigated with respect to the development of beta adrenergic receptor distribution.

Normal thymocytes, a cloned thymoma-derived cell line BW 5147, and a splenic-derived, activated cloned T-cell line T-12 (non-tumoregenic) were screened for the presence of beta adrenergic receptors. Iodopindolol was used as the ligand probe at concentrations ranging from 10(-12) M to 10(-9) M. Sixty minute incubations at 37C were carried out in RPMI at 2 X 10(5) cells per assay point (in quadruplicate). Non-specific binding was determined by incubation in the presence of 1 X 10(-6) M propranolol.

The results of these experiments indicate that there is an increase in beta adrenergic receptor number in the mature activated T-cell line, as compared to the immature thymocyte cell line BW 5147, and to the normal thymocytes. These findings are consistent with a previous study that showed mature peripheral lymphocytes express a significantly greater number of beta adrenergic receptors than do normal thymocytes (Van De Griend, R.J. et al., Clin. Exp. Immunol. 53:53, 1983). Binding in the BW 5147 cell line is comparable to levels observed in normal thymocytes.

Further differences may become evident in receptor type, number, and distribution on the various effector function subsets of T-cells. It is also apparent that the use of cloned "normal" and tumoregenic T-cell lines may provide a useful specific tool in a more precise analysis of neuroimmune interaction. 400.8 THE EFFECT OF NUMBER OF MICE HOUSED/CAGE ON IMMUNOLOGIC COMPETENCY. B.S. Rabin*, T. Caggiula, M. Lyte*, E. Hamill* (Spons: H. Barry, III). Depts. of Pathology and Behavioral Neuroscience, University of Pittsburgh, Pittsburgh, PA. 15261

This study has identified a change in immunologic functional activity at the level of the T-helper cell in male C3H mice housed 1 or 5 per cage. This resulted in elevated numbers of spleen lymphocytes producing antibody to sheep erythrocytes in individually housed mice, but did not affect the T-cell independent antibody response to PVP. Nonspecific responsiveness to the T-cell mitogens Con A and PHA, as well as IL-2 release, was also higher in the individually housed mice, but the mitogenic response to the B-cell mitogen LPS was not changed. No differences in IL-1 production between the differentially housed animals were found. The data suggest that functional changes have primarily occurred in the T-helper cell population of the male C3H mice. The difference of immune reactivity to S-RBC of the differentially housed was not present at 1 and 4 days of housing but was detected on days 8 and 10. By day 21 the difference in the antibody response to S-RBC was no longer present, but Con-A reactivity was still higher in the mice housed 1/cage. Castration of young male mice abolished the immune difference associated with housing. Four additional strains of mice housed individually or in a group (5/cage) were immunized with sheep erythrocytes (SRBC) to determine if the major histocompatibility complex (MHC) was associated with altered immune reactivity based on housing. Individually housed mice from two strains which shared neither the H_2D or H_2K loci, produced more antibody forming spleen lymphocytes to SRBC than group housed mice. Corticosterone levels were not related to the level of the immune response. Thus, genetic factors related to the MHC do not influence alteration of the immune response and male sex hormones may contribute to the immunologic differences which occur with differential housing conditions.

400.9 ALTERED IMMUNE FUNCTION IN YOUNG ADULT BASAL FOREBRAIN DAMAGED AND NORMAL AGED RHESUS MONKEYS. L.J. Kraus, M.B. Moss and D.L. Rosene. Departments of Neurology and Anatomy, Boston University School of Medicine, Boston, MA. 02118

A wide variety of recent research has demonstrated the important role of neural and endocrine influences in regulation of the immune system. Damage to specific brain areas has been shown to result in various changes in immune function. We previously reported preliminary findings of a decrease in one aspect of cell mediated immune function, natural killer cell activity (NKCA), in young adult rhesus monkeys with bilateral lesions of the basal forebrain. We report here our continuation of these studies to include a larger number of monkeys and several additional measures of immune function. We have now examined 10 young adult animals (5-10 yrs.) with lesions of the basal forebrain. Bilateral lesions of the basal forebrain, involving principally the substantia innominata and nucleus basalis (SI-NB), were produced by intracerebral injection of the neurotoxin, ibotenic acid. We have also examined 4 monkeys with caudate lesions and one with hippocampal lesions, 11 sham operated controls and 5 nonoperated controls in this age range. Further, 6 monkeys with SI-NB lesions and one animal with caudate lesions were assessed both before and after creation of the lesions. Finally, we have examined 17 normals in other age groups including 8 animals 25+ yrs. old. The immune measures studied include NKCA, response to T and B cell mitogens, production of interferons (IF), and percent of specific lymphocyte subsets determined by reactivity with monoclonal antibodies. As part of a multidisciplinary study of the basal forebrain and aging in the rhesus monkey, these measures were compared with chemical and behavioral data obtained from many of the same animals. Changes in the cholinergic system were evaluated with histochemical studies of the cholinergic marker, acetylcholinesterase (AChE) and were quantified with a scanning and integrating microdensitometer. NKCA, IF production, and response to T cell mitogens were all depressed in monkeys with SI-NB lesions. All immune measures tested in monkeys with caudate or hippocampal lesions were within normal range. NKCA and IF production were depressed in some, but not all, aged normal monkeys and mitogen response was depressed in this group. Monoclonal antibody reactivity was not altered in any test group. In aged monkeys and monkeys with SI-NB lesions where behavioral data were available, degree of behavioral deficit was correlated with immune impairment. Further, immune impairment appeared to correlate with AChE depletion in animals for which these data were available. These data suggest that cholinergic loss due either to specific brain lesions or degenerative processes associated with normal aging may greatly influence immune function and thus host resistance to autoaggression and disease.

ACTION POTENTIALS AND ION CHANNELS XIII

401.1 PHYSIOLOGICAL INTERACTION BETWEEN CALCIUM AND CYCLIC AMP IN AN APLYSIA BURSTING NEURON. Richard H. Kramer* and Irwin B. Levitan Graduate Dept. of Biochemistry, Brandeis Univ., Waltham MA 02254

Ca^{2+} and cyclic AMP are well established intracellular messengers in neurons. Studies of physiological interactions between these messengers, however, are still in their infancy. The Aplysia bursting neuron R15 is ideal for studying such interactions because the individual roles that Ca^{2+} and cyclic AMP play are well understood. Intracellular Ca^{2+}, which increases during bursts of action potentials, regulates several ionic currents that participate in generating the bursting pattern of electrical activity. Cyclic AMP mediates the effects of serotonin (5-HT) and egg-laying hormone (ELH; see Levitan, Kramer and Levitan, this volume) on several ionic currents in cell R15. These include an increase in an inwardly rectifying K^+ current (I_R) and a voltage-gated Ca^{2+} current (I_{Ca}).

Last year we reported that Ca^{2+} influx during bursts of spikes or under voltage-clamp leads to the inactivation of I_R. We have investigated two possible mechanisms of this inactivation of I_R: 1) Ca^{2+} could bind to I_R channels and directly regulate their activity, and 2) Ca^{2+} could alter the cyclic AMP cascade and thus regulate I_R indirectly. Several types of evidence suggest that the second possibility is more likely. Greatly elevating the level of cyclic AMP, by application of high concentrations of 5-HT, forskolin, or PCPT-cyclic AMP, all block the effect of Ca^{2+} on I_R. This happens in spite of the fact that these agents increase I_{Ca} and also increase the number of I_R channels available to be inactivated by Ca^{2+}. Loading neuron R15 with Ca^{2+}, by applying periodic depolarizations, reduces the magnitude and speeds the decay of the I_R increase evoked by locally applied "puffs" of 5-HT or ELH. Thus, Ca^{2+} can decrease the magnitude and duration of cyclic AMP action, possibly by accelerating the removal of cyclic AMP by activating a phosphodiesterase (PDE), or by accelerating the dephosphorylation of proteins that regulate I_R by activating a phosphatase. We favor the hypothesis that Ca^{2+} causes the inactivation of I_R by activating a Ca/calmodulin-dependent PDE because 1) we have measured such enzyme activity in extracts of single R15 somata, 2) R15 neurons which have been hyperpolarized to prevent Ca^{2+} influx have more cyclic AMP than control (bursting) R15 neurons, and 3) the Ca^{2+}-dependent inactivation of I_R is reduced by adding the PDE inhibitor IBMX. We propose that Ca^{2+}-dependent modulation of cyclic AMP metabolism has at least two consequences in neuron R15. First, it causes a nearly complete inactivation of I_R in the normal bursting neuron. Second, it decreases the sensitivity of I_R, and perhaps other ionic currents, to neurotransmitters that elevate cyclic AMP.

401.2 MODULATION OF CHARYBDOTOXIN-SENSITIVE CALCIUM-DEPENDENT POTASSIUM CHANNELS BY PROTEIN PHOSPHORYLATION. Peter H. Reinhart* and Irwin B. Levitan (SPON: Daniel Dagan) Graduate Dept. of Biochemistry, Brandeis University, Waltham MA 02254.

The regulation of calcium-dependent potassium channels from rat brain has been investigated using single channel recording techniques. When plasma membrane fractions from rat brain are reconstituted into planar lipid bilayers, at least three types of calcium-dependent potassium channels with different single channel conductances (approximately 240 pS, 140 pS and 75 pS in symmetrical 150 mM KCl), and distinct gating kinetics, can be observed. These channels do not exhibit any rectification between -40 mV and +40 mV, nor do they show any inactivation at hyperpolarized potentials. The open probability of the 240 pS channel can be increased dramatically by the addition of the catalytic subunit of the cAMP-dependent protein kinase; this increase is due largely to an increase in the channel mean open time. In contrast, the gating activity of a 240 pS channel from muscle t-tubules, which has similar properties to the brain channel, is not modulated by the catalytic subunit. The open probability of the 75 pS channel from rat brain is also increased by phosphorylation, but in this case resulting from a decrease in the channel mean closed time. Preliminary experiments suggest that the activity of the 140 pS channel may be decreased by the catalytic subunit. All three types of rat brain channels are inhibited by nanomolar concentrations of the polypeptide scorpion toxin charybdotoxin (CTX). Thus there may be a family of calcium-dependent potassium channels which differ in their single channel conductances, but have certain common regulatory and toxin binding sites.

Channel	Voltage-Sensitive	Calcium-dependent	CTX-sensitive	Modulated
1. Muscle 240 pS	Yes	Yes	Yes	No
2. Brain 240 pS	Yes	Yes	Yes	Yes ↑
3. Brain 140 pS	Yes	Yes	Yes	? ↓
4. Brain 75 pS	Yes	Yes	Yes	Yes ↑

401.3 MODULATION OF MEMBRANE CURRENTS AND EXCITABILITY BY SEROTONIN AND cAMP IN PLEURAL SENSORY NEURONS OF APLYSIA. D.A. Baxter and J.H. Byrne, Department of Neurobiology and Anatomy, The University of Texas Medical School, Houston, TX 77225.

In the pleural sensory neurons of Aplysia, serotonin (5-HT) modulates not only the novel 5-HT sensitive K^+ current (Ik,s), but also the delayed K^+ current (Ik,v) (Baxter & Byrne, 1986). In order to determine whether modulation of both of these currents by 5-HT is mediated by cAMP, two-electrode voltage- and current-clamp techniques were used to compare the effects of application of 5-HT, 8-bromo-cAMP and 8-4-chlorophenylthio-cAMP on membrane currents, spike duration and excitability in isolated clusters of sensory neuron cell bodies.

Computer isolation of membrane currents modulated by 5-HT clearly revealed two affected currents (Baxter & Byrne, 1986). One current had properties consistent with Ik,s. It was relatively voltage-independent, noninactivating, not blocked by 4-AP and relatively insensitive to TEA. The second current had properties consistent with Ik,v. It was highly voltage-independent and was blocked by 4-AP and TEA. Computer isolation of the membrane currents modulated by the cAMP analogues revealed only one prominent current, Ik,s. The cAMP analogues occluded further modulation of Ik,s by subsequent application of 5-HT, but did not occlude modulation of Ik,v by 5-HT. Thus, application of the cAMP analogues mimicked the action of 5-HT on Ik,s, but did not mimic the action of 5-HT on Ik,v.

During current-clamp, sensory neurons were held at -45 mV, and spikes were elicited by short (3 ms, 5 nA) or long (1 s, 0.5 to 3 nA) depolarizing current pulses. The brief pulses produced single spikes that had an average duration of 7 ms. The long pulses usually produced brief bursts of no more than 5 spikes. Application of 5-HT broadened the spikes to an average duration of 23 ms and doubled the number of spikes produced during long pulses (also see Klein et al, 1986). Application of cAMP analogues produced similar increases in the number of spikes during long pulses, but only modestly broadened the spikes to an average duration of 9 ms. The cAMP analogues occluded further increases in spike number during subsequent 5-HT application, but did not occlude 5-HT induced spike broadening.

These results suggest that in pleural sensory neurons only one of the two currents modulated by 5-HT is sensitive to elevated intracellular levels of cAMP. This current (Ik,s) appears to be critical for membrane excitability, with modest effects on spike duration. In contrast, modulation of Ik,v by 5-HT dramatically broadened the spike. This action of 5-HT may require an as yet unidentified second messenger system. Supported by AFOSR grant 84-0213.

401.4 MYOMODULIN, A NOVEL NEUROPEPTIDE, MODULATES ACTION POTENTIALS IN PLEURAL SENSORY NEURONS OF APLYSIA. L.J. Cleary, D.A. Baxter and J.H. Byrne. Department of Neurobiology and Anatomy, The University of Texas Medical School, Houston, TX 77225.

Myomodulin is a neuropeptide that has recently been purified from buccal muscle of Aplysia (Weiss et al, this volume). This peptide contributes to arousal of feeding behavior by potentiating muscle contractions evoked by motor neurons. Because other transmitters that modulate feeding behavior also modulate defensive behaviors, we were interested in determining whether myomodulin alters the properties of neurons mediating the tail withdrawal reflex. We therefore examined the effects of myomodulin on the action potential produced by tail sensory neurons in the pleural ganglion.

Clusters of pleural sensory neurons were isolated, and myomodulin (12.5-165 uM final concentration) was applied to the bath. In artificial sea water (ASW), there was no apparent change in the duration of action potentials produced by brief depolarizing current pulses. Myomodulin could, however, narrow action potentials that were first broadened by serotonin (5-HT) or tetraethylammonium (TEA). 5-HT (50 uM) increased the average duration of action potentials from 7 to 20 msec. When myomodulin was subsequently applied, the average duration was reduced to 15 msec. Similarly, 10 mM TEA broadened the action potential from an average of 6 to 12 msec, and myomodulin narrowed it back to 10 msec. Myomodulin also decreased membrane excitability, but this effect was not apparent in ASW alone. When 50 uM 5-HT or 10 mM TEA was added to the bath, the number of spikes produced in response to long (1 sec) depolarizing current pulses was increased. Application of myomodulin reduced the number of spikes to control levels. These effects are similar to those produced by another modulatory peptide, FMRFamide.

The effect of myomodulin on synaptic potentials was examined by eliciting action potentials in sensory neurons and monitoring the monosynaptic EPSPs in tail motor neurons. On average, application of myomodulin does not affect the amplitude of the EPSP. However, preliminary results indicate that it reduces the facilitation produced by subsequent application of 5-HT.

While we do not yet know if myodulin is, like FMRFamide, present in the pleural and pedal ganglia, the close similarity between the effects of these two peptides is intriguing. We suggest that they modulate sensory neuron activity by a "silent depression". The effects of myomodulin or FMRFamide on the pleural sensory neurons seem most prominent when membrane conductances are first modulated by transmitters such as 5-HT. This suggests that the neural circuits utilizing these peptides have a function antagonistic to that of facilitatory circuits.

401.5 INVOLVEMENT OF G PROTEINS IN THE INHIBITORY ACTION OF FMRFAMIDE THROUGH LIPOXYGENASE METABOLITES OF ARACHIDONIC ACID IN APLYSIA SENSORY NEURONS. A. Volterra, J.D. Sweatt* and S.A. Siegelbaum. HHMI, Ctr. for Neurobiol. & Behav., Dept. of Pharmacol., Columbia Univ., NY, NY 10032.

The molluscan neuropeptide FMRFamide hyperpolarizes Aplysia sensory neurons as a result of an increase in K conductance due to an increase in the open probability of the resting S K channels (Belardetti et al., Nature 325:153, 1987). This effect of FMRFamide is mediated by the lipoxygenase metabolites of arachidonic acid (Piomelli et al., submitted). Here, we investigate the possible role of GTP-dependent processes in this cascade by studying the effects of intracellular injection of GTP-γ-S, an irreversible activator of G proteins, in Aplysia sensory neurons.

Membrane potentials were recorded from sensory neurons of Aplysia abdominal ganglia using microelectrodes filled with 0.5 M KCl (resistance of 20-50 megohms) with or without addition of 25 mM GTP-γ-S. In the absence of GTP-γ-S, brief pressure application of FMRFamide (from a wide-mouthed pipette containing 10 μM peptide) onto the sensory neurons produced a transient hyperpolarization of 4.56 ± 2.55 mV (mean + S.D., n = 7) associated with an increase in membrane conductance that lasted for 1-2 min. After impalement of a sensory neuron with a GTP-γ-S containing microelectrode, a similar application of FMRFamide produced a hyperpolarization of 5.75 ± 2.21 mV (n = 12) that was now largely irreversible. Upon subsequent iontophoresis of GTP-γ-S into the cell (using 0.5 sec hyperpolarizing current pulses of 0.1 -0.3 nA, 1 Hz), the cell membrane potential further hyperpolarized irreversibly by 5.83 ± 2.76 mV over 5-15 min with a large increase in resting conductance. These effects of GTP-γ-S were blocked by about 85% in presence of 50 μM NDGA, a lipoxygenase inhibitor (n = 8). Current injections from a microelectrode lacking nucleotide had no effect.

Reapplication of FMRFamide after injection of GTP-γ-S produced little or no further hyperpolarization, suggesting that the FMRFamide cascade was already fully activated. The normal depolarizing response of the sensory neuron to serotonin was also blocked at this time. Serotonin normally activates adenylate cyclase through a G protein and leads to S channel closure via cAMP-dependent phosphorylation. Thus, the net effect of G protein activation via GTP-γ-S appears to be the opening of S channels (leading to the increase in membrane conductance and hyperpolarization). This result suggests that the activation of the FMRFamide cascade antagonizes the excitatory action of 5-HT, in agreement with Belardetti et al.

G proteins thus appear to play an important role in mediating the inhibitory action of FMRFamide in Aplysia sensory neurons (see also Brezina and Eckert, Soc. Neurosci. Abstr. 12:1341, 1986). Since blockade of the lipoxygenase pathway of the arachidonic acid cascade with NDGA inhibits the response to GTP-γ-S, a likely role for a G protein lies in the receptor-mediated release of arachidonic acid metabolites.

401.6 SUPPRESSION OF IA AND BACKGROUND K+ CURRENT IN HERMISSENDA NEURONS BY cAMP, 5-HT, THE NEUROPEPTIDE SCPb AND INJECTION OF EXOGENOUS Ca++/CALMODULIN DEPENDENT KINASES. Juan Acosta-Urquidi. Friday Harbor Labs, Univ. Washington, Friday Harbor, WA 98250.

Voltage-clamp studies of a set of identified Hermissenda neurons revealed two species of IA, based on different kinetics and voltage range of activation-inactivation. Pedal cells (LP1-3) with short duration spikes (3-6 ms at half-amplitude), little broadening and accomodation to sustained depolarization, have a "fast" IA (IAf). IAf peaks in<10ms, has tauoff ca. 30-50 ms, activates ca. -40 mV and is half-maximally inactivated at ca. -65 mV, at 18°C. Left pleural cells (LP1tc, LP1c and LP11) have slow spikes (10-20 ms) with a shoulder on the falling phase which show pronounced broadening and rapid accomodation to depolarization. These cells have a "slow" IA (IAs), which peaks ca. 20-30 ms, has tauoff ca. 200-300 ms, and activation-inactivation curve shifted more positive (activation at ca. -35 to -20 mV and half-maximal inactivation at ca. -40 mV). Both IAf&s are blocked by 5mM 4-AP. IAs has kinetics of decay that closely match IK(v) decay, but IK(v) is resistant to 4-AP and is blocked by 100mM TEA which does not suppress IAs.

The following compounds all reduced peak IAf&s amplitude and the steady-state (s-s) component of outward current: 8-BrcAMP (25 uM), Forskolin (25 uM), Ro-20-1724 (25 uM), SCPb (10 uM) and 5-HT (10 uM). The s-s component corresponds to IR, a "background" residual K+ current sensitive to 5-HT and cAMP (Cell. Molec. Neurobiol. 5: 407-412; Soc. Neurosci. Abstr. 11:788,1985) that resembles the S K+ current. IR is linear and voltage-insensitive in the range -30 to -160 mV. At Em more positive than -30 mV, IR shows moderate voltage-dependence. IR is Ba++ and TEA-resistant, is slightly reduced by Cd++, 4-AP and EGTA injection, and is blocked by internal Cs+. IR is probably carried mostly by K+ ions since it reverses at ca. -65 mV and shifts more positive in high external K+ in agreement with the Nernst equation. Iontophoretic injection of exogenous Ca++/calmodulin kinases: Phosphorylase kinase (Phk) and type II CaM kinase also suppressed IAf&s (Soc.Neurosci. Abstr.11: 788,1985) and IR. These data suggest that activation of cAMP and Ca++/CaM second messenger pathways, interact or converge at some stage to effect phosphorylation of a common substrate which modulates the same two distinct K+ channels.

401.7 NERVE GROWTH FACTOR RESTORES ACTION POTENTIAL AFTERHYPERPOLARIZATION BUT NOT SPIKE WIDTH IN EXPLANT CULTURES OF BULLFROG SYMPATHETIC GANGLIA. P. Traynor*, W.F. Dryden and P.A. Smith. Dept. of Pharmacology, Univ. of Alberta, Edmonton, Alberta, Canada, T6G 2H7.

Transection of the axon (axotomy) of a peripheral vertebrate neurone promotes biochemical, morphological and electrophysiological changes in the cell body. These changes may be related to the neurone's ability to regenerate an axon. Axotomy of B-cells in bullfrog sympathetic ganglia results in an increase in action potential (a.p.) duration (spike width) and a reduction in the amplitude and duration of the afterhyperpolarization (a.h.p.) which follows the a.p. (Kelly et al., Neurosci. Letts., 67: 163, 1986). One explanation for this effect may be that axotomy prevents the retrograde axonal transport of a trophic substance from the periphery. In the case of a sympathetic neurone, such a trophic substance could be nerve growth factor (NGF, Levi-Montalcini, Prog. Brain. Res. 45: 235, 1976). To test whether loss of NGF was responsible for axotomy-induced electrophysiological changes, we studied the electrophysiological properties of (axotomized) bullfrog sympathetic neurones growing in explant culture (Groul et al., Brain Res. 233: 81, 1981) and examined the effect of NGF. Standard current clamp microelectrode techniques were used to measure electrophysiological characteristics of cultured neurones. A.p.s were generated by injection of brief, depolarizing current pulses. As the neurones regenerated in culture, there was a significant increase in spike width and a decrease in the duration and amplitude of the a.h.p. These changes were similar to those previously seen in axotomized neurones (Kelly et al., Neurosci. Letts., 67: 163, 1986). When 2.5 S NGF (50 ng/ml) was included in the culture medium, the duration and amplitude of the a.h.p. were restored towards control values, whereas the spike width was further increased. These results support the hypothesis that part of the electrophysiological response to axotomy (attenuation of a.h.p.) results from loss of a retrograde supply of NGF. Furthermore, since different Ca^{2+} sensitive K^+ channels contribute to a.p. repolarization and to a.h.p. generation (MacDermott and Weight, Nature 300: 185, 1982); Pennefather et al., Proc. Natl. Acad. Sci. USA 82: 3040, 1985), it is possible that NGF has different effects on each type of Ca^{2+} sensitive K^+ channel.

401.8 Ca^{2+} AND K^+ CURRENTS IN UTERINE SMOOTH MUSCLE. DIFFERENTIAL EFFECT OF NOREPINEPHRINE ON TWO K^+ CURRENTS. L. Toro*, E. Stefani and S. Erulkar. Dept. Physiology. Centro de Investigación y de Estudios Avanzados del IPN. Apdo. Postal 14-740. México, D.F. 07000. Dept. Pharmacology and Mahoney Inst. Neuroscience. Univ. Pennsylvania. Philadelphia, PA. 19104.

Single isolated cells from the uterus of Wistar rats (200 g) were patch clamped, using the whole cell configuration. Cells were used up to 5 days after culture. Their dimensions varied from 50 to 200 μm in length, and from 7 to 13 μm width. When the cells were stimulated from a holding potential, V_H, of -90 mV to more positive potentials than -50 mV, inward and outward currents were elicited. K^+ currents were recorded in normal Krebs and with an intracellular solution containing (mM): 150 AspO-K, 1 $MgCl_2$, 2.5 $CaCl_2$, 10 HEPES-K, 5 EGTA-K_2 and 5 ATP-Na_2. Two types of voltage dependent K^+ currents were observed: an early one, I_{K-f} with a time to peak, t_p of about 3 ms (at +20 mV) and a slow K^+ current, I_{K-s}, with a t_p=35 ms (at +20 mV). Norepinephrine (NE), 1 μM, had a distinct effect on these currents. I_{K-f} was enhanced about 4 times, while I_{K-s} was greatly diminished. Ca^{2+} currents, I_{Ca}, were recorded with an external solution containing (mM): 120 TEA$(CH_3SO_3)_2$, 5 HEPES-TEA, 1 3,4-diaminopyridine, 65 sucrose; and a pipette solution where K^+ was substituted by Cs^+ and 20 mM TEA. Two calcium currents were observed: fast I_{Ca} had a t_p=2 ms (at 0 mV) and an activation potential, V_a=-70 mV; slow I_{Ca} had a t_p=20 ms (at 0 mV) and a V_a=-20 mV. These results show that channels at the plasma membrane of myometrial cells can be modulated by NE in a different way. NE is capable to suppress a K^+ current, as other neurotransmitters, like substance P and acetylcholine. A: Ca^{2+} currents. Bar=40 pA, 5 ms. B: Enhancement I_{K-f}. Bar=100 pA, 5 ms. C: Suppression I_{K-s}. Bar=100 pA, 5 ms.

401.9 ESTROGEN REGULATION OF UTERINE mRNA THAT INDUCES POTASSIUM CHANNELS IN XENOPUS OOCYTES. M.B. Boyle, N.J. MacLusky, F. Naftolin, and L.K. Kaczmarek, Depts. of Pharmacology, Physiology, and Obstetrics and Gynecology, Yale Univ. Sch. Med., New Haven, CT 06510.

The electrical excitability of the smooth muscle of the mammalian uterus varies dramatically during adult life, depending upon the hormonal status of the animal. Administration of steroid hormones to ovariectomized animals can be used to mimic, at least in part, the changes in excitability occurring during pregnancy. In particular, estrogen treatment leads to a dramatic increase in the excitability of this smooth muscle.

We used the Xenopus oocyte translation system to express mRNA coding for potassium channels from the uterus. Previous work has shown that an unusual potassium current is expressed in oocytes injected with RNA from the uteri of ovariectomized rats treated for a few days with estrogen. This current takes many seconds to activate during depolarizations.

We have now compared the ability of mRNA prepared from mid-gestational and term pregnant, as well as from estrogen- and non-estrogen-treated uteri, to induce this current. Xenopus oocytes were injected with polyA+ RNA (200 ng), incubated for at least 3 days, and then voltage-clamped using 2 microelectrodes. The expression of the slowly activating potassium current was quantitated by measuring the amplitude of the slowly decaying outward tail currents measured at -40 mV following a pulse of several seconds to +70 mV in Na- and Ca-free saline. Control noninjected oocytes do not show slow tail currents resembling those in uterine-RNA-injected oocytes. The outward tail currents in oocytes expressing the slowly activating current from estrogen-treated uterine RNA ranged from 40 to 660 nA. No expression of the slowly activating current has been detected in any oocytes (n=25 oocytes, 5 frogs, 2 RNA samples) injected with polyA+ RNA from uteri of rats not treated with estrogen, although the current was expressed in oocytes from each of the same frogs injected with RNA from the estrogen-treated uteri. Oocytes injected with RNA from term (21-day, before parturition) uterus expressed the slowly activating current (n=10 out of 18 oocytes from 4 frogs, 2 RNA samples), although only at about 5% to 20% of the levels found in oocytes injected with RNA from estrogen-treated uteri. No expression of the slowly activating current has been seen in oocytes injected with RNA from uteri at 15 days of pregnancy (n=9 oocytes from 3 frogs, 1 RNA sample).

These findings support the hypothesis that estrogen regulates the concentration of the messenger RNA coding for this ion channel in the rat uterus. The current is expressed in oocytes injected with RNA, either from estrogen-treated uteri or from term pregnant uteri, which are largely under the influence of estrogen. In contrast, no expression of the slowly activating K current has been seen in oocytes injected with RNA from uteri of ovariectomized rats not given estrogen or from uteri at mid-pregnancy, which are mainly under the influence of progesterone. These findings suggest that regulation of the concentration of mRNA species coding for ion channels may play a physiological role in the changes in electrical excitability occurring during pregnancy.

401.10 ON THE IONIC MECHANISMS OF α_2-ADRENOCEPTOR MEDIATED PRESYNAPTIC INHIBITION IN GUINEA-PIG SUBMUCOUS PLEXUS NEURONES. A.Surprenant, Vollum Institute, Oregon Health Sciences Univ. Portland, OR. 97201.

Cholinergic neurones that have their cell bodies in the submucous plexus send processes which make synaptic connections with other cells in the plexus; the amount of acetylcholine (ACh) released at these synapses can be measured by recording the amplitude of the fast excitatory synaptic potential (epsp). Noradrenaline (NA) reduces the epsp, suggesting a presynaptic inhibition of ACh release. NA also increases an inwardly rectifying K^+ conductance (gK) by activating postsynaptic α_2 receptors; such an action on the cholinergic nerve fibres might underlie the presynaptic inhibition. The present study was undertaken to characterize the receptor involved in presynaptic inhibition of ACh release and to determine whether other postsynaptic actions of NA (i.e. calcium conductance decrease) might be due to α_2-adrenoceptor activation. All methods were as described in detail previously (Surprenant & Williams, J.Physiol., 1987).

NA, UK 14304 and clonidine caused a dose-dependent depression of the epsp; EC_{50} values (200 nM, 30 nM and 10 nM respectively) for this presynaptic inhibition were the same as EC_{50} values for agonist-induced hyperpolarizations or outward currents recorded from these neurones. Antagonist dissociation equilibrium constants (K_d) for idazoxan (25 nM) and phentolamine (100 nM) in preventing agonist-induced inhibition of the epsp were also the same as those obtained for the α_2-mediated gK increase. Experiments in which brief (0.5 - 5 ms) pressure (or ionophoretic) pulses of NA were applied showed that the time course of inhibition of the epsp mirrored that of the gK increase with a minimum latency of onset being 75 - 100 ms. These results indicate that NA-induced presynaptic inhibition of ACh release in sumbucous neurones is due to α_2-adrenoceptor activation and that it is not distinguishable from that causing gK increase.

Membrane currents in response to step depolarizations from -50 to -20 mV were recorded in the presence of TTX, TEA replacing Na^+ or with CsCl-filled intracellular electrodes plus external CsCl replacing KCl. Currents recorded under these conditions were an inward calcium current and a calcium-activated outward current. These manipulations abolished NA-induced outward current at -50 mV. NA, UK14304 and clonidine decreased the inward current; agonist EC_{50} values were 10 to 50-fold higher than for agonist-induced gK increase/presynaptic inhibition but idazoxan K_d determinations showed that this action was also mediated by α_2-adrenoceptors.

401.11 VOLTAGE AND TRANSMITTER GATED CHANNELS IN PURKINJE CELLS FROM ORGANOTYPIC CULTURED SLICES. I.Llano *, B.H. Gähwiler and A. Marty * (Spon:J. Bruner). Ecole Normale Supérieure, Paris, France and Sandoz Laboratory, Basel, Switzerland.

We have applied patch-clamp recording techniques to the study of voltage and transmitter activated channels from Purkinje cells in organotypic cultured slices of newborn rat cerebellum (Gahwiler, B.H., J. Neurosc. Meth. , 4:329:342). GΩ-seals were reliably formed without previous enzymatic treatment. In whole-cell recording mode (WCR) cells dialysed with K saline had resting potentials of -60mV and displayed spontaneous synaptic activity as well as action potentials similar to those recorded in in vitro slices. Under voltage-clamp, depolarizing pulses elicited large TTX-sensitive inactivating inward currents with fast on-kinetics, as well as large outward relaxations. Cs dialysis revealed TTX-insensitive inward currents with slower time course and incomplete inactivation. Whole cell voltage-clamp recordings showed evidence of lack of spatial control.

In contrast to the large inward currents observed in WCR, most outside-out patches (OOP) from cell somata had no inward currents. In some cases, a small inward current could be discerned in the absence of TTX. The channels giving rise to this current opened with short latency after pulse onset, had brief open times and γ of 14 pS. However, OOP displayed large voltage-dependent outward currents with an activation threshold of -30 mV (at -10 mV, peak current: 100-300 pA, time to peak: 3-4 ms). For depolarizations greater than -10 mV, the outward relaxations decayed to approx. 50% of their peak value during 40 ms. At least two types of K channels were identified from single channel recordings, with γ of 25 and 90 pS.

The responses to excitatory amino acids and GABA were studied in both WCR and OOP. Under symetrical Cl and cationic gradients, the application (via a fast perfusion system) of GABA (2 μM), led to large current responses (-0.5 to -1.8 nA at -60 mV) which were blocked by bicuculline (10 μM). The glutamate agonists quisqualate (2 μM) and kainate (10 μM) elicited currents of similar size. N-methyl-D-aspartate (100 μM) was ineffective, even in Mg-free saline and in the presence of glycine (10 μM).

In OOP from somatic membrane, application of GABA (0.5-2 μM) produced large currents (-100 to -300 pA at -60 mV). In contrast, quisqualate and kainate at concentrations which elicited large currents in WCR, led to none or very small (less than 5 pA) responses in OOP, suggesting that the current observed in WCR comes from dendritic membrane.

These results indicate that, in Purkinje cells, voltage-gated and transmitter-activated channels are spatially distributed in a highly differentiated manner.

401.12 REGIONAL DISTRIBUTION OF VOLTAGE-DEPENDENT SINGLE CHANNEL CONDUCTANCES IN CULTURED HIPPOCAMPAL NEURONS FROM THE RAT. Leona M. Masukawa and Anker Hansen*, Section of Neuroanatomy, Yale University School of Medicine, New Haven, CT 06510.

A previous study demonstrated that pyramidal neurons of the hippocampus possess distinct types of electrical responses that are different in cell bodies when compared to dendrites (Benardo, Masukawa and Prince, J. Neurosc., 2:1614, 1982). These specific ionic conductances function to control the activity of the different regions of the neuron. To study further the distribution of ionic conductances in different regions of hippocampal neurons, we have used the patch clamp technique. Cell attached and inside-out patches were examined for the presence of specific voltage-dependent single channel currents. Gigaohm seals were formed on cell bodies and dendrites of cultured hippocampal neurons dissociated from 1 day old rats. Cells were examined 2-15 days after plating.

Na single channel events which rapidly inactivated were observed only on cell bodies. They were activated by a step depolarization of 30 mV after a hyperpolarization of 60 mV in the cell attached configuration. The single channel events remained open for a period of 2-3 msec and then were inactivated. The conductance was approximately 20 pS and the channel was never observed when the pipette solution contained TTX or was Na free. The ensemble average of single channel events to a step depolarization produced a macroscopic current that had a similar time course to that of the inward Na current of the fast action potential.

Several types of K currents were observed. The most well defined of these was the outward delayed rectifier. This current was observed in both cell body and dendritic patches, and had similar characteristics in both areas. The single channel conductance was 10 pS and the channel opened at 20 mV depolarization. It did not inactivate during the 120 msec depolarization step. From ensemble averages of many traces the macroscopic current showed that there was a 5 msec delay before the current reached its peak amplitude and consequently resembled in time course a whole cell delayed rectifier current.

Both Ca and Na single channels that did not inactivate during a 120 ms depolarizing step were seen in both cell body and dendritic membrane patches. Their conductances were between 15 to 25 pS.

During the time period of 2-15 days in culture, dendritic patches did not show rapidly inactivating inward currents that would be consistent with Na and Ca action potential currents. It is possible after longer times in culture, that these channels will be incorporated into the dendritic membrane. At the time period studied here, the dendritic processes are in a state of development and rapid turnover of membrane as arborizations are extended. At the time of insertion of action potential channels into dendritic membrane the necessary K channels will be in place to regulate the inward currents. Supported by NIH grant NS 23077 (LMM) and NSF grant BNS 8519610 (LMM).

401.13 LOOSE-PATCH MAPPING OF ION CHANNEL DISTRIBUTIONS IN CULTURED LEECH NEURONS. R.J. Bookman*, H. Reuter*, J.G. Nicholls and W.B. Adams. Dept. of Pharmacology, Biocenter, CH-4056 Basel, Switzerland.

The excitable properties of axons, nerve terminals, and growth cones can often be infered only from measurements made at the cell body. We have used the loose-patch technique to measure directly qualitative and quantitative regional differences in voltage-dependent ion channels on single identified leech neurons. Retzius cells were removed from the ganglion with a 100-500μm length of stump (5-20μm in diam.), plated on a ConA substrate and studied after 1-8 days in culture. Low resistance (300-1000kohm) pipettes (filled with SES = 115NaCl, 5KCl, 5$CaCl_2$, 10HEPES, pH7.4) were sealed repetitively onto different regions of the cell surface to map the local currents. Seal resistances were 1-10Mohm. The density of Na channels was greatest at the tip of the stump where the neurites emerged and decreased sharply towards the cell body. Most somatic locations showed no inward current. Outward K currents showed a similar pattern of decline away from the stump tip although the decrease in density was not as steep. Pressure sensory (P) neurons differed in that clear Na currents were recorded from the cell body. Recording in a Ba-TEA solution, currents through Ca channels have been measured using Ba tail currents. These experiments set the stage for a mapping of currents in pairs of co-cultured cells that have formed synaptic connections.

Supported by grants from the Swiss Nationalfond and the U.S. Navy.

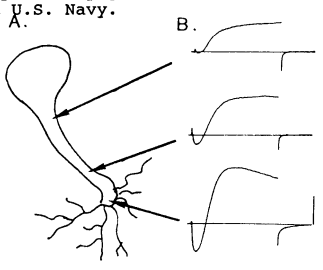

Fig. 1. A. Drawing of a Retzius cell in culture. B. Currents recorded from three locations on the cell. The pipette contained SES solution. The patch was depolarized by a 10ms pulse of -100mV applied to the inside of the pipette. Scale = 5nA.

402.1 SOMATOSTATIN (SS) AUGMENTS THE M-CURRENT IN HIPPOCAMPAL CA1 NEURONS. S.D. Moore*, S.G. Madamba*, M. Joëls*, and G.R. Siggins. Division of Preclinical Neuroscience, Research Institute of Scripps Clinic, La Jolla, CA 92037.

Recent immunocytochemical evidence indicates the presence of abundant SS-containing somata and nerve fibers in the hippocampal formation. Previous studies in our laboratory suggest that SS acts as an inhibitory transmitter in the hippocampus and also interacts with other neurotransmitters, including acetylcholine (ACh). To investigate the mechanisms of these interactions, we applied current- and single electrode voltage-clamp methods to CA1 pyramidal neurons in vitro. Rat hippocampal slices were prepared for electrophysiology in the conventional manner, completely submerged and continuously superfused with artifical CSF. Intracellular recordings were made in pyramidal neurons using 3M KCl-filled micropipettes (60-80 Mohm). In some voltage recordings, SS-induced hyperpolarizations were verified. After obtaining a stable current-clamp recording (at least 10-30 min), TTX (0.5-1.0 μM) was added to the perfusate. In discontinuous voltage-clamp mode (Axoclamp amplifier; switching frequency: 3-5 KHz) the M-current was recorded as a slow inward relaxation during small hyperpolarizing command pulses (5-25 mV; 0.7-1 sec) from a depolarized holding potential (-40 to -45 mV). The peak M-current was measured as the difference between the instantaneous and steady state currents, the former determined by exponentially extrapolating the current relaxation back to command onset. The M-current was characterized on the basis of size and kinetics, voltage and K^+ sensitivity, inactivation by muscarine or barium ions, and insensitivity to extracellular CsCl (Halliwell and Adams, Brain Res. 250: 71, 1982).

In 6 of 9 cells, superfusion of SS-14 or SS-28 (0.5-1.0 μM) increased the amplitude of the M-current ($\bar{x}$=160%, range = 15-480%). These concentrations of SS also produced a steady outward holding current but had no apparent effect on other K^+ mediated currents such as the A-,Q- or AHP- currents. Muscarine (25-40 μM) or carbachol (50 μM) consistently blocked the M-current even in the presence of SS. To our knowledge this is the first demonstration of a putative transmitter-mediated facilitation of the M-current and thus of a unique reciprocal regulation of such a conductance by two different transmitter candidates, SS and ACh. Furthermore, the M-current augmentation might explain the SS-induced potentiation of cholinergic excitations seen in vivo (Mancillas et al, PNAS (USA) 83: 7518, 1986): in the presence of SS more M-channels are open for ACh to act upon. Supported by NIAAA (AA-06420, AA-07456), NIADDKD (AM-26741), and the C & C Huygens-Stipendium from the Dutch Z.W.O. (H88-145).

402.2 SOMATOSTATIN DEPRESSES NEURONAL EXCITABILITY IN THE SOLITARY TRACT COMPLEX (STC) VIA HYPERPOLARIZATION AND AUGMENTATION OF THE M-CURRENT. G.R. Siggins[1], J. Champagnat*, T. Jacquin* and M. Denavit-Saubie. (SPON: L. Koda). Lab. Physiol. Nerv., CNRS, Gif-sur-Yvette, France and [1]Div. Preclin. Neurosci., Research Institute Scripps Clinic, La Jolla, CA 92037.

The function of somatostatin- (SS) containing fibers in the extrahypothalamic nervous system is controversial. The complex of nuclei (STC) comprising the nucleus tractus solitarius and the n. dorsal motor vagus contains a profuse network of fibers and cell bodies immunoreactive for SS (Kalia et al, J.Comp.Neurol. 222: 409, 1984). Several fragments of the pro-somatostatin derived prohormone, including SS28, a precursor to SS14, and the N terminal fragment, SS28(1-12), also appear to co-exist in this STC network (L. Koda, unpublished). Therefore we used a slice preparation of the rat brain stem, prepared as described by Champagnat et al (Brain Res. 280: 155 and 325: 49), and current- and single electrode voltage-clamp recording to test the effects of pro-somatostatin-derived peptides on neurons of the STC. The slices were completely submerged and continuously superfused with artifical CSF. In extracellular and intracellular recordings superfusion of either SS14 or SS28, but not SS28(1-12) or SS28(1-10), inhibited spontaneous spike and subthreshold activity in 69% of 26 neurons tested. In intracellular recordings of 29 neurons, SS28 and SS14 hyperpolarized about 65% of the neurons, in association with a slight but reproducible decrease (8-25%) in input resistance. These responses were slow in onset and recovery. Response thresholds were about 0.2 μM with both SS14 and SS28. An increase in K^+ conductance may be the basis of these hyperpolarizations as they were augmented in depolarized cells and persisted in cells in which spontaneous inhibitory postsynaptic potentials became depolarizing after Cl^- injection. Under voltage-clamp, SS28 and SS14 induced a steady outward current of about 50-100 pA and augmented the voltage dependent, non-inactivating outward conductance (I_M) shown in previous studies on the STC (Champagnat et al., Pfluger's Arch 406: 372, 1986) to be blocked by activation of muscarinic cholinergic receptors. These results suggest: 1) that both SS14 and SS28 should be considered as candidates for novel inhibitory transmitters in the STC; 2) that SS-containing elements in the STC exert an inhibitory role through the activation of postsynaptic permeability to potassium ions, and 3) a novel reciprocal control of the same ion channel (M) by two different neurotransmitter candidates, SS and ACh. Supported by grants from the USPHS (AM-26741 and AA-06420), Fondation de l'Industrie Pharmaceutique pour la Recherche, and the Fondation pour la Recherche Medicale.

402.3 ACTIONS OF SUBSTANCE P AND CARBACHOL ON NIE-115 NEUROBLASTOMA CELLS M.A.Schumann*, J.Whitbread*, J.Prives, and I.Spector. Dept. of Anatomy, SUNY at Stony Brook, Stony Brook, N.Y. 11794.

The actions of substance P (SP) carbachol (CCh), cholecystokinin octapeptide (nonsulfated) (CCK), bradykinin and vasoactive intestinal polypeptide (VIP) on differentiated cells of the mouse neuroblastoma clone NIE-115 were examined with intracellular microelectrodes. The N1E-115 cells used were grown in the presence of 2% dimethylsulfoxide (DMSO) to induce morphological and electrophysiological differentiation. Among the compounds tested, only SP and CCh showed a consistent effect on the N1E-115 cells. Bath application of SP (0.02 to 0.05mM) induced a prolonged hyperpolarization with an amplitude averaging 5.9±1.6 mV (30 out of 35 cells tested). The hyperpolarization was associated with an increase in cell membrane input resistance (17.8±8.1%) in 77% of the responsive cells and lasted for 21.1±11.1 sec. Application of carbachol (CCh) (0.1 to 0.25mM) also caused a prolonged hyperpolarization with an associated increase in membrane input resistance. The decreased membrane conductance elicited by both SP and CCh suggests closure of ion channels that may contribute to membrane depolarization at the resting state. The direction of the response (hyperpolarization) further suggests that SP and CCh do not affect potassium currents. These actions are thus very different from the recently described effects of bradykinin on potassium channels in the NG108-15 neuroblastoma-glioma hybrid cell line (Higashida & Brown, Nature, 323:333, 1986).

To determine if the SP-induced membrane conductance change is controlled by the intracellular messengers produced by the hydrolysis of the membrane inositol lipid, PLP_2,we monitored the effects of SP on the incorporation of ^{3}H-myo-inositol into inositol phosphates in DMSO-differentiated N1E-115 cultures. We found that in the presence of SP there is an increase in labeled inositol phosphates (IP_1,IP_2, and IP_3) suggesting that at least one of second messengers (IP_3) may have a role in the membrane conductance changes induced by SP. This work was supported by NIH grant NS22028

402.4 WHOLE-CELL AND CURRENT-CLAMP RECORDINGS REVEAL DIRECT AND INDIRECT EFFECTS OF RECEPTOR-SELECTIVE NEUROKININ ANALOGUES ON THE ACTIVITY OF SPINAL CORD NEURONES IN CULTURE. M. Wienrich*, J. DePeyer*, K. Reuss*, J. Harting*, G. Häusler* and A. Haase. E. Merck, Pharmaceutical Research, Frankfurter Str. 250, D-6100 Darmstadt, FRG.

The presence of three neurokinins, Substance P (SP) and Neurokinins A (NKA) and B (NKB) has been shown in the spinal terminals of primary afferents and in interneurones of the mammalian spinal cord. They have been proposed as neuromediators/neuromodulators of nociception at the spinal level. Moreover, in peripheral organ systems, three distinct neurokinin receptors have been identified (NK-1, NK-2 and NK-3). Since none of the endogenous agonists is selective at these sites, neurokinin analogues with high preference for a given receptor have been developed. The analogues Pro^9-C6 (pGlu^6, Pro^9SP6-11) and DiMe-C7 (pGlu^5, $MePhe^8$, $MeGly^9$ SP5-11) have been shown to be highly selective for the NK-1 and NK-3 receptor, respectively. We have investigated both direct and indirect effects of these neurokinin analogues on membrane potential, electrical activity, and membrane currents of rat spinal cord neurones in culture.

Both Pro^9-C6 and DiMe-C7 induced membrane depolarizations accompanied by an increase in spike activity in some neurones. The depolarizing action of both peptides was maintained after blockade of synaptic transmission by tetrodotoxin (TTX). No change in membrane resistance was observed. Whole-cell recording revealed an inward current being the cause for the observed membrane depolarizations. This could have been due to an activation and inactivation of two distinct channels by neurokinins.

In other neurones, the neurokinin-induced increase in spike activity occurred without membrane depolarization. Whole-cell recording showed that this increase was essentially due to enhanced synaptic discharge. In the presence of TTX these responses were abolished.

These results provide evidence for direct as well as indirect effects of neurokinins on spinal cord neurones in culture.

402.5 A NOVEL FORM OF LONG-TERM POTENTIATION OF EXCITATORY AMINO ACID TRANSMISSION IN LATERAL SEPTUM IN VIVO, ELICITED BY VASOPRESSIN AND BRAIN STIMULATION. I.J.A. Urban, P. van den Hooff and A. Ontskul. (SPONS. ENA). Rudolf Magnus Institute for Pharmacology, University of Utrecht, The Netherlands.

Electrical stimulation of fimbria-fornix (fi-fx) fibers elicits in lateral septum (LS) of rats large negative field potentials (NFPs), and induces in LS neurons in vitro excitatory postsynaptic potentials (EPSPs). Both, the NFPs and EPSPs are presumably mediated by excitatory amino acid (EAA) released from the fi-fx fibers. LS is innervated a.o. by a brain VP system that originates from neurosecretory neurons in the bed nucleus of stria terminalis (BNST) and projects to the LS via the medial forebrain bundle and the medial septum (MS).

Exogenous VP, added in 10^{-12} M concentration to the medium superfusing LS neurons in vitro, increased for many minutes the EPSPs elicited by fi-fx stimulation in the neurons. A VP-induced increase in the magnitude of EPSPs was also seen when inhibitory postsynaptic potentials that closely follow the EPSPs, were suppressed with picrotoxin. In series of experiments in vivo we used the NFPs as a measure of EAA transmission on LS neurons and examined the effect of the BNST and MS stimulation on the transmission. A three min. long stimulation with 30 sec long trains of stimuli at 8 Hz alternated with 30 sec rest periods, markedly increased the NFPS in 8 of 15 Wistar rats thus stimulated in the MS, and in 7 out of 14 Wistar rats stimulated in the BNST. The increase in NFPs elicited by the stimulation attained on average 18% of the NFPs amplitude measured prior to the stimulation, and lasted for more than 3 hrs following the stimulation. In the remaining rats, the NFPs did not changes or decreased following the stimulation. None of the 12 Brattleboro rats homozygous for a genetic deffect in synthesis of the brain and pituitary VP manifested by diabetes insipidus (HODI), showed an increase in NFPs following the MS stimulation. The litte mates heterozygous for the deffect, showed a mild increase in the NFPs, and homozygous normal Brattleboro rats exhibited a similar increase in the NFPs as did the Wistar rats. It is for the first time that a novel, long term potentiation of EAA transmission, elicited by electrical brain stimulation releasing presumably VP, is in vivo demonstrated.

402.6 **THE EFFECT OF THYROTROPIN-RELEASING HORMONE (TRH) ON SPINAL CORD NEURONS.** **M.M. Behbehani, R.Y.K. Pun and E.D. Means. Dept. of Physiology and Biophysics, and Dept. of Neurology, University of Cincinnati College of Medicine. Cincinnati, OH 45267-0576.**

There is considerable evidence that in addition to its involvement in hypothalamic function, TRH has a significant effect on other CNS neurons. Of particular interest is the observation that neurons in the rostral ventral medulla that have a direct projection to the spinal cord contain TRH and, in many instances TRH is co-localized with serotonin and with substance P. Since this pathway plays an important role in pain inhibition, it is possible that TRH plays a role in the transmission and modulation of pain. Currently the effect of TRH on the spinal cord and its mechanism of action is not clear. In experiments that are described, the effect of TRH on spinal cord neurons in vivo and in tissue culture was examined.

Male Sprague-Dawley rats were used for in vivo experiments. Animals were anesthetized with chloral hydrate and were not paralyzed. Single unit recordings were made from dorsal horn nociceptive and ventral horn neurons using a mutibarrel electrode containing recording,glutamic acid and TRH electrodes. TRH was applied using micropressure injection procedures. In tissue culture experiments, dorsal and ventral horn neurons were obtained from 12 to 14 day old mouse embryos. After dissociation, they were cultured separatel. Intracellular recordings were made from cultured cells two to eight weeks after plating using whole cell patch clamp techniques.

Application of TRH caused a significant increase in the firing rate of both ventral and dorsal horn neurons recorded in vivo. Usually application of TRH caused firing of silent neurons. In the majority of the neurons, the effect of TRH lasted for more than two minutes. There was no correlation between the response to TRH and response to peripheral stimulation.

The effect of TRH on dissociated spinal cord neurons was similar to its effect in the in vivo experiments. Application of TRH caused a short lasting hyperpolarization. This was then followed by a slight depolarization and a significant increase in the firing rate of the cell that lasted for a period as long as 20 minutes. The most striking finding in these experiments was the effect of TRH on synaptic potential. In TTX treated culture plates, application of 10 to 50 uM TRH produced a significant increase in synaptic activity as manifested by an increase in the frequency of post synaptic potentials.

In voltage clamp experiments, the outward current produced by step depolarization was affected by TRH. In 20% of the cells TRH caused an increase, and in 40% of the cells it caused a decrease, in the outward current. The increase in the outward current was frequently seen when ATP was included in the solution used to fill the patch electrode. The effect of TRH could be blocked by cesium,cobalt and barium, suggesting that it may be due to changes in potassium and/or a calcium activated potassium current.

It is concluded that TRH has an excitatory effect that is mediated through reduction of potassium currents. In addition, TRH has a considerable presynaptic effect that leads to significant increase in transmitter release.

402.7 HIPPOCAMPAL MOSSY FIBER DENERVATION INDUCES A SUPERSENSITIVITY TO CHOLECYSTOKININ OF CA_3 PYRAMIDAL NEURONS IN THE GUINEA PIG BUT NOT IN THE RAT. G. Debonnel and C. de Montigny. Centre de Recherche en Sciences Neurologiques, Université de Montréal, Montréal, Canada H3C 3J7.

Immunohistochemical studies have revealed the presence of cholecystokinin (CCK) in the guinea pig hippocampal mossy fiber projections (Gall, Brain Res., 306: 73, 1984), whereas CCK appears to be absent in these fibers in the rat (Greenwood et al., J. comp. Neurol., 203: 335, 1981). However, the rat mossy fiber system shows a strong opiate-like immunoreactivity which would consist mainly in methionine-enkephalin (mENK) and dynorphin (McGinty et al., P.N.A.S., 80: 589, 1983). The present electrophysiological studies were undertaken to determine the effect of mossy fiber denervation on the responsiveness of target pyramidal neurons to mENK, CCK and non-peptidic excitatory agents in these two species.

Colchicine, a selective neurotoxin for dentate gyrus granule cells (Goldschmidt et al., P.N.A.S., 77: 3047, 1980), was injected directly into the right dentate gyrus (20 µg in 5 µl in the rat and 1 µg in 3 µl in the guinea pig) under chloral hydrate anesthesia (400 mg/kg i.p.). Two to three weeks later, electrophysiological experiments were carried out under urethane anesthesia (1.25 g/kg i.p.). Five-barrelled glass micropipettes were used for extracellular unitary recording and microiontophoretic applications. The central barrel was filled with a 2 M NaCl solution and the side barrels with four of the following solutions: CCK 10 µM in 200 mM NaCl, pH: 5; mENK 0.5 mM in 200 mM NaCl, pH: 4; acetylcholine (ACh) 20 mM in 200 mM NaCl, pH: 4; quisqualate (QUIS) 1.5 or 3 mM in 400 mM NaCl, pH: 8; ibotenate (IBO) 100mM in 200 mM NaCl, pH: 8.

In both species, histological sections, prepared with a simplified Timm stain procedure for heavy metals (Sloviter, Brain Res. Bull., 8: 771, 1982), revealed a virtually complete destruction, by colchicine, of the dentate gyrus and its mossy fiber projection.

In the guinea pig, the mossy fiber denervation induced a 20-fold increase in the responsiveness of CA_3 pyramidal neurons to CCK, as compared to the intact side, but did not modify their responsiveness to mENK, QUIS, IBO and ACh.

In the rat, the mossy fiber denervation did not modify the responsiveness of CA_3 pyramidal neurons to CCK, mENK, QUIS, IBO and ACh.

These results provide novel electrophysiological evidence for the physiological role of CCK in the hippocampal mossy fiber projection of the guinea pig. The absence of supersensitivity to CCK in the rat is consistent with the lack of CCK-like immunoreactivity in the mossy fiber projection of this species. The failure of mossy fiber denervation to induce a supersensitivity to mENK in the rat might be due to the fact that such a lesion produces only a 50% decrease of the mENK content in the rat dorsal hippocampus (Grimes et al., Neurosci. Abst., 12: 116.13, 1986), the remaining mENK being presumably sufficient to maintain normosensitive postsynaptic opiate receptors.

402.8 MECHANISM OF ACTION OF PERIPHERALLY ADMINISTERED CHOLECYSTOKININ OCTAPEPTIDE ON BRAINSTEM NEURONS IN THE RAT. H. Raybould and G.J. Dockray, Physiological Laboratory, University of Liverpool, U.K.

Peripheral administration of cholecystokinin octapeptide (CCK8) has been shown to influence the discharge of brainstem neurons responding to gastric distension; injection of CCK8 close-arterial to the stomach suggested a site of action within the splanchnic bed. We have investigated the pathway and the mechanism by which CCK-8 given peripherally may influence the discharge of brainstem neurons receiving an input from the stomach. Extracellular recordings of sponaneous activity were made from neurons in the nucleus of the solitary tract and the dorsal motor nucleus in urethane anaesthetized rats. Catheters were placed in the stomach through the oesophagus for gastric distension by instillation of saline and through the duodenum to measure intraluminal pressure in the body of the stomach. Gastric distension (2 ml) and CCK-8 (100 pmol) injected close-arterial to the stomach evoked excitatory (GE, n=29) or inhibitory (GI, n =29) responses. The responses were abolished by vagal section (6 GE and 2 GI), but maintained in animals from which the coeliac/superior mesenteric ganglion had been removed four weeks previously (4 GE and 5 GI). The responses originated at least in part from the gastric corpus as they remained intact in animals from which the gastric antrum was removed two weeks previously. The effects of CCK8 are unlikely to be secondary to changes in smooth muscle tone as CCK8 decreases pressure in the gastric corpus while distension increases it. Intravenous injection of VIP and noradrenaline (NA) also decreased intragastric pressure, but their action on neurons in the dorsal vagal complex were distinct from those of CCK8. Thus, while the response to gastric distension and CCK-8 were concordant, only 43% and 33% of GE, and 75% and 18% of GI neurons gave concordant responses to distension and NA and VIP respectively. Also, neurons that did not respond to gastric distension and CCK-8 were affected by VIP and NA. The results are consistent with the idea that CCK8 acts directly on vagal mechanoreceptor endings within the stomach wall. It is well known that peripheral administration of CCK8 influences feeding behaviours; the effects described here may represent the pathway by which circulating CCK8 influences CNS function.

402.9 CHOLECYSTOKININ-ENHANCED [3H]DOPAMINE EFFLUX FROM SLICES OF RAT NUCLEUS ACCUMBENS/OLFACTORY TUBERCLE: EVIDENCE FOR A DIRECT ACTION ON MESOLIMBIC DOPAMINE-CONTAINING NERVE TERMINALS. T.W. Vickroy and B.R. Bianchi*. Abbott Laboratories, Neuroscience Research Division, Abbott Park, IL 60064.

Cholecystokinin octapeptide (CCK-8) is the major form of CCK-related peptides that are present in brain and is believed to be the predominant biologically active form of this neuropeptide family. Studies in vivo with CCK-8 have demonstrated that direct injection of this peptide into discrete brain regions where CCK and tyrosine hydroxylase immunoreactivities are co-localized (primarily mesolimbic structures) causes a profound potentiation of dopamine (DA)-evoked behaviors (Crawley et al., J. Neurosci. 5:1972, 1985). However, few in vitro neurochemical correlates of this CCK-DA interaction have been reported. In this report, we describe a selective neurochemical action (enhanced [^{3}H]DA overflow) for CCK-8 in slices from the nucleus accumbens/olfactory tubercle region from rats.

For [3H]DA efflux experiments, all tissues were obtained from male albino Sprague-Dawley rats. Tissue blocks were removed from the nucleus accumbens/olfactory tubercle region or striatum and miniprisms (0.35 x 0.35 x 2.0 mm) were prepared with a mechanical tissue chopper. Tissue slices were prelabelled with [3H]DA (100nM, 30 min) and subsequently transferred to parallel chambers for superfusion with a warm, oxygenated physiological salt solution. Following an initial exposure to superfusion medium containing 35mM KCl (S1-drug free), CCK-8 or other drugs were added to the buffer and a second pulse of high KCl medium was applied (S2). Addition of CCK-8 (0.1-1000nM) to the superfusion buffer produces a concentration-dependent increase in the S(2)/S(1) ratio from 0.71 (control) to 0.85 (maximal response to CCK-8). The EC(50) for CCK-8 is approximately 3nM and the response achieves a maximum at 100nM peptide. Additional observations include: (1) desulfated CCK-8 (1-1000nM) and CCK-4 (10-1000nM) do not elicit this effect nor do these peptides block the action of 100nM CCK-8; (2) the magnitude of the CCK-8 effect is unaltered in the presence of the muscarinic antagonist atropine (1uM), the dihydropyridine calcium channel antagonist nifedipine (1uM) or tetrodotoxin (1uM); (3) under identical assay conditions, CCK-8 does not significantly alter [3H]DA efflux from rat striatal slices; and (4) CCK-8 enhanced [3H]DA efflux is not additive with the stimulatory effects of (-)sulpiride, a D2 selective antagonist, or phorbol 12,13-dibutyrate, an activator of protein kinase C. Taken together, these results imply that CCK-8 and certain related peptides selectively modulate the release of recently accumulated DA from mesolimbic neurons and that these changes may be related to the modulatory effects of CCK peptides upon DA-sensitive behaviors in animals.

402.10 KAPPA RECEPTOR MODULATION OF THE NIGRO-COLLICULAR GABA PATHWAY IN THE RAT. P.L. Wood, H.S. Kim, and C. Cosi Neuroscience Research, Research Dept., Pharmaceutical Division, CIBA-GEIGY Corp., Summit, N.J. 07901.

The nigrostriatal dopaminergic pathway in the rat is is modulated by mu and delta opioid receptors but not kappa receptors, as evidenced by work with synthetic opiates. In addition, the endogenous kappa ligand, dynorphin(1-13), does not alter striatal dopamine metabolism. However, there is a prominent dynorphinergic pathway with cell bodies in the striatum and nerve endings in the pars reticulata of the substantia nigra. The negative data with regard to kappa opiate effects on nigrostriatal dopamine metabolism, therefore, raise the question of what is the role of this dynorphinergic innervation of the substantia nigra? We now report a specific modulation of the pars reticulata GABAergic neurons which innervate the rat superior colliculus, by the kappa agonist U50488H.

In these studies, rats were treated with U50488H, morphine or saline and subsequently infused with [$^{13}C_6$]glucose for 9 min. The flux of this label through the CNS glucose, glutamate and GABA pools was monitored by gas chromatography-mass spectrometry and the turnover rates for glutamate and GABA were determined simultaneously in the same tissue extract. Using this method, morphine was found to significantly elevate GABA turnover in the superior colliculus in a naloxone-reversible manner. In contrast, the kappa agonist, U50488H, decreased GABA turnover and the effect was naloxone-reversible.

These data are consistent with a kappa receptor modulation of pars reticulata output neurons by the striatonigral dynorphinergic pathway.

402.11 ENDOGENOUS PEPTIDE RECEPTORS IN XENOPUS OOCYTES. E.M. Landau, T.M. Moriarty*, B. Gillo*, and S. Sealfon*. (SPON: J.R. Thornborough). Dept. of Psychiatry and Fishberg Center in Neurobiology, Mt. Sinai School of Medicine and Bronx V.A. Hospital, New York, N.Y.

Oocytes of the African frog Xenopus laevis have been shown by electrophysiological methods to possess receptors for a number of transmitter substances including acetylcholine, adenosine and norepinephrine. We report here that Xenopus oocytes possess receptors for the neuropeptides corticotropin releasing factor (CRF), arginine vasopressin (AVP), and cholecystokinin (CCK).

Oocytes were taken from mature female frogs. Oocytes with the follicular cell layer intact (follicles) and oocytes with the follicular cell layer stripped away by treatment with collagenase (denuded) were studied. Single cells were voltage clamped in a superfusion apparatus in standard fashion.

Application of 2 uM CRF to follicles induced an outward hyperpolarizing current. Voltage ramp studies revealed this current to be carried by K^+ ions. Pretreatment of follicles with 0.2 uM forskolin or 1 mM isobutylmethylxanthine (IBMX) potentiated the outward current indicating that the hyperpolarization is mediated by cAMP. Application of CRF to denuded oocytes (which cannot generate a cAMP dependent K^+ current) did not induce a current.

Application of 2 uM AVP to follicles also induced an outward hyperpolarizing current. Voltage ramp studies and denuded oocyte studies revealed this to be a K^+ current. Pretreatment of follicles with forskolin or IBMX showed that the AVP induced current was mediated by cAMP.

Application of 2 uM CCK to follicles induced an inward depolarizing current. Voltage ramp studies showed that this current is carried by Cl^- ions. Application of CCK to denuded oocytes gave the same inward current. This current is similar in shape, time course, and reversal potential to the Cl^- current produced by intracellular injection of IP_3 and that induced by transmitters known to act through the breakdown of polyphosphoinositides. This suggests that CCK acts through the phosphatidylinositol pathway.

Approximately 60% of our population of frogs were responsive to these peptides. We conclude that the native Xenopus oocyte possesses peptide receptors in addition to those receptors previously described.

403.1 SELECTIVE DEAFFERENTATION OF THE HIPPOCAMPUS PROTECTS CA1 NEURONS AGAINST ISCHEMIC INJURY.

A. M. Buchan* and W.A. Pulsinelli
Dept. of Neurology, Cornell Medical College, New York, NY10021

Hippocampal CA1 neurons are selectively vulnerable to ischemic injury, dying between 48 and 72 hours following a period of global ischemia. To test the hypothesis that an excitatory input may determine this vulnerability, afferents to CA1 were cut and then the animals were exposed to ischemia.

Adult male rats were anesthetized and the right dorsal hippocampus was exposed by cortical and white matter aspiration. Septal afferents in the Fimbria/Fornix, Schaffer Collaterals and entorhinal afferents in the Perforant Path were cut. Separate groups were subjected to cortical aspiration only (sham); all 3 cuts (Tricut); Fimbria/Fornix only; Schaffer Collaterals only and Perforant Path only. All lesions were made on the right side, the left side serving as a control. Following 10-16 days rats were subjected to 30 minutes of complete forebrain ischemia using the four vessel occlusion model. 72 hours later animals were perfused, serial sections of dorsal hippocampus were then examined and irreversible injury to CA1 neurons was graded (0=normal;1<10%;2=10-50%;3>50% damaged). Differences in the degree of damage were analysed using Mann-Whitney U (MWU) and Kruskal-Wallis (K-W) tests.

	Mean grade of CA 1 neuronal damage (±SD)	
Type of lesion (no. of animals)	Intact left side	Deaff . right side
SHAM (5)	3.0 ±0	3.0 ±0
TRICUT (11)	2.73 ±0.3	0.5 ±0.6*
FIMBRIA/FORNIX (12)	2.97 ±0.1	1.85 ±0.8†
SCHAFFER COLLAT. (4)	2.89 ±0.1	2.86 ±0.1
PERFORANT PATH (4)	3.0 ±0	2.46 ±0.5

* p<0.0001vs.left side(MWU) and p<0.001 vs . right side of shams(K-W).
† p<0.002 vs. left side (MWU) and p<0.01 vs. right side of shams(K-W).

These data indicate that deafferentation of the hippocampus will protect CA1 pyramidal neurons against transient ischemia. They also indicate that the the septal (Fimbria/Fornix) input is more important than either the Schaffer Collateral or Perforant Path input. Specific neurotransmitters or neuromodulators carried with the Fimbria/Fornix pathway may be involved in the process of delayed but selective neuronal vulnerability.

403.2 DEXTROMETHORPHAN REDUCES NEOCORTICAL ISCHEMIC NEURONAL DAMAGE AND EDEMA IN AN *IN VIVO* MODEL OF TRANSIENT FOCAL CEREBRAL ISCHEMIA.

C.P. George*, T.C. Gross*, D.K. Shibata*, M.P. Goldberg, D.W. Choi, R. DeLaPaz* and G.K. Steinberg* (SPON: K.L. Chow). Div. of Neurosurgery and Depts. of Neurology and Radiology, Stanford University Medical Center, Stanford, CA 94305

The dextrorotatory morphinan dextromethorphan (DM) is an N-methyl-D-aspartate (NMDA) antagonist which has recently been shown to attenuate neuronal injury in cortical cell culture (Neurology 37,S1:250). DM was tested in an *in vivo* acute reperfusion model of cerebral ischemia to assess neuronal protective effect.

Twenty male New Zealand white rabbits underwent 1hr transient transorbital two or three vessel cerebral arterial occlusion. Fourteen animals had the left internal carotid artery (ICA) and distal A1 (dA1) segment of the anterior cerebral artery (ACA) clipped; six animals had the left ICA, dA1 and proximal middle cerebral artery clipped. Animals having two vessel or three vessel occlusion were separately randomized into DM or control normal saline (NS) groups. One hour prior to occlusion animals were blindly given either a 20mg/kg bolus followed by 10mg/kg/hr of 0.4% DM in NS or an equivalent volume of NS alone. Bilateral median nerve somatosensory evoked potentials (SEP) were obtained throughout the experiment. Brains were formalin-fixed and subsequently analyzed for changes in water content with magnetic resonance imaging (MRI). Axial and coronal T2-weighted images (TR2000, TE20 and 80) were obtained on a high field 1.5 Tesla GE Signa scanner using multiple spin-echo sequences. Ischemic neuronal damage (IND) was assessed at four coronal levels as a percentage of structural area with conventional hematoxylin and eosin (HE) histology.

There was a significant decrease in the percentage of left neocortical (CX) IND at all four levels examined in the DM treated group. However in the striatum only the tail of left caudate (CD) and most posterior left putamen (PU) showed a significant decrease in % IND with DM treatment.

	CX1	CX2	CX3	CX4	CD1&2	PU1&2	CDtail	PUpost
DM	24.1	8.6	6.7	3.5	42.9	38.5	12.3	21.4
NS	61.7	53.6	41.1	29	64.8	63.6	63.9	65.0
p	<.01	<.01	<.01	<.02	ns	ns	<.01	<.05

MRI lesions were localized to cortex and subcortical white matter with no evident basal ganglia involvement. MRI images were blindly scored according to area and intensity of lesion. The DM treated animals showed a significantly lower MRI score than the NS group: DM 13.3, NS 88 (n=19, p=.002). The abnormal cortical signal corresponded most closely to spongiform change in the neuropil (probable edema).

Amplitude ratios were calculated from the SEP primary cortical potential as a percentage of preocclusion values. Both left and right primary cortical potential amplitude ratios were greater in DM than in NS treated animals throughout reperfusion.

In summary, DM markedly decreases neocortical IND and edema. The disparity between neocortical and striatal DM effect as assessed by histology may reflect 1) differential NMDA receptor densities in each region, 2) the relative contribution of NMDA receptor mediated neurotoxicity to ischemic neuronal degeneration in each region, and/or 3) relatively more severe striatal ischemia in this model. Further investigation into the mechanism of action and possible therapeutic applications of this clinically available compound in cerebral ischemia should be undertaken.

403.3 DEXTROMETHORPHAN PROTECTS AGAINST HYPOXIC-ISCHEMIC BRAIN INJURY IN THE LEVINE RAT MODEL.

D.A. Prince and H.R. Feeser (SPON: F. Zajac). Dept. of Neurology, Stanford Univ. Sch. of Med., Stanford, CA 94305.

Dextromethorphan (DM), an over-the-counter oral antitussive agent, and its metabolite dextrorphan (DX), are NMDA antagonists that have been recently shown to have a protective effect against anoxic neuronal injury in a cortical cell culture model (Goldberg et al., Neurology 37:250, 1987). Although most NMDA blockers have not been tested for their safety in man, DM and DX are readily available at present and appear to be relatively non-toxic. We therefore studied the effects of DM in an in vivo animal model of hypoxic-ischemic brain injury.

Eight day old Sprague-Dawley rat pups were divided into two groups using a split-litter design, anesthetized by cooling, and injected i.p. with either 35 mg/kg DM or with an equal volume of saline. The right common carotid artery was then isolated and ligated. One hour following the completion of surgery, animals were placed in a 92% N_2, 8% O_2 environment at 37°C for two hours, allowed to recover in room air, then returned to their dams. A group of control animals without carotid ties were treated identically to the saline-injected experimental animals except that the exposed carotid was never ligated. No obvious behavioral seizures were observed during or immediately following the hypoxia, although hypoxic animals appeared tremulous and unresponsive. After seven days, rats were anesthetized, perfused and sections stained with celestine blue and acid fuchsin for assessment of abnormalities.

Sections from unligated controls, ligated controls, and DM animals were assessed blind and rated for degree of hypoxic/ischemic damage. Types of abnormality included 1) presence of acidophilic or pyknotic neocortical neurons, 2) acidophilic and pyknotic hippocampal CA3/CA4 pyramidal cells with cells loss, 3) laminar cortical necrosis, 4) cortical microinfarction, and 5) frank cortical macroinfarction. Abnormalities 2-5 were ipsilateral to the occluded carotid and abnormality 1 was bilateral but more prominent on the occluded side. Cortical macroinfarctions were not seen in DM animals and laminar necrosis was much more prominent in untreated subjects. Both groups showed scattered dark cells and degrees of hippocampal damage. These preliminary results suggest that DM has protective effects against brain injury in this model and might be useful in treatment or prophylaxis of hypoxic/ischemic damage in man.

403.4 PET STUDY OF THE EARLY CHANGES IN CEREBRAL BLOOD FLOW, OXYGEN AND GLUCOSE METABOLISM IN A PRIMATE MODEL OF STROKE.

J. Clothier*, D.F. Wong*, T.K. Natarajan*, R.F. Dannals*, M. Feldman*, H. Nauta, S. Tanada*, W. Jankel*, J. Toung*, H.J. Ravert*, A.A. Wilson*, M. Stumpf*, R. Adams*, J. Links*, D. Nibbelink*+, H. Klein*+, H.N. Wagner, Jr*, H. Solomon*+. (SPON: H. Nauta). Johns Hopkins Medical Institutions. Baltimore Md. & Merck, Sharp & Dohme Research Laboratories, West Point Pa.+

We have adapted a primate model of stroke for repeated measurements with PET for determination of regional cerebral blood flow (CBF), metabolic rate for oxygen ($CMRO_2$), and metabolic rate for glucose (CMRglu) during the first week following cerebral infarction. The motivation for this model is the need to obtain a controlled lesion in a species closely related to man. By using PET techniques a single animal can be studied repeatedly during the post stroke phase to assess the time course of the response to infarction/ischemia.

The cerebral infarction was carried out in Papio Anubis baboons (15-25 kg) by a transorbital coagulation occlusion of the M_1 segment of the middle cerebral artery while the animal was under anesthesia with alphaxalone and alphadolone. The animals were extubated 6-12 hours after the occlusion. During the study period the animals were progressively more independent with no major complications other than hemiparesis. PET studies were carried out 2 days before and 1-4hrs, 48 hrs, and 7 days after the lesion. Animals received similar doses of the anesthetic during each of the PET studies. EEG and Arterial blood gases were monitored during each study.

CBF, $CMRO_2$,and OEF were measured using the ^{15}O labelled CO_2 and O_2 steady-state method. CMRglu was obtained from a kinetic determination of k1-k4 derived from a 90-180 min dynamic PET scan of ^{18}F-deoxyglucose (FDG). CMRglu was calculated using these constants and the arterial histories of plasma FDG and glucose. An index of relative metabolism was calculated from the molar ratio of $CMRO_2$ to CMRglu. This ratio was correlated to CBF, ($r=0.8$, $p<0.01$) for pooled data obtained from regions of interest from each PET scan day and from the involved and uninvolved regions. The accuracy of these preliminary data might be improved by consideration of a regional blood volume correction and the effects of ischemia on the lumped constant.

A well defined lesion encompassing approximately 25% of the brain could be visualized on the initial post-occlusion PET image. This model combined with PET could offer an opportunity for repeated study of physiologic variables and could result in an understanding of the time course and the factors involved in the cerebral response to ischemia and stroke.

403.5 ATTENUATION OF THE MPTP-INDUCED DOPAMINE DEPLETION IN PRIMATE CAUDATE NUCLEUS BY FETAL NEURON TRANSPLANTS. J.D. Elsworth, D.E. Redmond, Jr., A.Y. Deutch, T.J. Collier, J.R. Sladek, Jr., R.H. Roth. Yale Univ. Sch. of Med., New Haven, CT 06510, Univ. Rochester Sch. of Med., Rochester, NY 14641.

MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) damages the nigrostriatal dopamine (DA) pathway and produces parkinsonism in monkeys and humans. Since transplantation of fetal DA neurons into the caudate nucleus (CN) appears to reverse the MPTP-induced motor abnormalities in monkeys, the concentrations of DA and homovanillic acid (HVA) in the CN of monkeys following MPTP treatment and fetal transplants have been measured to provide neurochemical quantitation of both MPTP-induced deficits and of the dopaminergic influence of transplanted fetal neurons.

Adult male African green monkeys were treated with MPTP (2-3 mg/kg IM over 5 days). Some animals showed no gross parkinsonism after MPTP ("asymptomatic"), while others became severely parkinsonian ("symptomatic"). These monkeys were compared with untreated control monkeys. Two symptomatic monkeys subsequently received fetal substantia nigra neuron transplants aimed at the CN, with sacrifice 7 months later. Areas were punch-dissected from coronal brain slices and assayed for catecholamines (by HPLC) and metabolites (by GC-MS).

In the MPTP-treated monkeys a large decrease in DA concentration was observed in the caudate nucleus; the reduction was greater in the symptomatic (98-99%) than in the asymptomatic group (88-98%). DA content of the central substantia nigra was markedly reduced in the symptomatic group (75-95%), but not significantly decreased in the asymptomatic animals. MPTP-treatment was found to reduce DA and/or norepinephrine concentration in anterior cingulate cortex and septum but not in medial orbital frontal cortex, suggesting differences in susceptibility to MPTP within the DA mesolimbic and mesocortical systems.

At some sites in the CN, MPTP-treated animals with nigral grafts had increased DA and HVA concentrations which exceeded those of the symptomatic animals and approached those of the asymptomatic group. The DA concentrations in the central substantia nigra of the grafted and symptomatic animals confirmed comparable damage by MPTP. Related behavioral and anatomical data will be presented by Redmond, Sladek, and Taylor *et al*.

These results extend the biochemical similarities between idiopathic Parkinson's disease and MPTP-induced parkinsonism and indicate that fetal neuronal grafting may restore diminished neurochemical measures of DA function in localized areas.

(Supported in part by NINCDS PO1 NS24032, RSA KO5-MH00643 and Axion Research, St. Kitts, W.I.)

403.6 EFFECT OF FETAL SUBSTANTIA NIGRA TRANSPLANTS ON ACQUISITION AND PERFORMANCE DEFICITS IN MPTP-TREATED MONKEYS PERFORMING OBJECT RETRIEVAL/DETOUR TASK. J.R. Taylor, R.H. Roth, T.J. Collier, J.R. Sladek, Jr., D.E. Redmond, Jr. Yale Univ. Sch. of Med., New Haven, CT 06510 and Univ. Rochester Sch. of Med., Rochester, N.Y. 14641.

To assess functional correlates of dopamine system deficits produced by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), and possible restoration following fetal substantia nigra transplants, we studied the acquisition and performance of an object retrieval task in monkeys. The task requires retrieval of a banana slice ("reward") from a transparent box open on one side and fastened to a tray attached to the front of the cage. Successful performance requires suppressing a tendency to reach directly at the reward ("detour") as (a) orientation of the open side, (b) position on the tray, and (c) position of the banana in the box are manipulated to vary the cognitive and motor difficulty of the trial. Each test session consists of 20 trials delivered and analyzed to detect and dissociate cognitive and motoric deficits. The frequency of "awkward reaching," a more complex motor movement with the hand furthest from the opening, was recorded. Lesions of the dopaminergic dorsolateral prefrontal cortex reveal performance deficits on this type of task, as well as dopamine-depleted "asymptomatic" and obviously motorically impaired monkeys after MPTP treatment.

Thirty adult male African green monkeys *(Cercopithecus aethiops sabaeus)* were treated with MPTP (2-3 mg/kg cumulative doses over 5 days) or sham-treated as controls. After MPTP treatment alone subjects showed retarded acquisition of the task. They made errors on sets of trials that were related to cognitive complexity, performed awkward reaches and displayed motor impairments not found in control subjects. Either before or after training, some monkeys were transplanted with fetal neurons (of variable gestational age) from the substantia nigra or other brain regions as controls. Both the motor and cognitive impairments were modified by fetal nigral cell transplants into the caudate nucleus, which improved performance in some monkeys. This task appears sensitive to MPTP-induced deficits in dopamine systems and to the specific site of placements of fetal neuronal transplants, perhaps separating cognitive from motor recovery.

403.7 REVERSAL OF MPTP-INDUCED PARKINSONISM UP TO 7 MONTHS AFTER FETAL NEURON TRANSPLANTS IN GREEN MONKEYS. D.E. Redmond, Jr., T.J. Collier, P.N. Foster, V.O. Lewis, J.P. Blount, R.H. Roth, J.R. Sladek, Jr. Yale Univ. Sch. of Med., New Haven, CT 06510 & Univ. Rochester Sch. of Med., Rochester, N.Y. 14641.

Transplantation of fetal substantia nigra (SN) neurons into the caudate nucleus (CN) appeared to reverse 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) induced parkinsonism for 10 weeks in 2 monkeys, but not in a third with less mature neuroblasts transplanted outside the striatum. This previous study raised questions about the effect of fetal age, other placement sites, trophic factors vs. structural integration of grafts, the limits of graft survival, and duration of recovery.

Six *Cercopithecus aethiops sabaeus* (green monkeys) have now been treated with MPTP (2-3 mg/kg i.m. over 5 days) and 4-5 weeks later transplanted with neurons from 8.5, 11, and 21 cm. crown-rump length fetuses in further pilot studies. Small solid grafts were placed through cannulae into the caudate nucleus, lateral ventricle, and cerebral cortex. SN cells were implanted in four animals and cerebellar cells in two. Behaviors were scored, rated, and videotaped by blind observers, and CSF samples were drawn throughout the experiment. Monkeys were sacrificed 5 months or 7 months after transplantation. The morphological, biochemical, and cognitive data are reported by Sladek, Elsworth, and Taylor *et al* in companion papers.

After MPTP treatment, severe parkinsonism was seen in four monkeys, and moderate in two, requiring extensive individual feeding, nursing care, and physiotherapy before and after the transplants. Four required nasogastric tube feeding. After transplantation, behavioral improvement was variable, but slower in all animals than seen previously with less impaired animals and with later gestational-age donor cells. There were clear behavioral differences between some monkeys which improved and some which did not. Others showed intermediate effects. There was also variability in dopamine (DA), homovanillic acid (HVA), and HVA/DA ratios between striatal punch sites, brain regions, and animals, as well as in the specific graft sites, structural integration, and patterns of graft development.

Fetal neural grafts survive in monkeys up to 7 months without adverse behavioral effects, show structural integration with the host brain, restore DA neurochemical activity in localized areas, and restore behavioral function in some parkinsonian monkeys. The influence of several important factors remains unclear. (Supported by PO1 NS24032, Axion Res. Found., St.Kitts Biomed. Res. Found., West Indies, and RSA KO5-MH00643 to DER).

403.8 LONG TERM SURVIVAL OF TRANSPLANTED FETAL NEURONS IN MPTP TREATED AFRICAN GREEN MONKEYS. J.R. Sladek, Jr., T.J. Collier, J.D. Elsworth, R.H. Roth, and D.E. Redmond, Jr. Depts. of Neurobiology and Anatomy, Univ. of Rochester Sch. of Med., Rochester, NY 14642 and Depts. of Pharmacology and Psychiatry, Yale Univ. Sch. of Med., New Haven, CT 06510

As part of our ongoing investigation of the effects of fetal nerve cell grafts on the experimental Parkinsonism induced by the toxin, MPTP, in primates, we have extended the post surgical survival periods in order to test the continued and progressive therapeutic value of neuronal grafts. This study also has incorporated control grafts of cerebellar cortex as a source of non-dopaminergic (DA) neurons from the same donor tissue that supplied DA grafts of substantia nigra. Moreover, various gestational stages have been utilized to further examine survival potential over a wide range of neuroblast development. Twelve, young adult male African green monkeys from the St. Kitt's colony were treated with 2-3 mg/kg of MPTP as a cumulative dose delivered over 5 days. Following the development of parkinsonian signs after 4-5 weeks, we stereotaxically grafted neurons from 3 fetal African green monkey donors (crl 8.0, 11.0, 21.0 cm) into the caudate nucleus of 6 treated monkeys. One donor supplied cerebellar or nigral tissue to each of two pairs of hosts, and one donor provided nigral tissue to one pair. Multiple "solid" grafts were placed into each animal at either 4 or 6 penetration points. Behavioral and biochemical indices of functional improvement were monitored and are reported in the accompanying abstracts by Redmond and colleagues. At 5 months after transplantation, 3 animals were perfused with 4% paraformldehyde and were stained immunohistochemically for tyrosine hydroxylase (TOH). The other 3 monkeys were prepared after 7 months for co-analysis of DA and metabolite content, neurochemically, and TOH distribution, morphologically, by combining "punched" tissue procedures with immunohistochemistry. Morphological analysis revealed the presence of bilateral "plugs" of fetal tissue in each host monkey. These grafts were positioned both deep within the head of the caudate nucleus and also were seen more dorsally where they extended into and expanded in size within the lateral ventricles. Grafts of cerebellar cortex were devoid of TOH perikarya, whereas such neurons were common features of nigral grafts. In some instances, TOH fibers appeared to radiate from nigral grafts into the host striatum, suggestive of growth of neuronal processes, perhaps favored by the extended survival times in comparison to our earlier study (i.e. 10 weeks). Evidence of graft rejection was not observed, however some erosion of superficial cortical tissue was noted in some animals in and adjacent to the cannula tracts. Survival of grafted neurons over a wide range of gestational ages supports the view that the optimal "window" for graft viability is considerably wider in primates than in rodents and survival and growth of grafted neurons over 5 to 7 months suggests that long term functional improvement may coincide with these observations.

403.9 EFFECTS OF MPTP ON SOME INDEXES OF ANTIOXIDATIVE PROTECTION IN THE MOUSE SUBSTANTIA NIGRA. R.G. Fariello, O. Ghilardi*, T.N. Ferraro, G.T. Golden, A. Peschechera*, M.T. Ramacci*, and L. Angelucci*. Research & Neurology, VAMC, Coatesville, PA; Neurology, Thomas Jefferson University, Philadelphia, PA; Univ. of Rome and Sigma Tau, Rome, Italy

The administration of MPTP to mice causes initial selective dysfunction of nigral neurons. Searching for mechanisms and cellular sites of action of this potent neurotoxin we have administered a single dose of 30 mg/kg MPTP i.p. to C57 black mice and sacrificed them at 30 min, 1 h, 6 h, or 24 h afterwards. Nigrae, neostriata, and cerebelli were dissected and frozen within 2 min 45 sec after decapitation. Levels of tocoferols (cytosolic, liposoluble antioxidant) and reduced (quinol) and oxidized (quinone) forms of Q9 and Q10 ubiquinoles (mitochondrial antioxidant) were measured by reverse phase HPLC with electrochemical detection with dual electrode. A statistically significant depletion of Q10 in its reduced form with a shift of the reduced/oxidized ratio toward oxidation was found only in the nigra at 1 h after MPTP, with a return to baseline value at 6 and 12 h. Levels of tocoferols remained unchanged at all times. In another series of experiments 30 mg/kg MPTP was administered i.p. daily for 5 days and the mice sacrificed 24 h after the last MPTP injection. Brain regions were dissected and analyzed as in the acute experiments. Again only the Q10 ubiquinol was selectively depleted in the nigra and not in the other regions. These data suggest that MPTP has an early site of action at the inner mitochondrial membrane of nigral neurons at the ubiquinone step, a crucial point linking the respiratory chain to the oxido-reducing systems. Multiple administrations are necessary to produce a long lasting ubiquinol depletion. (Supported by Sigma Tau Pharmaceuticals and the Veterans Administration.)

403.10 MPTP AND [^{3}H]2-DEOXYGLUCOSE (2DG) AUTORADIOGRAPHY IN THE SUBSTANTIA NIGRA OF MICE. Arthur Hess, Dept. of Anatomy, UMDNJ, Robert Wood Johnson Med. Sch., Piscataway, NJ 08854.

It is assumed that the process by which MPTP causes dopaminergic neurotoxicity is as follows: MPTP binds to extraneuronal tissue, probably neuroglia, where it is metabolized by MAO-B; the resulting toxic product MPP^{+} then enters the dopaminergic neurons through the dopamine uptake system. Hence, MAO-B inhibitors and dopamine uptake blockers, as expected, are effective in preventing the dopamine depletion caused by MPTP.

MPTP (30mg/kg, 1-2 hours after administration) causes an increase in 2DG uptake in the zona compacta of the substantia nigra and adjacent ventral tegmental area. It is possible that this increase in 2DG uptake, induced very rapidly, is an initial step and the first sign of the degenerative process resulting from MPTP administration.

The MAO-B inhibitor deprenyl (10mg/kg, 30 min preceding MPTP) prevents 2DG increase. Deprenyl, irreversible and long acting, does not block increase in 2DG if administered overnight before MPTP. Clorgyline (10mg/kg), an irreversible MAO-A inhibitor, or mazindol (10mg/kg), a dopamine uptake blocker, have no effect on the 2DG reaction induced by MPTP when injected 12 hrs or 30 min before MPTP. Thus, there are discrepancies in the correlation between the presumed mechanism of neurotoxicity and the 2DG increase in the substantia nigra induced by MPTP.

Further studies are under way to determine the significance of the 2DG reaction induced by MPTP. Dose response studies have shown so far that weaker doses of MPTP (½ dose, 15mg/kg; ¼ dose, 7mg/kg for 2 hours) still produce increase in 2DG uptake. Time response studies have revealed thus far that there is no increase in 2DG uptake if 30mg/kg MPTP is administered 15 minutes or overnight before 2DG injection.

The effects of MPTP on 2DG increase in the locus coeruleus will also be presented; similarly, the effects of various neurotropic substances in blocking this increase will be illustrated.

Some comparative effects of analogs of MPTP on 2DG uptake will also be discussed.

403.11 NEURAL BASIS OF CEREBRAL VASOSPASM: HYPOTHESIS AND EXPERIMENTS. S.H. Tsai, M.S. Greenberg, J.M. Tew, and M.T. Shipley. Dept. of Anatomy/Cell Biology and Neurosurgery, Univ. of Cincinnati College of Med., Cincinnati, OH 45267.

Subarachnoid hemorrhage (SAH) has devastating secondary effects on cerebral circulation and massive cerebral infarction is produced by delayed vasospasm. Cerebral arteries are innervated by perivascular nerves containing classical transmitters and neuropeptides. Both classes of neuroactive molecules influence vascular diameter and regulate cerebral circulation. We hypothesize that imbalance in the action of these vasoconstrictive and vasodilatative neurotransmitters on the wall of cerebral arteries following subarachnoid hemorrhage (SAH) is a major factor in the cause of cerebral vasospasm. We have examined the changes of transmitters and peptides in perivascular nerves following experimentally induced SAH in rats.

The quantity and distribution of nerves containing norepinephrine (NE) (using antisera to dopamine beta-hydroxylase [DBH], the key synthetic enzyme for NE), neuropeptide Y (NPY), vasoactive intestinal polypeptide (VIP) and calcitonin gene related peptide (CGRP) in perivascular nerves were studied by injection of 0.3 ml non-heparinized autologous arterial blood into the cisterna magna. Rats with saline injection into cisterna magna and rats without any manipulation served as controls. Animals were processed for ICC at different time intervals after injection. The entire circle of Willis was dissected free of the brain and split in the middle parasagittally. One half was processed for vasoconstrictive molecules (DBH or NPY) and the other half was for vasodilatative molecules (VIP or CGRP).

Cerebral arteries from non-injected and saline injection rats showed no change in either DBH/NPY or VIP/CGRP. In SAH rats, significant decreases of vasodilatative VIP and CGRP fibers were found at 2 and 3 days after SAH. In contrast, the vasoconstrictive NPY and DBH fibers were unchanged. One week after SAH, all the vasoactive fibers returned to the levels as normal controls.

Delayed vasospasm has been demonstrated 2 to 3 days after SAH in rats. The present results suggest that vasoconstrictive transmitters are relatively unaffected by SAH but vasodilatative transmitters are drastically reduced at precisely the time that the animals develop vasospasm. Loss of vasodilatative function system coupled with the survival of vasoconstrictive function could lead to unchecked vasoconstrictive control of the vascular walls, leading to vasospasm and failure of cerebral perfusion. 403.12 DISEASES IN ASSOCIATION AREAS FOUND IN SCHIZOPHRENIA USING $C^{15}O_2$, $^{15}O_2$ AND ^{11}C-GLUCOSE PET. H.Kishimoto, S.Ohno*, H.Sato*, S.Endo*, O.Takazu*, K.Sakurai*, T.Ishii*, M.Matsushita* and M.Iio*. Department of Psychiatry, Yokohama City University, Yokohama 232 and Nakano National Hospital, Nakano, Tokyo 165, JAPAN.

The authors describe new findings in the impaired cortical areas of the brain in patients with schizophrenia using $C^{15}O_2$, $^{15}O_2$ and ^{11}C-glucose PET. It is important to point out that PET images of ^{11}C-glucose showed amino acid pools whereas ^{18}F-deoxy-glucose showed the utilization of glucose.

Ten chronic schizophrenic patients (5 men, 5 women, mean age 36) who were out-patients on a chronic course without medication at the Yokohama City University Hospital, and five control subjects (3 men, 2 women, mean age 36) who agreed to give written informed consent participated in this study. Diagnoses were based on DSM-III criteria and were confirmed by another psychiatrist. Seven to ten minutes after the administration of $C^{15}O_2$, $^{15}O_2$ and ^{11}C-glucose, three to six scans parallel to the orbital meatal (OM) line were done as quietly as possible. The PET instrument was a Headtome-II which was made in Shimazu, Japan. For the present analysis, OM 40, 49, 58, 67, 75 and 84 mm slices were chosen. The authors also took brain X-ray-CTs at the same slice line as the PET and evaluated each part of the brain using the human brain map for computerized tomography by Matsui and Hirano, 1978 (Igaku Syoin , Japan) and identified Brodmann's areas 10, 40 and others. In chronic schizophrenic patients there were three types of PET images when using $C^{15}O_2$, $^{15}O_2$ and ^{11}C-glucose to inspect the cortical area of the brain. The first (type A) was a hypofrontal PET image. The second (type B) was a right side hypoparietal PET image in right-handed schizophrenic patients. The third (type C) was a left side hypotemporal PET image in right-handed schizophrenic patients.

The lowest count area in the brain in type A schizophrenia was Brodmann's area 10, in type B chronic schizophrenia, Brodmann's area 40 and in type C chronic schizophrenia, Brodmann's area 22-38. The percentage of the pixel count reduction in the frontal gyri (Brodmann's 10) in type A schizophrenia using ROI (region of interest, the mean of 25 pixels, 16x16mm) was 34 ($p<0.01$), in the non-dominant side parietal gyri (Brodmann's 40) in type B schizophrenia using ROI was 24 ($p<0.025$), and in the dominant side temporal gyrus (Brodmann's 22-38) in type C schizophrenia using ROI was 20 ($p<0.05$) in each gyri of the brain.

These areas of Brodmann 10 and 40 are the association areas which are important parts of the brain for organizing the personality and for integrating all of the information from the outside and inside of the body in human beings. Supported Grant 86-10-11

404.1 **SEGREGATION OF X AND Y AFFERENTS INTO AREAS 17 AND 18 OF CAT VISUAL CORTEX.** David Ferster, Department of Neurobiology and Physiology, Northwestern University, Evanston IL 60201.

I have been investigating the convergence of X and Y afferents onto single cortical cells with intracellular recording and electrical stimulation of the optic nerve (ON). X and Y axons in the optic nerve have very different electrical thresholds. By virtue of their non-overlapping diameters, one may stimulate Y axons alone at low stimulus currents, and X and Y axons together at high stimulus currents. The origin, X or Y, of PSPs evoked in cortical cells from the ON may therefore be identified by their thresholds.

Each ON was fitted with a cuff-shaped electrode and X and Y thresholds determined from optic tract (OT) recordings. As the stimulus current was raised from zero, a short-latency field potential appeared and grew in the OT, associated with recruitment of Y axons. With further increases in the stimulus current, this early potential reached maximal amplitude, and a second, longer latency potential associated with recruitment of X axons appeared and grew in amplitude. In a control experiment, geniculate X and Y cells were stimulated visually with sine-wave gratings and identified from their non-linearity of spatial summation. The threshold of Y-cells to ON stimulation always fell below the threshold of the later OT potential; X-cell thresholds were always above. Potentials evoked in cortical cells by stimulating the ON at the lower stimulus currents must therefore be mediated by Y axons, and those evoked at higher currents by X axons.

While single cortical neurons have been found with pure Y, pure X, and mixed input (Ferster, Neuroscience Abstr. **12**:128), the distribution of these neurons was surprising. I have found X-mediated synaptic input from the LGN throughout the layers of area 17, but I found Y input only in neurons of area 18. Mixed X and Y input to single cells was found only near the border between the two areas. The failure to find Y input to any of the 35 neurons recorded in area 17 is unlikely to reflect a sampling problem since current source density analysis confirms the pattern: No significant current sources were evoked in area 17 by activating Y-cells from the ON. Conversely, in area 18 only Y-activated sources were found. The latencies of the earliest sink and of the earliest PSPs in area 18 preceded those in area 17 by 1.1 ms (1.9 ms vs. 3.0 ms).

This result is in agreement with Spitzer and Hochstein (J. Neurophysiol. **53**:1245), who could find no Y-like non-linearities in the receptive fields of neurons in area 17. While a segregation of X and Y afferents into areas 17 and 18 would bear on the function of the two afferent types as well as on the function of the two distinct cortical areas, this result clearly requires confirmation given the weight of evidence for Y input to area 17.

404.2 OCULAR DOMINANCE AND BINOCULAR DISPARITY TUNING IN CAT VISUAL CORTEX. Simon LeVay and Thomas Voigt*. Salk Institute, PO Box 85800, San Diego, CA 92138

It has long been suspected that the cortical ocular dominance system is part of the mechanism for stereoscopy. To investigate this issue further, we have used quantitative, automated techniques to determine ocular dominance ratios (OD; 0 = contra, 1 = ipsi), disparity sensitivity (DS; (max. response - min. response)/min. response), best disparity (BD; 0 = fixation plane, + = near disparity, - = far) and best orientation for 272 units in areas 17 and 18 of paralyzed, anesthetized cats. Disparity was varied orthogonal to the cell's best orientation. Zero disparity was determined with a reference electrode at the border of layers A and A1 at the area centralis representation in the LGN.

Both DS and BD values formed continuous distributions. Confirming previous studies, we found no correlation between a cell's best orientation and its disparity tuning properties. We also found no correlation between ocular dominance and disparity sensitivity. There was however a relationship between ocular dominance and best disparity: units with BDs near the fixation place (within 1° of zero) had OD ratios clustered near 0.5 (equal dominance), confirming Ferster, '81, while units with BDs 1° or more from zero had a broad distribution of OD ratios (significance of difference of variance = 0.002, F-test). For units with receptive fields near the vertical meridian (VM) a further correlation emerged: the OD ratios of units in the 'far' range (BDs $\leq -1°$) were biased towards the contralateral eye (median OD = 0.39, n = 37), while those in the 'near' range ($\geq +1°$) were biased towards the ipsilateral eye (median OD = 0.60, n = 37). The difference of medians was significant at p = 0.003 (2-tailed Mann-Whitney). (Cells oriented near horizontal were excluded from this analysis.)

The results confirm a relationship between ocular dominance and disparity tuning. The unexpected contra-far, ipsi-near relationship for units near the VM is explicable in terms of visual geometry and the pattern of decussation in the visual pathway: the required excitatory and inhibitory inputs for the less-frequently encountered cell types (e.g. the ipsi-dominated far cell as sketched here) are directed to the hemisphere opposite to the side being recorded. One might expect interhemispheric connections to supply the missing inputs. Our results, however, suggest that callosal connections do not fully replace, for units near the 17-18 border, the intrinsic horizontal connections within one hemisphere.

404.3 STIMULUS-SPECIFIC NEURONAL OSCILLATIONS IN THE CAT VISUAL CORTEX: A CORTICAL FUNCTIONAL UNIT. Charles M. Gray* and Wolf Singer, Max Planck Institute for Brain Research, 6000 Frankfurt/M. 71, F.R.G., (SPON: J.E. Skinner)

It is well established that the cortical column constitutes the fundamental unit of neocortical structure and function. However, relatively few studies are available which provide a measure of the temporal dynamics of columnar activity. In the course of investigating experience-dependent changes in cortical function in waking kittens, we have observed that neuronal responses are associated with a stimulus-dependent oscillation of the local extracellular field potential (LFP) in the range of 40-65 Hz. Thus, we sought to determine the stimulus specificity of these oscillations and their relation to the underlying neuronal activity.

Experiments were performed on 4 adult cats (6 months of age) previously implanted with a linear array of 8 microelectrodes in area 17 of the visual cortex. The animals were lightly anesthetized with Rompun (Xylazine) 5 mg/kg or nitrous oxide supplemented with Nembutal (1 mg/kg/hr), and fixed in a head holder previously attached to the animals' skull. Drifting light bars, of constant velocity and 5 separate orientations, were passed separately across the receptive fields of isolated unit activity at each electrode site. The LFP and multiunit activity were sampled from each electrode and subjected to off-line analysis of frequency spectra, LFP-unit cross correlation, and conditional firing probability.

Analysis of the LFP power spectra revealed a brief and significant increase in amplitude of activity in the range of 40-65 Hz during the passage of the light bar across the receptive field at the optimal orientation. Cross correlation and conditional pulse probability analyses showed that the neuronal firing probability oscillated in the same frequency range of 40-65 Hz, and showed a steep nonlinear dependence on the extracellular field negativity. Non-optimally oriented stimuli produced corresponding amplitude reductions in neuronal and LFP oscillatory responses. Thus, the data dmeonstrate that orientation-specific neuronal responses exhibit a nonlinear transition to an oscillatory active state in the range of 40-65 Hz, and suggest that a local nonlinear oscillator may provide a good model of the cortical columnar functional unit.

404.4 FACTORS DETERMINING THE VERNIER ACUITIES OF NEURONS IN AREA 17 OF CAT VISUAL CORTEX N.V. Swindale* and M. Cynader (SPON:I. A. Meinertzhagen) Dept. of Psychology, Dalhousie University, Halifax, N.S. Canada, B3H 4J1

We have previously shown (Nature,**319**,591-593,1986) that many cells in cat visual cortex are sensitive to the presence of a Vernier break in a moving bar stimulus, and that this sensitivity lies in the hyperacuity range when expressed relative to spatial resolution. Here we consider how this acuity is distributed amongst cortical cells and what factors determine high and low acuities. Sensitivity was measured as the percentage depression in firing rate caused by a given Vernier offset.

For any one cell, sensitivity was largely unaffected by changes in stimulus parameters such as velocity, bar length or the position of traverse across the receptive field. There was a wide and continuous variation in sensitivity between different cells: some showed no sensitivity at all, while in the most sensitive, response could be halved by an offset equal to a fifth of receptive field width. The highest absolute sensitivities of complex and simple cells were similar, although the majority of cells with little or no sensitivity were complex. Sensitivity was negatively correlated with receptive field width, measured as twice the standard deviation of a Gaussian fitted to the receptive field profile.

A measure of length summation was obtained by comparing the responses to each component bar of a Vernier stimulus with the response obtained when both bars moved in alignment across the field. This measure was defined as $H = 1 - (R_a + R_b)/R_{ab}$ where R_a and R_b are the responses to bars a and b individually, and R_{ab} is the response to both bars in the aligned condition. H is zero when length summation is linear; is > 0 when there is a facilitatory interaction between the two bars and is < 0 when there is an inhibitory interaction. Vernier acuity, expressed relative to receptive field width, was correlated with H, being highest in cells with large values of H and least in cells where H was negative.

A linear model of the simple cell receptive field, together with a threshold, can explain the correlation between Vernier acuity and length summation. However such a model, based on measurements of receptive field profiles made with stationary flashed bars, fails to predict tuning curves as sharp as those actually observed in many simple cells.

404.5 **THE SPATIAL SPREAD OF ADAPTATION IN NEURONS OF CAT AREA 17.** Stuart G. Marlin* and Max S. Cynader, (SPON: G. Eskes) Department of Psychology, Dalhousie University, Halifax, N.S., Canada, B3H 4J1.

We have investigated the effects of adaptation of small regions of striate neuron receptive fields on responsivity across the entire receptive field. During adaptation, a bar of light (0.2 to 1° wide) was flashed on and off at one point in the receptive field twice per second for a period of one minute. Immediately following this adaptation period, responses to lined stimuli at each of 15 receptive field positions were tested. Line-weighting functions (LWFs) were obtained for the responses to stimulus onset and stimulus offset separately and the post-adaptation LWFs were compared with those obtained prior to adaptation. The spread and location of the adaptation effects were related to the spatial properties of the cell's receptive field. The spatial wavelength, , of a simple cell receptive field was determined from the location of the on and off subregions, and from the results of double-line interaction experiments in complex cells (Baker & Cynader, 1986).

In both simple and complex cells **decreased** responsivity was observed at the point of adaptation. The degree of adaptation decreased as the distance from point of adaptation increased until at some point (approx. 0.4) the adaptation effects were negligible. The spread of response decrement around the point of adaptation thus averaged 0.8 . In many neurons, in addition to a focal line of decreased responsiveness, there was an area of the receptive field surrounding the zone of reduced response in which **increases** in responsivity were observed. This was true in both simple and complex cells and was independent of the initial site of adaptation. This area of increase often occurred on both sides of the point of adaptation and was strongest approximately 1.0 away from the center of the response decrement zone. These areas of increased responsivity which surround the zone of adaptation may reflect inhibitory interactions between adjacent subunits in cortical receptive fields. Since LGN cells do not show these adaptation effects and binocular cortical cells can show interocular transfer of this spatial adaptation, the adaptation effects observed here appear to reflect cortical mechanisms rather than more peripheral ones.

404.6 **THE DISTRIBUTION OF INHIBITION IN THE TWO DIMENSIONAL SPECTRAL RESPONSE OF SIMPLE CELLS.** R. A. Stepnoski*, A. Gottschalk* and L. A. Palmer. (SPON: J. Saunders) University of Pennsylvania, Philadelphia, Pa. 19104

We have previously shown that the 2D spectral response of simple cells in cat is well described as an elliptic Gaussian and that the parameters of this Gaussian are predicted from independently obtained 2D spatial response profiles. Our data are consistent with the notion that simple cells are linear and functionally independent. However, other workers using conditioning-and-test paradigms have demonstrated inhibition by grating stimuli lying outside the excitatory spectral response of a cell. These results imply that the spectral response of simple cells depend in part on local interactions among cells tuned to a range of spatial frequencies and orientations. This inhibition was not apparent in our earlier experiments since only one grating was presented at a time and most cells had virtually no spontaneous activity.

We have developed a method for mapping both excitatory and inhibitory responses over the full 2D spectral domain. A band-limited white noise stimulus is used to elevate the discharge rate while single sinusoidal gratings are simultaneously presented in random order. The d.c. and fundamental component of cyclegrams obtained for each grating stimulus are plotted as a surface and reveal inhibitory zones surrounding the excitatory spectral response. Significantly, this inhibition is maximal at orientations near those which excite the cell and minimal or nonexistent for orthogonal orientations. Further, spatial frequencies above those which excite the cell elicit inhibition; the result for lower spatial frequencies is unclear.

These observations suggest that nearest neighbor inhibitory interactions may operate within the cortex, possibly refining the simple cell spectral response. A simulation exploring this possiblilty is under development and will be compared with experimental results.

404.7 EFFECTS OF AREA 17 AND 18 ABLATIONS ON LINE ORIENTATION DISCRIMINATION IN THE CAT. J.M. Sprague, E. Vandenbussche*, G.A. Orban, B. Gulyas* and P. De Weerd*. Laboratorium voor Neuro- en Psychofysiologie, K.U. Leuven, Campus Gasthuisberg, B-3000 Leuven, Belgium, and Dept. of Anatomy, Sch. of Med., Univ. of Pennsylvania, PA 19104-6058.

From our study on velocity sensitivity we have concluded that area 17 is more suited for analysis of stationary objects than 18 (Orban et al., J. Neurophysiol., 43:1043,1981). In addition area 17 not 18 contains receptive field types of which the preferred orientation shows meridional anisotropies (Orban, Springer-Verlag, 367p., 1984; Schall et al., J. Neurosci., 6:123, 1986). Normal cats show an oblique effect in orientation discrimination (Vandenbussche and Orban, Behav.Brain Res., 9:237, 1983. One would therefore expect lesions of area 17 to have more effect on orientation discrimination measured with stationary lines and to reduce the oblique effect in orientation more severely than area 18 lesions. We tested these predictions in 8 cats trained for up to 1 year to discriminate the orientation of long (12°) lines at a principal and oblique reference orientation. The contrast log $(\Delta I/I)$ of the lines ranged from 0.3 to 2.5 and the width from 0.2 to 1.2°. In six cats area 17 was removed with variable involvement of area 18 while in two cats area 18 and most of 19 was removed. The extent of the lesion was evaluated physiologically by recording in areas bordering the lesion, and histologically by reconstruction of the lesion. This evaluation showed that the size of the 17-18 lesion ranged from a near complete ablation of area 17 (smallest lesion) to an almost complete lesion of both areas 17 and 18 (largest lesion). The effects of the lesions were measured up to one year after the surgery. The effect of the 17-(18) lesions depended on the size: the smallest lesion only increased the jnds in orientation for narrow widths (0.2°) and low contrast; the intermediate lesion increased the jnds in orientation for narrow widths even at high contrast, and the large lesion impaired even the high contrast, large width condition. In all but the smallest lesion the oblique effect in orientation was severely reduced. Our results support the view that area 17 is crucial for fine resolution of the orientation of single lines, especially at low contrast. They also indicate that area 18 supplements 17 at greater line widths and higher contrasts. Most of the oblique effect in orientation is dependent on area 17 cells. The results underscore the importance of varying the stimulus conditions (line width, contrast) to reveal deficits after cortical ablations. (Supported by Univ. Penn. Research Foundation; NIH-EY04906).

404.8 ORIENTATION-SPECIFIC VISUAL MASKING OF SINGLE UNIT RESPONSES IN CAT STRIATE CORTEX. S.B. Nelson Vision Center Lab, Salk Institute and UCSD Dept. of Biology, San Diego, CA 92138

Psychophysical studies have demonstrated that the perception of a brief visual stimulus may be suppressed by a preceding stimulus. This effect is called visual masking. The suppression is orientation-specific and has been correlated with a reduction in amplitude of visually evoked potentials (Tootle and Berkley, J. Neurophys. 53 (1985)1287). In an attempt to study masking at the single neuron level I have presented pairs of briefly flashed "mask" and "test" stimuli to paralyzed, anesthetized cats while recording extracellular responses of single units in area 17. The stimuli were light bars of optimal size and orientation presented consecutively for 200 msec each, separated by a 200 msec inter-stimulus interval (ISI). Both stimuli were presented at the most responsive region within the receptive field (RF). In 30 of 71 cells studied, the mask stimulus caused a significant suppression of the response to the test stimulus (T-test comparison of peak firing rates, P-.05). The degree of suppression varied from cell to cell. In 9 cells the response to the test stimulus was abolished completely. 11 of the 41 cells not showing suppression at a 200 msec ISI were suppressed when the ISI was decreased to 100 or 50 msec. Shorter ISIs were not tested. For 10 cells the suppression extended beyond 200 msec (maximum of 900 msec). No clear correlation was found between masking and cell type (simple, complex) or laminar position.

Psychophysical masking is orientation-specific. I studied this at the cellular level by varying the orientation of the mask stimulus while continuing to present the test stimulus at the cell's preferred orientation. Of 20 cells tested, 2 showed equal masking at all orientations. For the remaining 18 cells the suppression was maximal at the cell's preferred orientation and minimal at the orthogonal orientation. The suppression was however more broadly tuned for orientation than were the cell's excitatory responses. It fell to half-maximal at a mean of 40 deg. from optimal, compared with a mean of 21 deg. for the excitatory responses. For many cells, mask stimuli of 30 deg. from optimal failed to elicit any excitatory response but still caused substantial suppression. This suggests that masking was not due to fatigue of the cell.

These data are consistent with the hypothesis that the inhibition caused by optimally oriented stimuli lying outside the classical RF (Blakemore and Tobin, Exp. Brain Res. 15(1972)439 and Nelson and Frost, Brain Res. 139(1978)359) is also present within the RF. The orientation selectivity of the suppression observed in this study is consistent with the recent finding that intracellularly recorded IPSPs are strongest at the cell's preferred orientation and absent at orthogonal orientations (Ferster, J. Neurosci. 6(1986)1284).

404.9 A NETWORK MODEL FOR CORTICAL ORIENTATION SELECTIVITY IN CAT VISUAL CORTEX. C. Koch. Division of Biology 216-76, Caltech, Pasadena, CA 91125.

The vast majority of cells in the cat's visual cortex are orientation selective. Two classes of models have been proposed to account for this phenomena. Hubel and Wiesel (1962) have orientation selectivity arising from a row of geniculate neurons with appropriately aligned receptive fields. However, various experiments (e.g. Sillito, 1979) underscore the crucial nature of intracortical inhibition in shaping orientation selectivity. Thus, a number of models have been proposed (e.g. Heggelund, 1981; Koch and Poggio, 1985), such that inhibitory non-oriented interneurons prevent the cell from responding at non-optimal orientations. However, no population of non-oriented cells has been found in area 17 of the cat.

I propose a model of orientation selectivity, based primarily on the interactions between inhibitory interneurons, in which cells of the same orientation inhibit each other in such a manner that the entire network acquires orientation selectivity. Thus, interneurons in the "vertical" column inhibit their neighbors to the "left" and "right," but not those to the "top" and "bottom," while horizontal cells inhibit each other along the top-bottom axis (relative to the diagram plane). In addition, cross-inhibition between cells of differing orientation enhances the orientation tuning. This network model explains how orientation selectivity arises within the input layer to striate cortex and predicts cross-inhibition between neighboring interneurons of similar orientations. It can be tested using multiple-electrode techniques. A fundamental property of the model is its reliance on massive feedback among its elements, in contrast to previous models which are of the feedforward type. I will demonstrate a computer implementation of this model based on anatomical and electrophysiological properties of cortical cells.

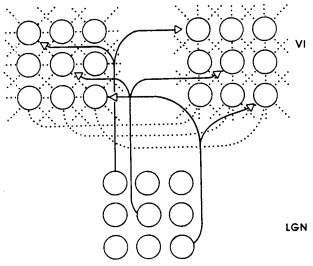

Figure illustrating the model. Only some of the excitatory geniculocortical projections (solid lines) and the cross-inhibitory connections between interneurons of different orientations (dotted lines) are drawn in. Cells in the left (resp. right) group have vertical (resp. horizontal) oriented receptive fields.

404.10 HOW DO STRIATE NEURONS REPRESENT CURVED STIMULI ? G.A. Orban, M. Versavel*, and L. Lagae*. Laboratorium voor Neuro- en Psychofysiologie, K.U.Leuven, Campus Gasthuisberg, B-3000 Leuven, Belgium.

Curved lines such as half circles contain many different local orientations, while chevrons contain only two orientations. From the receptive field properties of endfree and endstopped cells (Orban et al., J.Neurophysiol., 42:833, 1979) one would expect endstopped cells to respond far better to curved lines than to long straight lines. However it is not known whether this ability depends on the mean orientation difference or on the many orientation differences contained in a curved line, and whether endstopped cells can encode curvature, signalling both the degree and sign (concave, convex) of the curvature. In order to address these questions, responses of striate neurons to convex and concave curved lines and to chevrons were compared in anesthetized and paralyzed cats. Chevrons were made out of two 6° long line segments intersecting at different angles. Curved stimuli were made of circles of different radii. For small radii half circles were used, while for large radii only 12° long segments of circles were used. Endstopping was assessed by measuring the responses to straight lines, ranging in length from 0.5 to 12°. Our results show that all striate neurons, including strongly endstopped cells, fail to respond to chevrons with small angular differences. This observation fits with the known orientation tuning properties of the discharge region and the endzones (Orban et al., J. Neurophysiol., 42:833, 1979). Endfree cells respond to a wide range of curved lines except the most curved ones. Endstopped cells respond best to moderate or large curvatures. Degree of endstopping and optimal curvature are correlated : the stronger the endstopping, the larger the optimal degree of curvature. These results indicate that endstopped and endfree cells together are able to sample all degrees of curvatures but only a limited range of orientation differences. Our results further suggest that endstopped cells could not only sample curved stimuli but could also encode curvature. Distinction of concave from convex curvatures seems to require the endstopped cells to have two more properties : direction selectivity and narrow RFs. While our results suggest that curvature can be coded at the level of the striate cortex by a local mechanism using all orientations in the curved line, the results are also compatible with the hypothesis that curvature is encoded, in addition, further along the visual pathway by a multilocal mechanism based on the difference in mean orientation at different loci (Koenderink and van Doorn, Biol. Cybern., 55:367, 1987).

404.11 **EXTRACTING 3-D CURVATURES FROM IMAGES OF SURFACES USING A NEURAL MODEL.** Sidney R. Lehky * and Terrence J. Sejnowski. (SPON: G. F. Poggio). Department of Biophysics, Johns Hopkins University, Baltimore, MD 21218.

Many neurons in primary visual cortex have oriented receptive fields, and consequently are often interpreted as "bar detectors" or "edge detectors". However, in addition to edges, there is significant information contained in the continuous gradations of shading within an image. We have investigated this by constructing a computer model of a neural network that extracts curvatures from the shading information contained in images of simple geometrical surfaces. Specifically, the network determines the principal curvatures (largest and smallest curvatures) at the center of the surface, and their orientation, independent of illumination direction, and the precise location of the surface within the overall receptive field of the network. The network, which is meant to reflect processing occuring within a single cortical column, has model neurons arranged in three layers. Each unit within a layer is synaptically connected to every unit of the next layer. The input layer is an hexagonal array of overlapping, circularly-symmetric, center-surround units with both ON and OFF centers. The output layer is a set of units in which each unit is broadly tuned to both principal curvature, and the orientation of that curvature. Therefore, the activity of a single output unit is ambiguous, and the output information is contained in the joint activities of the output units. Finally, there is the middle, or "hidden unit" layer, which transforms the retinotopic coordinates of the input layer to the curvature-orientation coordinates of the output layer.

We used the "back-propagation" learning algorithm[1] as a design technique to construct a network with the desired characteristics. The network was presented with many sample images, and for each presentation, the actual responses of the output units were compared with the correct output. Then the synaptic weights throughout the network were slightly modified to reduce the error. Following this procedure, the individual units within the hidden layer formed a variety of receptive fields, mostly oriented but a few non-oriented. The response properties of the units were mapped out using "simulated neurophysiology". Using bars of light as stimuli, the oriented hidden units appeared to have characteristics of simple cells. The output units, which receive input from many hidden units, appeared to have some properties of complex cells. We conclude that neurons which can extract curvature can have receptive field properties similar to those which previously were interpreted as bar or edge detectors. Yet other interpretations may be possible. The receptive field properties of a sensory neuron are necessary but not sufficient to determine its function within a network.

404.12 RESPONSE PROPERTIES OF STRIATE CORTEX NEURONS IN BEHAVING MONKEY: INSIGHTS FROM STABILIZING THE RETINAL IMAGE. D.Max Snodderly and Moshe Gur*.
Eye Research Institute of Retina Foundation, Boston, MA, USA, and Department of Ophthalmology, Harvard Medical School; and *Department of Biomedical Engineering, Technion-Israel Institute of Technology, Haifa, Israel.

Responses of single neurons in the striate cortex of a Macaca fascicularis monkey were studied while the monkey performed a fixation task and eye position was monitored by a double Purkinje image eyetracker. For most trials, the stimulus was stabilized on the retina. On other trials the stimulus remained stationary in space while the eye movements of fixation moved the stimulus on the retina. Both drifts and small saccades excited the neurons when they resulted in appropriate retinal image motions. Cells with receptive fields 1 to 6 deg. eccentricity were studied.

The receptive fields of cortical neurons move in space with the eye. When the image is not stabilized, estimates of receptive field activating areas are influenced (usually inflated) in unpredictable ways. When more precise control of retinal stimulus position is achieved by image stabilization, responses are vigorous and reliable. Response rates are often more than one hundred spikes per second with less than one log unit of stimulus contrast. There is a gradient of response rate with retinal eccentricity so that stronger responses occur in the fovea.

Receptive field subregions like those described in anesthetized animals can also be characterized in a behaving monkey when the image is stabilized. In addition, powerful inhibitory fields outside the activating regions shape the stimulus selectivity of the cell. These inhibitory fields are strikingly apparent in the behaving animal because of the high response rates that they cancel. When an appropriate stimulus is correctly identified, it stimulates the activating regions without eliciting the powerful inhibition. This means that the absolute response rate becomes an important indicator of the degree to which the experimenter has been able to establish the optimal stimulus for a neuron. Such a criterion has not been applied in the past because of inability to specify the physiological state of anesthetized animals, and inability to be confident of stimulus placement in behaving animals. The results from using a stabilized image with a trained, behaving monkey suggest that we have succeeded in controlling the major experimental variables. We refer to this as a fully calibrated experiment in visual neurophysiology.

404.13 A NETWORK MODEL USING BACK PROPAGATION LEARNING SIMULATES THE SPATIAL TUNING PROPERTIES OF POSTERIOR PARIETAL NEURONS. D. Zipser and R.A. Andersen. Inst. for Cognitive Science, UCSD, La Jolla, CA 92093; Dept. of Brain and Cognitive Sciences, MIT, Cambridge, MA 02139.

Area 7a in the posterior parietal lobule of the monkey is involved in visual spatial representation. Neurons in Area 7a respond to both the retinal location of a visual stimulus and the position of the eyes but are virtually insensitive to the qualities of the stimulus such as size, color, or shape. By combining these two afferents Area 7a neurons code the spatial location of external objects; however, the responses of Area 7a neurons are not directly correlated with spatial location, so additional decoding is required. We have developed a network model that not only demonstrates how spatial information can be decoded from Area 7a neurons but also accounts for their observed quantitative response properties.

The modeling technique we employ makes use of a powerful network learning procedure called "back propagation." Back propagation is able to program the computation carried out by a network using only examples of input and output. Back propagation accomplishes this programming by adjusting the strengths of the synapses within the network. The networks generated by back propagation are optimized to reduce error by a gradient-descent algorithm.

The experimental data that must be accounted for was previously collected in studies with awake behaving monkeys. The retinal receptive fields observed for Area 7a neurons are large and often complex in shape. The receptive fields have one peak or a few peaks that form a smoothly changing, hilly landscape. Most of the eye-position gain fields (which represent the effects of different eye positions on the magnitude of the visual response for retinotopically identical stimuli) are planar and exhibit a characteristic nonlinear interaction between eye position and retinal information.

Our model consists of a three-layer network of neuron-like units. The first layer supplies the retinal and eye-position input information. The middle, or hidden, layer represents the neurons in Area 7a, and the third, or output, layer is trained to represent spatial location. We have found that, after training, the output layer accurately represents the true spatial location of the stimulus. What is more, the hidden unit responses re-create the retinal receptive fields of Area 7a neurons, and also their eye-position gain fields, complete with the characteristic nonlinear interactions between retinal and eye-position signals. There is no topographic organization of the hidden units for spatial tuning, eye position, or retinal position. This lack of topography has also been found for the cells in Area 7a.

LEARNING AND MEMORY: ANATOMY VI

405.1 ADDITIONAL NEURAL AND COGNITIVE EVIDENCE IN PATIENT DRB. A.R. Damasio, H. Damasio, D. Tranel, K. Welsh, and J. Brandt. Div. of Behav. Neurol., U. of Iowa Col. of Med., Iowa City, IA 52242.

Patient DRB has now been studied with advanced magnetic resonance imaging allowing for detailed neuroanatomical mapping of his lesions. In the left hemisphere these include the entorhinal cortex, the hippocampus, the amygdala, areas 38, 20, 21, and part of area 37. Damage in the right hemisphere is comparable but slightly more extensive within area 37; it undercuts the occipitotemporal junction. The basal forebrain region is destroyed bilaterally and so is the anterior insula. The medial aspect of the orbital frontal regions is partially destroyed bilaterally. Thus, virtually all the principal cortical and subcortical limbic structures have been ablated in DRB, and so have several of the key higher-order association cortices. In this light, the extent of DRB's preserved cognitive processes deserves special attention.

DRB's acquisition of new memory remains confined to covert forms of learning, e.g., (a) in rotor pursuit and mirror-tracing tasks DRB is comparable to controls although he has no declarative knowledge of the tasks; (b) in a priming task using word stems DRB shows evidence of priming, albeit at a lower rate than controls; (c) in a forced choice recognition of the words used in the priming task DRB performs at an 80% level; (d) daily observation of his behaviors in a constrained setting reveals covert learning of affect-laden stimuli.

In both the anterograde and retrograde periods of his history, DRB remains unable to recognize or recall at overt level any unique episode or stimulus and entirely unable to retrieve the specific temporal or spatial reference of any knowledge (this is true even for key items of his autobiography). By contrast, his access to "non-episodic" knowledge acquired prior to his illness is largely intact although the degree of preservation depends on the conceptual domain to which the stimulus belongs (natural kinds are less well preserved than man-made or ontologic kinds). DRB's linguistic knowledge (assessed with fine linguistic experiments), reveal the intactness of fundamental phonemic, phonetic, morphological, syntactical, and intonational representations and rules of language.

In order to study DRB's profile outside traditional memory assessment, he was administered several projective personality tests. On the Rorschach test, both the qualitative and quantitative features of his response protocols were normal. He uses typical determinants (predominantly form but also texture, color, etc.), and the responses contain an appropriate mixture of wholes and major and minor details. The stories that DRB created for the Thematic Apperception Test did not reveal "psychopathology." (They are sparse and unimaginative but contain appropriate temporal sequencing, and contingent actions and relationships between characters. Inconceivable events or relationships are not described).

405.2 ALZ-50 DEMONSTRATES THE DESTRUCTION OF HIPPOCAMPAL PROJECTION NEURONS IN ALZHEIMER'S DISEASE. W.G. Tourtellotte, G.W. Van Hoesen, B.T. Hyman, L.J. Kromer* and A.R. Damasio. Depts. of Anatomy and Neurology, University of Iowa College of Medicine, Iowa City, IA 52242.

The hippocampal formation is a major target for pathological changes that occur in Alzheimer's disease (AD), such as neurofibrillary tangles. The Sommer sector has been implicated consistently, especially in its more medial or subicular part, which is the source of projection neurons that send axons to both telencephalic and diencephalic areas. By contrast, comparatively less pathology has been reported in the adjacent CA1 part of Sommer's sector, a field that is connected powerfully with the subiculum and shares many extrinsic projections with it. We have examined and compared the extent of subicular and CA1 pathology in AD using both conventional pathological stains, such as Congo red and thioflavin S, and a highly sensitive monoclonal antibody, Alz-50, which recognizes an antigen found in high concentrations in AD. Both conventional stains and Alz-50 immunocytochemistry reveal pathological involvement of the subiculum and CA1 zones. However, the pattern of immunoreactivity using Alz-50 reveals that nearly the entirety of the CA1 zone is targeted in many AD brains as well as some neurons in the CA3 and CA4 zones. These findings are of interest because they reveal that all neurons that form Sommer's sector are undergoing alterations in this disorder. Left unaffected, is only a partial population of CA3 and CA4 hippocampal neurons which project to the septal region (many reports suggest that the cholinergic neurons of the septem, may themselves be targets for pathologic involvement in AD). The CA1 and subicular pyramids are highly interconnected allocortical areas and they project massively to layer IV of the entorhinal cortex. Since the latter is also targeted in AD, it is clear that both intrinsic connections as well as extrinsic connections of the hippocampal formation are explicitly affected, with both the cell of origin for axons within Sommer's sector affected as well as its postsynaptic target. This leads to a nearly total deefferentation of the hippocampal formation. Combined with significant alterations in hippocampal input due to both entorhinal and basal forebrain pathology, there seems little doubt that the integrity of hippocampal neural systems are highly compromised in AD. In fact, it is likely that these changes have no less devastating functional consequences for memory processes than hippocampal destruction itself. (Supported by: NS 14944, PO NS 19632 and the Mathers Foundation. We thank P. Davies and B. Wolozin, for providing Alz-50).

405.3 COVERT DISCRIMINATION OF FAMILIAR STIMULI OTHER THAN FACES IN PATIENTS WITH VISUAL RECOGNITION IMPAIRMENTS CAUSED BY OCCIPITO-TEMPORAL DAMAGE. D. Tranel, A.R. Damasio, and H. Damasio. Div. of Behav. Neurol., U. of Iowa Col. of Med., Iowa City, IA 52242.

Using the electrodermal skin conductance response (SCR) as a dependent measure, we have previously demonstrated that subjects with severe defects of face identity recognition can discriminate, at a covert level, stimuli that they fail to recognize overtly. Those patients often show recognition impairments in other categories of stimuli, such as cars or buildings, although this has received little systematic investigation. The current study probed the recognition performance of three subjects, in the categories of cars, buildings, personal effects, and faces, using SCRs and verbal ratings as dependent measures of covert and overt levels of processing. The data were related to detailed neuroanatomical analysis of each subject, based on magnetic resonance imaging.

For each category (cars, faces, etc.), the set of stimuli consisted of 40 items, 10 of which were targets (items the subject was highly familiar with) and 30 of which were nontargets (items the subject had never encountered before). Targets and nontargets were randomly mixed and presented one at a time, while skin conductance was recorded from the palm of each hand. During a second presentation, the subject used a preassigned scale to make a verbal rating of the degree of familiarity of each stimulus.

Based on their verbal ratings, all three subjects showed marked difficulty in the overt recognition of target items in the four classes of stimuli. However, the subjects often produced discriminatory SCRs to the targets they could not overtly recognize. For example, subjects #1 and #2 showed significantly larger SCRs to target faces, buildings, and cars, and subject #2 even showed this effect for familiar personal belongings. Neuroanatomical findings were as follows: Subject #1 has bilateral subcalcarine damage in areas 18/19 and unilateral right hippocampal damage; Subject #2 has bilateral damage to areas 20/21, 37, and the hippocampal region; Subject #3 has right subcalcarine damage in 18/19, and left parahippocampal damage.

The results suggest that both in relatively "pure" visual agnosics (whose lesions are placed in "early" visual association cortices), as well as in so-called global amnesics (whose lesions involve higher-order association cortices and the hippocampal region), the brain "recognized" stimuli to which it had been previously exposed. Given the diverse placement of the lesions, this indicates that the multi-component records necessary for recognition of unique familiar stimuli are laid down at multiple levels of CNS and can be accessed by different routes. For all 3 subjects, access of those records was capable of triggering autonomic responses, but failed to lead to the evocation of pertinent factual representations which are necessary for "conscious" recognition.

405.4 MEMORY DEFICITS IN CALLOSAL AGENESIS. I. Brown and F. Wood.* Bowman Gray Sch. of Med., Winston-Salem, NC 27103.

Agenesis of the corpus callosum (ACC) often occurs in conjuction with a complex of serious CNS malformations which are symptomatic with widely varying degrees of severity. Thus, in agenesis, when cognitive deficits are noted, they tend to be attributed to the accompanying anomalies rather than to the agenesis, per se. Indeed, the consensus has been that when agenesis occurs alone, symptoms are absent or so mild as not to attract clinical attention.

Compensatory mechanisms hypothesized to account for this apparent lack of symptoms in acallosals have included overdeveloped ipsilateral pathways and assumption of information transfer by remaining interhemispheric commissures. Additionally, it has been suggested that a more parsimonious explanation may be that we have not applied sufficiently sensitive measures to study the question adequately. For example, eliminating cross-cueing, Gazzaniga found deficits in acallosals similar to those shown by commissurotomy patients. Milner concludes that both cognitive and skilled performances probably suffer as a result of agenesis, but that there are great individual differences. Our experience with two adolescent boys supports this view.

Case 1 had onset of seizures at age 16 months, but despite this, early development progressed normally and the boy demonstrated advanced verbal skills. By age 10, his grades had declined, he was easily disoriented, and memory problems were severe. At age 11, magnetic resonance imaging (MRI) revealed complete ACC and enlarged anterior cerebral arteries, but no other abnormalities.

Case 2 has had no seizures, but was slow in achieving developmental milestones and has a history of academic difficulty. Parents report that he has poor motor skills and poor short-term memory. CT scan revealed complete ACC with dilated ventricles, but no other abnormalities.

Both boys have WISC-R scores in the low average range. Scores on neuropsychological tests were somewhat inconsistent across the two profiles except for a substantial deficit in memory for structured verbal and visual material as measured by the Cowboy Story and the Rey-Taylor figure.

Nakamura and Gazzaniga have suggested that while a single hemisphere may perform as well as a whole brain on a simple short-term memory task, each hemisphere may have certain load limits which, if exceeded, will result in memory deficit. The imposition of structure onto a memory task such as the Cowboy Story and Rey-Taylor figure may add to the memory load so that a limited capacity becomes overloaded. Further, if, as they speculate, a major commissural function is that of suppressing competing motor responses, such responses may act as a source of interference in memory tasks. These cases lead us to suspect that it is premature to assume that ACC is asymptomatic and that memory deficit in ACC must be explored.

405.5 LONG TERM MEMORY DISTURBANCES IN BRAIN-DAMAGED ADOLESCENTS AS ESTABLISHED BY A COMPREHENSIVE MEMORY TEST BATTERY. H.J. MARKOWITSCH* and E. HOFMANN* (SPON: ENA). Dept. Psychology, Univ. Konstanz, D-7750 Konstanz, Fed. Rep. Germany.

Brain-damaged adolescents with memory disturbances as a principal symptom were tested with the help of a newly developed memory battery. This consisted of 1) self-assessment scale, 2) a questionnaire on general orientation and remote memory, 3) a prose text, 4) remembering a name, 5) remembering a short route and message, 6) a word list (Buschke), 7) a cube test, 8)-11) memory for faces, tonal sequences, odors, tactile stimuli, 12) prose (after long delay), 13)remembering a name, 14) remembering a route and message (after long delay), 15) a word list (after long delay), 16) the tower of Hanoi problem, 17) paired-associate learning, 18) the Benton test, 19) selective visual-spatial reminding (Muramoto), 20) digit span, 21) episodic remote memory, 22) a delayed-match-to-sample task, 23) the Wisconsin Card Sorting Test, 24) paired associate learning under a sentence condition, 25) solving the tower of Hanoi problem after a long delay, 26) keeping a diary, 27) a verbal short term memory test. Furthermore, 28) a personnel assessment of the patient's memory was filled out by the testing psychologist.

In building the test battery emphasis was laid on including memory tests in several sensory modalities, on episodic and skill memory, and such tests emphasizing everyday memory situations.

Of the 8 patients one had suffered from cerebral hypoxia, one from a hypophysis-adenome with fronto-basal damage; 2 others had fronto-temporo-basal damage; 2 had traumata (in the temporo-parietal cortex in one case and in the occipital cortex, with additional encephalitis, in the other); one patient had an occlusion of the internal carotis with left basal ganglia changes; and the last had a rupture in the middle of the corpus callosum with possible fornix damage. The behavior of these patients was compared with that of a matched control group.

While the test profiles varied between individuals, the following findings were consistent: Largest deficits were obtained in tests using long delay periods, while short delays usually had little effect; IQ points generally were superior to the patients' performance in everyday situations. There was - compared to normal controls - a poor adaptation of strategies and a slow speed in processing memory tasks.

405.6 RADIOLOGICAL (CT) FINDINGS IN PATIENTS WITH KORSAKOFF'S SYNDROME AND THEIR RELATIONSHIP TO MEMORY IMPAIRMENT. A.P. Shimamura*, T.L. Jernigan and L.R. Squire. V.A. Med. Ctr. San Diego, CA 92161 and Dept. of Psychiatry, UCSD, CA 92093.

We obtained computed tomography (CT) scans from 7 patients with Korsakoff's syndrome, 7 age-matched alcoholic subjects, and 7 age-matched healthy control subjects. Quantitative analyses were performed by using CT values to estimate fluid volume and tissue density in several brain regions. We assessed fluid volume bilaterally in six regions, defined as frontal lobe, Sylvian fissure, vertex, third ventricle, superior quadrageminal cistern, and medial cerebellum. Brain density was estimated by averaging CT values in small (5 mm x 5 mm) areas sampled bilaterally in defined areas: thalamus, caudate nucleus, putamen, anterior white matter, posterior white matter, and centrum semiovale.

Compared with healthy controls, both patients with Korsakoff's syndrome and alcoholic subjects exhibited increased fluid volume in the frontal lobe ($ps < .05$) and Sylvian fissure ($ps < .08$). Compared with alcoholic subjects, patients with Korsakoff's syndrome exhibited increased fluid volume in the third ventricle ($p < .08$), low density values in the thalamus ($p < .01$), as well as marginally low density values in the caudate nucleus ($p = .09$). Moreover, they exhibited even greater fluid volume in the Sylvian fissure ($p = .06$) than alcoholic subjects. No other structural measures approached statistical significance. In summary, cortical regions were generally affected by alcoholism, whereas diencephalic regions were particularly affected by Korsakoff's syndrome.

We investigated the relationship between structural abnormalities and memory impairment in the 7 patients with Korsakoff's syndrome. A series of Spearman rank order correlations was performed between structural measures and each of 12 independent measures of anterograde amnesia. Because each brain region provided one measure for the left hemisphere and one for the right hemisphere, we obtained a total of 24 independent correlations for each region. Only two structural measures yielded a significant number of positive correlations with memory measures. These were the thalamus density measure (median $r = .34$, 18/24 positive correlations, $p < .025$) and the frontal fluid measure (median $r = .43$, 18/24 positive correlations, $p < .025$). No other correlational analysis approached statistical significance. Thus, the memory impairment observed in patients with Korsakoff's syndrome was correlated with thalamic and frontal lobe damage but not with other structural impairment.

405.7 Cognitive Deficits in Patients with Frontal Lobe Lesions: Significance for the Amnesia of Korsakoff's Syndrome
J.S. Janowsky*, A.P. Shimamura* and L.R. Squire (SPON: R. Sapolsky) V.A. Med. Ctr. and UCSD, Dept. of Psychiatry, La Jolla, CA 92093

Patients with Korsakoff's syndrome typically exhibit disorders of cognitive function in addition to severe anterograde and retrograde amnesia. These deficits include impaired verbal fluency, failure to release from proactive interference (PI), and impaired metamemory. These deficits are often absent in other etiologies of amnesia and are dissociable from the recall and recognition deficits of amnesia. It has been suggested that these deficits may depend on frontal lobe damage. We studied three patients who had lesions of the right frontal lobe, two who had lesions of the left frontal lobe and two who had bilateral lesions. The lesions were caused by a cerebrovascular accident or neurosurgery for abscess. All patients exhibited normal IQs and normal performance on the Weschler Memory Scale, but were impaired on the Wisconsin Card Sort Test.

Verbal Fluency: Patients with left or bilateral (but not right) frontal lesions were markedly impaired in verbal fluency as measured both by the Benton Verbal Fluency Test and by the Initiation and Perseveration subtest of the Dementia Rating Scale (DRS, ps<.05). This finding is consistent with the idea that the deficit in verbal fluency in patients with Korsakoff's syndrome is due to frontal lobe pathology.

Proactive Interference: Previous studies showed that a shift in the semantic category during list learning will improve recall (release from PI). Patients with Korsakoff's syndrome do not benefit from a category shift. All of the patients with frontal lobe lesions demonstrated release from PI, and their performance did not differ from that of control subjects. These results suggest that frontal lobe damage alone may not be sufficient to impair release from PI.

Metamemory: Patients with Korsakoff's syndrome are poor at judging how accurate they will be on a subsequent memory task We found that patients with frontal lobe lesions also show a deficit in metamemory performance compared to age-matched control subjects (p<.05). This finding suggests that metamemory is dissociable from the ability to remember new information and may depend on the integrity of the frontal lobes.

In summary, some cognitive deficits (verbal fluency and metamemory) are common to amnesic patients with Korsakoff's syndrome and patients with frontal lobe disease. Patients with frontal lobe disease do not exhibit severe memory impairment. These cognitive deficits may therefore be related to frontal lobe pathology in patients with Korsakoff's syndrome.

405.8 HIPPOCAMPAL LESIONS, BUT NOT FORNIX OR MAMMILLARY BODY LESIONS, PRODUCE LONG-LASTING AMNESIA IN MONKEYS.
Zola-Morgan, L.R. Squire and D.G. Amaral. V.A. Medical Center, San Diego, CA 92161, Dept. Psychiatry, UCSD, La Jolla, CA 92093 and Salk Institute, La Jolla, CA 92138.

We have used a battery of tasks sensitive to human amnesia to characterize in monkeys the severity, pervasiveness, and duration of memory impairment following damage to specific medial temporal and diencephalic structures implicated in the human amnesic syndrome. One traditional idea has been to suppose that amnesia results when damage occurs within a functional neural circuit that includes most prominently the hippocampal formation, fornix, and mammillary bodies.

To clarify whether these anatomically related structures contribute equally to memory function we administered six memory tasks to separate groups of monkeys with bilateral lesions of the hippocampus (H), fornix (FX), and mammillary bodies (MB), and to a group of normal monkeys (N). The H lesions damaged the hippocampus proper, dentate gyrus, subiculum, posterior entorhinal cortex, and most of the parahippocampal gyrus. On the first task, delayed nonmatching to sample, the H and MB groups, but not the FX group, were impaired. The H group was impaired on all subsequent amnesia-sensitive tasks (see Table), and the impairment endured for at least 1.5 years from surgery. The FX and MB groups were unimpaired on all subsequent tasks (except delayed response, on which the FX group was impaired).

SUMMARY OF BEHAVIORAL FINDINGS

	1 Delayed NMTS	2 Object Retention	3 8-Pair Concurrent	4 Delayed Response	5 Pattern Discrim.	6 Motor Skill
H	+	+	+	+	-	-
FX	-	-	-	+	-	-
MB	+	-	-	-	-	-

Tasks 1-4: tasks sensitive to human amnesia; Tasks 5-6: tasks analogous to those amnesic patients do not fail; NMTS = nonmatching to sample; + = impairment; - = normal performance.

These findings, together with previous anatomical findings suggest that the fornix and mammillary bodies may not be as prominent in the neuropathology of amnesia as once thought. In contrast, damage to the hippocampal formation and adjacent parahippocampal gyrus produces a significant and long-lasting memory impairment.

405.9 NEW EVIDENCE OF BRAIN INJURY IN THE AMNESIC PATIENT N.A. BASED ON MAGNETIC RESONANCE IMAGING.
L.R. Squire, D.G. Amaral, S. Zola-Morgan, M. Kritchevsky*, and G. Press*. V.A. Medical Center, San Diego, CA, Dept. Psychiatry, UCSD, La Jolla, CA, Salk Institute, La Jolla, CA, and Dept. Radiology, UCSD, La Jolla, CA.

N.A. has been amnesic since 1960 when he sustained a penetrating brain injury with a miniature fencing foil. The amnesia occurs as a strikingly circumscribed disorder, primarily affecting verbal material. Previous CAT scans demonstrated a lucency in the region of the left mediodorsal nucleus, but no additional damage was revealed. In 1986 and 1987 N.A., now 48 years old, was studied at the Magnetic Resonance Institute at UCSD. Initially, contiguous 3mm sections through the forebrain, diencephalon and mesencephalon were imaged using a T1 weighted sequence. Separate studies were carried out in the coronal, horizontal, and sagittal planes. Subsequently, other studies were conducted with 5mm sections and T1, T2 or balanced sequences. Three major areas of damage were identified. In the left thalamus there is a prominent linear defect. Its path approximates the internal medullary lamina, and it extends from within the third ventricle to nearly the lateral limit of the thalamus. The defect extends for approximately 15mm anteroposteriorly and likely involves the mediodorsal thalamic nucleus as well as the ventral anterior, ventral lateral and midline nuclei; it also likely interrupts the trajectory of the mammillothalamic tract. On the basal surface of the left anterior hypothalamus the T2 weighted images show an apparent mass that is interpreted as either gliosis, microcystic encephalomalacia or a highly proteinaceous cyst. There is extensive damage to the posterior hypothalamus which is both bilateral and symmetric. One important finding is that the mammillary nuclei are not visible in images from any of the three planes. Finally, the right anterior temporal lobe is replaced by signal that resembles CSF. This image represents either an actual parenchymal defect or macrocystic encephalomalacia, which could have occurred during the craniotomy that was done following N.A.'s injury. This damage extends from the temporal pole anteriorly, to a level approximately midway through the amygdaloid complex; the hippocampal formation on the right side appeared entirely intact. In summary, damage was found in left diencephalic structures, bilateral mammillary nuclei and right anterior temporal lobe. The significance of this damage for understanding N.A.'s circumscribed memory impairment will be discussed.

405.10 MULTIPLE RELATIONS BETWEEN FACT-LEARNING AND PRIMING IN GLOBAL AMNESIA.
M.M. Keane*, J.D.E. Gabrieli, and S. Corkin. (SPON: S. Wray). Department of Brain and Cognitive Sciences, and Clinical Research Center, MIT, Cambridge, MA 02139.

Despite their fact-learning deficit, globally amnesic patients can sometimes be influenced in a normal fashion by prior exposure to a stimulus, when subsequently asked to perform a task with that stimulus (priming). Until recently, the preservation of priming appeared to be unrelated to the severity and etiology of amnesia or to the locus of brain lesion. More recently, however, Graf and Schacter (1985) found that priming of new word associations was intact only in mildly amnesic patients. This link between an aspect of fact-learning (reflected in severity of amnesia) and some aspect of priming (for new word associations) led us to consider whether there are a variety of relationships between fact-learning capacities and different kinds of priming. In order to address this question, we examined the status of different kinds of priming (stem completion, homophone-spelling, lexical decision, fragment completion, naming of words and nonwords) in patients with amnesias of varying severity. These sorts of priming were selected because they have been dissociated from some measures of fact-learning in normal subjects.

In one experiment, we tested 4 patients with amnesias due to bilateral lesions of limbic-diencephalic structures. Two of them had severe amnesias (H.M. and a patient with Korsakoff's syndrome), and two had mild amnesias (a patient with bilateral stroke and another with encephalitis). Following exposure to a list of words, all four patients were impaired relative to normal control subjects in recall and recognition of the words, but the latter two patients were less impaired then the former. Nevertheless, all four patients showed similar and normal levels of stem-completion priming with the same words. In contrast, other studies with H.M. revealed an association between his fact-learning and priming performance on several tasks.

Thus, severity of amnesia interacts selectively with some but not other kinds of verbal priming. This finding suggests that some forms of verbal priming include a component mediated by neural systems subserving fact-learning. Further, these results call for reconsideration of some dissociations between priming and fact learning in normal subjects.

405.11 FAILURE TO IMPROVE A SKILL FOR MENTAL ROTATION IN GLOBAL AMNESIA. L. M. Parsons*, J.D.E. Gabrieli, and S. Corkin. Department of Brain and Cognitive Sciences and Clinical Research Center, MIT, Cambridge, MA 02139. (SPON: K. Nakayama).

Patients with global amnesia have been able to acquire and retain a variety of motor, perceptual, and problem-solving skills despite an impairment in fact learning. These patients demonstrated intact learning by gradually improving the efficiency of their performance across days. No explicit account exists, however, of the mechanisms of skill learning that specify what skills may be acquired by the neural systems that appear to mediate these patients' normal learning for such tasks as mirror reading and mirror tracing. By current understanding, it seems that an amnesic patient ought to possess and to be able to improve mental rotation skill. Observers often mentally rotate one object to the orientation of another when required to discriminate between identical and slightly different shapes seen at different orientations. The time to rotate an object mentally is usually a monotonically increasing function of the angle of rotation. The slope of the reaction-time/orientation function indicative of mental rotation can decline greatly with practice. Such decline in slope occurs gradually and does not appear to depend upon fact-learning processes.

In our study, the subjects were H.M., whose global amnesia followed bilateral medial temporal-lobe resection, and three normal control subjects of similar age and education. They pressed one button marked "normal" to indicate that an R was in the normal form, or another button marked "reversed" to indicate that an R was in the mirror-reversed form. Stimuli were presented at each of 12 rotations, 30° apart. Subjects performed 72 trials in each of two sessions (one hour apart) on three successive days.

As expected, H.M. had impaired memory for having performed the task or having seen the shapes in prior sessions. His initial performance was slow, but showed evidence of mental rotation comparable to that of normal subjects. Surprisingly, he showed no improvement in the mean reaction time of his judgment and no decrease in the slope of the reaction-time/orientation function. He did make fewer errors with practice, but the improvement could not be dissociated from a possible speed-accuracy tradeoff. Control subjects showed moderate improvements in all performance measures.

To the extent that these results indicate that fact-learning ability is necessary for improving skill in mental rotation, our finding suggests that we need to reformulate our conception of what skills amnesic patients can learn and what neural systems underlie mental rotation skill in normal subjects.

405.12 ACQUISITION OF PROBLEM-SOLVING SKILLS IN GLOBAL AMNESIA. J.D.E. Gabrieli, M. M. Keane*, and S. Corkin. Department of Brain and Cognitive Sciences, and Clinical Research Center, MIT, Cambridge, MA 02139.

The presence of spared learning capacities in global amnesia indicates that distinct neural systems subserve different kinds of memory. Understanding the functions of these neural systems requires knowledge about the cognitive mechanisms that support preserved learning. The present studies followed a report that an amnesic patient, H.M. (whose amnesia followed bilateral medial temporal-lobe excisions) could acquire and retain a skill for solving the Tower-of-Hanoi problem (Cohen and Corkin, 1981). In the Tower-of-Hanoi protocol followed by Cohen and Corkin, a prescribed set of questions was posed to subjects throughout the sessions in order to encourage all subjects to adopt the same effective strategy. In order to assess the role of those questions in H.M.'s learning, we readministered the problem to H.M. in a protocol in which examiner-subject discussions were minimized by not posing these questions. Under these conditions, H.M. failed to improve his solution efficiency across days. Unlike his performance in 1981, H.M. selected his moves very rapidly. His quick responses made it impossible to readminister the problem in the original fashion because there were no intervals in which an examiner could pose questions. Also remarkable was H.M.'s mastery, from the start of the current sessions, of some portions of the puzzle and his poor performance in other portions; his ability to extract himself from novel positions not encountered during efficient solutions was especially impaired. On a second test of problem-solving, the Missionaries-and-Cannibals problem, H.M. and two other amnesic patients (with amnesia due to Korsakoff's syndrome and bilateral stroke) demonstrated increasing efficiency across days.

These results are interpreted as being consistent with the idea that amnesic patients can learn problem-solving skills, but the role of examiner-patient interaction in shaping that skill merits further consideration in order to characterize the nature of that learning. Such consideration may be a prerequisite for understanding the theoretical significance of preserved problem-solving capacities in global amnesia.

SPECIFICITY OF SYNAPTIC CONNECTIONS AND SYNAPTOGENESIS

406.1 GROWTH CONES ISOLATED FROM IDENTIFIED *APLYSIA* NEURONS: ANALYSIS OF PROTEINS AND GLYCOPROTEINS. J. Protic* and R. T.Ambron, Dept. Anatomy and Cell Biology, Columbia University, New York, N.Y. 10032

Efforts to identify molecules that mediate synaptic interactions have been aided by the use of dissociated cell cultures. A particularly advantageous preparation utilizes *Aplysia* neurons, many of which are large and amenable to analysis by a variety of techniques. We have been using identified neuron L7, which innervates auricle muscles (Alevizos and Koester, '86), and the RUQ neurons that innervate muscles of the vasculature (Rittenhouse and Price,'86) When the individual neurons are grown in culture with their appropriate muscle cells, the growth cones firmly contact the target and in some cases induce spontaneous contractions. Intracellular stimulation of L7 causes contractions of the auricle muscles *in vitro* and evokes EJPs.

We presume that the molecules involved in target recognition are present on the surface of the L7 and RUQ growth cones. RUQ cells have extraordinarily large growth cones in culture that can be isolated and analysed directly (Flaster et al.,1986). We first used a general labeling procedure to survey how many membrane constituents are present and then focused on the glycoproteins. Isolated growth cones were iodinated using either ^{125}I-Bolton-Hunter reagent or the chloramine-T method and a crude membrane fraction was obtained by centifugation. The radiolabeled proteins were resolved by 2D PAGE followed by fluorography. Over 50 polypeptide species were detected, including 7 components that are rapidly transported along axons of *Aplysia* neurons *in vivo* . These then constitute a group of synaptic polypeptides that are also present at growth cones.

The oligosaccharide moieties present in the glycoproteins on the RUQ growth cone surface were fractionated using a combination of lectin affinity chromatography, gel filtration, and HPLC. This protocol has successfully resolved nine classes of glycopeptides from the glycoproteins of individual *Aplysia* neurons. RUQ cells were grown in the presence of ^{3}H-glucosamine for 24h and the growth cones collected. ^{3}H-glycopeptides, released from the glycoproteins by pronase treatment, were analyzed and six species were found to be enriched in the growth cones. None of these glycopeptides bound to Concanavalin A, but at least one binds to wheat germ agglutinin (WGA). The localization of this species was confirmed by the extensive binding of FITC-WGA to growth cone membranes. Interestingly, analyses of several neurons,including L7, have shown that similar WGA binding glycopeptides are constituents of axonally transported glycoproteins. These may then constitute a class of glycopeptide that is present at all growth cones. We do not yet know if there are differences in the composition of the glycopeptides among the cells. To see if these glycopeptides will bind to target cells, we used WGA-agarose to isolate the glycopeptides from neurons of 180 ganglia. The bound material was coupled covalently to 0.9um fluorescent beads which were then added to muscle cells in culture. We found intense labeling of certain muscle types. The nature and specificity of the binding is now under investigation. Supported by The MDA and NIH.

406.2 **SELECTIVE SYNAPTOGENESIS AND MODULATION OF JUNCTIONAL CONDUCTANCE IN CULTURED NEURONS OF *APLYSIA*.** G.M. Carrow and I.B. Levitan. Graduate Department of Biochemistry, Brandeis University, Waltham, MA 02254.

Neurons grown in primary culture after dissociation often exhibit selectivity in the formation of synapses. For example, pairs of neurons obtained from homologus ganglia or cell clusters ("homologous" pairs) in the mollusc, *Aplysia californica*, show different patterns of connectivity than cell pairs derived from heterologous ganglia ("heterologous" pairs). We have now found that selectivity in formation of electrical synapses between cultured *Aplysia* neurons is expressed as a difference in junctional conductance.

We examined electrical synapses in homologous and heterologous pairs of neurons derived from juvenile buccal and pleural ganglia as well as from bag cell clusters in the adult abdominal ganglion. The neurons were dissociated after treatment of the ganglia with dispase and were grown in a modified L-15 medium plus hemolymph at 19°C. After the neurons had grown overlapping neurites, each cell of a pair was voltage clamped with a single microelectrode by switching between current injection and voltage monitoring. In order to obtain a direct measure of junctional conductance, both cells of a pair were clamped to the same membrane potential, transjunctional voltage pulses were applied, and the resulting junctional current monitored.

Homologous pairs of cells were coupled with a high junctional conductance in the range 10 to 25 nS, similar to that previously shown for pairs of buccal neurons (Bodmer et al., 1987, *J. Neurosci.*, in press). Although heterologous pairs of cells were also coupled when grown in the presence of hemolymph, the junctional conductance in these cases was low, ranging from 1 to 5 nS. As previously found for buccal pairs, both classes of junction were non-rectifying, ungated by voltage, and resistant to treatment with 1 mM octanol. These shared properties indicate that the various cell types have similar junctional channels. Thus, the observed dichotomy in junctional conductance may result from modulation of a single type of junctional channel. A further indication that these channels may be modulated is our finding that the effect of Concanavalin A on promoting electrical coupling between heterologous cells (Lin & Levitan, 1986, *Soc. Neurosci. Abstr.* 12:540) likely results from an increase in junctional conductance induced by the lectin.

The observation of strong electrical coupling *in vitro* between neurons with a common ganglionic origin is consistent with observations of intraganglionic electrical coupling *in vivo* for each of these cell types. By contrast, interganglionic electrical coupling has rarely been observed in *Aplysia*. It remains to be determined how these cells are able to distinguish homologues from non-homologues. The ability to quantify and modulate electrical coupling in the simple system described here should facilitate study of this and other problems of connectivity. 406.3 IN VITRO ANALYSIS OF POSITION-DEPENDENT SELECTIVITY DURING THE INITIAL STAGES OF SYNAPTOGENESIS. D.H. Sanes*, D. Lo, and M.-m. Poo. Section of Molecular Neurobiology, Yale University School of Medicine, New Haven, CT 06510.

It has been proposed that the location of a cell within the pre- and postsynaptic populations may endow it with a unique molecular identity. This positionally derived information could be of use in establishing the appropriate pattern of synaptic connections. We have begun to test this hypothesis using an in vitro preparation of neurons and myocytes obtained from disparate axial positions of the Xenopus embryo.

Fertilized eggs were injected with rhodamine- or fluorescein-conjugated dextran. When the embryos had progressed to Nieuwkoop and Faber stages 22-24 they were prepared for primary culture. The neural tube and myotome were dissected free and sectioned into 4-6 equivalent pieces. The most rostral segments from rhodamine labeled animals, and those segments located approximately 75% caudally from fluorescein labeled animals, were dissociated and cocultured for 1-2 days at room temperature. Myoballs were manipulated into contact with neurons of same or different label (i.e. axial position), and the quality of induced synaptic transmission was monitored using whole-cell recording techniques.

Both rostrally and caudally derived myoballs were capable of eliciting transmitter release from the same neurite. There was no apparent difference in frequency or amplitude of the spontaneous end-plate currents over the course of 1-10 minutes. In addition, we have observed synaptically elicited contractions for positionally unrelated nerves and myocytes that had been in contact for several hours. We are currently investigating these more extended time points in a quantitative manner. The ability of rostrally or caudally derived myoballs to adhere with a neurite does not appear to be influenced by position either, although our assay is not quantitative. When a positionally unrelated myoball is withdrawan from a neurite after 10 minutes in contact, the adhesion is capable of lifting the neurite off of the substratum. We tentatively conclude that there does not appear to be an initial preference for synaptic transmission or adhesion between cholinergic neurons and myocytes based upon their original axial position within the embryo. Supported by NS-22764 and NS-12961.

406.4 SENSORY NEURONS THAT INNERVATE A SPECIFIC TARGET ARE GENERATED OVER A PROTRACTED DEVELOPMENTAL PERIOD. B. Mendelson and E. Frank. Dept. of Neurobiology Anatomy and Cell Science, University of Pittsburgh, Pittsburgh, PA 15261.

The times of last cell division (birthdays) of sensory and motor neurons that innervate the triceps brachii muscles of the bullfrog forelimb were determined to learn if neurons that innervate a specific target are generated at a specific developmental time. Previous investigators, examining the generation of unidentified sensory and motor neurons, have suggested that large muscle sensory afferents may develop at earlier times than smaller neurons innervating cutaneous targets. We have combined ^{3}H-thymidine (^{3}H-TdR) autoradiography with HRP histochemistry to focus specifically on the development of neurons that innervate a particular target.

A labeling paradigm was implemented such that ^{3}H-TdR was available continuously throughout a specific developmental period. After the tadpoles metamorphosed, triceps neurons were labeled by filling them retrogradely with HRP. Any HRP-filled triceps neuron generated during the period of ^{3}H-TdR administration thus had a ^{3}H-labeled nucleus. The retinae of the same frogs were also examined since retinal neurons are known to be added continuously around the circumference of the eye during development. The pattern of labeled retinal neurons served to verify the sharp onset and continuous availability of ^{3}H-TdR during the period of labeling. Retinal cells born after the termination of ^{3}H-TdR injections were weakly labeled compared to those generated during the administration of ^{3}H-TdR.

All neurons that innervated the triceps muscle were generated prior to metamorphosis. However, triceps sensory neurons were generated over a protracted period of larval development, from early limb bud through early pre-metamorphic stages. Their time course of generation parallels that previously described for all other brachial sensory neurons. We also observed no strict relationship between sensory soma size and birthdate; large and small triceps neurons were labeled at both early and late developmental times. Thus, the time of origin of triceps sensory neurons is not a discrete developmental event; triceps afferents appear to be generated at the same time as neurons that innervate other brachial muscles and those that innervate cutaneous targets.

Triceps motoneurons were born earlier than the sensory neurons. Fewer than 5% of the triceps motoneurons were labeled after ^{3}H-TdR injections performed at early limb bud stages, and no triceps motoneurons were labeled at later developmental times. Thus, triceps motoneurons are born only during embryonic and early larval stages.

406.5 SPECIFICITY OF DEVELOPING SENSORY PROJECTIONS TO THE SPINAL CORD. Carolyn L. Smith Dept. Neurobiol. Anat. & Cell Sci., Univ. Pittsburgh Sch. of Med., Pittsburgh, PA 15261.

Sensory neurons have highly stereotyped central projections. Neurons in each ganglion project to specific segments of the spinal cord and arborize in specific laminae. However, following removal of dorsal root ganglia from tadpoles, neurons in adjacent ganglia can project to areas of the spinal cord they do not normally innervate (Frank and Westerfield, J. Physiol. 324: 495, 1982; Smith and Frank, Brain, Behav. Evol., in press). A possible explanation of this plasticity is that developing sensory neurons project more widely than sensory neurons in adults and that partial deafferentation of the spinal cord allows the retention of these widespread projections.

To assess the specificity of sensory projections during their development, I used HRP to label central projections from dorsal roots in tadpoles at different developmental stages. Neurons in both thoracic and limb-level ganglia are generated throughout the first half of the larval period. Therefore, sensory fibers must grow into the spinal cord during these stages. Nevertheless, fibers from each ganglion arborize only at appropriate levels of the spinal cord. For example, thoracic sensory neurons form dense neuropils in the thoracic spinal cord and the brain stem. Although their axons pass through the brachial region, they rarely branch or form boutons at this level. This is true even at stages when no other sensory neurons arborize in the brachial region. Developing sensory neurons also project selectively to appropriate laminae. Thoracic sensory neurons, most of which are cutaneous afferents, arborize in the dorsal horn but not in the intermediate gray matter. Conversely, hypoglossal sensory neurons, which are muscle afferents, arborize in the intermediate gray matter but not in the dorsal horn. This specificity of developing sensory projections suggests that the novel projections formed by sensory neurons following removal of adjacent ganglia are actually *induced* by the operation. Since sensory neurons also innervate wider areas of the periphery than normal after removal of adjacent ganglia, one possibility is that they are induced to form novel central projections by their novel peripheral targets. An unexpected finding was that afferents from the limbs only begin to arborize in the regions around their own dorsal roots several stages *after* they form projections to more rostral and more caudal regions of the spinal cord. These differences in the stages at which projections to different spinal levels develop suggest that local properties of the spinal cord may control the timing of sensory fiber arborization.

406.6 **Specific Synaptic Connections Between Muscle Sensory and Motor Neurons Form in the Absence of Coordinated Patterns of Muscle Activity.** E. Frank, Dept. of Neurobiology, Anatomy & Cell Sci., Univ. Pittsburgh, Pittsburgh, PA 15261.

The synaptic connections between stretch-sensitive muscle sensory afferents and spinal motoneurons are highly specific, but the mechanisms responsible for assuring the specificity during development are unknown. One possibility is that the temporal correlation (or anti-correlation) of electrical activity in pre- and post-synaptic neurons reinforces appropriate synaptic connections. To test this possibility experimentally, I disrupted the normal motor activity patterns of limb muscles in tadpoles during the developmental period when sensory-motor connections are made centrally, and then assessed the effects of this disruption on the pattern of these connections after they had formed.

The motor innervation of forelimb muscles was disrupted unilaterally in bullfrog tadpoles at midlarval stages (Taylor & Kollros XIV to XVII) by removing a 0.5-1.0 mm segment of the second ventral root, which contains the axons of all motoneurons innervating the forelimb. Motoneurons subsequently reinnervated muscles in a non-specific manner (Farel, PB, *JCN* 254:125, '86). Sensory fibers were not disturbed. Because sensory-motor connections normally begin to form at Stage XVII, many synapses probably formed while the muscles had no motor input, and even after reinnervation had occurred, the motor activity was uncoordinated since each muscle was innervated by different kinds of motoneurons. After the tadpoles completed metamorphosis, the amplitudes of monosynaptic EPSPs from triceps muscle sensory afferents in identified limb motoneurons were measured by intracellular recording. The degree of disruption of motor innervation was checked in each frog by retrogradely labeling those motoneurons that reinnervated the triceps brachii muscles with HRP.

Whenever the reinnervation of triceps muscles was non-specific (as judged by HRP labeling), the projections of triceps sensory neurons onto limb motoneurons were functionally inappropriate. Motoneurons innervating triceps muscles, which normally have large triceps EPSPs, frequently received very little triceps input whereas motoneurons innervating other muscles, which normally receive little triceps input, often had large triceps EPSPs. However, different populations of triceps sensory afferents selectively innervated the same subpopulation of limb motoneurons; there was a strong positive correlation between the strengths of inputs from medial vs. internal-external triceps afferents onto individual motoneurons, even though these strengths did not correlate with the functional identity of the motoneuron, as they do in normal frogs.

The selective innervation of a specific subpopulation of motoneurons by triceps sensory afferents suggests that the mechanisms for assuring this selectivity have remained intact despite drastic changes of motor activity. This result is consistent with a chemoaffinity mechanism where connections are determined by matching chemical markers on sensory and motor neurons. Triceps sensory afferents would innervate "triceps" motoneurons even though some of them now project to non-triceps muscles, and "non-triceps" motoneurons would receive little triceps input even though some of them now project to triceps muscles. However, mechanisms dependent on correlated patterns of electrical activity in sensory and motor neurons would not produce selective patterns after such manipulations.

406.7 **CORRESPONDING SPACIAL GRADIENTS OF TOP MOLECULES IN DEVELOPING RETINA AND OPTIC TECTUM.** D. Trisler and F. Collins. Lab. Biochem. Genet., NHLBI, NIH, Bethesda, MD 20892 and Dept. Anat., Univ. Utah Sch. Med., Salt Lake City, UT 84132

The topographic map of cell position in avian retina is inverted in its projection to the optic tectum. Dorsal retinal ganglion cell axons project to ventral tectum and ventral retinal ganglion cells project to dorsal tectum. Topographic gradients of TOP molecules along the dorsoventral axes of retina and tectum also are inverted. In the retina the highest level of TOP detected with α-TOP monoclonal antibody was present dorsally; in optic tectum TOP was most abundant ventrally. Ten-fold gradients of TOP were detected in both the retina and tectum of 5-day embryos.

Immunofluoresence studies of α-TOP antibody binding to tissue sections from retina and tectum revealed a ring pattern of fluoresence around most or all cells from the pial surface to ventricular surface of tectum and from the vitreal surface to the pigmented epithelium of retina. All cells in any region along the dorsoventral axes expressed similar levels of TOP, but the amount of TOP per cell varied continuously along the axis of the gradient in both retina and tectum. Thus, TOP can be used to identify cell position along the dorsoventral axis of developing tectum as well as retina.

TOP was present in retina and tectum at all ages tested from embryonic d.3 to adult. The level detected in tectum decreased during this period while that in retina increased. Five-fold more TOP was detected in ventral than in dorsal half tectum of d.3 to d.8 embryos. The level of TOP in tectum after d.10 was too low for us reliably to detect dorsal-ventral differences. TOP gradients were present in both retina and tectum when retinal axons arrive at the tectum on day 6 of development and were present during the initial retinal-tectal interactions as retinal axons are growing across the tectum. The presence of corresponding TOP gradients in retina and tectum at this time in development suggests a possible role for the molecule in orienting the dorsoventral axis of the retinal projection onto the tectum possibly by homophilic interactions between TOP molecules.

406.8 NEONATALLY DEAFFERENTED TRIGEMINAL INTERPOLARIS CELLS EXPRESS CERVICAL RECEPTIVE FIELDS WITHOUT CERVICAL PRIMARY AFFERENT SPROUTING. L.A. Morse*, B.G. Klein & M.F. Jacquin (SPON: K.R. Smith). Dept. of Neuroscience, N.Y. Coll. of Osteopath. Med., Old Westbury, NY 11568.

Trigeminal (V) brainstem subnucleus interpolaris (SpVi) contains an anatomically and functionally diverse population of neurons. In normal adult rat, local circuit neurons have small receptive fields (RF), each reflecting input from 1 class of receptor organs (e.g. 1 whisker). Thalamic- or cerebellar-projecting SpVi cells have larger RF's and correspondingly larger dendritic trees; yet convergence is restricted to 1 class of receptor organs (e.g. multiple whiskers without intervening guard hairs or skin). However, these intramodality convergent RF's never include receptor surfaces innervated by cervical primary afferents (PA's). We have previously shown that neonatal infraorbital nerve section results in a sparse infraorbital PA projection to SpVi in adulthood, and that surviving deafferented cells often have altered RF's which incorporate a variety of V receptor organs (Stennett et al., Soc. Neurosci. Absts. 12:543, 1986). We now report that some neonatally deafferented SpVi cells express intermodality-convergent RF's spanning V and cervical fields. Intra- and extracellular recording, electrical stimulation, and RF mapping procedures were used to study the responses of SpVi neurons. In 23 Nembutal-anesthetized rats subjected to left infraorbital nerve section at birth, 141 cells were isolated in left SpVi. Cells recorded in the medial half of SpVi, while often exhibiting unusual forms of V convergence, never expressed cervical inputs. However, of 86 cells isolated in the lateral half of SpVi, 12 (6 thalamic-projecting, 3 cerebellar-projecting, 3 local circuit neurons) had RF's which included V vibrissae, guard hairs, and/or skin, as well as ipsilateral cervical ear, neck, shoulder, arm, forepaw glabrous and/or hairy skin. Their latencies to V ganglion, thalamic, or cerebellar shocks did not differ from normal. In 4 cases, the V component was restricted to the extreme caudal mandibular vibrissa and/or guard hairs, though in the remaining 8 cells it extended well into the whisker pad. Mechanical displacement thresholds for discharging these cells from each of these regions were equivalent.

In 4 similarly lesioned adults, HRP was injected subcutaneously and bilaterally into forepaw, arm, and shoulder regions. The distribution of PA terminals in cervical dorsal horn and dorsal column nuclei was identical on the 2 sides. In 1 case, 1 labeled axon penetrated lateral SpVi on the left side; otherwise, SpVi was free of label. Thus, it is unlikely that cervical PA sprouting into SpVi will account for cervical RF's in deafferented SpVi cells. An alternative mechanism is postsynaptic morphological changes. 5 SpVi cells with cervical RF's were stained with HRP; 4 of these had morphologies which were indistinguishable from normal. Cervical RF's in deafferented SpVi cells may, therefore, reflect plasticity in descending systems or activation of normally ineffective synapses.

406.9 THE COMBINED EFFECTS OF UNILATERAL ENUCLEATION AND LIGHTING CONDITIONS ON THE SYNAPSE-TO-NEURON RATIOS IN THE RAT VISUAL CORTEX. K.S. Bedi* (SPON: L. Crnic). Department of Anatomy, University of Aberdeen, Marischal College, Aberdeen AB9 1AS, Scotland.

Unilateral enucleation of rats soon after birth or rearing animals in dark conditions during early postnatal life have both been shown to affect the morphology of the visual system. One of the questions which arises from these studies is whether combined dark rearing and neonatal enucleation interact with each other in their effect on the visual centres. This study was designed to examine this question.

Rats whose right eye was removed on day one after birth and non-enucleated rats were raised in either light or dark conditions from birth until 39 days of age when they were killed. Stereological procedures were used to estimate the synapse-to-neuron ratios in layers II to IV of both the right and left visual cortices of each rat.

Light reared non-enucleated rats had about 16100 synapses-per-neuron in both right and left cortices. Rearing non-enucleated rats in the dark reduced this value to between 11000 and 12000. There were no significant differences in the synapse-to-neuron ratios in the right or left visual cortices between enucleated and non-enucleated rats raised in the light. However dark reared enucleated rats showed significant deficits in the ratio in both visual cortices. The extent of this deficit was more marked in the contralateral than the ipsilateral (to the enucleated eye) visual cortex. The decrease in the contralateral visual cortex was not significantly greater than that observed in the corresponding cortex from dark reared non-enucleated rats.

These results provide useful information on the combined and separate effects of unilateral enucleation at around birth and dark rearing during early life on the interneuronal connectivity of both the ipsi- and contralateral visual cortices of rats. They also show the vast importance of visual stimulation for the normal development of the subcortical visual centres.

406.10 **DEVELOPMENT OF PERFORATED SYNPASES IN THE ECTOSTRIATUM OF NORMAL AND MONOCULARLY DEPRIVED ZEBRA FINCHES.** Barbara Nixdorf*, University of Bielefeld, Department of Biology, Postfach 8640, 4800 Bielefeld, FRG

An electron-opaque postsynaptic density (PSD) is one of the defining characteristics of synapses. Siekevitz (1985) has suggested that this feature is functionally important and may participate in plastic changes in brain structure and function. Perforations are frequently observed in the PSD. Nieto-Sampedro et al. (1982) have proposed that synapses with perforations may represent intermediate stages in an ongoing cycle of synapse turnover that is part of the normal maintenance and adaptation of the nervous system. Thus, the incidence of perforations may be an indication of synaptic turnover and synaptogenesis.

I studied the incidence of perforated synapses at several early ages in the ectostriatum (the telencephalic projection area of the tectofugal pathway) of zebra finches which were visually normal or had been monocularly deprived. Normal finches were prepared for EM at ages 5, 10, 20 and 100 days (n=3 each;details in Nixdorf & Bischof, JCN 250: 133, '86). Micrographs covering more than 4000 μm^2 were scanned at each age. At 5 and 10 days, ectostriatum contains about 7 perforated synapses/ 1000 μm^2. This rises to about 19 at 20 days ($p<.05$) and stays high at 100 days. Although synapses with a *single* perforation increased only slightly in number ($p=0.1$) from 10 to 20 days, synapses with *two or more perforations* increased by 600% ($p<0.05$). At 100 days, the number of multiple perforated synapses decreased again ($p=0.02$), however the number of perforated synapses of all sorts per unit area remained constant.

Monocular deprivation affects the incidence of perforated synapses. In birds with one eye occluded from hatching to day 20 (n=5), the incidence of perforated synapses is 30% lower on the deprived than the nondeprived hemisphere ($p<.01$). The nondeprived hemispheres are similar to those of controls. After 100 days of deprivation (n=5), the number of synapses with single perforations is similar across groups. The number of synapses with multiple perforations is higher in the nondeprived hemispheres than either the deprived hemispheres or the control hemispheres ($p<.02$) Thus monocular deprivation seems to have a twofold effect on the development of perforated synapses: in juvenile birds the ultrastructural effects are found on the deprived side, whereas in the adult bird the effects appear on the nondeprived side.

If perforated synapses indicate intermediate stages of synapse turnover, then the highest activity in normally reared birds would be found at the 20 day stage when they are just fledged and start to fly. Visual deprivation could cause a delay in synaptic development in deprived areas and subsequent hypertrophy in nondeprived areas. 406.11 THE SYNAPTIC COMPOSITION OF NEOCORTICAL TRANSPLANTS, A QUANTITATIVE ANALYSIS. B.C. Cree*, L.M. Smith, F.F. Ebner. Center for Neural Science, Brown University, Providence, R.I.

The synaptic composition of normal (5 week, age-matched control) BALB/c mouse parietal neocortex was compared to that of transplanted E-14 and E-18 embryonic cortex after maturation in adult host neocortex. Electron micrographs were quantified for the type and frequency of axon terminals and synaptic contacts. Stereological techniques were used to determine axon terminal, synapse, and cell soma densities. Several striking features of synaptogenesis under transplant conditions are that the ratio of round to flat to unknown vesicle types, the ratio of asymmetric to symmetric to unknown membrane differentiation, and the ratio of dendritic shaft to dendritic spine contacts are almost identical to the ratios found in age-matched normal neocortex. Therefore, the types of axon terminals and synapses in the transplants appear to be closely regulated by the transplant neurons since thalamocortical and commissural fibers from the host brain do not grow into intact block transplants in normal hosts.

Both transplants and controls developed the same density of axon terminals; however, the axon terminals in the transplants formed fewer synapses than controls. Furthermore, the numerical density of E-18 cell bodies was comparable to the controls while the E-14 transplants exhibited a substantially higher cell body density. As a result, the synapse to neuron and axon terminal to neuron ratios were significantly lower in the E-14 transplants than in controls and E-18 transplants.

These results suggest that use dependant (sensory experience) and state dependant (changes in the level of excitation) mechanisms do not influence the density of axon terminals and the types of synapses; however, these factors seem to influence synapse density. Finally, donor age significantly affects the number of neurons present in the transplants and therefore strongly influences the synapse to neuron ratio (supported by NIH grant #NS-13031).

CATECHOLAMINES V

407.1 RADIOAUTOGRAPHIC DEMONSTRATION OF THE INCREASING IMPORTANCE FROM RODENT TO PRIMATE, OF DOPAMINERGIC AS COMPARED TO SEROTONERGIC INNERVATION OF THE CEREBRAL CORTEX. B.Berger*, S.Trottier*, C.Verney*, P.Gaspar*. INSERM U106, Hopital Salpetrière, 75651 Paris cedex 13, and U97, 2ter Rue d'Alésia, 75014 Paris FRANCE (sponSOTELO)

Biochemical(Brown & al.)and catecholamine fluorescence studies (Levitt & al.),immunodetection of tyrosine hydroxylase(TH)(Lewis & al.)have suggested an extensive dopamine(DA)innervation in the primate cerebral cortex.To specifically visualize DA and serotonin (5HT) afferents to the neocortex in Cynomolgus monkeys,we developed an in vitro approach using uptake of tritiated amines.Vibratome sections were incubated with pargyline 10-4M and with: either DMI 5.10-6M and (3H)DA 2.10-7M for DA-axons labeling or cold norepinephrine 5.10-6M and (3H)5HT 5.10-7M for 5HT-axons labeling.Addition of specific uptake inhibitors:benztropine or fluoxetine prevented the visualization of DA or 5HT axons respectively.

The 3 motor areas (4,6,SMA) exhibited the densest DA innervation with a characteristic pattern of cluster-like accumulations in layer III(Berger & al.Neurosc.Let.1986,72,121).In the other areas,the presence or absence of a layer IV was paralleled by a distinct pattern of laminar distribution.In the agranular anterior cingulate cortex, DA fibers reached all layers but more densely layer I and V-VI. On the contrary,the granular prefrontal,parietal,temporal and posterior cingulate cortices exhibited a bilaminar-like pattern with two dense bands in deep layer I and in layers V-VI. A variable number of labeled axons crossed layers II to IV,sometimes forming small ascending fascicles with an occasional cluster in layer III. In the transition zone between the primary motor area 4 and the postcentral area 3: area 3a where a layer IV is hardly visible,much more DA fibers ran through layer III than in the other parts of the granular parietal cortex. The primary visual cortex (a.17) displayed the weakest DA innervation almost confined to layer I whereas in area 18,both layers VI and V also received a slight innervation.

A widespread 5HT innervation characterized all cortical areas. Contrary to the DA innervation,its regional density followed a general rostrocaudal increasing gradient,the highest density being observed in the visual areas 17 & 18,with the characteristic laminar distribution described by Morrison & Foote using immunocytochemistry and the lowestdensity in the motor areas.

When compared to the restricted DA terminal fields in the rat, this extensive DA innervation of the cerebral cortex in monkey and probably also in man as shown by TH and DBH immunodetection,suggests an increasing and diversified functional role of this amine in phylogeny. Whether these DA afferents constitute different systems with distinct origin and timing of development as shown in the rat is now worthwhile further analysis.

407.2 **DOUBLE LABELING USING FLUORO-GOLD REVEALS NEUROTRANSMITTER IDENTITY OF AFFERENTS TO LOCUS COERULEUS.** V.A. Pieribone, G. Aston-Jones, M. Bohn[1] and H. Bernstein-Goral[1] (Spon: D. Schuster), Dept. Biol., New York Univ., NY 10003 and [1]Dept. Neurobiol. Behav., SUNY-Stony Brook, NY 11794.

We have reported that retrograde transport of wheat germ agglutinin-horseradish peroxidase (WGA-HRP) reveals major afferents to LC in paragigantocellularis (PGi) and prepositus hypoglossi (PrH), in the area of C1 and C3 adrenergic neurons in rostral medulla, respectively. To study the neurochemical identity of these afferents to locus coeruleus (LC), we have developed a sensitive retrograde method using small deposits of Fluoro-Gold (FG). We agree with Schmued and Fallon (1986) that this tracer offers many advantages over others. We have found that (i) FG can be microiontophoresed to produce dense focal deposits, (ii) cellular recordings from injection pipettes allow physiologic identification of injection sites, (iii) FG is not taken up by fibers of passage, (iv) FG is as sensitive as the WGA-HRP/TMB method, and (v) FG can readily be combined with immunofluorescence to identify neurotransmitter(s) of afferent neurons.

Dense iontophoretic deposits of FG, restricted to LC, were made from micropipettes (10 um tips). Single cell recordings from the injection pipette were used to locate LC. After 5 days animals were perfused, and brain sections were subjected to rhodamine-immunofluorescent detection of phenyl-N-methyl transferase (PNMT), a marker of adrenergic cells, or serotonin (5-HT). Alternate fluorescent illumination revealed cells in the same section that fluoresced for FG, rhodamine, or both.

The most common LC afferent neurons in PGi and PrH were medium-sized (380 um^2) fusiform and triangular cells, but a more lateral group of large (700 um^2) multipolar LC-projecting cells could also be identified in the PGi area. LC afferents were closely intermingled with PNMT-positive cells in PGi and PrH. In PGi, 21% of FG-labeled neurons were also immunoreactive for PNMT. Doubly labeled neurons appeared to be preferentially located in rostral and medial PGi, while the larger LC afferent neurons in lateral PGi were devoid of PNMT. In PrH, only 4% of LC afferent neurons also stained for PNMT. Initial results indicate that a minority (<10%) of LC-projecting neurons in these areas exhibit 5-HT immunoreactivity. These results reveal that LC receives adrenergic and serotonergic inputs from its two major afferents, but that the majority of inputs from PGi or PrH supply neither transmitter; thus, multiple neurotransmitter systems innervate LC from each of these areas. Additional studies are underway to determine the neurochemical identity of other LC afferents in PGi and PrH.

407.3 Effects of Stress on the Estimated Activity of Discrete Populations of Mesoamygdaloid Dopamine Neurons. C.D. Kilts, T.D. Ely* and C.M. Anderson* (Spon: N. Cant). Dept. of Psychiatry and Pharmacology, Duke Univ. Med. Center, Durham, NC 27710.

Populations of dopamine (DA) neurons have been demonstrated to be selectively activated or inhibited by stress. In spite of the fact that the amygdala has been shown to be critically involved in neuroendocrine, autonomic and gastric responses to stress, the effect of stress on mesoamygdaloid DA neurons has not been well examined. Mesoamygdaloid DA neurons are organized into distinct populations innervating the discrete component nuclear groups of the amygdaloid complex and exhibit a composite of mechanisms of regulation and signal transduction strikingly different from that of other DA systems. We have undertaken a systematic study of the effects of physiological and psychological stress on the biochemically estimated activity of mesoamygdaloid DA neurons with the initial results being presented here. Groups of rats were subjected to 60 min of restraint stress and then immediately sacrificed and the amygdaloid and other brain nuclei of interest were micropunch dissected. The content of DA, DOPAC and HVA were determined by on-line trace enrichment HPLC with electrochemical detection. Consistent with previous reports (Demarest et al., Neuroendocrinology 41:437, 1985), restraint stress decreased the estimated activity (DOPAC, DOPAC/DA) of tuberoinfundibular DA neurons. Mesoamygdaloid DA neurons were differentially responsive to restraint stress with the activity (DOPAC/DA) being decreased in the lateral and cortical, but not central or basal amygdaloid nuclei.

These results suggest that DA neurons may modulate the stress response mediated by amygdaloid mechanisms and further support the functional heterogeneity of populations of mesoamygdaloid DA neurons. The response of mesoamygdaloid DA neurons to stress is opposite that of other mesotelencephalic DA neurons and resembles that of tuberoinfundibular DA neurons. The examination of the response to other forms of stress as assessed by distinct techniques of biochemical estimation will further test these preliminary observations and are in progress.

407.4 IN VIVO NEUROCHEMISTRY OF STRESS: BIOGENIC AMINE METABOLITES IN FRONTAL NEOCORTEX OF ESCAPABLY VS. INESCAPABLY STRESSED RATS WITH BRAIN MICRODIALYSIS PERFUSION. F. Petty and G. F. Kramer.* VA Med Ctr and Univ of TX Health Science Ctr, Dallas, Texas 75216

We here report use of the new technique of brain microdialysis perfusion to study biogenic amine metabolism in frontal neocortex of rats before, during and after exposure to stress. Probes for microdialysis perfusion were implanted in frontal neocortex of anesthetized rats under stereotaxic guidance one day prior to stress exposure. A yoked experimental design was used in which pairs of rats received identical amounts of tail-shock (0.8 mA) while confined to small plexiglass boxes equipped with wheels, which one rat could turn to terminate the tail-shock (coping). Eighty unsignaled shocks were delivered during the 90-minute stress session. Control rats were similarly confined and had electrodes attached but no shock delivered. Perfusion of the microdialysis probe was maintained before and after shock presentation. Samples of perfusate were collected at 20-minute intervals and injected immediately onto a electrochemical HPLC. Levels of DOPAC and HVA rose rapidly to 150-200% of baseline during the shock presentation, and returned to baseline soon after shock offset. Levels of 5-hydroxyindolacetic acid (5-HIAA) increased only slightly during shock. One day after the stress session, perfusion was reestablished, and the rats were tested for stress-induced behavioral depression (learned helplessness). No neurochemical differences were found between escapably vs. inescapably shocked rats during stress presentation and immediately after stress. On the day after stress there were no significant differences among the three experimental groups in levels of DOPAC or HVA, but animals receiving escapable shock had a significant higher level of 5-HIAA in cortical perfusate than either controls or animals receiving inescapable stress.

In a separate experiment, diazepam administered intraperitoneally was found to block the stress- induced rise in dopamine metabolism in frontal neocortex in vivo, in a dose-dependent manner. These findings support the possibility that benzodiazepines may exert their effects in protecting against harmful effects of stress at least in part through an interaction with the mesocortical dopaminergic system. The results also support an involvement in frontal neocortical serotonergic metabolism in the development of behavioral depression after exposure to inescapable stress.

407.5 BILATERAL MICRODIALYSIS MONITORING OF STRIATAL DOPAMINE METABOLISM IN THE UNILATERALLY NIGROTOMIZED RAT: RESPONSES TO L-DOPA. P.J.Knott[1,2,5], T.S.Brannan*[3], H.C.Kaufmann*[3], C.Harden*[3], L.K.H.Leung*[4] and J.G.Young[2,4]
Departments of Neurobiology[1], Psychiatry[2], Neurology[3], Pediatrics[4] and Pharmacology[5]. The Mount Sinai School of Medicine, New York, N.Y. 10029, U.S.A.

We have used the microdialysis perfusion technique to bilaterally monitor the changes of striatal dopamine metabolism in the extracellular fluid (ECF) of unilaterally nigrotomized rats in response to L-DOPA administration both in the presence and absence of a peripheral decarboxylase inhibitor.

Male Sprague-Dawley rats (200-220g), unilaterally lesioned with 6-OHDA were tested one week after lesioning with apomorphine (1.0mg/kg). Rats demonstrating contralateral circling were selected for microdialysis studies under chloral hydrate anesthesia which were performed 4 weeks after lesioning. Bilateral microdialysis samples were obtained from striata at 20 min intervals using previously described probes (Clemens,J.A. and Phebus,L.A. Life Sci., 35: 671, 1984) and subsequently analysed by HPLC for dopamine (DA), dihydroxyphenylacetic acid (DOPAC), homovanillic acid (HVA) and L-DOPA. L-DOPA (50mg/kg i.p.) was administered immediately after obtaining three basal samples from each side in control (n = 9), or carbidopa-treated rats (100mg/kg i.p., injected one hour previously, n =5). Over the baseliine period, values for DA, DOPAC and HVA in dialysates from the lesioned side were always lower than from the intact side. In the absence of carbidopa, L-DOPA induced increases of extracellular DOPAC and HVA were found in the lesioned striatum to be about 50% of those observed from the intact side. In carbidopa-pretreated rats however, increases of ECF DA metabolites were comparatively minor when compared to those observed in the intact striatum (less than 10%). In all studies striatal tissue measurements of DA showed that lesions were near complete. These data indicate that in the absence of carbidopa, significant quantities of L-DOPA are metabolised peripherally to DOPAC and HVA and are able to reach the centrally implanted dialysis probes where they contribute significantly to to ECF concentrations of DA metabolites. We also noted that ECF L-DOPA concentrations were very similar in both lesioned and non-lesioned sides although tissue L-DOPA concentrations (presumably intracellular) were generally higher in the lesioned striatum. These findings have important implications to studies of precursor loading on DA metabolism, measured either by microdialysis or in striatal tissue.

407.6 MECHANISM(S) OF THE NICOTINE-INDUCED RELEASE OF NEWLY SYNTHESIZED DOPAMINE FROM RAT STRIATAL SLICES. T.C. Westfall, L. Vickery* and L. Naes*. Department of Pharmacology, St. Louis University School of Medicine, St. Louis, MO 63104.

Studies of nicotinic-cholinergic receptors in the mammalian brain have revealed high concentrations of nicotinic-high affinity binding sites in both midbrain and target areas of dopamine containing neurons. We have previously observed that high concentrations of nicotine (100-10,000 µM) release dopamine from striatal slices by either displacement of the amine in a manner similar to amphetamine or to activation of an atypical receptor since the response was not antagonized by classical nicotinic-cholinergic antagonists and was independent of extracellular calcium levels. In the present investigation we report the effect of low concentrations of nicotine and studies which have examined the mechanism by which low concentrations of nicotine release dopamine. Male Sprague Dawley rats were decapitated and striata rapidly removed over ice. Striata were dissected with glass manipulators, sliced sagittally with a MacIlwain tissue chopper at a thickness of 0.5 mm. The slices were placed in isolated chambers and continuously superfused with a buffer containing ^{3}H-tyrosine. Superfusate effluents were continuously collected by means of a fraction collector and ^{3}H-dopamine separated from other ^{3}H products by amberlite and alumina column chromatography and measured by liquid scintillation spectrometry.

Nicotine (1-100 µM) produced a concentration dependent release of newly synthesized ^{3}H-dopamine. The evoked release of ^{3}H-dopamine by 1 µM nicotine was attenuated by mecamylamine (10^{-5}M) or d-tubocurarine ($5x10^{-5}$M), was dependent upon extracellular calcium and reduced in the presence of tetrodotoxin (10^{-5}M).

Attempts were made to determine if cyclic AMP acted as a second messenger in mediating the nicotine-induced release of dopamine. The effect of 8-bromo cyclic AMP, dibutyryl cyclic AMP, 3-isobutyl-1-methylxanthine (all of which increase intracellular cyclic AMP levels) as well as 2',5'-dideoxyadenosine (known to inhibit adenylate cyclase) alone or in the presence of nicotine on the release of dopamine were examined. The cyclic AMP analogues as well as 3-isobutyl-1-methylxanthine released dopamine by themselves and dibutyryl cyclic AMP was found to produce an additive effect with nicotine. 2',5'-dideoxyadenosine failed to reduce the nicotine-induced release of dopamine.

It is concluded that low doses of nicotine release dopamine by activation of nicotinic cholinergic receptors. It does not appear that cyclic AMP is a second messenger in mediating this response.

407.7 ESTRADIOL STIMULATES DOPAMINE RELEASE FROM STRIATAL TISSUE IN VITRO. J.B. Becker, C.J. Moore*, J.-H. Cha* and B.L. Firestein*. Psychology Department and Neuroscience Laboratory Bldg. The University of Michigan, Ann Arbor, MI 48104-1687.

The systemic administration of estradiol potentiates amphetamine-stimulated striatal dopamine (DA) release and amphetamine-induced rotational behavior (Becker & Beer, Behav. Brain Res., 19:27, 1986). However, it is not known where estrogen acts to induce changes in these indicies of striatal DA activity. The absence of genome-activating estradiol receptors in the striatum has lead some investigators to hypothesize that these effects are indirectly mediated by estrogen's action on other brain areas and/or the pituitary. Nevertheless, local application of estradiol to the striatum is found to induce behavioral effects in ovariectomized (OVX) female rats, suggesting that estradiol can directly influence neural activity in the striatum (Becker et al., Pharmacol. Bioch. Behav., 1987, in press). In the experiments to be reported, we examine the influence of estradiol on the release of DA from striatal tissue in superfusion.

Striatal tissue from OVX adult female rats was dissected, sliced ($1mm^3$) and placed into superfusion chambers (Becker et al., J. Neurosci. Meth., 11:19, 1984). A modified Krebs-Ringer phosphate medium continuously flowed through the chamber at a rate of 100µl min, and samples were collected over 10 min intervals. In one experiment, after the collection of baseline samples, estradiol (0, 10,100, or 1000 pg/ml was infused for 30 min followed by infusion of 60mM K^+ for 2.5 min. In a second experiment, after collection of baseline samples, estradiol was infused in pulses [10 min estradiol (90 pg/ml); 20 min without estradiol] for 3 pulses (90 min). This was compared with the effect of estradiol infused continuously (30 pg/ml) for 90 min. Control superfusion chambers received infusions of vehicle (0.0015% ethanol in medium). DA in the effluent was measured by HPLC-EC.

The prior presence of estradiol in the superfusion medium at concentrations of 10,30,90 or 100 pg/ml (but not 1000 pg/ml) potentiated the subsequent responsiveness of striatal tissue to K^+ stimulation. The continuous infusion of estradiol had no effect on the basal efflux of DA at any concentration. In contrast, when estradiol was infused in pulses, estradiol alone stimulated the release of DA from striatal tissue slices in addition to potentiating the subsequent response to K^+-induced depolarization.

We conclude that estradiol can act directly on striatal tissue to both stimulate the release of DA and increase the responsiveness of DA terminals to stimulation. Since genome-activating receptors for estradiol are not present in the striatum, this suggests that estrogen is able to influence neural activity through an alternative mechanism or receptor. (Sponsored by NSF: #BNS84-11763).

407.8 REGULATION OF STRIATAL DOPAMINE SYNTHESIS: LACK OF DEPENDENCE ON PRECURSOR AVAILABILITY. N. Lake and J. Commissiong. Dept. of Physiology, McGill Univ., Montreal, Quebec, Canada H3G 1Y6.

Neurotransmitter in monoaminergic neurons may be regulated by the two following mechanisms: 1) the released transmitter is returned to the Ca^{2+}-dependent pool of releasable transmitter by an active uptake process, and re-released. 2) The released transmitter is catabolized, the synthetic enzymes are activated, and transmitter synthesis is enhanced. Two corollaries of mechanism #2 are that transmitter metabolites should rise, and in the homeostatic control of transmitter synthesis, precursor availability may become a limiting factor during release. Experiments were done using ♀ Sprague Dawley rats, 250 g, anaesthetized with Brietal (50 mg/kg i.p.). In the first experiment, the left medial forebrain bundle (MFB) was stimulated electrically (15 Hz; 400 µA; 20 min) using a stereotaxically-placed (L -1.4; H -1.9;AP+2.8) bipolar electrode. Under these conditions, striatal dopamine (DA) concentrations remained stable, and there was no increase in DOPAC or HVA, the major metabolites of DA. After the infusion of TTX (1.5 µl; 3.0×10^{-7} M) into the left MFB there was a sustained increase in the synthesis and metabolism of DA in the left striatum, which peaked at 4 hrs. At this time DA, DOPAC and HVA were all significantly increased ($p < 0.001$). This effect of TTX is linear over the 1.0×10^{-9} M to 1.0×10^{-5} M range. None of the precursors of DA, phenylalanine (PHE), tyrosine (TYR) nor L-aspartyl-L-phenylalanine methyl ester (aspartame or APM), each given at 250 mg/kg caused any significant increase in the TTX-induced synthesis and metabolism of DA, versus the saline-treated control. Valine, a member of the class of large, neutral amino acids (LNAAs), shares a common transport mechanism into the brain with PHE and TYR. It was administered at 400 mg/kg, i.p. to the TTX-treated rats, and is expected to block the transport of PHE and TYR into the brain, leading to a reduction in the TTX-induced increased synthesis of DA. However, after 4 hr, there was no statistically significant difference between the saline-saline and saline-valine groups, or between the TTX-saline and TTX-valine groups, for DA, DOPAC and HVA. The results suggest that 1) increased DA metabolism is not a necessary accompaniment of increased DA release. 2) The mechanisms that control dopamine homeostasis during episodes of real, increased synthesis are robust, and that within limits, neither increased nor decreased precursor availability exerts a significant effect on the enhanced synthetic process. Reuptake, not de novo synthesis, appears to be the important variable. Despite the wealth of published data, the mechanisms that regulate changes in monoamine release, synthesis and metabolism in the brain are still somewhat obscure.

Supported in part by the NutraSweet Co., Skokie, Ill.

407.9 THE EFFECT OF CHRONIC COCAINE TREATMENT ON CATECHOLAMINE DISPOSITION IN DIFFERENT BRAIN REGIONS IN RAT: A SPECIFIC TARGET EFFECT ON FRONTAL CORTEX DOPAMINE. F. Karoum, R. Fawcett* and R.J. Wyatt. Neuropsychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Cocaine is a non-amphetamine stimulant with poorly understood central catecholamine effects. Efforts to compare cocaine behavioral properties with changes in central catecholamine steady state concentration and metabolism generally reveal poor correlations. Nevertheless, the prevailing view in the literature favor a tendency for cocaine to preferentially influence central dopamine (DA). Paradoxically, in spite of a reported long-term reduction in tyrosine hydroxylase (Trulson et al.: Expt. Neurol. 94:1986) in the substantia nigra and caudate nucleus following 1 week chronic cocaine treatment, dopamine metabolism in the mesolimbic and caudate nucleus was reported to remain unchange or increased following acute (Bagchi: Neurosci. Abst. No# 38.17:1986) and chronic cocaine (Roy et al.: Neuropharmacology 17:1978) treatments. In an attempt to gain a better understanding of cocaine's effects on central catecholamines, we chronically administered cocaine (10 mg/kg twice daily) to rats for 1,2 and 3 weeks. Their hypothalami (Hy), hipocampi (HP), septa (SP), caudate nuclei (CN) and frontal cortex (Fx) were removed for analysis of norepinephrine (NE), DA and their metabolites 1 hour after the last treatment. In another experiment, rats were treated chronically for 1 week and their brains analyzed 6 weeks later. All biochemical analysis were carried out by mass fragmentography. There were five rats in each study.

One hour after an acute dose of 10 mg/kg, cocaine produced no reduction in NE, DA or their metabolites in any of the 5 brain regions analyzed. During the course of 1,2 and 3 weeks chronic treatment with cocaine (10 mg/kg twice daily) no change in NE or 3-methoxy-4-hydroxyphenylglycol (MHPG) concentrations was found in the above 5 brain regions. DA concentration was reduced by about 50% in the frontal cortex while remained unchanged in the Hy, HP, SP and CN during the course of the 3 weeks chronic cocaine treatment. The concentration of 3,4-dihydroxy-phenylacetic acid (DOPAC) was slightly (about 20%) but significantly reduced in the Hy, CN and SP. In contrast DOPAC concentration was markedly (about 50%) reduced in the Fx.

The results of brain analyses 6 weeks following the discontinuation of 1 week chronic cocaine treatment, indicated a continued long-term suppression of DA metabolism in the Hy, CN and Fx. Consistent with effects observed during chronic cocaine treatment, the Fx was the area most affected. NE and MHPG concentrations remained unchanged.

The results of the present study suggest a preferential effect of cocaine on central dopaminergic systems. Of the various regions assessed chronic cocaine appears to exert its best effects on Fx and Hy DA turnover or metabolism. These 2 brain regions may therefore play important roles in the long-term effects of cocaine.

407.10 BRAIN CATECHOLAMINE CONCENTRATIONS FOLLOWING SYSTEMIC TRETINOIN AND/OR HALOPERIDOL IN RATS. G.M. Straw*,F. Karoum (SPON: P. Oliver). Neuropsychiatry Branch, NIMH, Saint Elizabeths Hospital, Washington, D.C. 20032.

Previous work in this laboratory has suggested that behavioral habituation to arousal may be altered by retinoic acid administration, in synergism with co-administered haloperidol. A corollary hypothesis is that brain catecholamine activity is altered by such treatment. Evaluation of two areas of the brain was done in male Sprague-Dawley rats. All animals were dosed intraperitoneally. Control animals, Group 1 (N=5), received vehicle only. Group 2 (N=5) received haloperidol 1 mg/kg/day. Group 3 (N=4) received tretinoin 5 mg/kg/day. Group 4 (N=4) received haloperidol 1 mg/kg/day and tretinoin 0.5 mg/kg/day. Group 5 (N=4) received haloperidol 1 mg/kg/day and tretinoin 5 mg/kg/day. Four hours after the last injection the animals were sacrificed by decapitation and the hypothalamus and the right caudate nucleus were removed and assayed for catecholamines and metabolites by mass fragmentography (Karoum, F., in Methods in Biogenic Amine Research, ed. S. Parvez et al., 237-255, 1983). Dopamine (DA), homovanillic acid (HVA), and dihydroxyphenylacetic acid (DOPAC) were measured in the caudate nucleus; and DA, HVA, norepinephrine (NE), and 3-methoxy,4-hydroxyphenethyl glycol (MHPG) were measured in the hypothalamus. Multivariate analysis of variance results were consistent with significant changes in caudate DA ($p<.03$), caudate HVA ($p<.002$), caudate DOPAC ($p<.02$), and hypothalamic DOPAC ($p<.0001$). No significant changes were measured in hypothalamic DA, NE, or MHPG. Comparisons of group means by Tukey's method ($p<.05$) showed that the combination of haloperidol and tretinoin raised caudate DA and lowered both caudate HVA and caudate DOPAC. Tretinoin alone tended to lower caudate HVA, and haloperidol alone tended to raise caudate DOPAC, but neither effect reached significance. Haloperidol with tretinoin at 5 mg/kg/day caused a clear increase in hypothalamic DOPAC ($p<.05$) over all other conditions. A trend for tretinoin alone to increase hypothalamic DOPAC, but no effect from haloperidol alone is seen. These results are consistent with the hypothesis of a synergistic effect of tretinoin and haloperidol on central catecholamine activity. A dose dependency is seen for tretinoin in the hypothalamus.

407.11 DOES CYCLO(HIS-PRO)(CHP) ACT LIKE A DOPAMINERGIC AGONIST? C.PRASAD. Section of Endocrinology, Department of Medicine, Louisiana State University Medical Center, New Orleans, LA

CHP is a cyclic dipeptide that is ubiquitously distributed throughout a number of tissues and body fluids of both man and animals. Administration of exogenous CHP to animals has been shown to elicit a variety of endocrine as well as central nervous system-related biologic activities. Although the mechanism through which CHP acts is not understood, some of its biologic activities (e.g. attenuation of prolactin secretion, inhibition of dopamine (DA) uptake by striatal synaptosomes, and hypothermia in rats) suggest the potential involvement of a dopaminergic mechanism. To further examine the mechanism of action of this peptide, we have investigated relationship between CHP and DA using two different behavioral paradigm.

First, experiments were conducted to explore whether dopaminergic drugs modify CHP-induced hypothermia. Subcutaneous injection of CHP to cold-exposed (5°C for 12-14 hrs.) rats led to a dose-and time-dependent decline in rectal temperatures. Hypothermia increased with increasing CHP dosage reaching to a maximum of -0.91°C at 10 mg/kg. Fifty minutes following treatment with 10 mg/kg CHP, rectal temperature declined to a nadir of 0.91°C and then steadily rose to control levels by 90 min. Pretreatment of rats with DA-antagonists (0.05 mg/kg SCH23390 or 10 mg/kg sulpiride, in vitro antagonists of D_1- and D_2- receptors respectively) led to a significant attenuation of CHP-induced hypothermia (control, -0.63 ± 0.07; +SCH23390, -0.35 ± 0.04; sulpiride, -0.40 ± 0.03; $p < 0.05$). Furthermore, chronic oral treatment of rats with CHP (1.96 ± 0.4mg/kg/day for 24 days) led to a significant ($p < 0.01$) increase in the ability of apomorphine (APO, 1mg/kg) to induce hypothermia.

Next, we chose to investigate the effect of this peptide on stereotypic behavior (SB), a behavior associated with the activation of postsynaptic DA receptor, induced by APO or amphetamine (AMP). APO elicits this behavior by direct stimulation of postsynaptic DA receptor, whereas AMP acts indirectly by making more DA available at postsynaptic site. Thirty min. pretreatment of rats with 0.5 mg/kg CHP led to a significant augmentation of median SB induced by 5mg/kg AMP, but not APO (AMP, 1.85 ± 0.1; AMP + CHP, 3.60 ± 0.2; $p < 0.0025$ and APO, 2.0 ± 0.1; APO + CHP, 2.1 ± 0.18; $P > 0.10$). However, administration of large dosage of CHP alone to naive rat (50 mg/kg i.p. or s.c.; 5mg/kg i.c.v.) does not induce any motor activity change. In conclusion, our data suggest that within hypothalamus (thermoregulation) and/or basal ganglia (SB) CHP may act via a dopaminergic mechanism.

407.12 BRAIN IRON/FERRITIN ASYMMETRIES IN HEMI-PARKINSON RATS DEMONSTRATED BY MAGNETIC RESONANCE IMAGING. S. Hall*, J. N. Rutledge* and T. Schallert (SPON: E. Bigler). Dept. of Psych and Inst. Neurol. Sci., Univ. Texas, and St. David's Hospital, Dept. of Radiology, Austin, TX. 78712.

High concentrations of iron accumulates in the brains of several species, including rat, monkey and man. Because iron exists in areas that correspond roughly to the distribution of catecholamines and is necessary for dopamine (DA) metabolism, it has been suggested that iron may be involved, at least in part, in the function of DAergic neurons in the brain.

The distribution of iron can be demonstrated either by Perls' histochemical stain for ferric iron or by magnetic resonance imaging (MRI). Heavily T2-weighted images produced by MRI exhibit a decreased signal (T2*) caused by iron, probably in the form of ferritin.

Investigators studying MR T2-weighted images of patients with Parkinson's Disease and related disorders have reported both increased and decreased iron in the nigrostriatal system. To explore this issue further, brain iron distributions in rats were measured using T2-weighted MR images and Perls' method. Severe unilateral catecholaminergic depletions were produced by infusing 6-hydroxydopamine (6-OHDA) into the medial forebrain bundle or striatum of one hemisphere. Sham-control infusions were placed in the contralateral hemisphere of these same animals. Rats with bilateral-sham operations and naive controls were also examined.

Postoperatively, animals with unilateral lesions exhibited sensorimotor asymmetries which recovered in about 5 months. The behavior of control and bilateral sham-operated rats was normal. Asymmetries in iron/T2* effect were found in all unilaterally- lesioned rats scanned by MRI; however, some demonstrated an increased iron/T2* effect in the contralateral nigrostriatal region while others showed an increased iron/T2* effect on the ipsilateral side. Bilateral sham-operated and control rats had no asymmetries with either iron analysis.

MRI provides an analysis of brain iron unique from Perls' method that may be more relevant to studying diseases of catecholaminergic dysfunction. The finding that the side of catecholamine depletion did not predict the side of T2*/iron effect may bear importantly on conflicting reports of increased vs decreased iron in diseases of the extrapyramidal system.

AGING AND DEMENTIA: ANATOMY

408.1 PATHOLOGY IN BRAINSTEM CHOLINERGIC NEURONS IN ALZHEIMER'S DISEASE. E.J. Mufson and D.C. Mash. Inst. for Biogerontology Res., Sun City, AZ 85351 and Univ. Miami Med. Sch. Miami, FL.

Alzheimer's disease (AD) is characterized neuropathologically by neurofibrillary tangles (NFT) and senile plaques in the cerebral cortex, hippocampus and amygdala. Brainstem cortical projection neurons (e.g., serotonergic dorsal raphe and noradrenergic locus coeruleus) also contain NFT in AD. Recently, we have shown that all cholinergic neurons located within the monkey mesencephalic tegmental nuclei cuneiformis and tegmenti pedunculopontinus (Ch5) contain choline acetyltransferase as well as acetylcholinesterase (AChE) and these cholinergic perikarya project to widespread cortical areas (Mufson et al., Neurosci. Abstr. 8:135, 1982). The purpose of the present study was to determine whether these cholinergic neurons also contain NFT in AD. Both AChE and nicotinamide adenine dinucleotide phosphate (NADPH)-diaphorase histochemistry delineate tegmental cholinergic neurons (Vincent et al., Neurosci. 17:186, 1986). We used these histochemical procedures to localize cholinergic perikarya in the tegmentum of 4 AD (70-78yrs.) and 3 normal (66-78yrs.) patients.

Tissue reacted for either AChE or NADPH-diaphorase revealed positive neurons within a region of the deep tegmental grey corresponding mostly to the nuclei cuneiformis and tegmenti pedunculopontinus according to Olszewski and Baxter (1954). AChE stained neurons appeared brown and NADPH-diaphorase positive cell bodies dark blue. These enzyme positive neurons were arranged into a compact lateral and a diffuse medial subdivision. Both AChE and NADPH-diaphorase positive perikarya were seen to penetrate into adjacent fiber bundles. In order to demonstrate that NADPH-diaphorase and AChE co-localized within the same neuron, tissue was simultaneously stained for NADPH-diaphorase and AChE. Virtually all NADPH-diaphorase containing cell bodies also contained AChE.

Cortical and brainstem tissue stained with Thioflavin-S revealed many tangles and plaques in the AD samples and only a few in the normal aged brains. Tissue reacted individually or concurrently for NADPH-diaphorase and AChE was counterstained with Thioflavin-S. Tangles were found in many of these cholinergic neurons as well as within the locus coeruleus, dorsal and ventral raphe nuclei, medial parabrachial nucleus and pontine central grey. Plaques were found throughout the mesencephalic and medullary tegmentum as well as in the inferior colliculus. These results demonstrate that cholinergic neurons within the mesencephalic tegmentum which project to cortex exhibit neurofibrillary degeneration similar to that seen in noradrenergic and serotonergic cortical projection systems in AD. Supported by an ADRDA Faculty Scholar Award (EJM).

408.2 MAPPING OF TANGLES AND ALZ-50 IMMUNOREACTIVE CELLS IN AGED HUMAN BRAINS WITH AND WITHOUT ALZHEIMER'S DEMENTIA. J.L. Price, P. Davis* and L. Robins* (Spon: L. Berg). Depts. of Anat. & Neurobiol. and Psychiatry, Washington Univ. Sch. Med., St. Louis, MO 63110.

Previous studies have shown characteristic patterns of neurofibrillary tangles in the hippocampal formation of brains of Alzheimer's Disease patients (M.J. Ball, Acta Neuropath., 42:73, 1978; Hyman et al., Ann. Neurol., 20:472, 1986), and other reports indicate tangles in further structures of the limbic forebrain, including the amygdala, olfactory cortex and nucleus basalis. The present project is designed to precisely map tangles and other neuropathological markers in these areas and adjacent parts of the brain. Alternate series of sections were stained for plaques and tangles with the Bielschowsky silver method and thioflavin-S, or were stained immunohistochemically with the Alz-50 monoclonal antibody, which reacts with a protein closely associated with tangles (Wolozin et al., Science. 232:648, 1986). The distribution and density of tangles and Alz-50 immunoreactive cells (A50-IC) were mapped throughout the limbic forebrain and correlated with a clinical assessment of the degree of cognitive impairment in each individual, based on the clinical record and on a structured interview with a collateral informant. To date, six cases have been examined, ranging from 59 to 83 years of age, and from normal to severely demented in cognitive status.

Tangles and A50-IC have similar patterns of distribution in all cases. Affected cells are consistently found in the perirhinal and entorhinal cortices and the subiculum, although the degree of involvment varied from very slight in the unimpaired individuals to extensive in the severely affected individuals. The para- and presubiculum contain almost no neuropathological markers even in the most severe cases. Elsewhere, the amygdaloid nuclei and the anterior olfactory nucleus consistently contain tangles and A50-IC, although at lower densities. The nucleus basalis, and the temporal and frontal cortex are only slightly affected except in the most severely demented case.

In general the A50-IC have the same distribution as tangles, but are more plentiful. However, a major difference is seen in the caudate/putamen. Very few tangles are stained in these nuclei with silver or thioflavin in any of the brains, but substantial numbers of A50-IC are found in the unimpaired, mild and moderately affected cases. These reactive neurons in the striatum are stained relatively lightly, unlike the more dense, filamentous staining seen elsewhere. Also, in the mild to moderately affected cases Alz-50 staining is seen along the pial and ventricular surfaces apparently in reactive astroglia.

Supported by NIH grants NS09518 and AG05681 (JLP), and MH14677 (PD).

408.3 DISTRIBUTION OF MAP-2 IMMUNOREACTIVITY IN THE HIPPOCAMPAL FORMATION OF NORMAL AGED AND ALZHEIMER'S DISEASE BRAIN. A.C. McKee* and N.W. Kowall (SPON: E.T. Hedley-Whyte). Dept. Neuropathology and Neurology, Massachusetts General Hospital, Boston MA 02114.

Microtubule-associated protein 2 (MAP-2) is restricted to neuronal perikarya and dendrites in the hippocampal formation of rodents. Using a well defined monoclonal antibody raised against MAP-2, we investigated the morphology and distribution of MAP-2 immunoreactive neurons in the hippocampal formation of 8 patients with pathologically verified Alzheimer's disease (AD) and 6 elderly controls. Normally, MAP-2 in the dentate gyrus is confined to granule cell neurons whose distal brush-like dendritic branches are especially prominent. In the AD cases, these distal branches, which receive inputs from the entorhinal cortex via the perforant pathway, are much less prominently stained. In field CA4, densely immunoreactive dendritic arbors and less intense neuronal perikarya are found that are not altered in the AD cases. In CA1-3 of control cases both pyramidal and basket cell perikarya and dendrites are positively stained. The long apical dendritic processes of the pyramidal neurons emerge in orderly radial register. In AD, the normal orientation of the pyramidal neurons is lost and their dendritic processes appear bulbous, tortuous, and truncated. Abnormal dendritic proliferation is occasionally seen suggesting that aberrant regeneration may occur. These changes are more severe in CA1 than CA 3. Pyramidal neurons , normally found in all layers of the subiculum are also severely affected in the AD cases. Densely immunoreactive Cajal-Retzius neurons and layer IV pyramids are found in entorhinal cortex. Intense fiber staining is evident in layer I and surrounding layer II cell clusters. Prominent infracortical MAP-2 neurons are evident throughout the parahippocampal gyrus. In periallocortical regions of the parahippocampal gyrus, pyramidal neurons are prominent in layers II-III and V-VI. These neurons are also morphologically abnormal in some cases.

Our findings show that MAP-2 immunoreactive neurons in the hippocampal formation are morphologically altered in AD. Further studies of this distinctive subset of cortical neurons will help define the nature and extent of cytopathological changes affecting AD cortex.

408.4 [^{3}H]-IMIPRAMINE BINDING IN THE HUMAN HYPOTHALAMUS AND NUCLEUS BASALIS OF MEYNERT: AGE AND ALZHEIMER RELATED CHANGES

D. Larry Sparks and B.A. Harrington*

Department of Neurology, University of Kentucky Medical Center and Sanders-Brown Research Center on Aging, Lexington, Kentucky 40536

This laboratory has previously reported age-and AD-related changes of serotonergic synaptic markers in both hypothalamus (Sparks et al. Ann Neurol 20:124, 1986) and nucleus basalis of Meynert (Sparks et al. Ann Neurol 19:602, 1986). Serotonergic changes in nucleus basalis of Meynert (nbM) correlated well with both cholinergic changes in nbM and cognitive dysfunction in AD. Serontonergic changes in sub-regions of hypothalamus correlated well with regional pathology in AD, and suggested a possible relationship to a number of non-cognitive abnormalities observed in the disease.

We have also found in both hypothalamus and nbM that the apparent turnover of serotonin (5HIAA content/5HT content) is increased in aging, and it is increased further in AD. To explore the possibility that altered serotonin (5HT) uptake could account for changes in 5HT turnover, we have investigated the binding of [^{3}H]-Imipramine to membrane preparations from rat and human hypothalamus and from human nbM.

Imipramine binding to rat hypothalamus was significantly inhibited by Flouxotine and Norelignine. Scatchard constants for this binding (Kd=3.3 nM; B max=35.7 f mol/mg wet) were consistent with previous reports (Severson, Neurobiol Aging 7:83, 1986).

Imipramine binding to human hypothalamus was also inhibited by Flouxotine, but not appreciably by Norelignine. Scatchard constants for this binding (Kd=1.5 nM; B max=26.5 f mol/mg wet) were also consistent with previous reports (Rehavi et al., Life Sci 26:2273, 1980).

In human nbM we found two Imipramine binding sites; a high affinity site (Kd=1.5 nM; B max=24.6 f mol/mg wet) and a lower affinity site (Kd=5 nM; B max=34.8 f mol/mg wet). The high affinity site appeared similar to that found in the human hypothalamus, and the lower affinity site appeared similar to that found in rat hypothalamus.

Age and AD related changes will be presented.

Supported in part by the Alzheimer's Disease and Related Disorders Association, Inc. (II-86-078) and NIH (1-P01-AG05119).

408.5 ARGYROPHILIC GRAINS IN THE HUMAN BRAIN CHARACTERIZE A DISEASE ASSOCIATED WITH ADULT ONSET DEMENTIA. H. Braak and E. Braak*. Department of Anatomy, University of Frankfurt, D-6000 Frankfurt 70, Fed. Rep. Germany.

Unusual cytoskeleton abnormalities were found in the brains of individuals afflicted with adult onset dementia. Most conspicuous were spindle-shaped argyrophilic grains loosely scattered throughout the neuropil. Additionally, coiled bodies of silver stained filaments were encountered, mainly located within the white substance. Argyrophilic grains and coiled bodies contained dense accumulations of straight tubules with a diameter of 6-8 nm.

The argyrophilic grains were found, in abundance, within sector CA1 of the Ammon's horn and layer Pre-β of the entorhinal region. A slightly less dense scattering occurred in layer IIIab of the adjoining temporal isocortex, insular cortex and orbitofrontal cortex. The basolateral amygdaloid complex and the hypothalamic lateral tuberal nucleus were the most affected subcortical structures.

Eighty brains of demented individuals were examined. Forty eight of them showed the features of Alzheimer's disease and four those of Pick's disease. Twenty eight cases revealed the abnormalities under consideration. Ten showed exclusively argyrophilic grains and coiled bodies, while 16 also had Alzheimer changes. One of the 28 cases was associated with Parkinson's disease and one showed features of both Alzheimer's and Parkinson's disease.

Twenty brains of non-demented individuals of about the same age and devoid or almost devoid of Alzheimer changes were used as controls. None of the control brains showed argyrophilic grains and coiled bodies. These changes, therefore, are considered the morphological substrate of an unknown disease associated with adult onset dementia.

Supported by the Deutsche Forschungsgemeinschaft.

408.6 CSF FROM SUBGROUPS OF ALZHEIMER'S PATIENTS CONTAIN ANTIBODIES RECOGNIZING CHOLINERGIC NEURONS IN THE RODENT CENTRAL NERVOUS SYSTEM

A.Dahlstrom*S.Booi,*K.Heglid*,L.Rosengren*A.Wallin*,IKarlsson*, L.Svennerholm,*C.G.Gottfries*A.McRae-Degueurce.
(SPON: S.Ehrenpreis). University of Guteborg Inst. of Neurobiology Goteborg,Sweden & INSERM-259 Bordeaux, France

The etiology of Alzheimer's (AD) disease is obscure. However, immunological abberations have been suggested to be critical factors in the pathogenesis of this disease. To this end an investigation was carried out to examine if the cerebro-spinal fluid (CSF) from AD patients and other forms of dementia contain antibodies which recognize neuronal populations in the rodent CNS. Rodents were perfused with a mixture that allows the fixation of acetylcholine (ACh) and dopamine (DA) in the rodent CNS. Immunocytochemical observations indicate that there are antibodies in the CSF of some AD and dementia patients capable of recognizing neuronal populations in the rodent CNS. Moreover these antibodies appear to be recognizing cholinergic or cholinergic-like neurotransmitter molecules for the following reasons: i) the antibodies recognize neurons in the medial septum and spinal motor neurons brain regions previously described as being predominantly composed of cholinergic neurons, ii) the CSF immunoreactivity of these regions was totally eliminated by prior incubation with anti-ACh antiserum and vice versa but not with anti-DA antiserum iii) there is a similarity in the location of neurons in the medial septum region following staining with patient CSF, acetylcholinesterase and anti ACh antiserum, iv) the immunocytochemical reacton was observed only following perfusion with a mixture previously demonstrated to fix ACh in the rodent CNS and v) CSF incubation of sections from rodents perfused with 4% paraformaldehyde instead of gluteraldehyde failed to mark neurons in the medial septum. Furthermore adsorption of the CSF with Protein A sepharose indicated that the immunoreactivity in these regions is due to the subclass IgG3. These observations show the presence of IgG in the CSF of a subgroup of AD and dementia patients that may be of importance for the diagnosis, the investigation of progression and for possible treatment of the disease. It may be speculated that the morphological changes (plaque formation) as well as decreases in presynaptic cholinergic markers in AD may be triggered by abnormalities in the immune system.

408.7 **A MODEL OF SENILE DEMENTIA IN YOUNG ANIMALS?** F. Cattabeni, M.P. Abbracchio*, M. Cimino*, D. Cocchi*, M. Di Luca*, L. Mennuni* and P. Zaratin*. Institute of Pharmacological Sciences, Via Balzaretti 9, 20133 Milan Italy.

Methyl-azoxy-methanol (MAM) is an antimitotic agent which kills cells in the mitotic phase. Its administration to pregnant rats at day 15 of gestation results in a dose-dependent microencephaly in the offspring. A single dose of 25 mg/Kg reduced the telencephalic mass by about 50%; 15 mg/Kg produced a reduction of about 20%, whereas 5 mg/Kg was ineffective in reducing the telencephalic size. Such a reduction is due to the impaired formation by the citotoxic agent of the neurons dividing at day 15 of gestation and eventually leading to the neuronal populations forming cortical interneurons. On the other hand, neurons providing the cortical afferents are not affected since their birth-date in rats preceeds the administration of MAM. This therefore results in animals with a chronic nor-adrenergic & cholinergic hyper-innervation in the cortex, without glial proliferation. In fact, neuronal markers of afferent fibers show higher concentrations with respect to normal animals, whereas markers for intrinsic neurons do not show any difference in concentration, indicating a non-selective loss of these neuronal populations. The only exception seems to be somatostatin, which is reduced (833 pmol/mg prot in controls, versus 450 pmol/mg prot in MAM animals). Interestingly, these microencephalic animals do not show dramatic signs of neurotoxicity, but they show deficits only in tests for learning & memory. For instance, a clear-cut dose-dependent impairment of memory can be observed in a passive avoidance test.

Since it has been recently hypothesized that in senile dementia of Alzheimer's type (SDAT) the cholinergic degeneration is probably a secondary event consequent to neuronal losses in the target area, these microencephalic animals might be a useful model to test such an hypothesis.

408.8 **HIPPOCAMPAL PATHOLOGY IN DOMINANTLY INHERITED ALZHEIMER'S DISEASE.** R.G. Strubleţ, R.J. Polinsky*§, J.C. Hedreenţ, L.E. Nee*§, R.G. Feldman§§, P. Frommeltţţ and D.L. Priceţ. ţNeuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; §Clinical Neuropharmacology Section, NINCDS; §§Dept. of Neurology, Boston Univ. Sch. of Med., Boston, MA 02118; ţţLemgo, Federal Republic of Germany.

Familial Alzheimer's disease (FAD), inherited as an autosomal dominant, is characterized by the presence of neurofibrillary tangles and amyloid deposits in plaques. The gene encoding for amyloid protein has been localized to a region of chromosome 21. In four pedigrees, a marker on chromosome 21 has shown linkage to FAD [St. George-Hyslop et al., Science 235:885-890, 1987]. Although a genetic abnormality on 21 appears to underlie FAD, other factors (including other genes, age, anatomical features, etc.) in brain could modify the distribution of pathology. We have hypothesized that, because cases of FAD presumably represent a homogeneous population, the distribution of hippocampal pathology in these cases should be relatively uniform. Variations within or among families would reflect factors (such as duration of disease, regional responses, etc.) other than the inherited loci. In eight cases of FAD (four from one pedigree and two each from two other pedigrees), the density of plaques and tangles was determined for hippocampal subdivisions CA1-4, subiculum, presubiculum, and dentate gyrus. Onset ranged from 37 to 56 years of age, and duration of disease varied from 4 to 16 years of age. In all families, there was a consistent pattern of pathology in these regions. CA1-2 had the highest density of both plaques and tangles; presubiculum showed little pathology. Plaque size was consistently largest in CA4. Statistical analysis disclosed no differences among families in plaque density, distribution, or size. Individual differences (e.g., plaque type, plaque and tangle density, or cerebellar plaques) did not assort by family. These observations suggest that the expression of hippocampal pathology in FAD is quite stereotyped and that characteristics of the pathology vary as a function of hippocampal region. However, it remains to be determined whether the pattern of pathology occurring in the hippocampus reflects a direct effect of a gene abnormality on chromosome 21 or some other determinant (such as transmitter specificity, connectivity, etc.) of cells in this region.

408.9 **PATHOLOGY IN THE LOCUS COERULEUS AND DEPRESSION IN ALZHEIMER'S DISEASE.** C.A. Rossţ, R.M. Zweig*§, J.C. Hedreen§, C. Steele*ţ, D.L. Price§ and M.F. Folstein*ţ. ţDept. of Psychiatry & Behavioral Sciences, The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205; §Neuropathology Lab., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD 21205.

Depression is a frequent complication of Alzheimer's disease (AD). We have recently found that patients with AD who become depressed tend to have a strong family history of affective illness [Pearlson et al., in preparation]. Since AD has a known neuropathology, it may provide a model for studying aspects of the neuropathology of depression. The noradrenergic system has often been linked to depression, and noradrenergic systems in the locus coeruleus (LC) degenerate in some cases of AD (e.g., Bondareff et al. [Neurology 32:164-168, 1982]). The number of neurons in the LC was measured in the brains of patients with pathologically proven AD; cell counts in patients who had depression (DSM-III criteria) were compared to counts in patients who did not have symptoms of depression. All pigmented neurons in the LC (on one side of one 12-µm cresyl violet-stained section at each of three levels of the LC) were counted by two investigators blind to clinical histories. At three levels, numbers of neurons were decreased in depressed AD patients compared to nondepressed AD patients: rostral level, 9.9 ± 3.4 (mean ± SD) (n = 6) vs. 21.9 ± 16.4 (n = 6); middle level, 15.1 ± 7.4 (n = 7) vs. 34.5 ± 21.7 (n = 9); and caudal level, 46.2 ± 6.7 (n = 5) vs. 51.8 ± 15.7 (n = 5). Control cases were: rostral, 54.1 ± 21.4 (n = 7); middle, 139 ± 41 (n = 9); and caudal, 147 ± 35 (n = 9). The difference between depressed and nondepressed AD cases was significant ($p < 0.05$) at the middle level of the LC, the region in which AD pathology was greatest. The difference between depressed and nondepressed AD cases was unlikely to be due to differences in age of onset or severity of dementia shortly prior to death, since forebrain pathology (blind ratings of neuronal loss, plaques, and tangles in amygdala, hippocampus, neocortex, and nucleus basalis) was indistinguishable in depressed vs. nondepressed individuals with AD. These findings provide evidence for a relationship between the presence of depression and the severity of cell loss in the LC in AD. Thus, AD may provide a disease in which to study aspects of the neuropathology of depression.

408.10 AGE-RELATED LOSS OF NERVE GROWTH FACTOR (NGF) SENSITIVE RAT BASAL FOREBRAIN NEURONS S. Koh, P. Chang* and R. Loy Depart. of Neurobiology and Anatomy, Univ. of Rochester, Rochester NY 14642

Basal forebrain magnocellular neurons contain NGF receptors, take up and retrogradely transport NGF from their terminals in the hippocampus and neocortex, and respond to exogenously administered NGF by increased production of choline acetyl transferase(ChAT). Following transection of the fimbria-fornix, there is a rapid loss of NGF receptor and subsequent cell death in the medial septum (MS) and vertical limb of diagonal band (VDB). This cell death can be prevented by continous intraventricular injection of NGF. Furthermore, chronic infusion of NGF into the subpopulation of behaviorally impaired aged rats improves their swim maze performance, suggesting that degeneration of NGF sensitive neurons in the basal forebrain may play a role in the cognitive loss in aging. We have used 192 IgG (E. Johnson, Washington U.) to immunocytochemically visualize NGF receptors in aged (30 mos) and young (10 mos) male Long Evans rats. The brains were removed from the perfused rats, 30 um thick freezing microtome sections cut, and every third section was collected and processed for immunocytochemistry. Immunoreactive neurons in MS, VDB and nucelus basalis(NB) were counted from every stained section (50 horizontal sections per brain). The entire nuclei spanning 20 sections for MS , 18 sections for DB and 33 sections for NB were included for analysis. A subpopulation of aged rats can be identified in which NGF immunoreactive cells in the basal forebrain appear vacuolated and shrunk, and the neuropill staining is makedly reduced. In these morphologically distinct aged rat brains, there is not only a shrinkage of neurons but an apparent cell loss: 30 % in MS, 26 % in DB and 29 % in NB. Even in the aged rats in which the qualitative change in cell morphology is not apparent, there is a moderate decrease in cell number relative to the young control: 7 % in MS, 17 % in DB and 18 % in NB. While age-related declines in neurochemical markers of the cholinergic system are well-documented, no actual loss of acetylcholine esterase- or Chat-positive basal forebrain neurons has been previously reported in rodents. Our finding is the first indication of apprent cell loss and degeneration of neurons in the basal forebrain in aged rats. Supported by Grant ADRDA PRG-86-041 (RL) and MH-09541 (SK)

408.11 **CHOLINE-INDUCED PLASTICITY IN NEOCORTICAL NEURONS OF THE AGING MOUSE BRAIN: EFFECT ON DENDRITIC BRANCHING AND SPINES.** M. Bedo-Wierdl*, R. Dvorak*, and R.F. Mervis. Div. Neuropathology, The Ohio State Univ. Med. Ctr., Columbus, Ohio 43210.

Loss of dendritic material may be found in advanced normal aging and in Alzheimer's disease. This may reflect deterioration of neuronal membranes and would involve changes in dendritic branches and spines. The resultant disruption of neuronal circuitry and synaptic elements would be the anatomical substrate of geriatric memory impairment. Diets enriched in choline may, however, provide a substrate for maintenance and/or synthesis of new membrane material. Thus, in this study we evaluated the effects of long term dietary enrichment with choline chloride, highly purified (95%) phosphatidylcholine (PC), and a commercial soy-lecithin (Centrolex). Male C57Bl/6NNIA mice were fed diets enriched with these choline-containing compounds at either 4.8 or 10.8 mg choline/gm of chow for 11 months -- from 13 to 24 months-old. Control mice were fed a standard lab chow (Purina) containing 2.3 mg choline/gm. Experimental diets were isocaloric and isonitrogenous. The 24 month-old mice were killed, and their brains stained using the rapid Golgi method. Dendritic branching of the basilar tree of layer V pyramidal cells of frontoparietal cortex was quantified using the Sholl Method of concentric circles. Dendritic spines were evaluated on the terminal tips of the basilar tree of this same neuronal population in terms of density, length, and categorized according to shape.

In these subjects, normal aging resulted in a 26% loss of distal dendritic branches (non-significant). However, high levels of dietary supplementation with choline and PC produced significant new growth in the distal third of the dendritic field. In comparision to age-matched controls, the increase amounted to 166% ($p < 0.006$) and 125% ($p < 0.02$), respectively, for choline and PC.

Analysis of dendritic spines from 20 micron terminal tip segments showed no significant loss of spine density with normal aging, nor was there a significant change in spine length. In view of the significant increase of branch length, these findings suggest that new dendritic branch growth was accompanied by new formation of dendritic spines.

408.12 EFFECTS OF PHOSPHATIDYLSERINE ADMINISTRATION ON AGE-RELATED CHANGES OF SEPTAL CHOLINERGIC NEURONS IN THE RAT. M.G. Nunzi, F. Milan*, P. Polato*, D. Guidolin* and G. Toffano. Fidia Research Laboratories, 35031 Abano Terme (PD), Italy

Derangement of the brain cholinergic system has been implicated in the cognitive deficits associated with advancing age. In this study we have investigated age-related structural changes in cholinergic nuclei of the rat septal complex and the possible counteracting effect of prolonged phosphatidylserine (BC-PS) treatment. Phosphatidylserine is a naturally occurring phospholipid, provided with pharmacological activity (Toffano and Bruni, Pharmacol Res Comm, 12:829-845, 1980). In this context, BC-PS has been shown to increase learning and memory functions in old rats (Drago et al., Neurobiol Aging, 2:209-213, 1981) and to stimulate brain cholinergic mechanisms (Pedata et al., Neurobiol Aging, 6:337-339, 1985). Six Sprague-Dawley rats for each of the following groups were studied: 4-month-old rats, 27-month-old rats and old age-paired rats which received BC-PS suspended in tap water (average intake: 50 mg/kg/die) from the age of 15 months. The cholinergic cell population of the medial septal nucleus and diagonal band, identified on 40 μm thick sections by using a monoclonal antibody to choline acetyltransferase (ChAT) and the PAP technique, was studied by means of an interactive image analysis system (IBAS, Kontron Zeiss). In old-untreated animals the mean cell number of ChAT-positive cells is reduced by 19.6% ($P<.05$; Student's t test) with respect to young animals, while in old BC-PS treated rats no significant differences were observed. Furthermore, the mean area and the mean diameter per cell body are significantly decreased in old untreated animals (-18.7% and -8.6%, respectively; $P<.01$) whereas no significant reductions are present in old BC-PS treated rats. In the same groups of rats a densitometric analysis of acetylcholinesterase (AchE) staining in the hippocampus, a major target of the cholinergic innervation from medial septal complex, also revealed a counteracting effect by the phospholipid on age-induced decrease of the AchE staining. This finding may be correlated with the capability of long-term BC-PS treatment to maintain dendritic spine density of hippocampal pyramidal neurons in old rats (Milan et al., Bess et al. (eds), John Libbey Eurotext 408-413, 1986). In conclusion, these data suggest that BC-PS may affect survival and trophic degree of cholinergic septal neurons by ensuring remodelling of synaptic connections throughout advancing age.

CELL LINEAGE AND DIFFERENTIATION V

409.1 THE SEX-DETERMINATION GENE DAUGHTERLESS IS NECESSARY FOR PERIPHERAL NEURON DIFFERENTIATION IN DROSOPHILA EMBRYOS. M.Caudy#, E.Grell*#, L.Jan#, Y.N.Jan#, C.Dambly-Chaudiere*+ and A.Ghysen+; # Howard Hughes Med. Inst., U.C., San Francisco, CA 94143; + Lab. de Genet., U. Lib. de Bruxelles, Belgium..

In order to analyse the genetic regulation of neuronal differentiation in Drosophila embryos, we began to study l(2)II, an embryonic lethal mutation reported to have CNS defects (Campos-Ortega, quoted in Nusslein-Volhard, et. al., (1984), Roux's Arch. Devel. Biol.; 193: 267-282). We found that in addition to CNS defects, l(2)II embryos are missing the entire peripheral nervous system (PNS).

l(2)II maps near the (maternal effect) sex-determination gene daughterless (da, genetic map, 2-41.3), and both lie within the deficiency Df(2L)J27 (chromosome map, 31D-31F). It was recently found (independently by E. Grell and J. Tomkiel) that l(2)II is lethal when in trans with da (as are the lethal da null alleles, da^2 and da^3, Cronmiller and Cline, 1987; Cell 48: 479-487). This suggested that l(2)II is a mutation in the same gene. To test this possibility, we stained da^2 and da^3 homozygotes and found that they also are missing the entire PNS and have (varied) CNS defects. Similar defects were seen in da^2/l(2)II embryos as well. l(2)II, da^2 and da^3 all are EMS induced mutations so that each is likely to be a point mutation rather than a deletion covering more than one gene. Furthermore, the original da hypomorph mutation has been found to show partial defects in PNS formation in many of the embryos in which it is in trans with either l(2)II or the deficiency Df(2L)J-27. Therefore, l(2)II and all of the da alleles are defective in PNS development, and appear to be mutations in the same gene.

In l(2)II and the da null homozygotes, neuron-specific antibodies reveal no sign of peripheral neuron differentiation at any time during (or after) the 9-11 h. stages during which the PNS normally is formed. However, the epidermis continues normal segmentation and cuticle formation at least until the 24 h. stage. Also, the gut continues to undergo morphogenesis well after the normal time of PNS differentiation, and the somatic muscles differentiate in their normal numbers and positions during the 10-14 h. stages. Therefore, it appears that the da+ gene product is not necessary for the differentiation of all tissue types (at least not at early stages), but is necessary for the differentiation of all peripheral neurons. Thus, the da+ gene product appears to have at least two widely different developmental functions: as a maternally derived factor which is necessary for sex determination in the embryo, and as a zygotically derived factor which is necessary for the embryo to form a peripheral nervous system.

409.2 **CELLS IN NEURONAL LINEAGES OF XENOPUS EMBRYOS PREFERENTIALLY SYNTHESIZE PARTICULAR PROTEINS.** S.L. Klein and M.L. King*. Dept. Anat. & Cell Biol. Univ. Virginia Sch. Med. Charlottesville, VA 22908.

The proteins that are synthesized by blastomeres that produce different amounts of the nervous system were compared. ^{35}S-methionine was injected into blastomeres whose progeny will express different fates and allowed to incorporate into newly synthesized proteins for several cell cycles. The proteins were extracted in Tris buffer long before primary embryonic induction and separated by 1-dimensional SDS polyacrylamide gel electrophoresis. Two proteins of about 200,000 daltons were preferentially synthesized by cells that produce a large portion of the nervous system. For example, between the 16-, and 64-cell stage, these proteins were synthesized in 10-fold excess by dorsal animal cells (the progeny of blastomere D1.1) compared to ventral animal cells (the progeny of V1.2); their synthesis was undetectable in ventral vegetal cells (the progeny of V2.2). The amount of these proteins that the cells synthesize is correlated with the proportion of nervous system that the cells produce. D1.1 populates extensively forebrain, midbrain, hindbrain and spinal cord, V1.2 populates dorsal hindbrain and spinal cord, and V2.2 contributes only a few cells to the spinal cord (Moody,S.A. '87. Dev. Biol. 119). These results show that cells that are in neuronal lineages display specific biochemical characteristics long before they display morphological differences.

The synthesis of these proteins was examined after performing manipulations that changed the proportion of cells that entered neuronal lineages. UV irradiation during the first cell cycle produces an embryo with virtually no nervous system and treatment with Li^+ during the fifth cell cycle produces an embryo that consists almost entirely of head structures. These manipulations had no affect on the overall pattern of protein synthesis, but preliminary observations indicate that the manipulations altered the synthesis of the 200,000 dalton proteins. If these results are substantiated they will suggest that these proteins are involved in regulating cell fate.

Supported by NIH grants HD06619 (SLK) and GM33932 (MLK).

409.3 IDENTIFICATION OF RADIAL GLIAL CELLS WITHIN THE DEVELOPING MURINE CENTRAL NERVOUS SYSTEM USING A NEW IMMUNOHISTOCHEMICAL MARKER. J.-P. Misson*, M. Yamamoto, M.A. Edwards,, G. Schwarting, V.S. Caviness Jr. E.K. Shriver Center, Waltham, MA 02254 and Neurology Dept., Mass. General Hosp., Harvard Medical School, Boston, MA.

The monoclonal antibody, RC2, was generated in mouse by conventional hybridoma methodology using rat brain homogenate as immunogen. Immunocytochemistry was performed on fresh-frozen cryostat sections and vibratome sections following fixation with periodate-lysine-parafomaldehyde. From the neural tube stage (E9-10) until the early postnatal period, RC2 delineates in the ventricular zone (VZ) of the CNS a subpopulation of radial bipolar cells similar to those described with another radial glial (RG) marker previously generated in our laboratory, RC1 (Edwards et al., Neurosci. Abst., 12: 182, 1986). A descending process extends to the ventricular margin and an ascending process contacts the external limiting membrane by one or more endfeet expansions. By E11, the radial processes are organized in fascicles. Between E12-E17, they adopt marked regional variations in their patterns of alignment and density, particularly in association with cerebral corticogenesis (Gadisseux et al., Neurosci. Abst., 13, 1987) and with cerebellar and basal ganglia development. A progressive perinatal loss of stained RG is observed which coincides with the appearance of monopolar and multipolar immunoreactive cell forms outside the VZ, as consistent with the transformation of RG into astrocytes. In the cerebellar cortex from E15 to P7, RC2-positive monopolar cells accumulate in the Purkinje cell layer and differentiate as Bergmann glia. Over the same period, morphologically similar RC2-positive cells appear in the cortical plate of the hippocampal formation. Between P7 and P14, immunoreactivity of all glial cell forms becomes undetectable. Antigenicity with RC2 sustains aldehyde fixation, thus allowing high resolution light microscopy and ultrastructural study of RG morphology in plastic sections following Epon-embedding of reacted vibratome sections. Such preparation combined with [^{3}H]thymidine autoradiography allow confident recognition of mitotically-active bipolar RG of the murine cerebrum, consistent with our previous study using RC1 (Misson et al, Neurosci. Abst. 12:1585,1986).

Antigens recognized by RC2 in immunoblots of E15 mouse brain include two discrete protein bands at 95 and 106 kD and a single species of ganglioside or acidic glycolipid. Such antigens have not previously been identified as associated with radial cell forms. Thus, in addition to providing a sensitive and robust marker for developmental studies of RG, the RC2 antibody appears to identify a novel glycoconjugate epitope associated with this cell class in the fetal mouse CNS. [Supported by NATO grant 27B85BE and NIH grants HD05515, HD21018, CA25532, NS12005].

409.4 CO-EXPRESSION OF MYELIN BASIC PROTEIN AND GLIAL FIBRILLARY ACIDIC PROTEIN BY IMMATURE OLIGODENDROCYTES IN VITRO. B.H. Choi. University of California Irvine, Irvine, CA 92717.

Although it is generally believed that oligodendrocytes (OC) originate from poorly defined cells referred to as "glioblasts" the nature of the precursor cells from which OC are derived is still debated. In previous studies from this laboratory, we presented evidence to suggest, in the developing human fetal CNS, (a) that "transitional" cells possessing the light and EM features of both astrocyte and OC appear just prior to the onset of myelination, (b) that immature OC transiently express glial fibrillary acidic protein (GFAP) and (c) that myelin-forming OC are probably derived from astroglial precursor cells.

In order to test this hypothesis further, we have prepared mixed glial cell cultures from neonatal rat cerebra according to the method of McCarthy and de Vellis (J Cell Biol 85: 890, 1985). Small round cells were separated from the mixed glial cell cultures at 7 to 9 days-in-vitro by shaking and plated onto the multi-well culture chambers containing cover slips. Eighteen to 24 hours later, the cultures were studied immunocytochemically by exposing the same population of cells to both antisera for myelin basic protein (MBP) and GFAP by the use of double-labeling (fluorescein or rhodamine-conjugated) indirect immunofluorescent technique. The cells were also double-labeled for galactocerebroside (GC) and GFAP. Mouse monoclonal anti-GFAP and rabbit polyclonal anti-MBP sera were used for double-labeling. Monoclonal anti-GC and polyclonal anti-GFAP sera were also used.

Although there were numerous small round cells on the cover slips expression of both MBP and GFAP was seen in the minority of the cell population that bear the morphological characteristics of OC by light and electron microscopy. There were small round cells showing immunoreactivity only for GFAP while others reacting positively for either MBP alone or GC alone. Many others reacted negatively for all three antisera. The demonstration of both MBP and GFAP in the same OC suggests that these cells correspond to the "transitional" cells that we have described previously and supports the hypothesis that OC probably originate from astroglial precursors.

409.5 CLONAL ORGANIZATION OF A GLIAL CELL LINEAGE IN VIVO. R.K. Small. Dept. of Zoology and Cell Biology, University College, London WC1E 6BT.

Myelin-forming cells of the rat optic nerve derive from migratory progenitor cells that enter the chiasmal pole of the nerve at embryonic ages (Small et al, 1987). These cells are bipotential 'O-2A' progenitors which give rise at postnatal ages, first, to oligodendrocytes and later, to type-2 astrocytes, the cells shown recently to contribute fine processes to nodes of Ranvier (ffrench-Constant and Raff, 1986).

When first detected in the embryonic nerve, the O-2A cell lineage is present in the chiasmal portion of the nerve as linear chains of cells occurring in the ventral half of the nerve and extending into the optic chiasma. Mitotic figures are frequently observed among the cells within these chains. With time, the number of linear chains increases and these chains spread into the retinal portion of the nerve. At embryonic ages, these cells are not present beyond the optic chiasma in the central continuation of the optic pathway, the optic tract. This suggests that progenitor cells migrating from a source in the vicinity of the chiasma, show directional migration into the optic nerve but do not enter the optic tract. Ultrastructural analyses of embryonic nerves reveal extensive surface contacts between cells of these chains and surrounding ganglion cell axons in the nerve; few contacts have been detected so far, between O-2A cells and the radially-oriented, early glial cell population of the nerve: type-1 astrocytes. The complex intercellular junctions seen between cells within chains at EM level, permit clusters of O-2A lineage cells to be obtained for in vitro analysis after gentle dissociation of embryonic nerves.

Cells of the O-2A lineage appear in the embryonic optic nerve shortly after ganglion cell growth cones reach the optic chiasma, perhaps indicating that these neurites provide a pre-formed substrate guiding progenitor cells into target areas which they eventually myelinate. Thus, the O-2A cell lineage seems to be intimately associated with, and perhaps even dependent upon, the axon surface for its first appearance in the embryonic nerve. This association may persist and form the basis for the later functional specialization shown by the lineage for ensheathing axon surfaces.

409.6 THE DEVELOPMENTAL EXPRESSION OF GLIAL SPECIFIC mRNAs IN PRIMARY CULTURES OF RAT BRAIN VISUALIZED BY IN SITU HYBRIDIZATION. E. Holmes*, G. Hermanson*, R. Cole*, and J. deVellis. Laboratory of Biomedical and Environmental Sciences, UCLA, Los Angeles, CA 90024.

In our model tissue culture system for studying glial differentiation, 1-2 day old rat brain cortex is dissociated and plated in serum-supplemented medium. A stratified mixed glial population results where phase-dark process-bearing cells astride a bedlayer of polygonal astrocytes. To more definitively characterize lineage and differentiation in these cells maintained in culture over time, the expression of mRNAs encoding glial fibrillary acidic protein (GFAP) and myelin basic protein (MBP), respectively astrocyte and oligodendrocyte markers, were mapped by in situ hybridization with ^{35}S-labeled riboprobes. The time points evaluated were 8, 12, 14, and 19 days in culture. GFAP mRNA expression, seen in astrocyte nuclei and cytoplasm as well as in some phase-dark cell nuclei, increased through day 12 and thereafter plateaued amid a concomitant increase in cell density. In contrast, MBP mRNA was barely detectable at day 8 but increased approximately 20 fold by day 12 and 14. As the phase-dark cells matured, labeled isolated round cells extended processes in which MBP mRNA was detected and by day 19, large clumps of labeled cells dominated the culture. Control hybridization with the sense RNA strand was equal to background emulsion. Extending the characterization of these cultures by in situ hybridization for glutamine synthetase (GS) and glycerol phosphate dehydrogenase (GPDH) (other glial markers) is in progress. The population distribution will be computer analyzed.

Supported by AWU/DOE and NIH.

409.7 **NEUROGENESIS OF IMMUNOCYTOCHEMICALLY IDENTIFIED CHOLINERGIC NEURONS IN THE BASAL FOREBRAIN OF RAT.** D.R. Brady, P.E. Phelps and J.E. Vaughn, Division of Neurosciences, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

The basal forebrain cholinergic system embodies a heterogeneous group of neurons that are distributed in the telecephalon extending from the medial septal nucleus at the midline through the diagonal band nucleus along the ventral forebrain, and continuing through the nucleus basalis of Meynert to the peripallidal region dorsolaterally. Neurons of this cholinergic system project topographically to the hippocampal formation and cerebral cortex, and have been implicated in the pathophysiology of neurodegenerative disorders such as Alzheimer's disease. This study was conducted to ascertain developmental relationships between cell birthdays and the expression of the cholinergic neurotransmitter phenotype of neurons that comprise the basal forebrain system.

The techniques of tritiated-thymidine autoradiography and ChAT immunocytochemistry were combined to determine the birthdays and neurogenetic gradients of cholinergic cells in this region of rat brain. Pregnant rats received a single intraperitoneal injection of isotope on embryonic days 12-17 (E12-17). Isotopically labeled progeny were processed as adults for ChAT immunocytochemistry followed by autoradiography. For quantitative analysis, ChAT-positive neurons with centrally sectioned nuclear profiles were counted and classified as being heavily radiolabeled or unlabeled according to grain counts over each nucleus.

ChAT-positive neurons in the medial septal and diagonal band nuclei are generated in a caudal to rostral gradient between E13 and E17. In these nuclei, a peak generation of double-labeled cells is observed on E15. A caudal to rostral gradient of neuronal birthdays is observed between E13-E16 in the basal nucleus of Meynert. Production of neurons in this nucleus peaked early (E13) during the generation period, and declined over succeeding embryonic days. These results demonstrate that the generation of cholinergic basal forebrain neurons obeys the neurogenetic gradient of all neurons previously described for this brain region (Bayer, S.A., Int. J. Devl. Neurosci. 3:229-243, 1985). This is consistent with the results of other combined immunocytochemical/autoradiographic studies of cholinergic cells (Phelps et al., Soc. Neurosci. Abstr. 12:767, 1986) that suggest position within a neurogenetic gradient is a more potent determinant of neuronal birthday than a cell's prospective transmitter phenotype. Supported by NIH grant NS 18858.

409.8 REGULATION OF VIP AND VIP RECEPTOR IN SUBCLONES OF SK-N-SH HUMAN NEUROBLASTOMA CELLS: EVIDENCE FOR A POTENTIAL AUTOCRINE FUNCTION OF VIP. J. Waschek*, J.M. Muller*, C.-M. Hsu*, V. Yu*, W. Sadee*, and L. Eiden* (SPON: J. M. Roberts). Unit on Molecular and Cell Neurobiology, Lab. of Cell Biology, National Institute of Mental Health, Bethesda, Md 20892 and Department of Pharmaceutical Chemistry, Univ. of California, San Francisco CA 94143.

The human neuroblastoma cell line SK-N-SH contains distinct cell subtypes, which after subcloning, interconvert at a very slow rate (Biedler and colleagues, J. National Cancer Institute, 1983). The SH-SY5Y and SH-EP subclones have neuronal and epithelial and morphologies, respectively, whereas the SH-IN subclone has a morphology in between the SY5Y and SH-EP. It has been previously shown that the parent cell line SK-N-SH expresses VIP (5-10 ng/mg protein), and that 12-O-tetradecanoyl-phorbol- 13-acetate (TPA) and forskolin induce further this expression. We now report similar studies with the subclones of SK-N-SH. The SY5Y cells contain smaller amounts of peptide (0.3 to 1.0 ng VIP/mg protein) than the parent cells, and can be stimulated to increase VIP levels 3- and 2-fold by treatment for 24 hours with TPA 10^{-8} M and forskolin 2.5×10^{-5} M, respectively. Prolonged (> 4 days treatment) with dibutyryl cAMP results in a 4- to 10-fold increases in VIP. SH-IN cells, on the other hand, contain a much higher basal amount of VIP (approximately 4 ng/mg protein) than SY5Y. Northern blot analysis of mRNA isolated from subclones confirm the differences in basal expression between SY5Y and SH-IN subtypes.

To study the tissue-specific expression and inducibility of VIP at the level of transcription, the VIP gene was isolated from a human genomic library, and a 3.2 kb fragment, containing more than 2 kb of 5' flanking sequence was fused to the gene encoding bacterial chloramphenicol acetyltransferase (CAT). TPA 10^{-8} M and forskolin 2.5×10^{-6} M caused 10- and 3-fold stimulation of CAT transcription from the VIP promoter, respectively. No stimulation above basal was seen with RSVCAT (Rous sarcoma virus promoter fused to CAT) in SY5Y cells, and no stimulation was seen with either the VIP/CAT construction or RSVCAT in HeLa cells, which do not respond to TPA and forskolin with an increase in endogenous VIP.

To study the action of VIP as an autocrine factor, subclones were assayed for the presence of membrane VIP receptors by radioreceptor binding. The EP cell line was found to be rich in high-affinity VIP receptors (>7,000/cell, Kd = 0.5nM), while the SY5Y and SH-IN lines had 7-fold fewer receptors (Kd = 0.5 nM). The differences in membrane receptor levels in different subclones may be due to the presence of VIP (see related abstract, J. Muller et. al.). The results show that there are differences in individual cell types in levels of expression of VIP and presence of membrane receptors. In addition to the possible interrelationship between levels of VIP and its receptor, we suggest that VIP has an autocrine role in the determination of neuronal phenotype.

409.9 INTRINSIC AND EXTRINSIC INFLUENCES ON NEURONAL PHENOTYPE: EXPRESSION OF GAD AND OTHER mRNAs IN THE CEREBELLA OF WEAVER, AND REELER MICE. C.W. Wuenschell[1], A. Messer[4], and A.J. Tobin[1,2,3]. [1]Department of Biology, [2]Molecular Biology Institute, and [3]Brain Research Institute, University of California, Los Angeles, CA 90024; and [4]Wadsworth Laboratories, New York State Department of Health, Albany, NY 12201.

Purkinje cells of normal mice characteristically contain mRNAs encoding glutamic acid decarboxylase (GAD) and the 28 kD calcium binding protein (CaBP, or calbindin D_{28k}). The production of these two mRNAs could result from the unfolding of a program established early in cerebellar development and dependent thereafter only on factors intrinsic to the Purkinje cells themselves. Alternatively, the expression of the genes for GAD and CaBP could depend on factors extrinsic to the Purkinje cells. The genetically altered cerebella of weaver and reeler mice offer the opportunity to distinguish these alternatives.

We have used in situ hybridization to ^{35}S-labeled antisense RNAs to examine the cellular distribution of mRNAs encoding GAD, CaBP, and proenkephalin in normal and mutant mice. In normal mice, Purkinje cells contain both GAD and CaBP mRNAs, but not proenkephalin mRNA. Golgi II cells contain GAD and proenkephalin mRNAs, but not CaBP mRNA.

Despite the nearly complete loss of granule cells in weaver mice, Purkinje cells contain both GAD and CaBP mRNAs. This result supports the view that the expression of these two genes proceeds independently of extrinsic cues.

In reeler, Purkinje cells lie in a variety of microenvironments -- orthotopically between molecular and granular layers, or ectopically within or below the granular layer. We initially identified ectopic Purkinje cells by their size, distribution, and staining. In situ hybridization reveals that both orthotopic and ectopic Purkinje cells contain both GAD and CaBP mRNAs. We do not detect proenkephalin mRNA in either orthotopic or ectopic Purkinje cells. Like our findings with weaver, these data support the autonomy of Purkinje cell development. At least for the aspects of neuronal phenotype that we have examined, the pattern of Purkinje cell cytodifferentiation does not depend on environmental influences from granule cells.

410.1 **THALAMIC AND CORTICAL AUDITORY PATHWAYS CONVERGE IN THE RAT AMYGDALA.** *J.E. LeDoux, C. Farb*, D.A. Ruggiero, and D.J. Reis,* Div. of Neurobiology, Cornell Univ. Med. Coll., New York, NY 10021.

Connections between the acoustic thalamus and amygdala play a role in the processing of the emotional significance of auditory stimuli (LeDoux et al, J. Neurosci., 4, 1984, 683-698; Neurosci., 17, 1986, 612-621; Iwata et al, Brain Res., 383, 1986, 195-214). The aims of the present study were to (a) precisely define the projection field of the acoustic thalamus in the amygdala and the thalamic origin of these projections, (b) determine whether the auditory cortex (ACX) and amygdala receive projections from common areas of the acoustic thalamus, and (c) determine whether the acoustic thalamus and ACX project to common areas of the amydgala.

Male Sprague-Dawley rats (n=22) were studied. WGA-HRP was injected iontophoretically under halothane anesthesia while the rats were held in a sterotaxic frame. After survival for 48 h, the rats were perfused and the brains processed histochemically using TMB as a chromagen.

The acoustic thalamus, defined as the projection field of the inferior colliculus, includes the ventral, medial and dorsal divisions of the medial geniculate body (MG), as well as adjacent regions, including the posterior intralaminar nucleus (PIN) and peripeduncular area (PP) (LeDoux et al, J.Comp.Neurol., 242, 1985, 182-213). Following injections in the ventral MG division, labeled cells and processes were confined to the posterior lateral neocortex (primary ACX). Injections centered on the medial MG division and the underlying PIN and PP produced anterograde and retrograde labeling in cortical areas ventral to the primary ACX, including the perirhinal cortex and an area between the perirhinal cortex and primary ACX (suprarhinal cortex). Anterograde labeling was also present in the lateral nucleus of the amygdala (AML) and the amygdalostriatal transition zone (AST). Injections in AML resulted in retrograde labeling in the medial MG, PIN and PP and in the perirhinal and suprarhinal cortical regions. Following injections in primary ACX anterograde and retrograde labeling was seen in the MG (especially in the ventral division) and in the suprarhinal cortical region. Injections involving the perirhinal and suprarhinal areas produced anterograde labeling in AML and AST and anterograde and retrograde labeling in PIN, PP, and medial and dorsal MG.

Acoustic information relayed from the inferior colliculus to the thalamus can thus reach the amygdala by several pathways, each of which converges on AML and AST. All parts of the acoustic thalamus project to cortical areas (primary auditory cortex, suprarhinal cortex, or perirhinal cortex). Perirhinal and suprarhinal areas, in turn, project to AML. Although primary auditory cortex does not project to the amygdala, it can influence this region through local connections with suprarhinal cortex. AML and AST also receive direct inputs from the medial MG, PIN, and PP. These multiple, parallel afferents to the amygdala may constitute pathways by which acoustic stimuli are transformed into emotional signals.

410.2 MORPHOLOGICAL EVIDENCE FOR INHIBITORY INPUTS TO THE INFERIOR COLLICULUS (IC) FROM THE DORSAL NUCLEUS OF THE LATERAL LEMNISCUS (DNLL). A. Shneiderman and D. Oliver, Dept. of Anatomy, Univ. Conn. Health Center, Farmington, CT 06032.

The DNLL may provide a significant ascending input to the IC. However, unlike other projections to the auditory midbrain, most neurons in the DNLL exhibit immunoreactivity for GAD antibodies (Adams and Mugnaini, Brain Res. Bull. 13:585-590, 1984). This implies that the DNLL could provide inhibitory inputs to the IC. In this study, the projections of the DNLL to the IC of the cat were characterized with anterograde autoradiographic techniques at the light (LM) and electron microscopic (EM) levels and with analysis of retrograde transport of HRP from the IC to the DNLL.

The bilateral projection of the DNLL to the IC had a topographic order that suggests a tonotopic arrangement of the afferent axons. At the LM level, the contralateral projection was organized into heavily labeled bands alternating with areas of lighter labeling. In contrast, the ipsilateral projection to the IC was more diffuse. If bands were present ipsilaterally, the contrast between the heavily and lightly labeled areas was not as sharp as it was contralaterally.

At the EM level, after axonal transport of 3H-leucine from the DNLL to the contralateral IC, the labeled axonal endings contained pleomorphic synaptic vesicles and made symmetric synaptic contacts. In these samples, labeling was significantly non-random ($p < .001$), and the endings which contained pleomorphic vesicles constituted approximately half of all the endings within pars centralis of the central nucleus. Of these endings with pleomorphic vesicles, 25% were labeled after injections in the contralateral DNLL. In contrast, 25-50% of the endings with round synaptic vesicles could be attributed to projections from the cochlear nuclei (Oliver, J. Comp. Neurol., In Press, 1987). Label in endings with pleomorphic vesicles was over 7 times background. Other tissue compartments were labeled at background levels or below except for unmyelinated (axonal) profiles in one sample. A few boutons with round synaptic vesicles could have been labeled, but they had radioactivity only 1.1 times background. Most labeled axonal endings formed synaptic contacts on medium or large dendrites or sometimes on cell bodies. Preliminary evidence showed the projection from the ipsilateral DNLL to be sparse, and labeled endings were widely distributed. Both types of axonal endings may have been labeled.

Thus, the DNLL could provide a major source of inhibition to the contralateral IC. Due to its proximal synapses and the banded, tonotopic organization of the axons, the DNLL could produce highly localized, significant IPSPs which are influenced by the frequency parameters of acoustic stimulation.

410.3 THE MEDIAL GENICULATE BODY OF THE GUINEA PIG: SUBDIVISIONS, TONOTOPY AND PROJECTIONS TO AUDITORY CORTEX. H. Redies* (SPON: B.B. Lee), Max-Planck-Institute for Biophys. Chem., Dept. of Neurobiol., 3400 Göttingen, Am Faßberg, Fed. Rep. of Germany

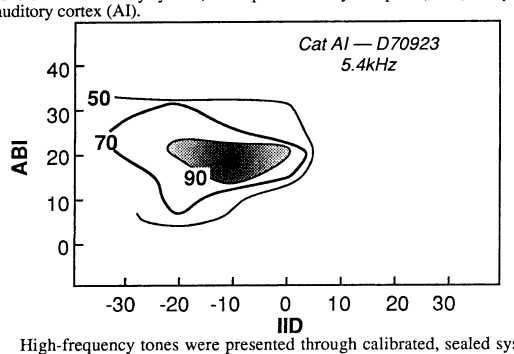
On the basis of microelectrode mapping experiments, cytoarchitectonics (Nissl stained frontal sections) and projections from the medial geniculate body (MGB) to the auditory cortex, a functional division of the MGB was achieved. The efferents of the subnuclei were determined by implanting retrogradely transported tracer substances into electrophysiologically identified fields of the auditory cortex.

(1) The **ventral nucleus** (MGBv) occupies a lateroventral position in the rostral two thirds of the MGB. It projects to the anterior and the dorsocaudal tonotopic cortical fields (see Redies and Creutzfeldt 1986, Neurosci. Lett., suppl. 26). This nucleus is tonotopically organized: in it's posterior half, low best frequencies are located laterocaudally, high frequencies mediorostrally. In the anterior half, the isofrequency laminae are curved, such that the low frequencies surround the high frequencies. The cells are of medium size and densely packed. (2) The **shell nucleus** (MGBs) surrounds the MGBv as a continuous shell dorsally, laterally and ventrally. It projects to a non-tonotopic cortical area situated ventrocaudally in the auditory cortex. A tonotopic order could not be discerned. Cytoarchitectonically, it is difficult to demarcate the MGBs from the MGBv, since the cells are often similar in appearance. (3) The **rostromedial nucleus** (MGBrm) is situated in the medial portion of the rostral part of the MGB. It projects to a small tonotopic cortical field located rostrally to the anterior field. The neurons in the MGBrm are medium sized and much less densely packed than in the MGBv. (4) The **caudomedial nucleus** (MGBcm) lies in the caudal half of the MGB. It occupies a medial position and becomes more and more prominent posteriorly. This nucleus projects to the entire auditory cortex. The neurons are large, not very densely packed and deeply staining.

A comparison of the guinea pig with other species reveals some unexpected differences. The magnocellular (medial) nucleus of the cat lies rostrally in the MGB (MOREST 1964, J. Anat., 98:611-630), while its putative homologue in the guinea pig, the MGBcm, is located caudally. Moreover, it it unclear what might correspond to the guinea pig's MGBrm in other mammals. The shell nucleus of the guinea pig corresponds topographically to the dorsal, marginal and ventrolateral nuclei of the cat's MGB. But in the guinea pig, it is clearly a continuous structure, and there is no ground for subdividing it into several functional units.

410.4 HIERARCHICAL PROCESSING OF BINAURAL LEVEL CUES IN THE ASCENDING AUDITORY SYSTEM. M.N. Semple* and L.M. Kitzes* (SPON: Y. Torigoe). Dept. of Anatomy and Neurobiology, University of California, Irvine, Irvine CA 92717.

In the central nucleus of the inferior colliculus (ICC) of the gerbil, *Meriones unguiculatus*, most high-frequency neurons are influenced jointly by the interaural intensity difference (IID) and the average binaural intensity (ABI) (Semple, M.N. and Kitzes, L.M., *J. Neurophysiol.*, in press). Many such neurons respond nonmonotonically to one or both binaural intensity parameters. Thus, some units have a best IID, some have a best ABI (BABI), and others seem to be influenced by a two-way intensity network (TWIN), responding maximally to a particular combination of IID and ABI. The present study was designed to assess the processing of binaural sound pressures at two other levels of the auditory system, the superior olivary complex (SOC) and primary auditory cortex (AI).



High-frequency tones were presented through calibrated, sealed systems. Single neurons in gerbil SOC were typically influenced both by IID and ABI. BABI responses were common, but none of 56 SOC neurons displayed TWIN tuning. By contrast, TWIN responses accounted for 10% of our sample in gerbil ICC and 47% of AI neurons studied in one cat. A typical TWIN response from cat AI is illustrated, showing iso-rate contours for 50, 70 and 90% of peak discharge rate. In that experiment, BABI responses (27%) were also frequently encountered.

These results reveal that nonmonotonic tuning to IID and ABI is a property common to diverse mammalian species. Moreover, the finding that TWIN responses occur with increasing prevalence at successively higher levels of the auditory system indicates that TWIN tuning is a product of hierarchical processing of binaural information.

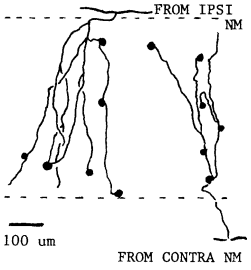
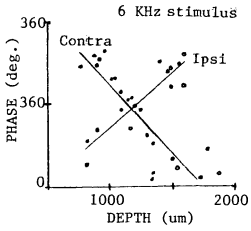
410.5 AXONAL DELAY LINES CREATE MAPS OF INTERAURAL PHASE DIFFERENCE IN THE OWL'S BRAINSTEM. C. E. Carr and M. Konishi. Div. Biology, California Institute of Technology, Pasadena, CA 91125.

Sensitivity to the interaural temporal disparities that underlie sound localization in the barn owl first appears in nucleus laminaris (NL), a brainstem auditory nucleus which is also the first recipient of binaural input. Eighth nerve afferents enter the brain and cochlear nuclei. Nucleus magnocellularis (NM) codes for phase information and projects bilaterally and tonotopically to NL.



The organization of NM afferents in NL provides a morphological substrate for a map of interaural delays. Incoming axons from the ipsilateral NM enter the dorsal surface of NL, while contralateral axons of the same frequency enter from the ventral surface. The afferents interdigitate (Fig. 1), and innervate NL neurons through the dorsoventral extent of the nucleus. If NM afferents act as delay lines, physiological recordings should reveal an orderly change in conduction delay with depth.

Period histograms were used to measure the timing of phase locked spikes in these afferents in over 200 intracellular recordings in NL. Systematic changes in phase were observed with depth; a gradual increase in delay was observed for ipsilateral afferents, and a decrease for contralateral afferents (Fig. 2). Outside the dorsal or ventral borders of the nucleus the phase shifts are less ordered, and the best frequency no longer constant. The conduction time through the nucleus reflects the time difference between the two ears (about 180 μsec) independent of frequency. Thus these afferents act as delay lines to create maps of interaural temporal disparities.



410.6 TUNING FOR INTERAURAL DIFFERENCE CUES VARIES WITH FREQUENCY FOR SPACE-SPECIFIC NEURONS IN THE OWL'S OPTIC TECTUM. S.D. Esterly and E.I. Knudsen. Department of Neurobiology, Stanford Univ. School of Medicine, Stanford, CA 94305.

The auditory system depends upon differences in the intensity and timing of a sound at the two ears to determine the location of the sound's source. The values of these interaural difference cues vary as a function of the frequency at which the cue values are measured. To exploit this information the auditory system must interpret interaural difference cues in a frequency-specific manner. The response properties of space-specific units in the optic tectum of the barn owl demonstrate that this is the case.

Interaural cue values were measured by placing probe tube microphones in the ear canals and presenting a wide-band noise stimulus from a moveable free-field speaker. The transfer function between the two microphone signals was calculated by a spectrum analyzer and provided values for interaural time differences (ITD's) and interaural intensity differences (ITD's). As expected, IID varied markedly with frequency for a given source location. In front of the owl, IID's were typically larger for high frequencies than for low frequencies. In contrast, for peripheral locations IID's could be larger at low than at high frequencies. ITD showed much less variation. Even so, at many locations there were large changes in ITD with frequency.

Space-specific units in the optic tectum respond to broad-band sounds only when the source is within a restricted region of space. We compared the responses of these neurons to free-field and dichotic stimulation. FFT-based filtering allowed precise control of dichotic parameters, including frequency-dependent specification of cue values within broad-band stimuli. Tuning for interaural cue values, within the frequency range of a unit, were well-matched to the probe tube data from the source location corresponding to the unit's receptive field. For example, units responding to frontal locations were typically found to be tuned to larger IID's at high frequencies and to smaller IID's at low frequencies. It is not yet clear whether tuning for ITD can also vary with frequency.

These results indicate that the frequency-specific interpretation of interaural difference cues is an important component of the auditory system's computation of the location of a sound source.

410.7 AZIMUTH AND INTENSITY SELECTIVITY OF SINGLE NEURONS IN FIELD AI OF CAT AUDITORY CORTEX. T.J. Imig, W.A. Irons, and F.R. Samson. Dept. of Physiology, Univ. Kansas Medical Center, Kansas City, KS 66103.

Single units (BFs 3-31 kHz) were studied using free-field stimulation. Barbituate anesthetized cats were placed in a support frame in a sound-isolated, quasi-anechoic chamber. Sounds were delivered from various locations (azimuths) in the frontal hemifield. Sound production, acoustic calibration, data collection and analysis were under computer control. Most units were studied in response to white noise bursts which varied between 0 and 80 dB SPL and in azimuth throughout the 180° frontal hemifield. Frequency selectivity and azimuthal selectivity to tone bursts were studied if time permitted. Isorate contours were computed and plotted in SPL-azimuth coordinates. Of a total of 51 well studied units, 10 exhibited labile or multipeaked functions and 12 were relatively insensitive to azimuth (omnidirectional). Many omnidirectional units were selective for intensity often exhibiting nonmonotonic intensity rate functions. Some exhibited similar best intensities for most or all azimuths. The remaining 29 units were azimuth selective, showing at least a 50% change in discharge rate with a change of <30° of azimuth. Sharper tuning was evident in 8/29 units in which a 50% change in discharge rate occurred over <10° of azimuth. Many azimuth selective units were completely unresponsive at certain azimuths. Many showed a well defined peak in discharge rate at a particular azimuth. Five units had peaks centered on the midline and did not respond at lateral locations. The remaining units had lateral receptive fields centered on the contralateral (18) or ipsilateral (6) sides of the head (hemifield and axial units, Middlebrooks and Pettigrew, J. Neurosci., 1:107-120, 1981). Within these receptive fields, there was a well defined peak of activity in some units and multiple peaks in others. Both the locations of the peaks and the boundaries of receptive fields varied among units. Most units were selective for stimulus intensity exhibiting nonmonotonic intensity rate functions. Best intensities ranged between 0 and 80 dB SPL. For many azimuth selective units, regardless of whether they were selective for a narrow or broad range of SPLs, azimuthal selectivity was relatively invariant with changes in SPL. At optimal or near optimal SPLs, azimuthal locations of receptive field peaks and one or both borders remained relatively invariant in spite of changes in SPL. This feature is appropriate for representing sound direction. Most units showed less (sometimes dramatically less) azimuthal selectivity in response to tones than to noise. In one case, a unit had a well defined midline receptive field when stimulated with noise, but was omnidirectional when stimulated with tones of various frequencies within its response area. Azimuthal selectivity of AI neurons is a product of interaural intensity differences, intensity selectivity and spectral complexity. (Supported by NINCDS Grant NS17720).

410.8 FREQUENCY CONTRAST FOR PURE AND COMPLEX TONES IN THE ALERT AUDITORY CORTEX. R.W.W. Tomlinson and D.W.F Schwarz. Lab. of Otoneurology, Div. Otolaryngology and Dept. Physiology, Univ. of British Columbia, Vancouver, B.C., Canada V6T 1W5.

In search for a neuronal pitch mechanism we recorded from neurons in the auditory cortex of monkeys which had previously been shown to perceive the pitch of a missing fundamental. While recording carefully isolated extracellular spikes, responses to pure tone stimuli were contrasted with thoses to harmonic complexes, with and without the fundamental and other low components. We have previously shown that "filter neurons" respond to pure or complex tones and noises whenever sound energy falls within their v-shaped response area. In contrast, "Fo neurons" are as sharply tuned to physically present complex tone fundamental frequencies, as they are to pure tones. Sharp tuning in these cell is independent of intensity and is associated with side band inhibition with a broad inhibitory band below the best (excitatory) frequency region. We now report on a new response class, the "contrast neurons". These cells exhibit adjacent excitatory and inhibitory frequency bands with pure tone stimuli, the inhibitory band being located above the excitatory band with a more or less sharp border between the two. Excitation and inhibition occur with identical or similar pure tone and Fo frequencies when complex tone stimuli are used. The frequency borderline (contrast) between excitation and inhibition is identical for complex tone fundamentals and pure tones, however, it drops by about one octave when the fundamental is removed from the complex. The contrast is stronger with complex tones and the border is also stable with respect to intensity. Excitation or inhibition can dominate the response to noise at different intensities in the same cell. It is conceivable (although uncertain) that contrast neurons represent an inhibitory input to Fo neurons, moulding their common sharply tuned excitatory band for both complex and pure tones.

410.9 ON-OFF CELLS IN THE INFERIOR COLLICULUS OF THE MUSTACHED BAT: ACOUSTIC GLINT DETECTORS? H.D. Lesser, R.D. Frisina, and W.E. O'Neill. Dept. of Physiology, Univ. of Rochester Sch. of Med. & Dent., Rochester, NY 14642.

Amplitude modulation is a dynamic feature common to communication sounds of many different species and plays a particularly important role in the case of echolocating bats pursuing flying insects. The mustached bat (Pteronotus parnelli) has a long constant-frequency component in its echolocation signal which, when reflected off of the beating wings of insect prey returns as an amplitude- (and frequency-) modulated echo. Modulations are also generated by interference between outgoing vocalizations and returning Doppler-shifted echoes (Henson et al., Nat'l Geographic Res. 3(1):82, 1987). Sudden amplitude changes in echoes ("acoustic glint") produced by reflections from insect wings may be important in both detection and discrimination of prey against a noisy background.

We have recorded from 354 neurons in the central nucleus of the inferior colliculus. Neurons were classified by their PST histogram response patterns to pure tones. Sinusoidal amplitude-modulated (SAM) stimuli (30 ms dur., 80% modulation, 33-800 Hz, 10 dB above threshold) were chosen to model echoes which occur during the approach phase of predation. Most units (81%) with on-off responses to pure-tone stimuli (n=42) showed no increase in firing or phase-locking to SAM stimuli. Many on-off units showed a period of inhibition preceding both the on and off responses. In units where background activity permitted detecting inhibition, 60% showed this biphasic, on-off response. Other unit classes, including on and on-sustained cells preferred SAM to pure-tone stimuli and showed phase-locked responses.

In one on-off unit, results of two-pulse stimulation and modulation of a pure tone with continuous pseudorandom (white) noise demonstrated the implications of this response pattern. This unit was unable to phase-lock to SAM and fired fewer spikes to SAM than to pure tones. It had a leading-inhibitory response to pure tone burst onset and offset.

In two-tone experiments, as the interval between two 2 msec tone bursts was reduced below 10 msec, the response to the **first** pulse decreased while the response to the **second** was unchanged. Two-pulse predictions made from the white-noise responses predicted the reduction in the first pulse response seen in the "classical" two-pulse experiment. This unusual response resulted from the interaction of the leading inhibitory response to the second pulse with late excitation from the first pulse.

In conclusion, a population of such neurons, whose high-pass characteristic makes them sensitive to transient, but not ongoing, amplitude modulations could function as "glint detectors" for echolocating bats hunting prey. 410.10 AUDITORY INPUTS AND RESPONSES OF SUPERIOR COLLICULAR NEURONS OF THE BIG BROWN BAT, EPTESICUS FUSCUS TO STATIONARY AND MOVING ACOUSTIC STIMULI. P.H.-S. Jen, W.P. Zhang*, X.D. Sun* and S.Q. Zhang*. Division of Biological Sciences, The University of Missouri, Columbia, MO 65212.

An echolocating bat has two well developed superior colliculi (SC) although its other visual centers are generally poorly developed. In order to study the functional role of the bat's SC during echolocation, we examined the responses of SC neurons of Eptesicus fuscus to stationary and moving pure tone pulses and/or frequency-modulated (FM) stimuli (4 ms duration, 0.5 ms rise-decay times) under free field stimulation conditions. Acoustic stimuli were broadcast either from a loudspeaker placed at several chosen azimuthal and elevational angles around the bat's head or from a moving loudspeaker broadcasting from the same azimuthal angles. Three angular velocities (36°/S, 90°/S, and 180°/S) were chosen and more than three stimulus intensities above the minimum threshold (MT) of each neuron were used. The MT and discharge rate of each neuron as a function of loudspeaker position was systematically examined. HRP solution was then iontophoretically ejected from micropipette glass electrodes onto the recording sites in order to study the auditory inputs to the SC. SC neurons generally discharged only a few action potentials to acoustic stimuli. Their response latencies were between 3.6 and 20 msec, but most were below 12.5 msec. All neurons had triangular threshold curves. They were more sensitive to downward-sweep FM stimuli than to pure tone pulses. They displayed their lowest MT and maximal discharge rate to acoustic stimuli delivered from the contralateral hemifield of the bat's frontal auditory space. The angle of maximal discharge rate of each neuron did or did not change as a function of stimulus intensity. The maximal discharge rate of SC neurons generally changed as a function of moving stimulus velocity. While some neurons discharged maximally at a specific angle regardless of direction of stimulus movement, other neurons only discharged maximally when the stimulus was moved at one direction or was moved away from the center line. The SC of Eptesicus fuscus can be classified into superficial, intermediate and deep layers according to the principal cell type of each layer. Neurons isolated from the superficial layer generally had poorer signal-to-noise ratio than those isolated from the deep layer. Histological examination showed that the SC receives auditory inputs from the inferior colliculus and nucleus of the lateral lemniscus. Labelled neurons were also found in visual cortex, medial vestibular nucleus, central gray, substantia nigra, reticular formation, lateral pontine nucleus, interpeduncular nucleus, fastigial and dentate nuclei. (Supported by NIH grant NS 20527 to P. Jen).

410.11 INTERCONNECTIONS BETWEEN THE MEDIAL GENICULATE BODY AND THE AUDITORY CORTEX IN AN FM BAT. Sharon Shannon* and Donald Wong. Department of Anatomy, Indiana University School of Medicine, Indianapolis, IN 46223.

The echolocating bat Myotis lucifugus contains delay-sensitive neurons that exhibit facilitative responses to FM sound pairs at specific echo delays (Sullivan, J. Neurophysiol. 48:1011, 1982). These delay-sensitive cortical neurons provide the bat with information about target distance. To explore the anatomical basis of how these physiological response properties are generated, the interconnections of this functional subregion in the auditory cortex with the medial geniculate body (MGB) were traced with horseradish peroxidase (HRP). HRP was iontophoretically injected into a zone containing delay-sensitive neurons mapped from extracellular single-unit recording. Cell and fiber labeling was found in the dorsal part of the MGB. Although larger injections (about 200 um dia.) resulted in more extensive labeling in the dorsal MBG, discrete labeling was also found in the ventral and dorsomedial parts. Injections made into the tonotopic central nucleus of the inferior colliculus resulted in a distinctive laminated pattern of fiber labeling. The differing patterns of geniculate labeling suggest that different parts of the MGB generate projections to functionally distinct delay-sensitive and tonotopic zones. These results are consistent with findings of separate FM-FM and tonotopic parts of the MGB as demonstrated in neurophysiological and neuroanatomical tracing studies in the mustached bat, Pteronotus parnellii (Olsen, Neurosci. Abstr. 8:349, 1982).

This work was supported by BRSF from Indiana University (PHS S01 RR 5371-H 46-821-01).

410.12 PERIODICITY OF SOUND WAVE ENVELOPES IS MAPPED IN THE FOREBRAIN OF THE MYNAH BIRD B. Hose, G. Langner, and H. Scheich (SPON: ENA) Zoological Institute, Technical University, 6100 Darmstadt, FRG

Coding of periodic acoustic signals was studied within field L, the avian analogue of the mammalian auditory cortex. Field L is trilayered and tonotopically organized. Isofrequency planes are oriented across the three layers L_1, L_2, and L_3 in a roughly orthogonal fashion. The central lamina L_2 receives most of the afferents from the thalamus while L_1 and L_3 are postsynaptic to L_2.

The synchronization of unit responses to envelopes of sinusoidally amplitude modulated tones (SAM) and repetetive narrow band noise bursts (RNB) were determined as a function of envelope frequency (EF). The degree of synchronization was expressed in terms of vectorlength of circular statistics.

From 428 acoustic field L units 77 % showed a synchronized response to RNB or SAM. 66% of these were tuned to a best envelope frequency (BEF). BEFs varied from 0.3 to 380 Hz and showed an orderly representation within isofrequency planes (Hose, B., Neurosci.Lett.Suppl., 22:170, 1985). BEFs were more or less symmetrically distributed above and below the input layer L_2. In L_2 units preferred significantly higher EFs than in the postsynaptic layers. A limen between overlapping ranges of EF representation could be drawn at about 20 Hz. 65 % L_2 units preferred EFs above 20 Hz, while in the postsynaptic layers L_1 and L_3 86 % respectively 83 % units had BEFs below 20 Hz. Sharpness of temporal tuning in terms of Q_{3dB} was significantly higher in L_1 and L_3 than in the input layer L_2.

The present results give a first idea of the organization of auditory forebrain fields: They demonstrate a spatial relationship between lamination, spectral (tonotopy), and temporal (EF representation) signal parameters. Along the ascending auditory pathway within the forebrain field the lamination separates coding of simple from specialized spectral (Langner, G., Exp. Brain Res., 43: 11, 1981) and temporal properties of sounds and high from low EFs. The latter finding may contribute to a discussion about a key issue of psychophysics and behavioural physiology of SAM signals: SAM signals with EFs below about 20 Hz in humans psychophysically elicit the perception of loudness fluctuations or rhythms. For higher EFs the sensation cannot follow the loudness fluctuations and, beside other sensations, one may perceive periodicity pitch. Temporal resolving power in birds was described to be only slightly better when compared to humans (Dooling, R.J., J.Comp.Physiol., 143: 383, 1981). Thus, following the comparison, the majority of postsynaptic L_1 and L_3 units were tuned to rhythms typical for animal communication sounds and speech, while units of the input layer L_2 covered at least four of five octaves of the range of periodicity pitch sensation. Supp. by DFG-SFB 45.

410.13 INTERHEMISPHERIC DIFFERENCES IN MID-LATENCY AUDITORY MAGNETIC SOURCES IN NORMAL SUBJECTS. M. Reite, P. Teale, J. Whalen, J.E. Zimmerman, and K. Davis. University of Colorado Health Sciences Center, Denver, CO 80262.

We recorded magnetic evoked fields (EF) from left and right hemispheres of 6 normal adult subjects ages 28-50, using a second order gradiometer with 20mm coil diameter, 6cm baseline, and DC SQUID. Recordings were obtained inside an aluminum room providing 50 dB attenuation at 60 Hz. We constructed a recording grid over each hemisphere referenced to the tragus-vertex (T-V) line and a line 2 cm above and parallel to the nasion-inion (N-I) line called the N-I reference line. Stimuli were 15 msec long 1 KHz 75 dB SPL tone pips delivered to the ear by a series of plastic tubing, with a repetition rate random within 800-1200 msec. Averages were obtained from 128 stimulus presentations. Averages were digitally filtered using a pass band of 4-40 Hz, resulting waveforms plotted, and the approximately 50 msec latency component (M50) identified. M50 amplitudes (in fT) were measured from a 200 msec pre-stimulus baseline and were used to construct isofield topographical contour plots, which were used in the calculation of subsequent source location estimates. Orientation of the source dipole (θ) was expressed in terms of positive degrees (forward tilt) or negative degrees (backward tilt) from the T-V line. Dipole strength (Q) in nA-m was estimated using the amplitude of the strongest extrema, and the calculated depth (d in cm). A prominent EF component with a latency of approximately 50 msec was clearly apparent over both left and right hemispheres in all subjects. The field was outgoing anteriorly (positive extrema anterior) and ingoing posteriorly (negative extrema posterior) over the left hemisphere and vice versa over the right hemisphere. Sources were significantly higher with reference to the N-I reference line over the left hemisphere (29.1$\pm$9.5mm) as compared to the right hemisphere (16.2$\pm$8.5mm) using a t-test (t= 2.48; df=10; p=.033, 2-tailed). This difference was not related to handedness. There was a trend for sources to be more anterior with respect to the T-V line over the right hemisphere (7.1$\pm$12mm) compared to the left hemisphere (-2.0$\pm$10.9 mm) using a t-test (t= 1.38; df=10; p=.10, 1 tailed). No significant differences were noted between left and right hemispheres for either θ, Q, or d, nor were these variables related to handedness. Magnetic resonance imaging in 5 of the 6 subjects demonstrated that the estimated sources were in the planum temporale bilaterally. Our findings are compatible with those of Geschwind and Levitsky (Science, 161:186, 1968), who demonstrated in a series of 100 brains examined postmortem that the planum temporale is larger over the left hemisphere and somewhat more anterior over the right hemisphere. Supported by USPHS MH41396 and MH46335.

NEUROTRANSMITTERS AND RECEPTORS: HISTAMINE

411.1 CIRCADIAN VARIATION OF HISTAMINE (Hm) RELEASE IN THE EXTRACELLULAR SPACE OF THE RAT BRAIN IN VIVO. W.L. Russell*, L.A. Phebus*, J.A. Clemens and D.P.Henry*. (Spon: L. Lemberger), Dept. of Pharmacology, Indiana Univ. Sch. of Medicine, 46202. Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN 46285.

Our in vivo release studies suggest that Hm functions as a neurotransmitter in the rat (Russell et al., Soc. Neurosc. Abst. 12:431, 1986). However, the physiological function of Hm in the CNS has not been established. All H_1 Hm antagonists that permeate the blood brain barrier are sedating, therefore, Hm may be involved in the regulation of sleep-wake cycles. To test this hypothesis, we have correlated Hm content in the extracellular space of the brain with the sleep-wake cycle of the rat. Using in vivo brain microdialysis coupled with a sensitive radioenzymatic assay (REA) (Verburg, K.M. et al., Life Sci., 32: 2855, 1983), we find that Hm in the brain extracellular fluid of conscious rats demonstrates a diurnal cycle. Male Sprague-Dawley rats were anesthetized and microdialysis probes were placed stereotaxically into the posterior hypothalami or striata. Three days after surgery, sterile ringer solution was pumped through the probe (1 microliter per minute) and dialysate samples were collected at 3-hour intervals. With this flow rate, in vitro recovery of Hm was 40%. Hm level in each sample was measured by REA. Lights were turned on at 4am and off at 6pm.

Hm Dialysate Level (pg/ml) in Rat Brain Areas

	Striatum (n=8) mean ± SEM		Hypothalamus (n=5) mean ± SEM	
11am- 2pm	147	113	760	255
2pm- 5pm	128	83	739	292
5pm- 8pm	187	76	1167	412
8pm-11pm	251	73	1298	571
11pm- 2am	306	81	1429	422
2am- 5am	282	82	1162	430
5am- 8am	123	85	530	146
8am-11am	141	44	677	300

In the hypothalamus and corpus striatum, Hm levels were lowest at 5am-8am and peaked at 11pm-2am. In both areas, Hm levels were higher during the dark portion of the light-dark cycle ($p<0.0001$). The hypothalamic Hm levels were 4 times higher than in the corpus striatum. These results are in agreement with immunocytochemical studies, demonstrating histaminergic neuronal cell bodies in the posterior hypothalamus (Pollard & Schwartz, Trends in Neurosci. Feb. 10, 1987). Lesion experiments in monkeys and rats also suggested that a posterior hypothalamic area was necessary for the maintenance of wakefulness. In conclusion, the 24-hour diurnal rhythms that we have demonstrated support a physiological role for Hm neurons in modulating sleep-wake cycles.

411.2 EVIDENCE FOR RELEASE OF HISTAMINE BY IDENTIFIED *APLYSIA* NEURON C2 *IN VITRO*. H. J. Chiel, W. L. Russell*, K. Revesz*, and D.P.Henry*. Mol. Biophys. Res. Dept., AT&T Bell Labs, Murray Hill, NJ 07974 and Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN 46285

Histamine appears to be a neurotransmitter in vertebrates and invertebrates. Its presence, synthesis, and postsynaptic actions have been demonstrated in the mammalian central nervous system (Pollard et al., TINS, 10(2):86-89, 1987). Recent work suggests that histamine may be released from neuronal cells (Russell et al., Soc. Neurosci. Abstr., Vol. 12, part 1, p.431, 1986). In the marine mollusc *Aplysia* , the identified neuron C2 has been shown to contain and synthesize histamine, and C2's postsynaptic actions can be mimicked by histamine application (Weinreich, Nature, 267:854-6,1977). Release of histamine from C2 has been difficult to demonstrate *in vivo* because of a ubiquitous metabolizing enzyme, gamma-glutamyl histamine synthetase (Stein et al., J. Neurochem. 38(1):204-214,1982). Recent advances, however, have made it possible to study this problem: (1) Improvement of techniques for culturing identified *Aplysia* neurons and (2) Development of a sensitive histamine radioenzymatic assay (Verburg et al., Life Sci., 32:2855-67,1983).

C2 neurons were identified morphologically, extracted from the cerebral ganglia of juvenile *Aplysia* (3-5 gms), and plated in Sylgard microwells whose volume was 100ul, and which had been prepared for cell culture using the techniques of Schacher et al. (J. Neurosci 3:2403-13,1983). Experiments were done on freshly extracted cells, and on cells that had been plated for 24-36 hours, at which time the cells were attached to the substrate and showed normal resting and action potentials. C2s had 1.2 $\pm$ 0.2 pmoles histamine per cell (n = 4; all values are mean $\pm$ s.d.), levels comparable to those reported by Weinreich et al. (Br. Res., 84:341-5, 1975). Metacerebral cells, which are known to contain serotonin and not histamine, had levels of histamine equal to those measured in cell-free *Aplysia* saline (88 $\pm$ 5.6 pg/ml, i.e., $<$ 0.1 pmole/cell, n = 2). Levels of histamine in microwells containing 4 C2s showed no significant change when washed with a 5x normal potassium saline (20mM) containing 0.1x normal calcium (1mM), going from 47 $\pm$ 1.4 pg/ml before wash to 52.5 $\pm$ 23.3 pg/ml after (n = 2), but showed very significant increases when washed with a 5x potassium saline containing normal calcium (10mM), going from 53 $\pm$ 17 pg/ml before wash to 159 $\pm$ 7.1 pg/ml after (peak values, n = 2, $p<.05$). Levels of histamine in microwells containing single C2s rose from a resting level of 60.5 $\pm$ 36.4 pg/ml to 149 $\pm$ 61.5 pg/ml after washing with 5x normal potassium *Aplysia* saline, and these levels fell back to control after two washes with regular *Aplysia* saline (n = 4). In another experiment, when a single C2 was bathed with 0.1x calcium saline, and the cell was impaled with a microelectrode, levels of histamine in the microwell showed no increase after the cell had been fired steadily for 1 minute (223 pg/ml before firing; 205 pg/ml after firing). In contrast, after several washes with 5x normal calcium saline, the levels increased from 137 pg/ml to 217 pg/ml after C2 was fired steadily for 1 minute, and declined to 169 pg/ml after two more washes with the same saline.

These results support the hypothesis that, *in vitro*, C2 releases histamine in a calcium dependent manner when it is physiologically activated. (H.J.C. was supported by a grant from AFOSR under contract F49620-85-C-0009.)

411.3 ACTION OF HISTAMINE AND HISTAMINE ANTAGONISTS ON ACTIVITY OF AFFERENT NERVE FIBERS IN THE XENOPUS LATERAL LINE. S. C. Bledsoe, Jr. and R. Sinard*. Kresge Hearing Research Institute, Univ. of Michigan Medical School, Ann Arbor, MI 48109.

Guth et al. (ARO Abstracts 10:107, 1987) reported that histamine, at micromolar concentrations, excites afferent nerve fibers in the frog semicircular canal. We examined the effects of histamine and histamine receptor antagonists on the lateral line of Xenopus laevis to explore further the mechanisms of action of histamine at a hair cell-afferent nerve synapse.

The in vitro methods for isolating and recording afferent nerve responses from a single lateral-line organ and applying drugs dissolved in frog Ringer solution to the serosal surface of the skin were as previously described (Bledsoe and Bobbin, Neurosci. Letters 32: 315, 1982).

Histamine at concentrations between 2 uM and 2 mM had no effect on lateral line afferent nerve activity. In contrast, pyrilamine, an H_1 receptor antagonist, beginning at 20-50 uM, suppressed spontaneous activity. At 250-500 uM, pyrilamine abolished spontaneous activity and suppressed water-motion induced excitation. The effects on spontaneous activity were not fully reversible. Cimetidine, an H_2 receptor antagonist, had similar actions but was about one-half as potent as pyrilamine. Pyrilamine (50-200 uM) suppressed responses to a number of excitatory amino acids, including L-glutamate and L-aspartate (0.5-2.0 mM), kainate (5-10 uM), quisqualate (2-5 uM) and N-methyl-D-aspartate (0.5-1.0 mM). Histamine (1.0-2.0 mM) failed to block the suppressive effects of pyrilamine and cimetidine suggesting their actions are mediated through a mechanism other than blockade of histamine receptors. The effects of tetrodotoxin (0.005-0.1 uM) on spontaneous activity and water motion- and amino acid-induced excitation were similar to those of the histamine antagonists.

Our results are inconsistent with histamine being an excitatory transmitter in the Xenopus lateral line. Moreover, they reveal that the actions of histamine antagonists in this hair-cell system are nonspecific and possibly mediated by blockade of voltage-sensitive Na^+ channels. (Supported by NIH Program Project Grant NS-05785.)

411.4 DISTRIBUTION OF HISTAMINE-IMMUNOREACTIVE NERVE FIBERS IN THE RAT AND GUINEA PIG BRAIN AFTER FIXATION WITH CARBODIIMIDE. P. Panula, M.S. Airaksinen*, S. Auvinen*, A. Virkamäki*, U. Pirvola* and L. Kivipelto. Dept. Anatomy, Univ. Helsinki, 00170 Helsinki, Finland.

Histamine (HA) is a putative neurotransmitter in mammalian brain and HA-immunoreactive neurons are located in the posterior basal hypothalamus in the rat brain (Panula et al., Proc. Natl. Acad. Sci. USA 81:2572-2576, 1984). Although nerve fibers immunoreactive for HA have been localized in different parts of the rat brain, a complete mapping of these fibers has not been done, and little is known about HA-containing neuronal systems in other species. In this study, rats and guinea pigs were studied with an antiserum against HA conjugated to hemocyanin with 1-ethyl-3(3-dimethylamino-propyl)carbodiimide (EDCDI) to reveal the distribution of HA-immunoreactive neurons and nerve fibers in the brain.

Adult Sprague-Dawley rats and guinea pigs were perfused through the left heart ventricle with saline followed by 50-150 ml of ice-cold 4% EDCDI in 0.1 M sodium phosphate buffer. The brains were immersed in the same fixative for 2 h and washed overnight in phosphate buffer containing 20% sucrose. 10-60 µm thick cryostat sections were incubated with the HA antiserum HA11C diluted 1:1000-1:2000 overnight, washed and processed according to the indirect immunofluorescence or PAP procedure. The specificity of the antiserum was established with blocking controls with histamine and related substances, model experiments on nitrocellulose filters and affinity-purified antibodies.

Widespread distribution of HA-immunoreactive nerve fibers was revealed in both species. Fibers were detected in all parts of the cerebral cortex, especially in the piriform cortex. Moderate densities of immunoreactive fibers were seen in the olfactory tubercle, lateral septal nucleus, nucleus of the diagonal band, stria terminalis, amygdala, substantia nigra and dorsal medullary nuclei. Many fibers were observed in the immediate vicinity of the cerebral ventricles, and fibers were also seen among myelinated fiber bundles including corpus callosum, tractus opticus and commissura posterior. Many nerve terminal-like structures but few fibers were seen in the nucleus accumbens and neostriatum. Dense networks of immunoreactive nerve fibers were found in several hypothalamic nuclei, especially in the peri- and paraventricular nuclei, in the vicinity of the supraoptic nucleus and chiasma opticum and in the posterior basal hypothalamic nuclei. Only occasional immunoreactive nerve fibers were seen in the rat cerebellum, while many fibers were found in the guinea pig cerebellum, mostly in the granular layer but also in the molecular layer. The results provide detailed information on the distribution of HA-containing fibers in the brain and offer an opportunity to study the connections of HA-containing neurons with their target cells.

411.5 ENDOGENOUS HISTAMINE EXCITES POSTGANGLIONIC NEURONS IN THE GUINEA PIG SUPERIOR CERVICAL GANGLION. E.P. Christian[1,*], D. Weinreich[1] and B.J. Undem[2,*]. [1]Dept. of Pharmacology, Univ. of Maryland Sch. of Med., Baltimore, MD. 21201 and [2]Dept. of Medicine, Johns Hopkins University, Baltimore, MD 21239.

Substantial evidence has accumulated that exogenously applied histamine can affect peripheral autonomic neurons and synapses. In addition, histamine has been shown to be present in mast cells which reside in autonomic ganglia. Nonetheless, it remains unsettled, whether histamine contained in peripheral autonomic ganglia is released under physiological (or pathophysiological) conditions in sufficient amounts to affect autonomic neurons. We have obtained evidence that endogenous histamine can be released by an appropriate immunological stimulus in the superior cervical ganglion (SCG), and has specific electrophysiological effects on postganglionic neurons.

Adult guinea pigs were actively sensitized to the antigen, ovalbumin. Approximately three weeks later the SCG were isolated and maintained in vitro in a perfusion chamber for intracellular recording studies. When tissue was challenged with ovalbumin (10 µg/ml), approximately 30% of the endogenous histamine stores were released. Ovalbumin-induced histamine release reached a peak within one min. of antigen exposure, and declined to below measureable levels within ten min. Coincident with the time course of this release, intracellular current clamp recordings in 24 of 32 neurons (32 preparations) revealed a transient depolarization of membrane potential 6.1 ± 3.91 mV (mean ± S.D.; range, 2-16 mV, n = 24). The depolarization was usually accompanied by an increase in total input resistance of the neuron. These effects could be mimicked by exogenously applied histamine (10 µM) and blocked by pretreatment with the H-1 histamine receptor antagonist, pyrilamine (1 µM).

Histamine can therefore be liberated within the SCG by a immunological stimulus in sufficient amounts to affect the passive membrane properties of postganglionic neurons in a manner that presumably increases cell excitability. These data support a hypothesis that endogenous histamine can influence the functional integrative properties in autonomic ganglia.

411.6 SPECIFIC BINDING OF [^{3}H]HISTAMINE IN GUINEA-PIG CEREBRAL CORTEX. W.G. Sinkins*, D.L. Cybulsky*, M. Kandel*, S.I. Kandel*, W. Schunack* and J.W. Wells (SPON: J.W. Goh). Faculty of Pharmacy, University of Toronto, Toronto, ON M5S 1A1, Canada, and Institut für Pharmazie, Freie Universität Berlin, D-1000 Berlin 33, FRG.

Saturable binding of [^{3}H]histamine at equilibrium in homogenates of washed tissue from guinea-pig cerebral cortex appears to reveal two classes of sites. Simultaneous analysis of data acquired by isotopic dilution of 1.4 nM [^{3}H]histamine and by varying the concentration of the radioligand yields parametric values as follows: log K_{P1} = -8.46 ± 0.02, log K_{P2} = -6.36 ± 0.18, $[R_1]_t$ = 77-120 pmol/g of protein, $[R_2]_t$ = 750-1200 pmol/g of protein. The inclusion of 0.1 mM GMP-PNP is accompanied by a 50% reduction in $[R_1]_t$ and an increase in log K_{P1} to -8.38 ± 0.03; there is no discernible change in either K_{P2} or $[R_2]_t$. The data thus suggest that the nucleotide promotes the conversion of sites from a state of high affinity to a state in which binding is not measurable. Values of K_{P1} and K_{P2} agree well with those reported for H_2 receptors labelled by [^{3}H]histamine in rat cerebral cortex (Steinberg et al., Biochemistry, 24:6095-6125, 1985).

The inhibitory behaviour of 20 histaminic drugs is well described by a model with either one or two classes of sites depending on the drug. There is no correlation among H_2 antagonists between inhibitory potency versus [^{3}H]histamine (IC_{50}) and pA_2 for blockade of the H_2 response of guinea-pig right atrium; the pattern thus differs from the H_2 pharmacological specificity observed previously in rat cortex. In contrast, there is good numerical agreement and an excellent correlation between IC_{50} and apparent affinity at the sites labelled by [^{3}H]histamine in digitonin-solubilised preparations from rat cortex ($r = 0.985$, $P < 0.00001$). Comparisons of rank order suggest that IC_{50} may correlate with the reported potency for agonists ($P < 0.025$) but not for antagonists ($P > 0.1$) at H_3 receptors. The identity of the sites labelled in guinea-pig thus remains unclear.

Two lines of evidence suggest that inhibition of [^{3}H]histamine by at least some unlabelled drugs is non-competitive. Firstly, 10 compounds, including the H_2/H_3 antagonist S(+)sopromidine, require two classes of sites for a competitive model to describe the data; the apparent distribution of sites varies significantly from drug to drug. Secondly, simultaneous analysis of binding patterns obtained for S(+)sopromidine at 1.2 nM and 10 nM [^{3}H]histamine yield values of log K_{P1} and log K_{P2} for [^{3}H]histamine of -8.59 ± 0.10 and -8.12 ± 0.05, respectively; the latter value differs from that measured with histamine alone (log K_{P2} = -6.36, P = 0.0043). The inconsistency is resolved, however, if the data are analysed in terms of three classes of sites; apparently non-competitive behaviour thus may reflect the limits of resolution in single experiments. (Supported by the Medical Research Council of Canada)

411.7 REGIONAL BRAIN HISTAMINE LEVELS IN RATS FOLLOWING PREOPTIC RECESS PERIVENTRICULAR TISSUE LESIONS. V. Schaumloffel*, J. Van Huysse*, and S. L. Bealer. Department of Physiology and Biophysics, University of Tennessee, Memphis, TN 38163.

Electrolytic ablation of the periventricular tissue surrounding the anteroventral portion of the third ventricle (AV3V-X) results in both acute and chronic attenuation of vasopressin (AVP) release in response to hyperosmolarity. Histamine (Hm) has been implicated as a mediator of AVP secretion. Intracerebroventricular injection of Hm produces dose-related increases in AVP secretion (Dogterom *et al., Experientia* 32: 659, 1976), and an excitatory action of Hm on supraoptic neurons has been demonstrated *in vitro* (Armstrong and Sladek, *Neuroscience* 16: 307, 1985). Furthermore, levels of Hm and HNMT, the Hm-metabolizing enzyme, in the posterior pituitary indicate increased Hm turnover following chronic hypertonic saline administration (Verburg *et al., Neurosci. Abstr.* 9: 705, 1983). To determine if Hm could be a potential mediator of AV3V-X-induced changes in AVP secretion, Hm concentrations in several brain areas following AV3V ablation were measured.

Rats were either electrolytically lesioned in the AV3V region or underwent control surgery (Con). Animals were decapitated 1-5 hours postoperatively. The brain was removed, immediately frozen, subsequently blocked, and homogenized in 1 M perchloric acid. Hm concentrations in six brain regions were determined by radioenzymatic assay.

	Con (ng/g; n = 5)	AV3V-X (ng/g; n = 6)
Spinal cord	93.2 ± 28.2	65.8 ± 7.7
N. tractus solitarius	25.3 ± 1.4	26.7 ± 3.1
Midbrain	23.4 ± 2.4	26.2 ± 3.7
Forebrain	40.6 ± 4.8	53.5 ± 5.4
Hypothalamus	305.8 ± 44.9	424.3 ± 29.6*
Pituitary	213.4 ± 18.9	299.5 ± 40.3

*$p < 0.05$.

Hm concentrations in the hypothalamus of AV3V-X rats were significantly elevated (424.3 ± 29.6) compared to control-operated animals (305.8 ± 44.9). However, there were no differences in Hm levels in other regions.

Since measured levels of Hm obtained in these experiments reflect total intracellular and extracellular Hm, increased levels can indicate increased synthesis and/or release, or decreased metabolism. Therefore, the precise relationship of the AV3V region, vasopressin secretion, and histamine cannot be established. However, these data are consistent with the hypothesis that histamine may act as a mediator of altered vasopressin release in AV3V-lesioned rats. (Sponsor: P.K. Law)

411.8 ONTOGENY OF HISTAMINERGIC TUBEROMAMMILLARY NEURONS IN THE RAT. P.B. Reiner, K. Semba, H.C. Fibiger and E.G. McGeer, Kinsmen Laboratory of Neurological Research, Department of Psychiatry, University of British Columbia, Vancouver, BC, Canada V6T 1W5.

The tuberomammillary (TM) nucleus is populated by a group of neurons which are immunoreactive to both histamine and its synthetic enzyme, L-histidine decarboxylase (HDC). These neurons have received increased interest of late with the realization that their somata stain positively for a large number of putative transmitters and related enzymes. The present study was designed to determine the stage of fetal development at which TM histaminergic neurons undergo their final mitotic division.

Tritiated thymidine autoradiography was combined with HDC immunohistochemistry, using a polyclonal antibody whose specificity has been previously documented (Watanabe et al.,'84), and counts of single (HDC immunoreactivity only) and double (HDC immunoreactivity and tritiated thymidine) labelled neurons were carried out. For the purposes of the present analysis, the TM nucleus was parcelled into five subdivisions as defined by Staines et al. (in press): caudal, ventral, lateral, tuberal and interstitial. Percentages of double labelled neurons were plotted for days 13-18 of fetal life (conception counted as day 0). Only immunopositive neurons in which the nucleus was clearly identifiable, and double labelled cells with heavy grain counts were included in the analyses. The data showed that TM neurons undergo a peak of final mitotic activity on day 16 of fetal life. There was no apparent difference between subdivisions of the TM nucleus. These data are consistent with the results of Altman and Bayer ('86) using tritiated thymidine autoradiography alone. Adenosine deaminase, a reliable marker of TM neurons, has been detected immunohistochemically on embryonic day 18 (Senba et al., '87) and our preliminary data indicate that HDC immunoreactivity is detectable at day 19. Thus, TM neurons appear to begin expression of their transmitter phenotype soon after becoming post-mitotic.

Parallels between histaminergic TM neurons and brainstem aminergic neurons have been drawn on the basis of their strikingly similar anatomical, biochemical and physiological properties. However, brainstem aminergic neurons become post-mitotic much earlier in fetal life, around embryonic day 11-13. Thus, while histaminergic neurons share a number of properties with brainstem aminergic neurons, their ontogenesis occurs much later.

411.9 DISTRIBUTION OF MAST CELLS IN THE LEPTOMENINGES AND ALONG BLOOD VESSELS ON THE SURFACE OF THE MOUSE BRAIN. E.L. Orr. Dept. of Anatomy, Texas Coll. of Osteopathic Med., Ft. Worth, TX 76107.

Since the leptomeninges and velum interpositum of many vertebrate species have been reported to contain large numbers of mast cells, we have determined the relative distribution of mast cells in the leptomeninges and along surface blood vessels of the mouse brain using toluidine blue to specifically stain the mast cells of formalin-fixed whole mouse brains. The presence and distribution of mast cells in the velum interpositum and along the blood vessels of the velum interpositum were assessed in the same mouse brains after removal of the cerebral cortex covering the velum interpositum.

Except for some small concentrations of mast cells at the ventral junction between the olfactory bulbs and frontal lobes, and in the leptomeninges of the cruciate sulcus, we found that mast cells on the surface of the mouse brain are essentially confined to the area of the velum interpositum of the transverse fissure, primarily in association with the blood vessels which enter, traverse or exit the brain via the velum interpositum. Only a very few mast cells were found associated with the remainder of the vessels and leptomeninges of the mouse brain surface.

In the area of the velum interpositum, most of the mast cells were found associated with the following blood vessels: Arteries: posterior cerebral, longitudinal hippocampal, transverse collicular, and posterior choroidal; Veins: thalamostriate, internal cerebral, and basal. Thus, mast cells are distributed along the blood vessels which perfuse or drain the thalamus, hippocampal formation, corpus striatum, corpora quadrigemini, and the choroid plexi of the lateral ventricles. Such a distribution suggests that mast cells and their products (e.g., histamine, serotonin, leucotrienes) may be involved in regulating the regional permeability of, or the blood flow through the vessels supplying or draining these important brain regions.

The results of this study demonstrate that mast cells are differentially distributed on the surface of the mouse brain, and cannot be considered to be general component of the leptomeninges. Moreover, since the mouse brain contains very few, if any, intracerebral mast cells, it is likely that mast cells are not a major source of non-neuronal histamine or serotonin in the mouse brain. (Supported by an Organized Research Grant from T.C.O.M.)

411.10 HISTAMINE METABOLITES IN CEREBROSPINAL FLUID OF THE RHESUS MONKEY: CISTERNAL-LUMBAR CONCENTRATION GRADIENTS. G.D. Prell, J.K. Khandelwal*, R. S. Burns and J.P. Green. Dept. of Pharmacology, Mount Sinai School of Medicine of the City University of New York, New York City 10029 and Section on Experimental Therapeutics, NIMH, Bethesda, MD 20205

Similar to metabolites of other aminergic transmitters, the histamine metabolites of brain, tele-methylhistamine (t-MH) and tele-methylimidazoleacetic acid (t-MIAA), could have a concentration gradient between rostral and caudal sites of CSF. To test this hypothesis, cisternal and lumbar CSF samples were collected in pairs from 8 monkeys (Macaca mulatta), and levels of t-MH and t-MIAA were measured by gas chromatography-mass spectrometry. pros-Methylimidazoleacetic acid (p-MIAA), an endogenous isomer of t-MIAA that is not a histamine metabolite, was also measured as a control. Cisternal levels (pmol/ml, mean ± S.E.M.) of t-MH (9.9 ± 1.4) and t-MIAA (40.8 ± 7.6), but not p-MIAA (9.7 ± 1.2), exceeded those in lumbar CSF (t-MH, 1.8 ± 0.3; t-MIAA, 6.8 ± 0.9; p-MIAA, 8.6 ± 0.6) in every monkey. The magnitudes of the mean cisternal-lumbar concentration gradients for t-MH (6.6 ± 1.1) and t-MIAA (6.5 ± 1.3) were indistinguishable. There was no gradient for the levels of p-MIAA (mean cisternal-lumbar ratio 1.1 ± 0.1). The cisternal, but not lumbar, levels of t-MH and t-MIAA were correlated. There was no significant difference between the means of the metabolite concentration ratios (t-MIAA/t-MH) in cisternal (4.0 ± 0.4) and lumbar (4.4 ± 0.9) CSF. The steepness of these gradients, which exceed the gradients of the metabolites of most other transmitters, suggest that the levels of t-MH and t-MIAA in lumbar CSF might be useful to probe histaminergic metabolism in brain. (Research supported by NIMH grant 31805).

412.1 **SEROTONIN (5-HT_2) RECOGNITION SITES AND ^{3}H-IMIPRAMINE BINDING (IB) SITES IN THE BRAINS OF SUICIDE VICTIMS.** R.C. Arora and H.Y. Meltzer. Department of Psychiatry, School of Medicine, Case Western Reserve University, Cleveland, OH 44106.

IB sites and 5-HT_2 recognition sites were studied in the brains of suicides and normal controls who died due to heart diseases. Previous studies have indicated decreased number of IB sites and increase number of 5-HT_2 sites in suicides than normals but there are conflicting reports. Frontal cortex (Broadman's areas 8 and 9) from eighteen suicides and normal controls were obtained at autopsy. The medical examiner had determined the cause of death in suicides and normal controls. The mean interval between death and collection of the sample was 13.05 ± 6.82 hrs and 12.95 ± 7.1 hrs for suicides and normals respectively. The mean age of the two groups was 43.6 ± 17.9 yrs and 46.2 ± 21.4 yrs. 5-HT_2 binding was studied using ^{3}H-spiroperidol as the binding ligand. IB was determined with ^{3}H-imipramine.

5-HT_2 binding (B_{max}) was significantly increased in the brains of suicides compared to controls. Mean B_{max} for suicides and normal controls was 271.4 ± 128.4 and 194.6 ± 106.1 fmoles/mg protein. ANOVA with age, sex and post-mortem delay as covariates indicates that there was a significant sex effect on binding ($F=5.52$, $p < 0.025$). There was no effect of age and post-mortem delay on the ^{3}H-spiroperidol binding. Further analysis of suicides indicated that increase in B_{max} was more pronounced in suicides who used violent means, i.e. gunshot wound and hanging than non-violent suicides. No difference in K_d was observed between suicides and normals. There was no difference in K_d and B_{max} of IB in the frontal cortex of suicides. There was no correlation between the number of IB and 5-HT_2 recognition sites. The observed increase in 5-HT_2 recognition sites may be related to diminished biogenic amine turnover. (Supported in parts by USPHS MH 30,059 and MH 41684).

412.2 CEREBROSPINAL FLUID CORRELATES OF DEPRESSION IN HUNTINGTON'S DISEASE. R. Kurlan*, I. Shoulson, E. Caine, A. Rubin*, Univ. of Rochester Sch. of Med., Rochester, NY 14642. C. Nemeroff, G. Bissette, Duke Univ. Sch. of Med., Durham, NC, R. Zaczek*, J. Coyle, Johns Hopkins, Univ. Sch. of Med., Baltimore, MD. F.J. Spielman*, Univ. North Carolina Sch. of Med., Chapel Hill, NC.

Depression occurs commonly in Huntington's disease (HD). Elevated cerebrospinal fluid (CSF) concentrations of corticotropin-releasing factor (CRF) have been associated with depression in psychiatric populations (Science 1984; 226:1342), and reduced CSF levels of 5-HIAA have correlated with depression in Parkinson's disease (Neurology 1984; 34:642). We obtained CSF by lumbar puncture from 56 non-medicated HD patients in the earliest stages (I and II) of illness and from 21 control subjects who underwent spinal anesthesia. HD subjects underwent standardized assessments to determine psychiatric diagnoses and severity of symptoms by DSMIII, Research Diagnostic Criteria and Life Psychiatric Status Ratings (J Nerv Ment Dis 1981;169:764). Investigators unaware of clinical status measured CSF concentrations of CRF by radioimmunoassay and 5-HIAA by HPLC. Twenty-four (46%) HD patients were judged to be depressed, including major depression (N=19) and dysthymia (N=5). CSF concentrations of CRF(107.2 ± 35.3 pg/ml, mean ± SD) and 5-HIAA (185 ± 97 pmol/ml) in the depressed HD patients were not statistically different from the non-depressed HD subjects (CRF = 95.8 ± 38.9, 5-HIAA = 201 ± 176). No significant correlations between Life Ratings and CRF or 5-HIAA levels were found. As a group, however, the 56 HD subjects had a significantly ($p < 0.01$) higher level of CRF than the control subjects (74.2 ± 27.1). Our findings indicate that CRF concentrations are elevated in the CSF of non-medicated early HD patients; however, neither CRF nor 5-HIAA levels correlate with the presence or severity of depression. (Supported by USPHS grants NS17978, NIMH 40524, NIMH 39415, NIA AG05128 and the U. of Rochester CRC USPHS RR-0044)

412.3 PLATELET ADRENERGIC RECEPTOR BINDING STUDIES IN DEPRESSIVE ILLNESS. J.E. Piletz, and A. Halaris. Dept. of Psychiatry, Case Western Reserve Univ. and Cleveland Metropolitan General Hospital, Cleveland, Ohio 44109.

At least 10 laboratories have reported radioligand binding to platelet alpha$_2$ adrenoceptors from depressed patients. The results have shown no differences using radio-labelled antagonists, but mixed conclusions of increased or decreased receptor density in depressed patients using agonists or broadly specific ergot derivatives. Based on the K_D values reported in those studies, we hypothesized that the previous data may be consistent with a redistribution of agonist-receptor states from high (~3nM) to lower (~6nM) affinity states in patients. In order to test this we developed an assay using sucrose gradient purified platelet plasma membranes which allowed detection of super-high affinity (K_D ~35pM) and high affinity (~1nM) binding sites for ^{3}H-p-aminoclonidine (^{3}H-PAC). This technique resulted in a high percentage of specific binding (avg = 69%). By contrast, ^{3}H-PAC binding to washed intact platelets displayed <10% specific binding and was non-saturable. ^{3}H-PAC binding to washed membrane lysates showed K_D >10nM, representing only about 40% specific binding, and did not display the super-high affinity site. By using purified plasma membranes we and others (Neubig and Szamraj, Biochim et Biophys. Acta 854, 1986 p.67) appear to have removed an inhibitor which probably confounded previous binding studies using platelet lysates. Results will be presented from Scatchard binding analyses with depressed patients versus normal volunteers and from depressed patients before and after a six week treatment with desipramine.

412.4 **SEASONAL RHYTHM OF [3H]-IMIPRAMINE BINDING TO HUMAN PLATELETS.** E. DeMet, R. Gerner*, C. Kaufmann*, K. Bell*, A. Chicz-DeMet*. Dept. of Psychiatry & Human Behavior, Univ. of California, Irvine, CA 92717.

Platelet [3H]-imipramine binding was studied in 20 normal controls (11 males, 9 females) at 6 week intervals for one year. The maximum number of binding sites (Bmax) and the binding affinity (Kd) were determined using Scatchard plots, linear, and non-linear regression. No significant differences were found in the Kd values between groups or across time. In contrast, a pronounced seasonal rhythm of Bmax values was found with a maximum variation (amplitude) of ± 35% of the yearly mean (mesor). Peak binding was found in March to April and minimum binding was found in July to September.

Platelet binding was also studied in 20 patients meeting DSM-III and RDC criteria for unipolar depression. The Bmax values of these patients were expressed as a percentage of the seasonally matched control mean. The results were then normalized to the control mesor in order to permit seasonally neutral statistical comparisons between the groups. As a group, depressed patients showed less binding (62%; $p<0.005$) than controls. However, the degree to which patients and controls differed was related to the date of sampling. Maximum differences were noted at the time of the normal seasonal peak whereas values obtained from patients sampled during the fall were indistinguishable from their matched controls.

412.5 A RE-EXAMINATION OF BLOOD ELEMENT ADRENERGIC RECEPTOR REGULATION IN PSYCHIATRIC DISORDERS. B.D. Perry[1], S.M. Southwick*[2], and E.L. Giller, Jr.,[2]. [1]Division of Child and Adolescent Psychiatry and Harris Center Developmental Studies, The University of Chicago, Chicago, IL 60637. [2]Dept. of Psychiatry, Yale University and West Haven VAMC, West Haven, CT 06516.

Preclinical and clinical studies have suggested that CNS adrenergic receptor dysregulation plays a role in the pathophysiology of a variety of psychiatric disorders. Parallel distribution of α_2- and β-adrenergic receptors (R) in brain and blood elements (platelet - PLT, α_2: monocyte-M - β) has motivated study of PLT α_2 and M-βR in psychiatric disorders using radioligand binding or other functional assays. The results have been variable and difficult to interpret. The current studies were performed to clarify and extend previous reports by 1) examining the multiple affinity states of a subject's PLTα_2- and M-β-R (drawn at same time) using extended saturation and competition assays, 2) using many subjects (total n> 250), 3) comparing "state" vs. "trait" binding values, 4) comparing binding parameters with symptom/s (as well as diagnostic category) and 5) by employing a dynamic, 'in vitro' assay of changes in R following incubation of intact PLT or M in agonist (Soc. Neurosci. Abstr. Vol. 12, 414, 1986).

Subjects were in good physical health and had no concurrent substance abuse (>2 wks). SADS/RDC diagnostic criteria were used. A variety of clinical rating tools were administered, including the DIB and DEQ. PLT and M were isolated from whole blood using standard techniques and membranes were prepared for binding assays using ^{3}H-rauwolscine (RAUW) for PLTα_2- and ^{125}Iodocyanopindolol (ICYP) for M-β-R. In vitro incubations of intact cells were performed as described previously (see above). Extended saturation (12 point) and epinephrine competition (12 point) studies were performed in both systems. Computer curve fitting techniques resolved two components of interaction for both RAUW and ICYP. No group differences in K_D (at either site) were demonstrated for either EPI, RAUW or ICYP. Significant findings include differences in the ratio of affinity states in PTSD and major depression (MDD) (e.g., PLTα_2-ratio α_2(L)/α_2(H)x100 + SEM: CONTROL = 13.1 + 1.33, (N=25); PTSD = 23.5 + 1.97, (N=25); MDD = 31.9 + 3.7, (N=15)). More interesting was the demonstration of population differences in rate of R "internalization" after EPI incubation (e.g., PLTα_2-R; PTSD 4 times more rapid than Control; Bipolar depressed 1/2 as rapid). The results demonstrate that standard radioligand binding assays using limited ligand concentrations can result in misleading results (e.g., inferred changes in either total R # or ligand affinity) and that dynamic assays of R-regulation may be more suitable for testing dysregulation hypotheses in psychiatric populations.

412.6 A COMPARISON OF BLOOD ELEMENT ADRENERGIC RECEPTOR BINDING SITES IN BORDERLINE PERSONALITY DISORDER AND MAJOR DEPRESSION. S.M. Southwick*[2], E.L. Giller, Jr.,[2], and B.D. Perry[1]. Child & Adolescent Psychiatry, Harris Center for Developmental Studies, The University of Chicago, Chicago IL 60637. [2]Dept. of Psychiatry, Yale University and West Haven VAMC, West Haven, CT 06516.

Borderline Personality Disorder (BPD) is a psychiatric diagnosis characterized by chronic impulsivity, affect lability, brief intermittent psychoses, and unstable interpersonal relationships. In DSM III it is classified as a character disorder on Axis II. An association between BPD and DSM III Axis I affective disorders (primarily major depressive disorder--MDD) has been suggested. Studies of putative biological markers for affective disorders (e.g., DST, REM latency) in BPD support this association. Other putative markers for affective disorders are the platelet (PLT)α_2 receptor (R) and monocyte (M)β-R. The present studies were performed to compare PLTα-2 and Mβ-adrenergic R in BPD and MDD relative to "controls" (C). These studies represent, to our knowledge, the first investigation of adrenergic R in BPD.

PLT and M were isolated from normal volunteers and from subjects meeting SADS/RDC criteria for MDD and DIB criteria for BPD. Subjects were in good physical health and drug free (>2 wks). Membranes were prepared, washed extensively with EDTA containing buffers, and radioligand binding assays were performed in PLT using ^{3}H-rauwolscine (RAUW) (Eur. J. Pharm. 84:79, 1982) and in M using ^{125}Iodocyanopindolol (ICYP) (N.S.A.Pharm. 317:277, 1981). In both systems extended saturation and competition studies (12 concentrations of (-)epinephrine--EPI) were performed to assess high and low affinity states of the R. Data were analyzed with LIGAND.

Under the assay conditions used, two sites of binding (high and low affinity) were demonstrated for PLTα_2 and MβR.

No population differences in the affinity of RAUW or EPI for the two PLTα2-R sites were seen (e.g. for RAUW, group: K_{D1}, K_{D2} (nM ± S.D.), N; C = 0.4±0.2, 27.3±8.8, N=30; BPD = 0.45±0.2, 24.6±10, N=20; MDD = 0.4±0.1, 22.8±9.9, N=15). The total number of PLTα_2 sites (SITES/PLT) in BPD was approximately equal to the total number in C (C = 229±92, BPD = 191±40, MDD = 228±90). Significant differences included altered ratios of high to low affinity states (α_2(L)/α_2(H) x 100±SEM: C = 13.1±1.3; BPD = 31.9±3.7; MDD = 28.1± 3.5) with a significantly higher number of α_2 low affinity states in the BPD and MDD groups (C = 24.4±10; BPD = 49±20; MDD = 47.4±18).

The findings suggest that BPD and MDD share certain pathophysiological features. Further studies investigating 'in vitro' regulation of blood element adrenergic R support this conclusion (see Perry et al., Neurosci. Abstr., 1987). Supported by VA funds.

412.7 IN VITRO INHIBITION OF ARYLSULFATASE C BY DOPAMINE AND RELATED COMPOUNDS. D.E. Enyedy* and T.J. Shickley. Department of Pharmacology and Toxicology, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.

There are three types of arylsulfatases known (EC 3.1.6.1): types A and B which are lysosomal sulfohydrolases necessary for the maintainance of myelin, and type C (ARS-C) which has been shown to be microsomal in liver but whose function in the CNS is unknown. The deficiency or absence of one or more of the arylsulfatases results in metachromatic leucodystrophy or multiple sulfatase deficiency, which are progressive demyelinating diseases. In the adult form of the diseases, a schizophreniform behavior has been observed, the onset of which can precede CNS demyelination by decades (Manowitz, P., Kling, A., Kohn, H. J. Nervous Mental Disease 166: pp500, 1978.). A possible arylsulfatase variant in the blood of schizophrenic patients has also been reported (Manowitz, P., Goldstein, L., Nora, R. Biol. Psychiatry 16: 1107-1113, 1981).

The potential involvement of arylsulfatases in schizophreniform behaviors and the lack of functional information concerning ARS-C, compelled us to explore the interaction of dopamine (DA) and ARS-C.

Purified ARS-C (Sigma, St. Louis, MO: S-1629) was assayed at 37°C (pH 7.1) with p-nitrophenol sulfate as substrate using a spectrophotometric technique modified from that of Fowler and Rammler (Biochemistry 3: pp 230, 1964.) which measures the absorption at 400 nanometers of enzymatically liberated p-nitrophenol. DA and other compounds were included in the incubation at concentrations up to 80 mM.

DA produced 50% inhibition of ARS-C activity at a concentration of 100 uM. Other catecholamines at equimolar concentration with the IC-50 of DA produced the following % inhibition: L-DOPA 34.6; Norepinephrine 30.8; Octopamine 29.2; Epinephrine 20.5. Related compounds produced lower inhibition: Catechol 19.4; Tyrosine 10.1; B-Phenethylamine 5.0. No inhibition was found with tyramine. Interestingly, the greatest inhibition of ARS-C was from 5-OH-DA and 6-OH-DA producing 87.6% and 77.6% inhibition at 100 uM, respectively.

These results suggest: (1) that a high electron density at the 2-position on the phenolic ring is necessary both for binding of arylsulfates and for strong inhibition of the ARS-C enzyme by dopamine and related compounds; (2) there may be an important link between ARS-C and the dopaminergic system which is relevant to schizophreniform behaviors.

412.8 NEUROCHEMICAL ANALYSIS OF COMPLEX BIOLOGICAL MATRICES USING MULTIPLE ELECTRODE LIQUID CHROMATOGRAPHY. C.N. Svendsen*, C.C. Hrbek* and E.D. Bird. SPON: (V. Shashoua). Brain Tissue Resource Center, McLean Hospital/Harvard Medical School, 115 Mill St., Belmont, MA 02178.

Using a newly developed neurochemical analyzer (Neurochem™, developed by ESA Inc., Bedford, Mass.), a wide range of biogenic amines and related metabolites, peptides, purines and pyrimidines, in addition to certain neuroleptic drugs, have been simultaneously quantitated in crude extracts of human and rat brain tissue and cerebral spinal fluid.

The equipment consists of a 16 electrode coulometric electrochemical detector, preceded by a high performance liquid chromatography system, which together are capable of separating and quantitating 150 compounds in a single sample within an hour. This inherent separating power has been interfaced with an enhanced IBM AT computer capable of saving real time data from each electrode and allowing extensive post-run analysis.

Preliminary data will be presented from two studies. The first uses this method to study a hypothesized, but as yet unproven, neurochemical pathology in schizophrenia, by screening tissues for the majority of the tyrosine and tryptophan neurotransmitters, precursors, metabolites and cofactors. The second shows the effects of administering the two isomers of thioridazine, a neuroleptic drug, on rat brain neurochemistry.

The method has been applied for determining 115 compounds including the following: ascorbic acid, biopterin, bufotenine caffeic acid, catechol, chlorpromazine and metabolites, dihydroxyphenyl glycol, dihydroxyphenylacetic acid, 4,8-dihydroxyquinoline, dopamine, dopamine sulfate, epinephrine, fluphenazine, formylanthranilic acid, homogentisic acid, homovanillic acid, 3-hydroxyanthranilic acid, 5-hydroxyindoleacetic acid, 5-hydroxytryptamine, kynurenine, l-dopa, leu/met enkephalin, melatonin, metanephrine, 3-methoxy-4-hydroxyphenyl glycol, n-methyl-5-hydroxytryptamine, neurotensin, norepinephrine, octopamine, pyrodoxamine, thioridazine & metabolites, tryptamine, tryptophan, ureic acid, vasopressin, vanillymandelic acid, and xanthine.

The compounds assayed will be subject to classical intersample multivariate statistical comparisons, in addition to newer statistical methods which can be used when large numbers of intrasample data points are available. This approach allows the investigation of disease or drug induced alterations in a number of neurochemical pathways simultaneously. By eliminating the use of multiple methods for different compounds, more consistent results can be attained in a shorter period of time.

412.9 EXPERIMENTAL DIABETES: DEGENERATIVE ATROPHY OF SUBSTANCE P PRIMARY AFFERENTS AND MET-ENKEPHALIN INTERNEURONS IN THE RAT SPINAL CORD. A. Gorio, °A.M. Di Giulio, °A. Mannavola*, °B. Tenconi* and °P. Mantegazza*. Inst. of Pharmacological Sciences and °Dept. of Medical Pharmacology, Univ. of Milano, 20133 Milano, Italy.

Well known consequences of diabetes include profound functional and morphological alterations of central and peripheral nervous system structures. It has been shown that experimentally induced diabetes is characterized by a decrease in slow axonal transport and by a reduction in the conduction velocity in both sensory and motor axons. These effects are accompanied by a progressive axonal atrophy and, at a later stage of the disease, by distal axonal degeneration.

In this report we show that alloxan-induced experimental diabetes causes a loss of the sensory input to the dorsal horn of the spinal cord, as indicated by the significant decrease in substance P innervation detected in the spinal cord of diabetic rats. In addition, we have found that such a change is correlated with a loss of radioimmunoassayable met-enkephalin, the opiate peptide contained in a selective population of second order neurons present in laminae I and II of the dorsal horn spinal cord. These results indicate that diabetes may cause profound alterations in peripheral as well as central sensory pathways.

It is well known that diabetic neuropathy is often accompanied by pain sensations and sensory perception modifications. We would like to suggest that these dramatic consequences of diabetes are related to the findigs here reported, showing significant alterations in substance P and met-enkephalin containing neurons in the spinal cord.

412.10 DIFFERENTIAL EFFECTS OF EXPERIMENTAL DIABETES ON THE CATECHOLAMINERGIC INNERVATION OF THE MAJOR CEREBRAL ARTERIES AND ON CENTRAL CATECHOLAMINE CONCENTRATIONS IN THE RAT. U. Wesselmann+, R. J. Konkol*, G. L. Leo* and D. R. Harder*. +Dept. of Physiology, Northwestern Univ. Med. Sch., Chicago, Ill. 60611 and Res. Serv. 151, Neurology, VAMC, Milwaukee, WI.53295.

Studies in experimental animals and man indicate that the activity of the sympathetic nervous system is altered during diabetes. The brain vascular bed receives an ample supply of sympathetic adrenergic fibres originating in the superior cervical ganglion. The purpose of the present study was to investigate the effect of diabetes on the sympathetic innervation of the major cerebral arteries. Ten weeks after induction of experimental diabetes by alloxan (50 mg/kg) the adrenergic innervation density (grading scale: 0-3) of the internal carotid, anterior cerebral, middle cerebral, posterior cerebral and basilar arteries in control and diabetic rats was studied by glyoxylic-acid-fluorescence-histochemistry. The density of adrenergic fibres was markedly decreased in all cerebral arteries of diabetic rats compared to age-matched controls. In contrast to the decrease of noradrenergic innervation in the brain arteries, central norepinephrine levels (LCEC-Assay) in diabetic rats were significantly ($P<0.05$) increased compared to controls: spinal cord (+109%), cerebellum (+17%), pons/medulla (+67%), mesencephalon/diencephalon (+39%), parietal/occipital (+33%). The pathophysiological mechanisms underlying these differential responses need to be clarified. Since one of the postulated functions of the adrenergic innervation of cerebral arteries is to maintain blood-brain-barrier (BBB) integrity (Edvinsson & MacKenzie, Pharmacol. Rev., 28:275, 1977), our hypothesis is that the observed decrease in adrenergic innervation of cerebral arteries in diabetic rats might be one of the reasons for the increase in BBB permeability described in diabetes (Stauber et. al., Diabetes, 30:500,1981; Lorenzi et. al., Diabetologia, 29:58, 1986). Such a disruption of BBB integrity could cause leakage of circulating catecholamines into brain tissue.

412.11 BLOCKADE OF N-METHYLASPARTATE-INDUCED ARCUATE NUCLEUS DAMAGE BY PCP, MK-801 AND RELATED COMPOUNDS. T.A. Fuller, J.J. Lawrence and J.W. Olney. Dept. of Psychiatry, Washington Univ. School of Medicine, St. Louis, MO 63110.

Systemic administration of the excitotoxic glutamate analog, N-methylaspartate (NMA), destroys neurons in certain brain regions that lie outside blood brain barriers (BBB), such as the arcuate hypothalamic (AH) nucleus. Competitive NMA antagonists such as D-2-amino-5-phosphonopentanoate, effectively block the toxic action of NMA on AH neurons, but non-competitive NMA antagonists, such as phencyclidine(PCP), MK-801 and related compounds, have not been tested in this in vivo model. Since these agents are potentially of value as BBB-permeable neuroprotective agents in the treatment of neurodegenerative conditions, we tested them for efficacy in protecting AH neurons in vivo against NMA toxicity.

Sprague Dawley rats (26-28 days old) were injected ip with saline or a test compound 15 min prior to NMA (50 mg/kg sc). Four hours after NMA treatment, the animals were sacrificed under deep anesthesia by perfusion fixation and their brains prepared for histopathological examination. Saline pretreated rats consistently had a circumscribed easily quantifiable neuron necrotizing lesion in AH. Pretreatment with PCP, m-amino-PCP or MK-801 provided complete protection against NMA toxicity at doses of 10, 5 or 1 mg/kg respectively; smaller doses of these agents provided partial protection in a dose related manner. Ketamine substantially protected (77% reduction in lesion size)at 20 mg/kg, but repeated doses were required. The prototypic sigma opiate agonist (+)-SKF 10,047 (which binds at both PCP and sigma receptor sites) provided 55 and 80% protection at 20 and 40 mg/kg respectively. Haloperidol, which reportedly blocks sigma but not PCP receptors, was administered either alone or together with MK-801 to NMA treated rats and did not protect against NMA toxicity or interfere with the NMA blocking activity of MK-801. Diazepam, an agent which has no NMA blocking activity in other systems, was administered at 20 mg/kg and failed to block NMA toxicity in this system.

Here we confirm, in an in vivo system, the in vitro observation that agents which have PCP receptor binding properties block the neurotoxicity of NMA, and we show that their order of potencies for blocking NMA toxicity is the same in vivo as in vitro. MK-801, which has been described as the most potent in vitro NMA antagonist known (Price et al., this meeting) is also the most potent known antagonist of NMA neurotoxicity in the in vivo AH.

Supported by RSA MH 38894 (JWO) and a grant from the Washington Univ/Monsanto Biomed. Res. Fund. MK-801 was generously provided by Merk Sharp & Dohme.

412.12 RELATIONSHIP OF VIP, A LIGAND FOR TWO DISTINCT RECEPTORS IN RAT BRAIN, TO THE AIDS VIRUS RECEPTOR. J.M. Hill*, N.E. Jelesoff, P.L. Hallberg, B.M. Martin, M.R. Ruff and C.B. Pert. Section on Brain Biochemistry and Section on Pre-Clinical Studies, Clinical Neuroscience Branch, National Institute of Mental Health, ADAMHA, Bethesda, Maryland 20892.

The pentapeptide sequence, TDNYT, occupying positions 7 to 11 within vasoactive intestinal peptide (VIP), shares homology with the proposed attachment sequence, peptide T, of gp120, the envelope protein of the AIDS virus HIV. Direct high affinity binding of peptide T to rat brain and human T-cells has been demonstrated. This binding is potently displaced by native gp120 as well as VIP. These data indicate that both VIP and peptide T are ligands for the same recognition molecule utilized by the HIV envelope protein gp120. This suggests that VIP or a VIP fragment may be an endogenous ligand for T4 (or CD4), the HIV receptor, present on brain cells, T lymphocytes and other cells. Autoradiographic studies of VIP birding in rat brain from different laboratories report dissimilar distribution patterns which may be due to the use of ligands iodinated on different tyrosines; for example, we have shown that iodination of the tyrosine at position 10 will prevent binding to T4 since this tyrosine is within the bioactive pentapeptide sequence. In the present study, autoradiography of the binding patterns of various isomers of mono- and diiodo ^{125}I-VIP are displaced with "cold" VIP, various VIP fragments and peptide T. By careful comparison with adjacent sections on which the brain distribution pattern of T4, localized with the antibody OKT4 and radioimmunocytochemistry was visualized, we have reached several conclusions.

The binding patterns achieved with the various VIP's differ from each other or from the T4 pattern depending on which tyrosine is iodinated and permit the discrimination of the differences in the regional distribution of the two receptors. The ^{125}I-Tyr^{10}-VIP pattern is the least like T4 distribution pattern since the iodination of Tyr^{10} apparently destroys the ability of VIP to bind to T4. With ^{125}I-Tyr^{10}-VIP the highest binding occurs in the thalamus, including the medial geniculate, with low binding in the ventral hippocampus. T4 is abundant in the hippocampus but is negligible in the thalamus.

The results of this study suggest that VIP functions as a ligand for two distinct receptor systems which have different regional distribution patterns in brain. One pattern visualizes T4 and thereby defines the recognition molecule for the HIV virion and peptide T related sequences such as TDNYT of VIP. The other pattern is likely associated with the classical VIP receptor which coupled to adenylate cyclase.

412.13 REDUCED LENGTH OF PRIMARY CLEFT IN DYSTROPHIC MICE; A SCANNING ELECTRON MICROSCOPIC STUDY. C. Labrecque*, J.P. Tremblay and M.A. Fahim. Lab. of Neurobiology, Fac. of Med., Laval Univ., Québec, Canada and Andrus Gerontology Center, Univ. of Southern California, Los Angeles, CA 90089.

The observation of smaller endplate potentials in the muscle fibers of dystrophic mice have led Law et al. (Exp. Neurol. 51, 434-443, 1976) to suggest that the muscle was functionally denervated. Our scanning electron microscopic study of the endplate regions of normal (C57BL/6J +/+) and dystrophic (C57BL/6J dy^{2J}/dy^{2J}) three month old mice supports this concept. The gastrocnemius was exposed and fixed in situ with 2.5% glutaraldehyde. The regions containing NMJs were identified by their cholinesterase activity (Tennyson et al., J. Neuropath. Exp. Neurol. 36, 245-275, 977) and isolated by microdissection. The presynaptic terminals were removed by treatment with 8N hydrochloric acid. The digestion was stopped by filtering the muscle fibers through a glass filter (Nucleopore 8 um pore-size). The fibers were rinsed with water, dehydrated, critical point dried and coated with palladium-gold on the filter. A sample of 40 normal and 53 dystrophic endplates were photographed at x2000 or x4500. The following parameters were measured: 1) muscle fiber diameter, 2) endplate area, 3) number of primary cleft, 4) length of primary cleft branches, 5) number of branch points. The appearance of the endplate is extremely variable in dystrophic animals. Some endplates are rather normal in appearance. Other endplates are smaller, elongated or fragmented or have wider and more shallow primary clefts. Quantitative analysis revealed a positive correlation between the endplate area and the muscle fiber diameter in both the normal and dystrophic animals. However, the motor endplate area is significantly lower (by 29%) in the dystrophic mice. The total length of primary cleft of an endplate correlates positively with the endplate area and with the muscle fiber diameter in both normal and dystrophic mice. However, the total length of the primary cleft is significantly lower (by 34%) in dystrophic mice, especially in large diameter muscle fibers. Finally, the endplate of dystrophic mice is characterized by shorter primary clefts with less branching points. The reduced length of primary cleft in dystrophic endplate is probably a consequence of the reduced presynaptic terminal length. Such a reduction of the terminal length could be responsible for a lower transmitter release capacity and for the smaller endplate potentials previously observed in dystrophic muscles.

412.14 SUBSTANCE P RECEPTORS MAY BE INVOLVED IN THE PATHOPHYSIOLOGY OF INFLAMMATORY BOWEL DISEASE. C.R. Mantyh*, S.R. Vigna*, P. Popper, J.E. Maggio, M.L. Welton*, E.P. Passaro Jr.*, and P.W. Mantyh. Center for Ulcer Research and Education, Department of Surgery, VA Wadsworth 90073, Brain Research Institute, UCLA, Los Angeles Ca 90024 and Harvard Medical School, Boston Ma 02115

Recent advances in understanding a variety of inflammatory diseases reveals a complex interaction between the nervous and the immune systems. One group of neurotransmitters which we have hypothesized form a critical link in communicating between the nervous and immune systems consists of two members of the tachykinin family, substance P (SP) and substance K (SK), which are expressed by sensory neurons. In preliminary experiments we have shown that in experimental animals SP and SK are involved in regulating several gastrointestinal activities including gastric motility, digestive enzyme secretion, mucosal ion transport, hemodynamics, neuronal excitability, inflammation, and the immune response. In the present report we have explored whether tachykinin receptor binding sites are abnormally expressed in inflammatory bowel disease and whether this expression is correlated with the extent of these diseases. To test this hypothesis we obtained fresh surgical specimens from normal patients during resection from malignancy (n=10), ulcerative colitis patients (n=7) and patients with Crohn's disease (n=3). In all cases the specimens were obtained less than 5 minutes after removal which greatly diminished the problems associated with degradation artifacts. The tissue was immediately placed in Tissue-Tek, frozen on dry ice and processed for quantitative receptor autoradiography using Bolton-Hunter labeled NK, SK and SP. In normal colon a high concentration of SP receptors is present in circular muscle, a moderate concentration in the myenteric plexus and submucosal blood vessels, and low concentrations in the mucosa. In the normal colon very high concentrations of SK receptors are present in the circular muscle while moderate concentrations are expressed by myenteric neurons. In colon tissue obtained from the ulcerative colitis and Crohn's patients, very high concentrations of SP receptors are seen in blood vessels in both the submucosa and all muscular layers, and in lymph nodes, whereas both SP and SK binding sites are greatly reduced in the circular muscle. Little change in SP receptor distribution is observed in the plexus or mucosa in the diseased tissue when compared to normal tissue. These results demonstrate that SP receptors are upregulated in the diseased tissues in the submucosal blood vessels and is ectopically expressed by blood vessels in both circular and longitudinal muscles which normally do not express detectable SP binding sites. In addition both SP and SK binding sites are downregulated in the circular muscle which may account for the changes seen in the motility of the gut in these diseases. These results suggest that tachykinins are involved in the pathophysiology of IBD and for the first time suggests a rational approach to designing neuropeptide analogues which may be efficacious in treating these and other inflammatory diseases. Supported by NIH 23970.

412.15 BIOCHEMICAL ACTIVATION OF LOCALIZED EEG ACTIVITY IN TOURETTE SYNDROME AND CONTROLS K.A.Bonnet, R.A.Primas, C.J.Walsh. Department of Psychiatry, New York University Medical Center New York, NY 10016

Tourette syndrome and control subjects males on no medication were studied with baseline brain electrical activity and during three successive hours following biochemical challenge with amino acid precursors of neurotransmitters. Each subject was challenged with L-tryptophan, choline chloride or L-DOPA each on separate days of study.

Brain electrical activity was recorded through 28 monopolar electrodes using ear reference electrodes. The computer-based EEG system permitted storage of all 28 active channels and four movement artifact channels. Age-matched comparisons between baseline records showed slight but significant increased slowing in the midline frontal and central regions of Tourette subjects, and decreased total power in left frontotemporal and right asymmetric alpha in the right parietooccipital area.

The comparison to controls challenged with the three amino acid substances showed Tourette syndrome (TS) subjects to show greater reduction in beta2 and reduction in slowing in the central region. L-DOPA reduced Tourette subjects' occipital alpha and betal activity, and increased midline frontal and central slowing. Each of these occurred in a time-dependent and reversible manner.

The localization of the effects are consistent with previous assumptions made from localization of effects reflected in neuropsychological testing of Tourette and control subjects (Bonnet, 1981). These findings correlate well with pharmacological history in the Tourette subjects in regard to benefits, and to history of side effects.

The patterns of "serotonergic", "cholinergic" and "dopaminergic" activation are empirically derived in this study with higher resolution based upon the use of computer-based EEG and use of 28 monopolar electrodes for better resolution.

412.16 TRH RECEPTORS ARE DECREASED AND 5-HT1A RECEPTORS ARE INCREASED IN ALS SPINAL CORD. S. Manaker, S.B. Caine* and A. Winokur. Depts. of Pharmacology and Psychiatry, Univ. of Penna., Philadelphia, PA 19104.

Numerous studies have demonstrated that thyrotropin releasing hormone (TRH) is highly concentrated in the ventral horn of the spinal cord and that it exerts potent effects on motoneuron activity. Recent evidence indicates that TRH is colocalized in the spinal cord with two other putative neurotransmitters, serotonin (5-HT) and substance P. Additionally, TRH appears to participate with 5-HT and substance P in a co-modulatory fashion in regulating motor function. In parallel with these preclinical observations, several findings link TRH to the severe neurodegenerative disorder amyotrophic lateral sclerosis (ALS). Thus, infusions of TRH to patients with ALS have been reported to produce transient improvement in motor strength and coordination. Additionally, reductions in TRH levels in the ventral horn of ALS spinal cord have been reported.

We have utilized the technique of quantitative autoradiography to evaluate changes in TRH receptors, 5-HT1A receptors, muscarinic cholinergic receptors, beta-adrenergic receptors, choline uptake sites, and norepinephrine uptake sites in discrete regions of spinal cord from patients with ALS and control subjects. Additionally, we have used saturation (Scatchard) analyses to evaluate both the binding affinity (Kd) and the total number of receptors (Bmax) in each region.

Our current findings confirm and extend our previous report of reductions in the concentration of TRH receptors in lamina IX of ALS spinal cord, the region containing the motor neurons. Reductions in binding are a result of reductions in the Bmax and not changes in Kd, and represent decreases of 55% to 75% in cervical, thoracic, and lumbar levels of ALS spinal cord (n= 8-10). Similar reductions occur in the same region for muscarinic cholinergic receptors. Significant increases in 5-HT1A receptors were observed in the ventral horn of ALS spinal cord utilizing the ligand [3H]-8-OHDPAT. The increases in Bmax ranged from 60% to 145% in the ventral grey and lamina IX regions, across all levels of spinal cord (cervical, thoracic, lumbar, and sacral) and were accompanied by similar increases in binding affinity (n= 6). No statistically significant changes were observed for beta-adrenergic receptors, choline uptake sites, or norepinephrine uptake sites. These findings suggest the involvement of TRH and 5-HT neurochemical systems in the pathophysiology of ALS. Alterations in TRH receptors and 5-HT1A receptors in ALS spinal cord might reflect compensatory changes between two neurochemical systems that are involved, through a comodulatory relationship, in regulating motor function.

412.17 ANTIDEPRESSANTS BIND TO P_2 PROTEIN OF PERIPHERAL MYELIN AND MAY INDUCE AUTOIMMUNITY. D.S. Dwyer and E. Grant*. Neuropsychiatry Research Program, University of Alabama at Birmingham, Birmingham, AL 35294.

The P_2 protein of peripheral myelin has been well-characterized, however, its function is not completely understood. P_2 is a highly basic protein with a molecular weight of about 15,000 daltons. Its amino acid sequence is known, and based on the sequence, P_2 has been assigned to a family of lipid-binding proteins which includes β-lactoglobulin, retinol binding protein and fatty acid binding protein. Immunological studies have shown that challenge of animals with P_2 protein elicits an autoimmune response and demyelination which is similar to the Guillain-Barre syndrome (GBS). GBS has also been observed in humans as a consequence of treatment with the antidepressant zimeldine. We have been investigating linkage between these two observations and the initiation of autoimmunity.

During these studies, we discovered that the P_2 protein binds antidepressants such as imipramine and zimeldine. Binding was demonstrated by equilibrium dialysis. Competitive inhibition experiments indicated that retinoic acid also binds to P_2. We suggest that the binding site for these substances is located in a region at the N-terminal which is highly conserved among lipid-binding proteins.

In related studies, monoclonal antibodies (Mabs) were raised against zimeldine. One Mab, ZMD 13, was purified for further characterization. In a second fusion, we obtained another Mab, from mice immunized with zimeldine, which reacts with P_2 protein. This Mab, ZP 3, also binds strongly to ZMD 13. These data suggest that P_2 protein and ZMD 13 are antigenically similar (they are both recognized by ZP 3) which is not surprising in view of the fact that both proteins bind antidepressants. We propose that antibodies like ZMD 13 (anti-zimeldine) may arise in susceptible individuals during treatment with antidepressants. In addition, antibodies like ZP 3, which is an anti-idiotype against ZMD 13, may be produced to regulate the anti-drug response. However, ZP 3 also binds to P_2 protein and is therefore an autoantibody. The existence of such autoantibodies could explain how zimeldine triggers GBS in certain patients. Alternatively, antidepressant bound to P_2 protein could render the P_2 immunogenic and directly initiate an autoimmune response.

412.18 CNS BETA-ENDORPHIN AND CHOLECYSTOKININ IN SEVERE LIVER DISEASE: PEPTIDE CONCENTRATIONS AND PRECURSORS' mRNA. A.Brini*, C.De Giuli Morghen*, P.Custode*, M.Bianchi*, A.E.Panerai, Dept. Pharmacology, University of Milano, Milano, Italy.

Severe liver disease is often accompanied in the human by signs of the involvement of CNS such as impairment in the accomplishment of simple tasks and derangement of neuroendocrine responses. This observation is consistent with the finding both in the experimental animal and in the human of modifications in the CNS patterns of neurotransmitters and aminoacids. We previously reported on the decrease of beta-endorphin and cholecystokinin concentrations in brain areas of rats suffering for experimental severe liver disease and of humans who died for esophageal bleeding consequent to liver cirrhosis (Salerno F., Life Sci., 33: 377, 1983; Panerai A.E., Brain Res., 247: 188, 1982). The changes observed were specific for the two peptides since neither met-enkephalin nor substance P or somatostatin concentrations were affected. The decrease in the concentrations of cholecystokinin and beta-endorphin can suggest both an increased and a decreased turnover of the two peptides and is therefore ambiguous. In order to obtain a more straightful insight in the involvement of CNS neuropeptides in severe liver disease, we repeated our previous study in the experimental animal, and paralleled the measurement of the concentrations of beta-endorphin, met-enkephalin and cholecystokinin with the evaluation of the mRNA for the respective precursors. We confirmed that both the concentrations of beta-endorphin and cholecystokinin and the mRNA for POMC and preprocholecystokinin decrease in the hypothalamus and the cortex of rats chronically treated with CCl_4, while preproenkephalin-A was only marginally affected. These data indicate that the synthesis of the two peptides is reduced and therefore the decreased concentrations are index of a decreased beta-endorphin and cholecystokinin mediated neurotransmission.

It is interesting also to observe that POMC mRNA is also present in the cortex and follows the modifications induced by severe liver disease in the hypothalamus, although it does not seem to be expressed, since the beta-endorphin immunoreactivity in this region was not detected both in normal or CCl_4 treated rats.

PROCESS OUTGROWTH V

413.1 EFFECTS OF DIVALENT IONS ON NEURONAL SURVIVAL AFTER LASER LESION IN CULTURE. X.-Y. Xie*, B. Brass* and J.N. Barrett. Dept. of Physiology and Biophysics, Univ. of Miami Med. Sch., P.O. Box 016430, Miami, Fla. 33101.

Neurons from the septum of E15 fetal rats were grown in cell culture to study the mechanisms involved in neurite repair and regeneration. Neurite processes were severed with a nitrogen laser using methods described by Higgins, Smith and Gross (J. Neurosci. Meth. 3:83, 1980). Survival of the lesioned neurons and regeneration of the processes were greater for younger neurons (in culture for less than 7 days) than for older neurons (14 to 28 days in vitro), and for lesion sites farther from the cell body (more than 100 μm) compared to lesions nearer the cell body (about 50 μm). Calcium influx is thought to have a role in the resealing of neuronal processes, possibly because of Ca-dependent activation of phospholipase A2 (Yawo and Kuno, Science, 222:1351, 1983). Lucas and Gross (Neurosci. Soc. Abstr. 12: 265, 1986) found reduced resealing and survival of neurons lesioned in low [Ca] solutions, although they found that some neurons did reseal and survive for at least 2 hours in low [Ca]. In our study more neurons (60 - 80%) survived when lesions were made in the presence of 2 mM Ca than in lower [Ca]. However, 20 - 40% of the neurons still survived and regrew processes when lesions were made in low [Ca] solutions (0.01 - 1 μM, buffered with EGTA); similar survival rates were seen when the lesion was made in solutions in which Ca was replaced with 1 mM Mn. These results indicate that membrane resealing in small neuronal processes probably occurs in extracellular solutions containing low [Ca] or Mn. Thus Ca-dependent activation of phospholipase A2 by Ca influx may not be absolutely necessary for resealing of small neuronal processes after neuronal injury. However, it does appear that Ca-dependent mechanisms do contribute to resealing and repair of neuronal processes. Supported by NIH grant NS 12207.

413.2 FLUORESCENCE IMAGING OF ENDOPLASMIC RETICULUM IN GROWTH CONES OF CULTURED RAT SUPERIOR CERVICAL GANGLION NEURONS. M.E. Dailey and P.C. Bridgman. Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, MO 63110.

The endoplasmic reticulum (ER) is believed to play a central role in lipid metabolism and regulation of intracellular calcium. At present, the exact role of the ER in neurite outgrowth and/or growth cone (GC) guidance is not well understood. We have used the fluorescent dye $DiOC_6(3)$ (Terasaki et al., Cell 38: 101-108, 1984) to localize the ER in living and fixed neuronal GCs in vitro. Explants from 21d rat superior cervical ganglia (SCG) were grown on laminin-coated glass coverslips. We found the best visualization of ER to be 12-30 hr after explantation, when GCs are large and before neurites have fasciculated. Cultures fixed with glutaraldehyde (0.25%, 2 min) and stained with $DiOC_6$ (2.5 μg/ml, 10 sec) were viewed with fluorescein fluorescence microscopy. The ER has a characteristic, polarized appearance. In general, the ER is concentrated at the base of the GC, and thin processes of ER often radiate from the base toward the GC margin. $DiOC_6$-stained growth cones were photographed, permeabilized (0.1% Triton X-100, 10 min) and immunofluorescently labelled with anti-tubulin antibodies (rhodamine secondary) to localize microtubules (MTs) and ER within single GCs. Superimposition of ER and MT images demonstrate that these structures are highly colocalized within GCs, especially along processes of ER that extend toward the GC margin. However, the colocalization is not absolute. For example, MTs occasionally extend beyond ER processes in the GC periphery, and the abundance of ER at the GC base precludes strict colocalization with MTs. Living cultures were stained with a reduced concentration (0.3 μg/ml) of $DiOC_6$ for 10 min, then grown in fresh, dye-free media. Control cultures not exposed to dye were otherwise treated identically. Measurements of maximum neurite outgrowth 14 hr after staining were not significantly different for stained and control cultures, suggesting that neurite outgrowth is unimpaired by $DiOC_6$ staining. Hence, we used fluorescence microscopy coupled with a SIT video camera and image processor to obtain still time-lapse images of the ER in living, motile GCs. As in fixed cells, finger-like processes extend from the intensely fluorescent GC base, suggesting that images of ER in fixed GCs correspond to the living condition. In addition, sequences of still images of single GCs reveal changes in the distribution of fluorescence, consistent with the possibility that processes of ER extend and retract during GC motility. These results demonstrate that: (1) ER is a polarized structure within GCs, concentrated at the base, and may extend to the GC margin; (2) finger-like extensions of ER are highly colocalized with MTs; and (3) ER is a dynamic structure in living GCs.

413.3 CHARACTERIZATION OF GROWTH CONE CYTOSKELETONS AND IDENTIFICATION OF AN ASSOCIATED TUBULIN TYROSINE KINASE. N. Cheng*, N. Sahyoun* (Spon: Susan K. Burgess) Dept. of Molecular Biology, Wellcome Research Lab., Research Triangle Park, NC 27709.

Lysed growth cone particles from one day old rats were resolved into detergent-soluble and cytoskeletal components. These two components could be distinguished by their polypeptide and glycoprotein composition, ^{125}I-calmodulin binding, and endogenous phosphorylation.

The cytoskeletal fraction was of relatively low density, sedimenting at the 0.4/0.8 M sucrose interface. Thin-section transmission electron microscopy revealed a homogeneous matrix composed of clusters of punctate structures. SDS-PAGE documented the prominence of tubulin in the cytoskeletal fraction; electrophoretic transfer of the separated polypeptides followed by overlay with enzyme-linked concanavalin A or wheat-germ agglutinin confirmed the presence of numerous high- and low-molecular weight glycoproteins. ^{125}I-Calmodulin gel overlay showed the presence of three high molecular weight (Mr: 140K, 230K and >230K) calmodulin-binding polypeptides.

The phosphorylation of several substrates by endogenous protein kinase(s) was also examined. Endogenous as well as exogenous tubulin proved to be the most heavily phosphorylated substrate. The phosphorylation reaction was greatly enhanced in cytoskeletal preparations compared to lysed growth cone particles, suggesting the presence of a phosphotubulin phosphatase or a tubulin kinase inhibitor. The phosphorylation reaction was not influenced by Ca^{++}, calmodulin, phorbol esters, phosphatidylserine, or cyclic AMP. Growth cones from fetal brains showed less tubulin phosphorylation, although isolated cytoskeletons had significant activity; in contrast, postsynaptic densities of mature rat brain had little tubulin kinase activity. Phosphorylated tubulin was partially resistant to alkaline hydrolysis, and upon partial acid hydrolysis phosphotyrosine as well as phosphoserine were released, indicating that at least one cytoskeletal tubulin kinase is a tyrosine kinase. These observations may prove relevant to critical growth cone functions including shape, motility and target recognition.

413.4 PROTEIN FATTY ACID ACYLATION IN RAT NEURONAL CULTURES. N.I. Perrone-Bizzozero, P.J. Apostolides*, S.P. Finklestein, L.I. Benowitz and O. Bizzozero*. Mailman Res. Ctr., McLean Hosp., Belmont, MA 02178; Dept. of Neurology, Massachusetts General Hosp.; Harvard Med. Sch.; and Eunice Kennedy Shriver Ctr., Waltham, MA 02254.

The modification of polypeptides by covalent attachment of fatty acids is a post-translational process that affects a number of cellular proteins. To determine which neuronal proteins are acylated during process outgrowth, primary cultures of E17 rat cortical neurons were incubated for 16-18 hrs with either [^{3}H]-fatty acids or [^{3}H]-amino acids. Proteins were analyzed by 2-D gel electrophoresis and radioactivity detected by fluorography. Of all the proteins synthesized, as visualized by amino acid incorporation, only four of these showed extensive labeling with myristic acid. The apparent molecular weight and pI of these were 80K, 4.2; 63K, 4.4; 40K, 4.4 and 20K, 5.3, respectively. All of these proteins were associated with the particulate fraction, and were enriched in a growth cone preparation. In all cases, the radioactivity was shown to be bound covalently and could only be removed by hydroxylamine treatment, indicating an ester linkage. Most of the radioactivity associated with these proteins was identified as myristic acid by reversed phase TLC. When [^{3}H]-palmitic acid was used as a precursor, the same group of proteins was labeled, though to a lesser degree.

By molecular weight and pI, the 80K and 40K proteins coincide with the identified growth cone phosphoproteins pp80 and pp40 (Katz et al, J. Neurosci. 5:1402-1411, 1985). However, the growth-associated protein GAP-43 (growth cone phosphoprotein pp46, F1, B-50) did not show acylation under the same conditions. The fact that the acylated proteins described here are membrane-bound and enriched in the growth cone suggests that this post-translational modification may play a role in the intracellular transport and attachment of these proteins to the membrane.

413.5 INDUCTION OF NEUROFILAMENT PROTEIN AND THY-1 ANTIGEN BY NGF IN PC12 CELLS IS MODULATED BY CELL-CELL INTERACTIONS. P. Doherty, D.A. Mann and F.S. Walsh. Institute of Neurology, Queen Square, London WC1N 3BG, U.K.

Nerve growth factor induced differentiation of PC12 cells is associated with up to a 30-fold increase in the level of a 155Kd neurofilament protein antigen (Doherty, Mann, Walsh, in review) and a 2-3-fold increase in the cell surface expression of the Thy-1 glycoprotein (Doherty and Walsh, 1987, J. Neurochem, in press). The former response can be taken as an index of morphological differentiation, whereas the latter is an early response that can be dissociated from morphological differentiation (see Walsh and Doherty, this volume). We have grown both naive and primed PC12 cells on monolayer cultures of non-neuronal cells to determine if a) the microenvironment can modulate both morphological dependent and independent responses to NGF, and b) if PC12 cell responsiveness to the cues in the microenvironment is in itself subject to regulation by NGF.

Over a 2-3 day period, and in the absence of NGF, both naive and primed PC12 cells failed to differentiate on any tested monolayer. NGF dependent increases in the neurofilament protein antigen and Thy-1 were greatly suppressed when naive cells were grown on fibroblast monolayers as compared to C2 and G8 myotubes and C6 glioma. This suppression was associated with an inhibition of neurite outgrowth. In contrast, there was no difference in the neurofilament protein response from PC12 cells that had been pretreated with NGF prior to co-culture and the now primed cells readily extended axons over fibroblast monolayers. There was no evidence that fibroblasts secrete soluble molecules that directly inhibited the neurofilament and Thy-1 responses.

The reported results suggest that 1) neuronal responsiveness to NGF may be critically dependent on the nature of the local microenvironment, 2) responsiveness is not immutable and may in itself be modified by pre-exposure to NGF, 3) responses other than overt morphological differentiation are also influenced by the microenvironment. It appears probable that control is mediated via direct cell-cell and/or cell matrix interactions.

413.6 INSULIN INDUCED NEURITOGENESIS AND TUBULIN MESSAGE STABILIZATION IN A CLONED HUMAN NEUROBLASTOMA CELL LINE. J.F. Mill*and D.N. Ishii (SPON: E. Freese). Lab. Molec. Biology, NINCDS, NIH, Bethesda, MD 20892 and Dept. Physiology, Colorado State Univ., Fort Collins, CO 80523.

Microtubules are important components of the axonal cytoskeleton. They are assembled from heterodimers comprised of alpha- and beta-tubulins. We have previously shown in a cloned human neuroblastoma cell line, SKN-SH-SY5Y (SY5Y), that physiological concentrations of insulin can increase tubulin mRNA levels as a prelude to neurite outgrowth. Both responses follow the same dependency on insulin dose. Here we explore whether the increase in transcript levels is due to an increase in the transcription rate or an increase in message stability. To address the first possibility, nuclear run-off experiments were performed. SY5Y can survive with no loss in cell number in serum-free medium for at least a week and resume growth on the addition of serum. After 2 days in serum-free medium some cultures were exposed to 0.1 uM insulin for 24 hours. Equal numbers of nuclei isolated from treated and control cultures were incubated in 100 ul of transcription buffer containing 500 uCi of ^{32}P-UTP at 29°C for 30 min. RNA samples containing equal numbers of precipitable counts were hybridized to nitrocellulose discs with 1 ug of plasmid DNA containing either no insert, alpha-, or beta-tubulin coding region cDNA inserts. Tritiated cRNA to either alpha- or beta-tubulin was included to determine the extent of hybridization, and nonspecific background counts were subtracted using the control disc with no insert. Results from these experiments showed no significant differences between treated and untreated control cultures.

To study tubulin message stabilization, cells were grown in serum-free medium without or with insulin for 2 hours to increase tubulin messages. Actinomycin D (2 ug/ml) was used to inhibit further RNA synthesis. Samples were collected every hour for 5 hours in guanidinium isothiocyanate, and the RNA was purified by CsCl step gradient centrifugation. Equal quantities of RNA were electrophoresed in denaturing formaldehyde gels and transferred to nitrocellulose. The blots were sequentially hybridized to the labeled nick-translated alpha- and beta-tubulin cDNAs. The blots were also hybridized to labeled oligo dT. Insulin was found to decrease the rate of decay of tubulin messages, showing that it stabilized these transcripts. In contrast, the oligo dT binding to total poly A mRNA indicated that the total pool of mRNA was not stabilized. We infer that insulin can increase the tubulin mRNA levels by specifically stabilizing these transcripts, and not through enhanced transcription. (Supported by NIADDK grant)

413.7 CHANGES IN THE PATTERN OF MAP2 EXPRESSION ARE CONSERVED IN AVIAN AND MAMMALIAN BRAIN. C.C. Garner, R. Tucker and A. Matus. Friedrich Miescher-Institut, P.O.Box, 4002 Basel, Switzerland.

The pattern of expression of microtubule-associated protein 2 (MAP2) in the neonatal rat brain changes abruptly between postnatal day 10 (P10) and P20. Prior to this time there are two MAP2 species, MAP2b (M_r 280,000) and MAP2c (M_r 70,000). By P20 the MAP2c levels have dropped more than 10-fold and a second high molecular weight species, MAP2a, has appeared and is equi-abundant with MAP2b. Earlier still, at embryonic day 14 (E14) MAP2c is the most abundant isoform suggesting that it is the first MAP2 species to appear in the differentiating neurons. In the developing quail brain a similar set of changes are seen. Again two major MAP2 forms are present, a very high (M_r 260,000) form and a smaller species (M_r c. 65,000). At embryonic day 10 (E10) the smaller MAP2c homologous form is the most prominent whereas by E14 both a large MAP2b-homologous form and the MAP2c species are present. By P2 the MAP2c form levels are many times lower and the pattern of expression resembles that of the adult rat brain. Given the differing rates of maturation in the two species these observations suggest that essentially the same changes in MAP2 gene expression are linked to the same set of events in brain development, namely the termination of axon and dendrite growth and the achieving of adult neuronal form. Then fact that the molecular changes are conserved in both avian and mammalian brain development suggests that these molecular mechanisms are of fundamental importance in neuronal differentiation.

413.8 CYTOSKELETAL ELEMENTS IN MOTOR NERVE OUTGROWTH IN VIVO: CHANGES DURING AXONAL REGENERATION AND TERMINAL SPROUTING. W.C. Yee* and A. Pestronk. Neuromuscular Unit, Johns Hopkins School of Medicine, Baltimore, MD. 21205.

Cytoskeletal elements play a variety of roles in the growth, maturation and maintenance of axons. In this study we have examined the distribution and forms of cytoskeletal elements in normal and growing rat motor axons in vivo. Cytoskeletal elements in the terminal portions of axons were visualized with immunocytochemical methods (peroxidase-antiperoxidase) in frozen longitudinal sections of muscle that were also stained for cholinesterase to localize neuromuscular junctions (NMJs). We compared the cytoskeletal composition of normal axons and their terminal branches to axonal processes forming during two types of outgrowth: 1) axonal regeneration - studied following a crush injury to the nerve at its point of entry into muscle, and 2) ultraterminal sprouting - induced by blockade of neuromuscular transmission with botulinum toxin. At times from 5 to 30 days after the onset of sprouting we stained axons and sprouts for neurofilaments, tubulin, and actin.

Our results show significant variations between in the distribution of different cytoskeletal elements, both in normal axons and in sprouts. In normal nerves neurofilaments are abundant in both preterminal axons and their terminal arborizations at NMJs. In contrast, tubulin and actin staining, while abundant in preterminal axons, decreases abruptly as axons reach NMJs. Tubulin and actin staining is minimal in terminal axonal arborizations. In regenerating axons 2 weeks after nerve crush, reinnervation of most NMJs can be demonstrated with neurofilament antibodies. The entire length of the regenerated axons is visualized. Tubulin staining of axons tends to end in intramuscular nerve bundles or in individual axons at least 100-200 μm before they reach NMJs. Staining of neurofilaments also precedes that of tubulin and actin during the formation of ultraterminal sprouts. By 15 days after botulinum treatment neurofilament antibodies often demonstrate multiple ultraterminal sprouts arising from NMJs. At the same time tubulin is apparent mainly extending in a single column from preterminal axons into the NMJ area and, occasionally, out into a single ultraterminal sprout.

These results show that the distribution of neurofilaments and tubulin in terminal axons is different. In general, neurofilament staining is abundant in terminal aspects of normal and growing axons while tubulin and actin are difficult to demonstrate. Actin and tubulin appear to be quantitatively or qualitatively different in preterminal axons than in terminal axons and sprouts.

413.9 PHYLOGENETIC CONSERVATION OF GAP-43, A GROWTH ASSOCIATED PROTEIN. E. Nedivi* and J. H. Pate Skene. Department of Neurobiology, Stanford University School of Medicine, Stanford, CA 94305.

GAP-43 is a protein induced in neurons during axonal outgrowth, in the course of both neuronal development and axon regeneration. If this protein performs a function fundamental to neural growth, then we would expect it to be highly conserved during evolution. We were therefore interested in studying GAP-43's evolutionary conservation as an indicator of the protein's functional importance.

We employed GAP-43 cDNA recently cloned from developing rat brain (Basi et. al., Cell, in press, 1987) to probe the genomes of a variety of vertebrate and invertebrate species, using genomic Southern blot hybridization. Genomic DNA isolated from human, rat, chicken, toad, turtle, goldfish, Botryllus(a tunicate), Aplysia and Drosophila was prepared and hybridized by the method of Southern with a cDNA probe containing the entire coding sequence for rat GAP-43. Under stringent hybridization conditions that allow reannealing of the probe with only closely related sequences, homologous DNA fragments were detected in all of the DNAs tested. The homologous sequences were confined to one or two restriction fragments in the pattern produced by an Eco RI digest. Our Southern blot screen of the genomes of members of the animal kingdom indicates that the GAP-43 gene is widely and highly conserved in metazoans. Whether the homologous genes function in axonal outgrowth is still unknown, but phylogenetic conservation of the GAP-43 coding sequence indicates that the gene is important for some fundamental neuronal process.

Of all the phyla we examined, Arthropods are phylogenetically most distant from rat. We have isolated several clones from a Drosophila genomic library that will permit detailed analysis of a GAP-43 gene separated from the mammalian gene by a wide evolutionary distance. Comparison of the rat and Drosophila Gap-43 sequences should disclose the most highly conserved structural aspects of the protein and its gene, possibly yielding insight into the functionally important parts of this molecule.

Supported by NIH grant NS20178, the Isabella Niemela Fund, and a Searle Scholars Award to JHPS.

413.10 IMMUNOHISTOCHEMICAL LOCALIZATION OF A MAJOR GROWTH-ASSOCIATED PROTEIN IN THE DEVELOPING HAMSTER VISUAL SYSTEM. K.L. Moya, S. Jhaveri*, L.I. Benowitz, and G.E. Schneider. Dept. of Brain and Cognitive Sciences, M.I.T., Cambridge, MA 02139 and Dept. of Psychiatry, Harvard Med. Sch., McLean Hosp., Belmont, MA 02178.

In previous studies that examined the transport of radiolabeled proteins we showed that the growth-associated protein GAP 48 (GAP 43/B-50) is synthesized in the retina at high levels during development and rapidly transported to maturing retinal axon terminals. In the present study, using a polyclonal antibody against GAP/B-50, we examined developmental changes in localization of this protein in the optic tract (OT), dorsal lateral geniculate nucleus (LGBd) and superior colliculus (SC) of postnatal hamsters. Postnatal day 2 (P2; P0= day of birth), P5, P8, P12, P19 and adult hamsters were perfused with 4% paraformaldehyde and the brains sectioned in the coronal or parasagittal plane at 40um. Sections were incubated with the antibody and processed using the ABC/HRP technique to visualize the protein.

In general, GAP/B-50 is preferentially localized in fiber tracts and in axon fascicles in the younger animals, whereas in more mature brains the staining shifts to the target neuropil. Thus, the optic tract is darkly stained on P2 and P5, is somewhat lighter by P8 and exhibits virtually no staining by P19. In the LGBd on P2 and P5, the predominant pattern is the dark staining of dorsoventrally coursing axon bundles, corresponding in position to the deeper-running retinal axons. By P12, the staining of fiber fascicles is no longer evident, but the antigen is found throughout the neuropil of the LGBd resulting in a dark background mottled by the presence of unstained perikarya. On P8, the staining is intermediate between the immature and the more mature patterns. In the SC, GAP/B-50 is localized in longitudinal axon fascicles throughout the superficial layers on P2, resembling the distribution of retinotectal axons at this age. By P5, stained axons are concentrated in the optic fiber layer (SO), where retinal as well as the later arriving cortical axons reside. Especially noteworthy at this age is a mediolateral gradient of staining in the SO with medial axons exhibiting more intense staining. By P8, this gradient is significantly diminished, as is the distribution of the antigen in all SO axons. The adult SC exhibits very little GAP/B-50; a light staining of the superficial tectal neuropil begins to resemble the mature pattern by P12.

Our results demonstrate that GAP/B-50 shows striking changes in location within developing axons during maturation. The protein is present in OT fibers when retinal axons invade their targets and initiate arbor formation, but appears to concentrate in terminal neuropil as arbors mature. Studies with prenatal hamsters are currently underway to determine if GAP/B-50 is also present in axons during the time of initial outgrowth from the eye and early elongation along the diencephalic surface. The mediolateral gradient of fiber development in the SC has not been reported previously, and may represent a gradient in maturation of retinal or cortical afferents to this structure. (Supported by an NSF graduate fellowship and NIH grants EY 00126, EY/NS 05504, EY 05690 and EY 02621.)

413.11 GAP-43 IMMUNOREACTIVITY IS CORRELATED WITH RATE OF GROWTH CONE TRANSLOCATION AND WITH INITIATION OF NEURITE OUTGROWTH IN CULTURED SYMPATHETIC NEURONS. M.I. Johnson+, N. Kleitman, M.B. Willard and K.F. Meiri*, Dept. Anat. & Neurobiology (+also Pediatrics), Washington Univ. Sch. Med., St. Louis, MO 63110.

GAP-43 is a neuronal protein synthesized at elevated levels during both developmental and regenerative axonal growth. In cultured rat sympathetic neurons, GAP-43 immunoreactivity is concentrated at the growth cone. On both collagen and laminin, neurites of these neurons from embryonic animals extend more rapidly than those of neurons from postnatal animals. Here we report experiments to investigate the relationship between GAP-43 immunoreactivity and the initiation and rate of neurite elongation.

Explants or dissociated neurons from the superior cervical ganglia (SCG) of embryonic (E21) or postnatal (P30) rats were cultured either separately or on the same laminin-coated coverslip. After 1-3 days, when E21 neurites are extending 2-3 times more rapidly than P30 neurites, the cells were fixed in paraformaldehyde, made permeable with digitonin and incubated with an affinity purified polyclonal antibody against GAP-43. Immunoreactivity was detected with a fluorescein-conjugated secondary antibody. Under phase microscopy, growth cones of E21 and P30 neurites with similar size and shape were paired, and each pair photographed under identical conditions in a fluorescence microscope. When 22 such morphologically matched pairs were evaluated by 12 observers unaware of their age, the E21 growth cones were considered to be unambiguously more fluorescent in 20 out of 22 of the pairs. These results are supported by a preliminary computer analysis of digitized images of growth cones; the average fluorescence per area of the P30 growth cones was 65% of that of E21 growth cones.

Over time in culture, E21 SCG neurons will extend neurites at a greatly reduced rate, but will re-initiate growth if they are re-dissociated and plated onto fresh coverslips. We assessed GAP-43 immunoreactivity in E21 SCG neurons that had been in culture for three to six months, both at the time of and after re-dissociation. Prior to re-dissociation, anti-GAP-43 immunoreactivity was much less than when the neurons were first cultured. Following re-dissociation, the number of cells with augmented immunoreactivity increased with time: at 1 day, 8% were more reactive, by 2 days, 19%, and by 9 days, 78%. At nine days, cells which had begun to extend neurites were intensely fluorescent. We conclude that GAP-43 immunoreactivity correlates with the initiation and the rate of neurite extension in SCG cultures. GAP-43 immunoreactivity increases in the somata of mature neurons when they have been stimulated to re-extend neurites by dissociation. 413.12 INDUCTION AND LOCALIZATION OF THE GROWTH-ASSOCIATED PROTEIN, GAP-43, IN NGF- STIMULATED PC12 CELLS. Brian Costello*, Jeanette J. Norden and John A. Freeman. (SPON: D. M. Buxbaum), Dept. of Cell Biology, Vanderbilt University Medical School, Nashville, TN 37232.

Expression of GAP-43, a fast-transported neuronal protein, is elevated during periods of axonal growth. We have utilized the PC12 line of rat pheochromocytoma cells as an in vitro model for studying the role of GAP-43 in neurite outgrowth. Previous work from this laboratory has demonstrated induction of GAP-43 in PC12 cells upon stimulation of neurite outgrowth by treatment with nerve growth factor (NGF). In the present studies, quantitative immunoblotting procedures were used to measure GAP-43 levels. Coincident with NGF-stimulated neurite outgrowth, levels of GAP-43 increase by an order of magnitude. Turnover rate studies employing [35S]-methionine pulse labeling show that this increase is attributable mostly to a corresponding increase in the GAP-43 synthesis rate. These results are consistent with a role for GAP-43 in neurite outgrowth in PC12 cells. In order to gain some insight into its precise function, electron microscopic immunolocalization of GAP-43 was performed using affinity purified antibody and the avidin/biotin/peroxidase method. In NGF-stimulated PC12 cells, GAP-43 is seen associated with vesicle clusters within varicosities along neurites and in growth cones. Such vesicle clusters are reminiscent of those present in cholinergic nerve endings and suggest that GAP-43 plays a role in synaptic vesicle function, possibly related to vesicle fusion and membrane addition. Supported by NIH Grants EY01117 and NS18103 to JAF.

413.13 THE GROWTH-ASSOCIATED PROTEIN, GAP-43, IS ASSOCIATED WITH SYNAPTIC VESICLES AND WITH PLASMA MEMBRANE IN PRESYNAPTIC TERMINALS. Jeanette J. Norden, Brian Costello*, and John A. Freeman. Department of Cell Biology, Vanderbilt University School of Medicine, Nashville, TN 37232.

GAP-43 is a 43 KDa fast axonally transported neuronal protein which shows a 20- to 100-fold increase in synthesis and transport during nerve growth and regeneration. Recently we have shown that GAP-43 is identical to the synaptic plasticity-associated PKC substrate F1 (Snipes et al, J. Neurosci, in press), which has been shown to undergo an increased phosphorylation during long-term potentiation in the hippocampus. In an effort to elucidate the possible role this protein might play in nerve growth and synaptic plasticity, we have raised specific antibodies to purified GAP-43. Using light microscopic immunocytochemistry, GAP-43 appears to be localized to growing processes throughout the rat brain during development. In the mature brain, GAP-43 immunoreactivity is localized to synaptic areas and is particularly intense in the molecular layers of the neocortex, cerebellum, and hippocampus. Using affinity purified antibodies, we have used immunoperoxidase methods to localize GAP-43 at the EM level in the adult rat brain. GAP-43 immunoreactivity is specifically localized at synapses to the synaptic vesicle membrane and to the presynaptic plasma membrane. Synapses in control sections in which affinity purified antibody was blocked with an excess of GAP-43 were completely negative. The localization of GAP-43 immunoreactivity to synaptic vesicles and plasma membrane suggests that GAP-43 might play a role in vesicle fusion and release of neurotransmitter. This also suggests that the PKC phosphorylation of GAP-43 is linked to the increased release of neurotransmitter which has been shown to occur during long-term potentiation. Supported by NIH Grants EY01117 and NS18103 to JAF.

413.14 POST-TRANSLATIONAL MODIFICATION OF A GROWTH CONE PROTEIN, GAP-43: AN ANALYSIS USING MONOCLONAL ANTIBODIES. D.J. Schreyer and J.H.P. Skene. Dept. Neurobiology, Stanford University School of Medicine, Stanford, CA 94305

GAP-43 is an acidic protein component of growth cones and synaptosomes whose expression is elevated during axon growth. It is the product of a single gene in the rat, and its primary structure is known. GAP-43 can be phosphorylated in vivo, and such modification is likely to be important to its function within growth cones and synaptic terminals. Isoelectric focusing reveals that native GAP 43 may be resolved into at least four species, representing isoforms differing in pI. In order to further investigate the nature of the post-translational modifications that produce heterogeneity of a protein translated from a single mRNA species, we have produced a panel of monoclonal antibodies against GAP-43.

Mice were immunized with a crude GAP-43 preparation produced by preparative isoelectric focusing. Antibody producing hybridoma cell lines were produced and cloned using standard methods, and screened for reactivity with the antigen preparation in a dot-blotting assay. Positive clones were further characterized using Western blot analysis of SDS-PAGE of solubilized membrane fractions from neonatal rat brain. Eight antibodies were identified which reacted with single bands possessing electrophoretic mobilities identical to purified GAP-43.

The monoclonal antibodies were then used to analyze "prints" of isoelctric focusing gels, using a technique analogous to Western blotting. Of the eight anti-GAP-43 monoclonal antibodies, six recognized all four isoelectric isoforms, one recognized only the three most basic isoforms, and one recognized only the three most acidic isoforms. The latter two antibodies thus recognize sites which are sensitive to post-translational modification. Preliminary Western blot analysis of GAP-43 from growth cone and synaptosome subcellular fractions in SDS-PAGE suggests that growth cones contain a slightly less mobile form of GAP-43 not found in synaptosomes. Investigations are underway to determine which of the isoforms of GAP-43 are present in growth cone and synaptosome subcellular fractions.

413.15 IMMUNOCHEMICAL EVIDENCE THAT A GROWTH-ASSOCIATED PROTEIN (GAP-43) IS LOCALIZED SPECIFICALLY TO DEVELOPING NEURONAL PROCESSES AND MATURE PRESYNAPTIC TERMINALS. C. Brian McGuire*, G. Jack Snipes* and Jeanette J. Norden (SPON: A.M. Burt). Dept. of Cell Biology, Vanderbilt University School of Medicine, Nashville, TN 37232.

A growth-associated protein designated GAP-43 is a developmentally regulated neuronal protein which is synthesized and rapidly transported to axonal endings in high amounts during periods of axon growth and synaptic terminal formation in both the peripheral and central nervous systems and is enriched in isolated growth cone particles, as well as in synaptic plasma membranes. Much evidence exists suggesting it is a phosphorylation substrate of protein kinase C (PKC), and may be identical to the B-50 protein associated with synaptic transmission and the F1 protein, which is involved in neuronal plasticity. We have raised a specific antiserum against GAP-43, and have used this to characterize the tissue distribution of this protein. Western blot analysis of proteins from a variety of rat organs, together with immunocytochemical data, provide evidence that the presence of GAP-43 is limited to neurons of the peripheral and central nervous systems. Careful analysis of GAP-43 immunolocalizations in paraffin sections of developing rat brain suggests that GAP-43 is limited to growing neuronal processes. In sections of mature brain, the distribution of punctate immunoreactive sites suggests a subcellular localization exclusively to presynaptic terminals. Its neuronal specificity and subcellular localization, together with biochemical data concerning the dynamics of its synthesis and probable role in the phosphatidylinositol cycle, are consistent with hypothesized functions of GAP-43 in axon growth or synaptic terminal differentiation.

413.16 DISTRIBUTION OF GAP-43 WITHIN ISOLATED NEURONAL GROWTH CONES. K.F. Meiri and P.R. Gordon-Weeks (SPON: M. Willard). Dept. of Pharmacology, SUNY Health Science Center, Syracuse, NY 13210 and Dept. of Anatomy and Human Biology, Kings College, London U.K.

Embryonic or neonatal rat forebrain can be fractionated to yield a population of particles which, by morphological criteria, appear to be derived from neuronal growth cones (GCPs). These GCPs have ultrastructural characteristics of growth cones, including filopodia, which many of them retain through the purification procedure. The neuronal phosphoprotein GAP-43, a polypeptide whose synthesis is induced in neurons when they grow axons during development or regeneration, is highly enriched in a particulate fraction derived from GCPs, but is probably not an integral membrane protein. We have used an affinity purified antibody against GAP-43 to determine its distribution within these growth cone particles.

Isolated GCPs were prepared from forebrains of neonatal rat pups and allowed to settle onto polyornithine-coated coverslips. The particles were then fixed, made permeable with digitonin and incubated with anti-GAP-43 antibody. Immunoreactivity was detected with a fluorescein-conjugated secondary antibody.

Upon attachment to the coverslips the spherical particles spread out (the average size of the particles was 2-5 μ), became phase bright and extended fine processes. All the particles that had attached reacted with the GAP-43 antibody, indicating their neuronal origin. GAP-43 immunoreactivity was present throughout the extent of every fine process. The punctate nature of the staining resembled that seen when growth cones from cultured neurons were reacted with anti-GAP-43.

The particulate fraction of GCPs probably contains both plasmalemma and intracellular membranes, as well as cytoskeletal proteins. To clarify which of these subcellular structures GAP-43 is associated with, the GCPs were further fractionated by extraction in non-ionic detergent followed by density gradient centrifugation of the detergent insoluble material. This yields a 'membrane skeleton' which is believed to comprise the plasma membrane which is closely associated with the cytoskeleton. From Western blotting GAP-43 appeared enriched in this membrane skeleton by a factor of about 5 compared with whole GCP homogenate. However, GAP-43 immunoreactivity was not present in a different detergent-insoluble fraction which is believed to contain only cytoskeleton. We conclude that the punctate staining with anti-GAP-43 antibody seen in both cultured growth cones and GCPs is likely due to the presence of GAP-43 in membrane which is closely associated with the cytoskeleton, but that under these preparation conditions GAP-43 is not directly associated with the cytoskeleton itself.

413.17 DEVELOPMENT OF QUANTITATIVE IMAGE PROCESSING METHODS TO QUANTITATIVELY ANALYZE mRNA REGULATION USING IN SITU HYBRIDIZATION. John A. Freeman, Jeanette J. Norden, Afshin Meymandi*, and Phillip Samson*. Department of Cell Biology, and Vanderbilt University Medical School, Nashville, TN 37232

We are interested in studying the regulation and function of GAP-43 (identical to protein F1 and B50), a 43 KDa acidic phosphoprotein whose expression is selectively enhanced in neurons that are in an active state of growth, and which undergoes a dramatic increase in phosphorylation during the changes in synaptic function that accompany long term potentiation. As a first step in studying the regulation of this protein, we constructed a specific GAP-43 [35S]-cDNA probe, using the base sequence previously obtained for the protein (Karnes et al, Science, in press), and have used *in situ* hybridization to probe for GAP-43 mRNA levels in different neural systems in the rat CNS and PNS during development and after nerve injury. To quantitate binding, we have developed several powerful digital image processing methods. Microscopic images are digitized by a 12-bit linear photodiode array and displayed on a high-resolution video monitor. The specific probe signal is isolated from non-specific binding by a new referred mapping technique that spatially transforms and subtracts from each section the optical densities of control sections brought into precise registration with experimental sections by a non-linear gradient search algorithm. The specific binding signal is further enhanced by a specially designed digital convolution filter. Images from serial LM sections are then reconstructed in 3 dimensions, and quantitative morphometric measurements are obtained of specific binding per unit neuronal area and volume in order to reveal quantitatively the amount and cellular localization of labeled mRNA. Combined quantitative densitometry of autoradiographic standards, in which OD measurements are calibrated in terms of DPM, allows specific binding to be expressed in terms of number of molecules of hybridized mRNA per neuron. These methods, which are implemented on a laboratory IBM AT computer, promise to be of general utility in quantitating gene expression in a variety of different systems. Supported by NIH Grants EY01117 and NS18103 to JAF.

414.1 DEVELOPMENT OF AUDITORY AND VESTIBULAR NEURONS IN CULTURE: MIGRATION AND FIBER OUTGROWTH. K. Book* and D.K. Morest (SPON: S.J. Potashner). Univ. Connecticut Health Center, Farmington, CT 06032

Neurons have been shown to migrate from the matrix zone of the rhombic lip to the presumptive cochlear and vestibular nuclei in the mantle zone of the E.4.5-7.5 chicken embryo (Hamburger-Hamilton staged) (Book et al, SN Abstr 1985). In the first stage of migration nucleus magnocellularis neurons extend leading processes which form axonal branches that enter the crossed cochlear tract at the border between the matrix and mantle zones. In the next stage of migration the cell bodies travel through their leading processes into the mantle zone by perikaryal translocation. Finally the young cell bodies lose the processes connecting with the matrix zone and start to differentiate. We now report our direct obervations of this process in living medullas in vitro.

At E5.5-7.5 nucleus magnocellularis neurons are the only ones known to send axonal processes across the midline within the crossed cochlear tract, projecting laterally beyond the medial longitudinal fasciculus (MLF). This circumstance allows one to label the migratory magnocellular neurons by retrograde transport through their crossed axons. Medullas (E5.5-7.5) were dissected, rostral to the Vth, and caudal to the Xth, cranial nerves, and embedded in collagen gel. Using a lipid soluble fluorescent dye, diI, as a retrograde marker (Honig & Hume, J Cell Biol 103, 1986), we made in vitro injections on one side of the medulla into the crossed tract between the rhombic lip and the MLF. In all ages examined, brightly labeled crossed tract fibers extended across the midline contralateral to the injection into the region occupied by nucleus magnocellularis during the first day in vitro (1 DIV). Labeled cell bodies could be seen in this region until at least 4 DIV. Observations of transverse slices of the explants confirmed that these labeled cells were in the matrix zone of the rhombic lip and in the position of nucleus magnocellularis at this stage of development. The morphology of the cells corresponded to each particular stage of the migration previously seen in situ.

In separate experiments unlabeled cell clusters from the rhombic lip (E5-7) were grown in cultures on various substrates. Individual cells migrating from the clusters were followed sequentially and photographed at intervals along their migration routes, thus providing direct visualization of the migratory process for a large number of neurons. Migration was effected by elongation of a leading process, neurite outgrowth, and perikaryal translocation. No locomotory cells were seen.

414.2 TEMPORAL AND SPATIAL DISTRIBUTION OF FIBRONECTIN DURING INNERVATION OF THE AUDITORY RECEPTOR IN THE CHICKEN EMBRYO. S.G. Hemond* and D.K. Morest. Department of Anatomy, University of Connecticut Health Center, Farmington, CT 06032.

The developing chicken auditory receptor, the basilar papilla (BP), elongates greatly from base to apex during St 20-30 (Hamburger-Hamilton), while auditory nerve fibers penetrate its basal lamina (BL) and contact hair cell precursors. We have previously described a distinct temporo-spatial pattern of fiber ingrowth (Soc Neurosci Abstr, '86). The present study examines fibronectin (FN) distribution in the BL and in the matrix surrounding the BP during innervation.

Fifteen white Leghorn chick embryos were fixed in buffered paraformaldehyde and prepared for cryotomy. Immunocytochemistry was performed on 10-20 um thick sections with 3 different antisera raised against either human or chicken plasma FN, followed by a biotinylated secondary antibody, avidin-biotin-HRP (Vectastain), and a DAB reaction. Control sections were treated either with buffer, secondary antibody, normal serum or pre-immune serum.

In the stages studied immunoreactivity is not observed in the auditory ganglion and BP, but it is conspicuous in the surrounding matrix, which is rich in FN fibrils. The distribution of FN in the BL changes during innervation. At early stages (St 20-25) only the base of the BP is infiltrated by fiber bundles. The fiber bundles themselves are not immunostained, but the BL exhibits a patchy distribution of FN. A patchy distribution of FN also appears in the basal and apical areas at St 26-29, when these regions receive fiber ingrowth. However, the mid-basal region at St 26-29, still to receive fiber ingrowth, exhibits an uninterrupted FN distribution in the BL. The mesenchyme separating the ganglion from this region of the BP is densely stained; FN fibrils are oriented parallel to the long axis of the BP. The mid-basal region of the BP is innervated after St 29, and at this time a patchy FN distribution of the BL can be observed in this area.

The present results suggest that 1) fiber ingrowth in the BP correlates temporally and spatially with disruption of FN distribution in the BL; 2) in the region of patchy immunostaining, where fiber bundles are penetrating, fibronectin is lodged between the unstained cochlear nerve fascicles; 3) the areas of the BP yet to be innervated in subsequent stages have an uninterrupted FN distribution. Perhaps the fibers themselves affect the distribution of FN in the BL.

414.3 IDENTIFICATION AND PURIFICATION OF A HIGH AFFINITY LAMININ RECEPTOR FROM EMBRYONIC CHICK BRAIN: EVIDENCE FOR DEVELOPMENTAL REGULATION IN THE CNS P. Douville*, W. Harvey and S. Carbonetto Neuroscience Unit, Montreal General Hospital Research Institute, McGill University, Montreal, Quebec, Canada H3G 1A4

Laminin, a glycoprotein of the extracellular matrix (ECM), is normally found in the PNS of both adult mammalian and avian species but is absent from adult CNS. Laminin is also found in developing CNS (Liesi, EMBO J.,4, 1163, 1985). Laminin mediates nerve fiber growth in culture through specific cell surface receptors and may be involved in nerve fiber growth during development and regeneration.

In earlier studies we have shown that a variety of neural cells grown in culture bind ^{125}I-laminin specifically with a single Kd of 10^{-9}M (Harvey and Carbonetto, Soc. Neurosci. abstr., 12, 1109, 1986). We have now identified and purified a high affinity laminin receptor from embryonic chick brain that is distinct from the low affinity fibronectin/laminin receptor integrin. ^{125}I-labelled membranes isolated from chick brains were passed over laminin-Affigel affinity columns and eluted with 0.2M glycine buffer pH3.5. Autoradiography of SDS polyacrylamide gels of the eluant reveal a single band with a M_r of 67,000 daltons. Peptide mapping with trypsin have shown this protein to be distinct from serum albumin (M_r=68,000) but homologous to the high affinity laminin receptor (M_r=67,000) found in skeletal muscle (Lesot et al, EMBO J., 2, 861, 1983). Moreover, both the skeletal muscle and brain receptors focus isoelectrically at a pI of 6.2 versus 5.7 for serum albumin.

We have begun to investigate the developmental regulation of high affinity laminin receptors in embryonic chick brain using ^{125}I-laminin binding to purified plasma membranes and to optic lobe cells in culture. ^{125}I-laminin binding to both membranes and cultures is constant from day 8 to day 12 and then falls to 25-30% of the day 8 value at days 14-16. This drop correlates with the decreased ability of optic lobe neurons to extend nerve fibers on laminin-coated substrata. Chick brain membranes (11d) or laminin-affinity purified proteins electroblotted with ^{125}I-laminin (10^{-10}M) reveal two distinct bands, one at 67kD and another at approximately 140kD. This 140kD polypeptide, which is present in trace amounts, may represent an additional high affinity laminin receptor which is not seen on stained gels nor after autoradiography of iodinated purified material. Thus, developing CNS neural cells have multiple high affinity laminin receptors in addition to the low affinity receptor (integrin). We are currently in the process of raising antibodies against these putative receptors to further characterize them structurally and functionally in nerve fiber growth.

414.4 ROLE OF LAMININ AND THE CYTOSKELETON IN CELL FLATTENING AND NEURITE OUTGROWTH IN NG108-15 CELLS. L. Luckenbill-Edds Dept. Zoological and Biomedical Sciences and College of Osteopathic Medicine, Ohio University, Athens, OH 45701

Laminin, a glycoprotein found in basement membranes, has several separate domains that mediate different functions, e.g., collagen binding, heparin binding, cell attachment, cell flattening, and neurite outgrowth. To learn more about how laminin promotes cell flattening and neurite outgrowth, we have investigated the response of a neuroblastoma x glioma cell line (NG108-15) to cytoskeletal inhibitors when cultured on a laminin substrate in the absence of serum. We used vinblastine (1 μg/ml) to depolymerize microtubules, and cytochalasin D (CD) at both high (1.0, 2.0, 5.0 μM) and low (0.01, 0.1 μM) concentrations to depolymerize microfilaments. On tissue culture plastic, vinblastine inhibits both flattening and neurite outgrowth. On a laminin substrate, vinblastine causes withdrawal of established processes, indicating depolymerization of microtubules, but has no effect on flattening. High CD inhibits flattening, and low CD permits flattening, regardless of laminin or plastic substrates. However, a laminin substrate alters the cells' response to CD with respect to process outgrowth. Cells on a laminin substrate treated with low CD extend morphologically normal processes, whereas on plastic, cells with low CD extend aberrant thin, curved, highly branched processes. Aberrant processes also form on a laminin substrate in high CD after a delay. Thus the effect of CD on cell flattening is independent of laminin, whereas the effect of CD on neurite outgrowth depends on the presence or absence of laminin. These results suggest that laminin-mediated flattening of the cell body and laminin-mediated outgrowth of processes involve different mechanisms in these cells.

414.5 INTERACTIONS BETWEEN GLIAL CELLS AND AXONS IN VITRO.
J.W. Fawcett*, I. Bakst* and I.Rokos* (SPON: R. Keynes) Physiological Laboratory, Downing Street, Cambridge, England, and Salk Institute, La Jolla, California.

Cultures of 7 day old rat optic nerve contain predominantly type 1 and 2 astrocytes and oligodendrocytes. When newborn rat dorsal root ganglia (DRG's) were added to mature optic nerve cultures in the presence of NGF, there was extensive neurite outgrowth. The neurites grew profusely on type 1 and 2 astrocytes, but avoided mature oligodendrocytes. The effect was very local, since DRG neurites grew right up to the oligodendrocyte processes. However, when growing neurites encountered an oligodendrocyte sitting on an astrocyte, they were able to grow on the surface of the astrocyte underneath the oligodendrocyte. Oligodendrocytes prepared in different ways (Percoll density gradient centrifugation, shaking of mixed glial cultures) have the same effects on DRG neurite growth. We conclude that oligodendrocytes are not adhesive to growing DRG neurites, but do not actually inhibit their growth.

Astrocyte cultures made in the usual way from neonatal rat forebrain soon become covered with a layer of oligodendrocytes, type 2 astrocytes and their precursors. We noted that in regions where there are few of these cells, the underlying type 1 astrocytes are generally flat and fibroblastic in appearance, whereas where there are many the type 1 astrocytes tend to be more numerous, have fine processes, and stain more strongly for GFAP. If all cells of the oligodendrocyte lineage are killed with tetanus toxin, anti-tetanus toxin, A2B5 monoclonal and complement, the culture contains only type 1 astrocytes, and these will maintain the flat fibroblastic morphology for much longer than usual, or indefinitely. However, if oligodendrocytes from an adult rat, obtained by Percoll density centrifugation are added, the astrocytes rapidly become process bearing and more strongly GFAP+ve. It appears that oligodendrocytes have a trophic effect on astrocytes, although this must be a very local effect, and cannot be transmitted with conditioned medium.

Dorsal root ganglia were plated onto forebrain astrocyte cultures. Neurites grew rapidly over the astrocytes, even when the type 1 astrocytes were covered with a layer of oligodendrocyte lineage cells; the axons could be seen in SEM pictures to be growing on type 1 astrocytes underneath the oligodendrocytes. Some cultures contained areas of leptominingeal cells; DRG neurites grew well on these also. However, at the boundary between astrocytes and meningeal cells there was often a "barrier" of piled up reactive looking astrocytes, and these could form an obstacle to neurite growth. Axons growing from chick retina grew well on astrocytes; however on meningeal cells they either did not grow at all, or grew sparsely in fascicles.

414.6 NEURITE-OUTGROWTH ON LAMININ BY CULTURED RETINAL GANGLION CELLS IS REGULATED BY THE TECTUM. J.Cohen* (SPON: K.Caddy) Dept. of Zoology, University College London, London WC1E.

Chick retinal ganglion cells (RGCs) send axons to their major target, the optic tectum, during the first two weeks of embryonic development. We have shown that between embryonic day 6 (E6) and E11, Thy-1-positive, cultured retinal ganglion cells lose the ability to extend neurites on laminin whilst retaining the surface laminin/fibronectin receptor complex, integrin, recognised by monoclonal antibodies CSAT and JG22 (Cohen et al., Nature 322, 465, 1986; Cohen et al., Dev.Biol. 1987 in press). One possible explanation for the loss of responsiveness to laminin by RGCs is that it is regulated by the target. To test this possibility optic tecta were removed in ovo at E6, prior to tectal innervation and the loss of responsiveness to laminin. Embryos were allowed to survive until E11, by which time most RGC axons would normally have reached the tectum. Retinae were dissociated and cultured for 48 hr on a laminin substrate. Compared with RGCs from unoperated E11 control retinae there was a three-fold increase (14% vs 44%) in the number of RGCs with neurites from tectum-less embryos. Our findings suggest that the down-regulation of response to laminin by RGCs may be controlled by tectal innervation and raise the possibility that the binding specificity of the integrin receptor complex may be modified during the transition from a target-independent to a target-dependent phase of RGC development.

414.7 **PROCESS OUTGROWTH ON CONTINUOUS AND DISCONTINUOUS GRADIENTS OF LAMININ.** **L.R. Dawes* and R.N. Pittman, Dept. of Pharm. Univ. of PA, Phila., PA 19104 (Spon: C. Romano).**

A challenging problem confronting neurobiologists is the elucidation of the mechanisms endowing the growth cone with the capacity for directed process outgrowth and pattern formation. A number of signals have been proposed to influence these phenomena. Among them are the various distribution patterns of extracellular matrix molecules which may mediate adhesive interactions, and in concert with intrinsic differences in neuronal cell membranes, could act to guide axons along their divergent pathways.

Therefore, an apparatus was devised, similar to a casting stand for multiple acrylamide gels, to apply a gentle, substrate bound gradient to glass coverslips. When a gentle gradient of laminin (LM) was applied, it was observed that neither rat sympathetic nor sensory neurons show any tendency to orient towards higher concentrations of LM. We concluded that either the gradient was outside a critical concentration range, or that it was of insufficient steepness to be detected by growth cones.

A more fruitful approach might be to analyze the smallest concentration difference detected by growth cones across a step gradient. Step gradients are prepared by sandwiching trituum labeled LM between the glass substrate and a piece of hemocytometer coverslip. The well is flooded with saline and additional LM is added and allowed to bind uniformly over the remainder of the substrate. Cells are cultured, fixed, and processed for autoradiography. LM is then quantified by densitometry with the DUMAS image analysis system. Cultures are analyzed by determining for each condition the proportion of neurites reoriented at the gradient boundary.

414.8 ELONGATION OF EMBRYONIC CNS NEURONS ON SCHWANN CELL-DERIVED EXTRACELLULAR MATRIX. M. Schinstine and C.J. Cornbrooks. Dept. of Anat. and Neurobiol., Univ. of Vermont, Burlington, VT 05405.

In the developing CNS, axons require permissive substrates in order to arrive at their appropriate targets. The ability of various substrata to modulate neurite outgrowth in vivo can be readily examined in culture. In our study, the pattern and rate of neurite outgrowth was examined on the following substrata: Type I collagen (control), detergent-treated collagen (dColl), and Schwann cell-derived extracellular matrix (ECM). ECM and dColl substrata were prepared by detergent extraction of mature Schwann cell-neuron cultures maintained in complete medium for at least 6 weeks. CNS explants from rats were prepared from embryonic day (E) 15 parietal cortex (PC), septal-basal forebrain (SBF) and lumbosacral spinal cord (LS) and E18 PC and SBF.

Neurite growth on collagen (9-12 um/hr) and dColl (5-9 um/hr) was independent of age. Explants on these substrata displayed radial neurite outgrowth with some fasciculation. In contrast, growth on ECM channels varied with age. E15 explants placed on matrix substrates exhibited 2 types of neurite outgrowth. One type was characterized by neurites that grew without deference to ECM channels (non-orienting neurites). Most non-orienting neurites were not deflected from their initial, radial trajectory by interposing ECM channels. Preferential growth on ECM channels typified the other outgrowth pattern. These orienting neurites were less abundant and were hallmarked by faithful alignment with ECM channels. The growth rate of orienting neurites was similar to those calculated for collagen with the notable exception of E15 LS which grew 1.7X faster on ECM than on collagen. Growth for all orienting neurites was consistently ~2.0X faster than neurites on dColl. Neurites that demonstrated preferential growth on ECM channels were occasionally observed to abandon the ECM and grow onto areas of dColl. In contrast to E15 explants, E18 explants only extended orienting neurites. Although these neurites consistently aligned with ECM channels, they differed from E15 orienting neurites since: a) E18 orienting neurites were rarely observed to elongate from ECM channels onto dColl substrata and b) the growth of E18 SBF on ECM increased significantly ($p<0.05$), rising to 1.7X the growth on collagen. Orienting PC neurites did not demonstrate an increase in growth rate as compared to rates on collagen. Growth for all orienting neurites was 1.5-2.0X faster than growth on dColl.

These observations suggest that ECM derived from Schwann cells can promote neurite outgrowth from CNS tissue in vitro; however, not all neurites respond to the neurite-promoting signals present in ECM. The ability to recognize these signals appears to be related to the developmental age of the neurons and may indicate a switch in the requirement for neurite-promoting factors as development proceeds.

414.9 RAT AMNION MEMBRANE IS A GROWTH-PROMOTING SURFACE FOR CULTURED PERIPHERAL AND CENTRAL NEURONS. M. Manthorpe, N. Danielsen*, H.L. Vahlsing*, B. Pettmann*, G.E. Davis*, E. Engvall* and S. Varon. Dept. of Biology, Univ. California San Diego, La Jolla, CA 92093; La Jolla Cancer Research Foundation, La Jolla, CA 92037.

We have recently reported (Dev. Brain Res. 1987, in press; Science 1987, in press) that the acellular basement membrane surface of human placental amnion membrane is a potent neurite-promoting culture substratum for developing peripheral and central neurons and that rolled up pieces of human amnion membrane implanted into the adult rat brain act to promote and guide regenerating adult cholinergic axons. Based on these results we attempted to use human amnion matrix grafts to promote and guide axonal growth in the adult rat peripheral nervous system using a silicone chamber model. In contrast to human amnion grafts in the rat brain, similar grafts were consistently rejected when placed in a silicone tube anchored between the transected stumps of an adult rat sciatic nerve. That the same type of human amnion graft was rejected from peripheral but not central neural tissues may be related to the relative isolation of the adult CNS from the immune system.

The same in vitro techniques used for human amnion membrane preparation have been used here to generate and characterize an analogous rat amnion membrane preparation. Fresh amnion membranes were dissected from 20 day old rat fetuses, the epithelial cell layer removed by incubation in dilute ammonium hydroxide, and the membranes washed extensively in sterile saline. Small pieces of membrane were anchored to nitrocellulose paper and used as a culture substratum for developing chick embryo parasympathetic, sympathetic, sensory and motor neurons, the latter three of which have adult counterparts contributing axons to the sciatic nerve. In all cases, neurons exhibited lavish neurite growth on the basement membrane surface but not on the opposing stromal surfaces or on the underlying nitrocellulose. Neurite growth on some pieces of membrane appeared strikingly oriented in parallel bundles, while on other pieces growth was randomly oriented. The underlying cause of these differences, if understood and controlled, could be used to increase directional guidance by the amnion grafts in vivo. Preliminary experiments have shown that the adult rat amnion membrane, unlike the human one, is not rejected when implanted between the stumps of the transected sciatic nerve.

414.10 REGULATION OF NEURITE OUTGROWTH BY CALCIUM, CYCLIC AMP, AND PROTEIN KINASE C SECOND MESSENGER SYSTEMS IN A DIVERSE POPULATION OF IDENTIFIED AND UNIDENTIFIED HELISOMA NEURONS. A. Taylor-Hunter*, M. P. Mattson, and S. B. Kater, Program in Neuronal Growth & Devolpment, and Dept. of Anatomy, Colorado State Univ., Fort Collins, CO 80523.

Growth factors, neurotransmitters, and electrical activity are known to act as signals which affect neurite outgrowth (i.e., neurite elongation and growth cone motility) in identified Helisoma buccal neurons. The intracellular messengers which communicate the outgrowth-regulating signals are unknown, but we have recently provided evidence that calcium (Ca) plays an important role. Cyclic AMP (cAMP) and inositol phospholipid-protein kinase C (PKC) are additional second messengers which mediate many physiological effects exerted on neurons by neurotransmitters and growth factors. These second messengers often act and interact in different ways in different cell types, but it is not known to what extent second messengers are involved in the regulation of neurite outgrowth. Here we used cultures of a relatively small population of diverse neurons (< 300) which comprise the buccal ganglion of Helisoma to test the possible involvement and interactions of the Ca, cAMP, and PKC systems in the regulation of neurite outgrowth.

Calcium ionophore A23187 (1 - 100 nM) suppressed both neurite elongation and growth cone motility (GCM) in all buccal neurons tested in a dose-dependent manner. The cAMP-elevating agents forskolin (5 - 100 uM) and dibutyryl cAMP (5 - 10 mM) suppressed neurite elongation and GCM in identified neurons B5 and B19 and in approximately 50% of all buccal neurons. This suppressive effect of cAMP required Ca influx in neurons B5 and B19 and in 25% of all buccal neurons tested (i.e., both La^{3+} and a reduced Ca medium prevented the suppression). Phorbol activators of PKC (e.g., phorbol-12-myristate-13-acetate; PMA; 1 - 100 nM) suppressed neurite elongation and GCM in neurons B19 and B5 and in 90% of the population of buccal neurons. The suppressive effects of PKC activators on neurite outgrowth did not require calcium influx since La^{3+} did not prevent suppression by PMA. Taken together, these results demonstrate that Ca is a general regulator of neurite outgrowth in buccal neurons while cAMP and PKC systems affect outgrowth in a neuron-specific manner. In addition, the effects of cAMP may either be dependent upon or independent of Ca. These results reveal that **within even a small population of neurons there is considerable variability in how individual second messengers and their interactions regulate neurite outgrowth.**

Additional results of these studies provided insight into the respective contributions of neurite elongation and GCM to the generation of neuronal form. Exposure of neurons B19 and B5 to 10 uM La^{3+} or a medium with reduced Ca caused, simultaneously, an accelerated neurite elongation and reduced GCM. Such neurites elongating with reduced GCM displayed a marked reduction in branching. These results indicate that while neurite elongation can occur without prominent GCM, **motile growth cones can act to significantly alter both the rate of neurite elongation and the branching pattern.** (Supported by NIH grants NS08054 [MPM]; NS24683, NS2456, NS15350 [SBK]).

414.11 RESPONSE OF CHICK SENSORY GROWTH CONES TO LAMININ AND FIBRONECTIN: EXTERNAL MORPHOLOGY. R. W. Gundersen. Biological Sciences, University of Wisconsin-Parkside, Kenosha, WI. 53141.

Laminin and fibronectin have been shown to exert both tropic and trophic effects on chick sensory neurons. One effect is the ability of laminin, but not fibronectin, to provide a preferred substrate for neurite elongation. The substrate preference for laminin was correlated with a marked decrease in growth cone-substrate adhesion (R. Gundersen. 1987. Develop. Biol. 122: in press). In order to better understand the substrate preference phenomenon, in the absence of an obvious adhesion increase, studies of growth cone external morphology in response to substrates of type IV collagen (control), laminin, and fibronectin were conducted after 24 H in vitro. The following growth cone parameters were quantified: overall area, numbers of microspikes and lamellipodia, microspike length and kinetics of microspike extension.

Microspike number significantly increased ($p<.05$) 280% and 250% in response to laminin and fibronectin respectively. The number of lamellipodia significantly ($p<.05$) increased 190% in response to both laminin and fibronectin. Growth cone area significantly increased ($p<.05$) 180% and 140% in response to laminin and fibronectin respectively; includes increase in process number. Neither microspike length or rate of extension (calculated at 50% maximal extension) changed in response to laminin or fibronectin. These results indicate that laminin and fibronectin can affect growth cone external morphology without an associated change in the kinetics of microspike extension. Only the increase in process number may provide an insight into the substrate preference for laminin.

In order to determine if the number of growth cone processes play a role in the substrate preference response to laminin, the numbers of microspikes and lamellipodia were quantified for growth cones following a type IV collagen-laminin border. The number of microspikes on the laminin side of the growth cone significantly ($p<.05$) increased by 380% while the number of lamellipodia remained unchanged. These results suggest that the growth cone preference for laminin involves the ability of laminin to promote the formation of a greater number of growth cone processes. However, fibronectin also increases the number of growth cone processes, without eliciting a substrate preference response, laminin must be modulating other growth cone parameters which are more important to the substrate preference response.

414.12 NEURITE GROWTH PROMOTING FACTOR(S) OF ASTROCYTE EXTRACELLULAR MATRIX: IDENTITY AND DEVELOPMENTAL REGULATION. Jerome R. Wujek and Ernst Freese. Laboratory of Molecular Biology, NINCDS, NIH, Bethesda, MD 20892.

Extracellular matrix (ECM) derived from cultured astrocytes has been shown to stimulate de novo neurite outgrowth from pheochromocytoma (PC12) cells (Wujek and Akeson, Dev. Brain Res., in press). Experiments have been undertaken to determine the identity and the developmental regulation of the neurite growth promoting factor(s) within the astrocyte ECM.

Primary cultures of astrocytes were dissociated from the cerebral cortex of neonatal Sprague-Dawley rat pups and maintained in culture flasks for 5 days to 3 months. At different times, the astrocytes were trypsinized, passaged into 35 mm Primaria culture dishes at $1x10^6$ cells/dish and incubated for 24 hrs. Using the method of Vlodavsky et al. (Dev. Biol. 93:285, 1982), astrocytes were then removed non-enzymatically by incubation with 0.5% Triton X-100 in phosphate-buffered saline (PBS) for 30 minutes, followed by extensive rinsing with PBS. This treatment leaves a layer of ECM attached to the surface of the culture dish. PC12 cells were seeded at low density onto the astrocyte ECM in serum-free medium and the outgrowth of neurites was measured at 24 hr intervals.

We examined whether astrocytes change their capability for promoting neurite outgrowth during extended growth in culture. Astrocytes were grown in culture, passaged into 35 mm culture dishes and incubated for 1 day; ECM was obtained and tested for neurite promoting activity as described above. Surprisingly, it was found that ECM derived from astrocytes cultured for 2-12 weeks had approximately 2 times more neurite promoting activity than ECM derived from younger astrocytes (5 days in vitro).

We investigated the identity of the neurite growth promoting factor(s) in astrocyte ECM by using an antibody blocking paradigm in the PC12 cell neurite outgrowth assay. Rabbit antiserum against laminin (an ECM protein) or normal rabbit serum was applied to the astrocyte ECM prior to seeding PC12 cells into the test dishes. Neurite outgrowth was inhibited significantly more by anti-laminin than by normal rabbit serum.

414.13 CHARACTERIZATION OF A NEURONAL SERINE PROTEASE WHOSE INHIBITION ALTERS NEURITE OUTGROWTH. J.K. Ivins*, P. Midgette* and R.N. Pittman. (SPON: B. Wolfe) Dept. of Pharmacology, Univ. of Pennsylvania School of Medicine, Philadelphia, PA 19104

Sympathetic neurons from neonatal rats release a urokinase-like plasminogen activator (PA) from distal processes and growth cones. To determine possible functions of the neuronal PA, cultures of sympathetic neurons were exposed to inhibitors of PA. In serum-free medium, inhibitors of urokinase-like serine proteases increase neurite outgrowth ca. 2 fold over an 18 hr period.

An IgG fraction of antiserum against human urokinase (UK) was fractionated into antibodies which bound at the active site of UK and antibodies that bound to other parts of the molecule. Only the antibodies that bound at the active site increased neurite outgrowth. Because active sites of all trypsin-like serine proteases are very similar, the ability of the antibodies to block activity of other serine proteases was determined. The fraction of the antiserum that bound to the active site of UK was 30-200 fold more selective for inhibition of UK activity than for inhibition of acitivity of other serine proteases. These data still leave open the possibility that the protease whose inhibition alters neurite outgrowth may not be UK but rather a serine protease with an active site similar to UK. The recent acquisition of selective peptide inhibitors of thrombin-like, plasmin-like, and UK-like proteases should help define the nature of this neuronal serine protease.

In order to determine the specific aspect of neurite outgrowth that is being affected by inhibitors of UK-like serine proteases, a videomicroscopy and morphometry system has been assembled. In addition to time-lapse video microscopy of neurite outgrowth, the system will be used to micropipette proteases, inhibitors, and antibodies near the growth cones to more directly determine effects of these agents on growth cone dynamics.

Supported by grants from the NIH (NS 22663) and McKnight Foundation. J.I. was supported by NIH training grant GM 07229.

414.14 NEURITE PENETRATION INTO 3-DIMENSIONAL COLLAGEN MATRICES CORRELATES WITH CALCIUM-DEPENDENT METALLOPROTEASE ACTIVITY. R.N. Pittman, H. Buettner*, A. Williams*. Dept. of Pharmacology, Univ. of PA Medical School, Philadelphia, PA 19104.

Sympathetic neurons from neonatal rats release a Ca^{2+}-dependent metalloprotease from their distal processes and growth cones (Dev. Biol. 110:91, 1985). Of protein substrates tested, only native and denatured Type I collagen appear to be substrates. This suggests that a possible function for this protease is to enable growing neurites to penetrate collagen rich extracellular matrices. To test the possibility that neurites use the Ca^{2+}-dependent metalloprotease to penetrate collagen-rich matrices, two assay systems have been developed.

Sympathetic neurons are plated either onto native collagen gels or onto a collagen film inside a doughnut-shaped native collagen gel. The activity of the Ca^{2+}-dependent metalloprotease is inhibited by specific peptide inhibitors, or by chelating calcium or zinc (the protease appears to have zinc at its active site). The ability of neurites to penetrate and grow within the collagen gel is then correlated with the metalloprotease activity. A good correlation exists between the activity of the metalloprotease, the amount of ^3H-collagen released into the culture medium and the ability of neurites to penetrate into the collagen gels. A 5-10 fold decrease in the penetration of neurites into collagen gels occurs when metalloprotease activity is inhibited > 95%; however, no effect is seen on the growth of processes on 2-dimensional collagen films. These data suggest that sympathetic neurons use the Ca^{2+}-dependent metalloprotease to penetrate and grow within 3-dimensional matrices of collagen, but not to grow along a 2-dimensional collagen substrate.

Supported by grants from the NIH (NS 22663) and BRSG RR-05415-25. We gratefully acknowledge the gift of peptide inhibitors from Dr. Bob Gray (NIH grant AM 31364).

414.15 **ACTIVITY OF TISSUE PLASMINOGEN ACTIVATOR IN THE DEVELOPING CNS.** **N. Cocero* and R.N. Pittman (SPON:R.Orkand) Dept. of Pharmacology, School of Medicine, Philadelphia, PA 19104.**

Plasminogen activator (PA) activity is present in the developing as well as the adult central nervous system. PA activity has been localized to granule cells of the developing cerebellum, to areas of the rat cortex rich in cell bodies and to synaptosomes from bovine cortex. Although the function of PA in the CNS has not been determined, PA activity has been implicated in granule cell migration in the cerebellum and in glial function in the spinal cord

We have assayed PA dependent proteolysis in the rat brain (cortex,cerebellum, brainstem, midbrain) as a function of age (from E18 to P120). Both urokinase and tissue plasminogen activator activities are present in the developing CNS. The majority of the PA activity is tissue-type PA (t-PA); therefore, we have concentrated in determining the location, regulation, and function of t-PA in the CNS. Considerable differences in t-PA activity exist as a function of age and brain area, with a general trend of decreasing t-PA activity with increasing age. Changes in the level of t-PA activity is not only dependent on the number of molecules of t-PA, but also on the form of t-PA (one chain vs. two chain), as well as the presence of endogenous inhibitors (for which we have evidence). To deal with ambiguity between t-PA activity and the number of t-PA molecules, we generated a panel of monoclonal antibodies (mAbs) against t-PA. These mAbs will be used to study the regulation, location and function of t-PA in the developing rat CNS as well as for studying the levels and location of t-PA in normal and pathological human CNS tissue.

Supported by a grant from the McKnight Foundation.

414.16 IN VITRO STUDIES OF TRIGEMINAL GANGLION SENSORY NEURONS AND MERKEL CELLS. P.M.Vos* and R.N.Pittman (Spon: P. G. Conway) Dept. of Pharmacol., U. of PA, Sch. of Med., Phila. PA 19104

Establishment of specific connections between sensory neurons of the trigeminal ganglion and their peripheral targets (epidermally located Merkel cells) is believed to play a critical role in directing subsequent development of centrally located, somatotopically organized, sensory maps.

Neurons from the trigeminal ganglia of neonatal rats were plated at low density in serum free medium on one of the following substrates: Collagen **(C)**, polylysine **(PL)**, laminin and collagen **(LC)**, laminin and polylysine **(LP)**, or fibronectin and collagen **(FC)**. Cultures were grown overnight and then fixed in glutaraldehyde. Morphometric analysis was carried out on 543 cells using a computer assisted morphometry program.

Growth on different substrates influenced the length, branching, and complexity of neurites. Average lengths for primary processes (processes extending directly from the cell body) were observed in the following descending rank order: **LP > C = LC = PL > FC**. Average lengths of secondary, tertiary and quartenary branches followed a similar pattern. The observed rank order of average numbers of primary processes per cell was: **LP = C = LC = FC > PL**. The observed rank order of average numbers of secondary branches per cell was: **LP > C = LC > FC = PL**. The observed rank order of average numbers of tertiary branches per cell was: **LP = C > LC > FC = PL**.

In conclusion, sensory neurons grown on **PL** exhibit fewer neurites overall, but the neurites that do grow are not markedly shorter than those grown on most other substrates. Neurons grown on **LP** demonstrated larger average process lengths as well as a generally increased average number of process branchings per cell.

Since the sensory neurons in the trigeminal ganglion are known to specifically innervate Merkel cells in vivo, we are currently developing conditions for establishing co-cultures of neurons and Merkel cells in serum free medium.

414.17 PLASMINOGEN ACTIVATOR (PA) PRODUCTION DURING THE "IN VITRO" DEVELOPMENT OF EMBRYONIC MOUSE SPINAL CORD CULTURES. C.B.Kahler*, J.S. Rao*, K.D. Tennant*, B.W. Festoff (SPON: P.A. Singer). Dept. of Neurology, UKMC, Kansas City, KS. and Neurobiology Research Laboratory at VAMC, Kansas City, MO 64128.

PAs play an important role in fibrinolysis, modifying the extracellular environment during embryogenesis, inflammation, and neoplasia. They also appear to be involved in neuronal migration, secreted both by glial and Schwann cells, as well as by the neuronal soma and growth cones. Our present studies focused on the production of PAs by spinal cord cells in culture. Embryonic mouse spinal cords were cleaned free of meninges, enzymatically dissociated, and grown in culture. At time points during the ten day culture period, growth media was replaced with media without serum. Twenty four hours later both conditioned media and cell layers were collected. Samples were analyzed for the presence of PAs using the chromogenic tripeptide S-2251. Two distinct enzymes were detected and characterized by their ability to produce a color reaction in the presence or absence of fibrin monomer (fm). FM-dependent PA (tissue or tPA) was detected only in the conditioned media, while a FM-independent PA (urokinase-type or uPA) was present only in the cell homogenates. Both types of enzymatic activity increased over the developmental time-course, the uPA showing the greatest change. Preliminary experiments with serially-passaged glial cells from these cultures show a high level of both enzymes, with a time-in-culture profile very similar to that of the spinal cord cultures. This pattern was distinctly different in primary glial cell cultures.

Support by the ALS Association, Muscular Dystrophy Association and the Medical Research Service of the Veterans Administration.

414.18 BOTH FIBRONECTIN AND LAMININ ARE NEURITE GROWTH INDUCING COMPONENTS OF RAT ASTROGLIAL CONDITIONED MEDIUM. C.Schmalenbach*, H.P. Matthiessen* and H.W.Müller. Molecular Neurobiology Laboratory, Department of Neurology, University of Düsseldorf, F.R.G.

The interaction of neurite growth stimulating proteins accumulating in serum-free conditioned media (CM) from highly enriched neonatal cerebral astrocytes (less than 5 % nonglial cells) with neurons from embryonic (E18) hippocampus was studied using a quantitative cell culture bioassay. CM were fractionated by FPLC (Pharmacia) on an anion exchange column (Mono Q) and by gel filtration (Superose 12). Column fractions were analyzed by SDS polyacrylamide gel electrophoresis, immunoblotting and ELISA using antibodies to laminin (LN) and fibronectin (FN). In addition, the neurite growth promoting activity was tested by incubating aliquots of the eluted fractions with poly-L-lysine precoated glass coverslips prior to addition of neurons suspended in chemically defined medium. The astroglial culture was characterized by immunofluorescence microscopy and expressed both LN and FN. Biological activity (percentage of viable neurons bearing processes > 2 cell diameters) was almost exclusively recovered in fractions containing either FN and/or LN. A separation of astroglial CM on Mono Q revealed two main peaks of biological activity. The highest activity (60 % neurite bearing cells) was eluted at 800-1000 mM NaCl and coincided with the highest anti-LN immunoreactivity. It possibly consists of a complex of LN with a heparan sulfate proteoglycan. The immunoreactivity for FN in these fractions was very low. A smaller neurite promoting activity (18 % neurite bearing cells) was eluted at 200-300 mM NaCl and corresponded to the peak fractions of anti-FN immunoreactivity for free FN. These fractions also contained small amounts of free LN (<1/20th compared to FN). By comparison with a dose response curve of pure LN in the bioassay, however, the concentration of free LN in these fractions was too low to account for the observed neurite promoting activity. We conclude that both LN and FN released from astrocytes express neurite promoting activities for hippocampal neurons in culture.

Supported in part by the Deutsche Forschungsgemeinschaft (SFB 200, TP C6). C.S. is recipient of a fellowship from DECHEMA.

414.19 GROWTH OF CNS AXONS ON A MODEL OF REACTIVE ASTROCYTES. D.G. Munoz* and A. Scaringi* (SPON: S.K. Ludwin). Department of Pathology (Neuropathology), University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0.

The formation by reactive astrocytes of glial scar following injury has been considered an obstacle to the regeneration of CNS axons. We have examined this hypothesis in an in vitro model of reactive astrocytosis. Treatment of astrocytic cultures with the cyclic adenosine monophosphate (cAMP) analogue dibutyryl cAMP (dBcAMP) results in marked morphological and biochemical alterations in these cells, including increased content of the astrocytic specific protein, GFAP, and extension of numerous processes. Fedoroff et al (J Neurosci Res 12: 15, 1984) have proposed that dBcAMP-treated astrocytes are the in vitro equivalent of reactive astrocytes. Furthermore, only type 1 astrocytes of Raff are responsive to dBcAMP and participate in the formation of the glial scar (Miller et al J Neurosci 6: 22, 1986). Normal astrocytes in culture are a preferred substrate for axonal growth. (Fallon, J Cell Biol 100: 198, 1985). We compared neurite extension on unmodified and dBcAMP-treated astrocytes. Glial monolayer cultures were prepared from newborn mouse neopallium by mechanical dissociation, plated at a density of 1000 cells/mm^2, and grown to confluence in medium containing 10% fetal calf serum for two weeks. During the third week some cultures were continuously treated with medium containing 0.25 mM dBcAMP and showed the expected morphological change; other cultures were maintained in standard conditions. Embryonic day 13 mouse retinal explants were placed on top of treated and untreated three-week-old glial cultures. At 48 hours post-explantation the cultures were fixed, and the profuse, radial neuritic outgrowth from the explant visualized by immunofluorescence using an antibody against neurofilaments. The average neuritic length of 55 explants on treated and of 36 explants on untreated cultures was identical (1.18 mm). Maintaining treated cultures on dBcAMP after explantation showed no effect on the length of neuritic outgrowth. Thus, the modifications of astrocytes induced by dBcAMP have no influence on the demonstrated high competence of the surfaces of these cells in supporting the growth of immature CNS axons.

415.1 RELEASE OF ENDOGENOUS ADENOSINE FROM RAT CORTICAL SLICES BY K^+ AND GLUTAMATE. K. Hoehn* and T.D. White, Dalhousie University, Halifax, Nova Scotia, Canada, B3H 4H7.

Extracellular adenosine acts at specific adenosine receptors in the CNS to inhibit the release of neurotransmitters and decrease firing of central neurons. In order to exert its CNS functions it must first be released. We have studied the release of endogenous adenosine from rat cortical slices following depolarization by K^+ or the excitatory neurotransmitter glutamate. 0.4 mm slices were incubated in 1 ml of oxygenated Krebs solution at 37°C. Medium surrounding the slices was exchanged at 10 min intervals. After an initial 130 min equilibration period, slices were exposed for 10 min to releasing medium. Samples were collected and reacted with chloracetaldehyde to form the etheno-derivative of adenosine, which was measured by HPLC with fluoresence detection. 30 mM K^+ released 800 pmoles adenosine/ g cortex/ 10 min. Release continued for a further 10 min after removal of the releasing medium. Similarly, 5 mM glutamate released approximately 2300 pmoles/ g cortex during exposure and release continued for 20 min after removal of the glutamate. Experiments were performed in which the specific NMDA antagonist, 2-amino-5-phosphonovaleric acid (APV), was present before, during, and after exposure to glutamate. APV had no effect on basal release of adenosine. It blocked adenosine release during exposure to glutamate, but failed to block the release of adenosine during the 20 min period following the removal of glutamate. It can be concluded that both K^+ and glutamate-evoked depolarization of cortical slices releases adenosine. The glutamate-evoked release is receptor-mediated and the NMDA receptor subtype appears to be involved. Adenosine may be released in the CNS following depolarization of central neurons to act in a negative feedback fashion, dampening the firing of neurons.

Supported by the Medical Research Council of Canada.

415.2 AUTORADIOGRAPHIC LOCALIZATION AND PHARMACOLOGICAL CHARACTERIZATION OF ADENOSINE RECEPTORS IN RAT BRAIN USING THE XANTHINE CONGENER, [^{3}H]XCC. George A. Stone*, Kenneth A. Jacobson*, William J. Brooks*, Michael Williams and Michael F. Jarvis (SPON: A. Mellow). Drug Discovery Division, Research Department, Pharmaceuticals Division, CIBA-GEIGY Corporation, Summit, NJ 07901 and Laboratory Of Chemistry NIDDK-NIH, Bethesda, MD 20892.

The use of alkylxanthines as radioligands for adenosine receptors has not been widespread due to their low potency at adenosine receptors as well as their high lipophilicity, low affinity and low specific activity. Recently, a xanthine carboxylic acid congener (XCC) of 1, 3-dipropyl-8-phenylxanthine has demonstrated favorable properties as a ligand for adenosine receptors. Autoradiographic studies have revealed that [^{3}H]XCC binds to rat brain sections with nanomolar affinity and in a heterogenous manner consistent with the labeling of adenosine A-1 receptors. The greatest density of [^{3}H]XCC binding sites occurs in the molecular level of the cerebellum followed by thalamus > cortex = striatum. In the present study, the activity of a number of adenosine agonists and antagonists was examined in various brain regions (hippocampus CA-1 region, cerebral cortex and striatum) using quantitative autoradiography. The pharmacological activity of these compounds in displacing [^{3}H]XCC was higly correlated ($r = 0.96$-0.99, $P < 0.01$) in the brain regions examined. For agonists, the rank order of activity was: R-PIA $\geq$ CPA > NECA $\geq$ 2-CADO > S-PIA. Thus the binding of [^{3}H]XCC was stereospecific, R-PIA being 20-fold more active (IC-50 = 0.5 nM) than S-PIA (IC-50 = 11 nM). For antagonists, in the various brain regions studied, the rank order of activity was: XCC > PACPX > DPX. Despite a close concordance in the pharmacological profile of both agonists and antagonists in the various brain regions, all ligands had greater affinity in striatum as compared to either hippocampus or cerebral cortex. The present data indicate that [^{3}H]XCC is a high affinity, selective ligand for adenosine A-1 receptors. However, [^{3}H]XCC may be active at striatal A-2 receptors since NECA, CPA and 2-CADO exhibited essentially equal activity in displacing XCC binding in this tissue.

415.3 CHARACTERIZATION OF A_1-ADENOSINE RECEPTORS IN PORCINE ATRIAL MEMBRANES. M. Leid, P.H. FRANKLIN AND T.F. MURRAY (SPON: M.I. SCHIMERLIK), College of Pharmacy, Oregon State University, Corvallis, OR 97331.

Adenosine and related compounds exert negative chronotropic and inotropic effects on the intact heart and in isolated atria. These inhibitory responses are thought to be mediated by an A_1-adenosine receptor (AR). Experiments were carried out to characterize the AR of porcine atrial membranes (PAMs) using the agonist radioligand [125-I]hydroxyphenylisopropyladenosine ([125-I]HPIA). Kinetic studies were undertaken to address the mechanism of [125-I]HPIA binding. The Kobs displayed a hyperbolic dependence on [125-I]HPIA concentration, consistent with a two-step sequential binding mechanism. [125-I]HPIA bound saturably, reversibly and with high affinity to an apparently homogeneous population of recognition sites with a Bmax of 51.8 $\pm$ 4.4 fmoles/mg protein and a K_D of 3.6 $\pm$ 0.6nM. Specific binding of [125-I]HPIA was enhanced by addition of 5mM Mg^{++} to the incubate. Moreover, guanine nucleotides were found to inhibit specific binding of [125-I]HPIA. These findings are consonant with an agonist-induced formation of a ternary complex consisting of the ligand, adenosine receptor and a guanine nucleotide binding protein. Competition binding experiments were used to determine the agonist pharmacological profile of the PAM AR. The rank order potency as inhibitors of the specific binding of [125-I]HPIA was as follows: R-phenylisopropyladenosine (R-PIA) > cyclopentyl-adenosine > hydroxyphenylisopropyladenosine > cyclohexyl-adenosine > N-ethylcarboxamidoadenosine = S-phenylisopropyl-adenosine > 2-chloroadenosine (2-CADO) >> CV-1808. Moreover, the potency difference between the diastereomers of PIA was approximately 22-fold. This rank order potency profile is consistent with the labeling of an A_1-AR.

Toward the goal of understanding transduction mechanisms associated with the AR of PAMs, the effects of R-PIA and 2-CADO on adenylate cyclase (AC) activity were studied. Both agonists dose-dependently decreased basal and isoproterenol- or forskolin-stimulated AC activity as measured by the conversion of [32-P]ATP to [32-P]cAMP. These findings provide functional evidence for the existence of A_1-adenosine receptors in PAMs. Thus, the results of both pharmacological competition binding and functional experiments suggest that the adenosine receptor of PAMs is of the A_1-subtype. (Supported by a grant from the Oregon Affiliate of the American Heart Association).

415.4 SEPARATION OF A_1 AND A_2 ADENOSINE RECEPTORS OF RAT BRAIN MEMBRANES BY HYDROXYLAPATITE CHROMATOGRAPHY. H. Nakata* (Sponsor: A. Laties), Laboratory of Clinical Science, NIMH, Bethesda, MD 20892.

Adenosine receptors have been divided into two major subclasses A_1 and A_2. A_1 adenosine receptors are linked to inhibition of adenylate cyclase whereas A_2 adenosine receptors are linked to activation of adenylate cyclase. Although it is important to characterize these subtypes biochemically and pharmacologically, poor selectivity of the agonist radioligands such as [^{3}H]phenylisopropyladenosine (PIA), [^{3}H]cyclohexyladenosine (CHA) or [^{3}H]N-ethylcarboxamidoadenosine (NECA) often makes such studies difficult. As a first step toward characterization of these adenosine receptor subtypes, we solublized these receptors from rat brain membranes where both A_1 and A_2 adenosine receptors are present and screened various chromatography systems which can resolve A_1 and A_2 adenosine receptors from the crude receptor solution. I chose to use hydroxylapatite columns.

Rat brain membranes were then prepared from whole rat brains and were solubilized using 1% digitonin. Typically 20-30% of [^{3}H]NECA binding sites were recovered in the supernatant after centrifugation at 100,000 g. The solubilized preparation was then applied to a hydroxylapatite column and the column was eluted with a gradient of potassium phosphate. Three major peaks which had adenosine binding activity were found (designated Peak A, Peak B and Peak C by the order of elution). [^{3}H]PIA (5 nM) binding activity was detected only in Peak A fraction and [^{3}H]NECA (16nM) binding activity was detected mainly in Peak B and Peak C. Displacement of [^{3}H]PIA bound to Peak A fraction by adenosine receptor agonist yielded the following rank order of potency: CPA>R-PIA>CHA>NECA>S-PIA. [^{3}H]NECA bound to Peak B fraction was displaced by NECA or NCCA. However CPA, R-PIA, S-PIA or 2CA did not displace the [^{3}H]NECA bound to Peak B fraction even at 200 µM. [^{3}H]NECA bound to Peak C fraction was displaced by the following order of potency: NECA>NCCA>CPA>R-PIA=S-PIA>IBMX. These displacement experiments suggest Peak A and Peak C correspond to A_1 and A_2 receptors, respectively. These results show hydroxylpatite chromatography appears to be useful for resolution of A_1 and A_2 adenosine receptors and particularly valuable as an initial step for the purification of these subtypes.

415.5 ADENOSINE RECEPTOR SUBTYPES: TOWARD AN UNDERSTANDING OF IN VIVO EFFECTS. R.M. Palmour* and F.R. Ervin. Dept Psychiatry and Centre for Human Genetics, McGill Univ., Montreal QUE H3A 1A1.

The relative contributions of A1 and A2 receptor actions to neuromodulation and to Ado analog-induced changes in behavior remain a topic of contention. In studying this paradox, we compared the actions of cyclopropylAdo (CPA), an A1 selective analog; N-ethylcarboxamideAdo, a potent but unselective A2 agonist and R-phenylisopropylAdo (PIA), a potent A1 agonist with pronounced A2 effects.

In cultured clonal neuroblastoma cells with both A1 and A2 receptors, CPA (1-1000 nM) reduces both basal and PGE1-stimulated cAMP accumulation, while nM concentrations of NECA, PIA and other analogs only reduce stimulated cAMP accumulation. Conversely, between 0.1 and 100 μM, NECA and PIA enhance cAMP accumulation. CPA only stimulates cAMP accumulation at concentrations above 10 μM. In addition, the maximum stimulation of cAMP accumulation varies inversely as a function of the potency of a given analog at the A1 receptor (NECA>PIA>Ado>CHA>CPA). Taken together with studies in cells possessing only A1 or only A2 receptors, these data suggest that maximal cAMP accumulation is the sum of opposing actions at A1 and A2 receptors.

In rat and monkey brain, and in neuroblastoma cell membranes, ^{3}H-NECA labels A1 or A2 receptors in the absence or presence, respectively, of 80 nM CPA. Caudate, hippocampus and cortex have both A1 and A2 receptors, as do neuroblastoma cells. Cerebellar receptors are mostly A1, while pituitary and amygdaloid regions primarily contain A2 receptors.

In the isolated male mouse, aggressive behavior (as measured by # attacks and duration of fighting) is enhanced at very low doses of PIA and NECA (narrow range) and over a much wider range for CPA. Aggressive behavior is dramatically diminished by doses of NECA which minimally reduce motor activity, and by doses of PIA which have a somewhat greater inhibitory effect. In grouped mice, effects of Ado analogs on motor activity follow these same patterns. All behavioral effects were shifted toward the basal state by pretreatment with 15-30 umol/kg caffeine, confirming Ado receptor mediation.

Taken together, these data suggest that in many brain regions, the net effect of Ado or Ado analog agonism is the sum of interactions with A1 and A2 receptors, and that the predominant inhibitory behavioral effects reflect actions at the A2 receptor, while stimulatory behavioral effects may involve A1 receptors. These observations are in concert with the hypothesis that Ado acts physiologically via a mechanism of balanced opposition to regulate levels of arousal in vivo .

415.6 CARDIORESPIRATORY EFFECTS OF MICROINJECTIONS OF ADENOSINE AND CYCLIC AMP INTO THE NUCLEUS TRACTUS SOLITARIUS OF RATS. P.M. Polasek*, C.J. Janusz*, W.R. Campbell*, E.P. Schoener*, M. Parizon* and R.A. Barraco. Wayne State Univ. Sch. of Med., Detroit, MI 48201.

It is well established that the Nucleus Tractus Solitarius (NTS) is a major relay nucleus for afferent input from baroreceptors and cardiopulmonary receptors and thereby plays a critical role in brainstem mechanisms involved in central cardiovascular and respiratory control. The NTS has been shown to have a complex morphology in addition to possessing a site-specific topographical distribution of a variety of neurotransmitters and putative neuromodulators. Numerous studies have shown that adenosine (ADO) and its analogs depress the release of both excitatory and inhibitory neurotransmitters in the brain. Many of the physiological effects of ADO are accomplished by modulating adenylate cyclase via extracellular receptors which are negatively and positively coupled to the enzyme. In our laboratory, we have recently shown that injections of ADO analogs into the cerebral ventricles of rats produced pronounced bradycardia and hypotension. In separate experiments, it was shown that the fourth ventricle in the region of the area postrema and the NTS were the most sensitive sites for ADO-induced cardiovascular responses. The aims of the present study were to (1) examine the dose-response effects of microinjections of ADO itself into the NTS and (2) to examine the possible involvement of cyclic nucleotides in ADO-mediated responses. Adult male Sprague-Dawley rats were anesthetized with urethane, the femoral artery and vein cannulated for blood pressure (P_A) and heart rate (HR) recordings and systemic drug administration, respectively, and the trachea was intubated and tidal volume (V_t) and respiratory frequency (f) were measured via a Fleisch pneumotachograph. Following a limited craniotomy to expose the brainstem in the region of the obex, microinjections were made via glass micropipettes (60-70 μm) at 100 nl · 15 sec. Drugs were dissolved in artificial CSF. The results show that ADO produced potent effects on P_A and HR. In fact, at lower doses, ADO produced pressor responses while at higher doses, ADO caused hypotension and bradycardia. These findings may reflect an A_1/A_2 receptor-mediated response difference. To examine this, 8-bromocyclic AMP (BcAMP) was microinjected into the same site (AP: -0.2; ML: 0.3; DV: 0.3). BcAMP produced dose-related decreases in P_A and HR. However, BcAMP elicited even greater effects on f and V_t, producing periodic apnea. These findings support the notion that ADO may play a neuromodulatory role in the NTS. (Supported by NSF (R1186-04084), NIH (RR-08167-OX) and Am. Heart Assoc. of Mich.).

415.7 CHARACTERIZATION AND AMINO ACID SEQUENCE OF RAT STOMACH PHOSPHOLIPASE A_2: A PREVIOUSLY DESCRIBED MODULATOR OF THE PERIPHERAL BENZODIAZEPINE RECEPTOR AND VOLTAGE-DEPENDENT Ca^{2+} CHANNEL. A.R. Lingford-Hughes*, B.M. Martin*, R.E. Martenson*, E.I. Ginns*, P. Skolnick*[1], S.M. Paul* (Spon: R.H. Cagan). Clinical Neuroscience Branch, NIMH, and [1]Lab. of Bioorganic Chemistry, NIDDK, NIH, Bethesda, MD 20892.

Recent studies have demonstrated inhibition of [^{3}H]Ro5-4864 binding to the peripheral benzodiazepine receptor and of [^{3}H]nitrendipine to the dihydropyridine Ca^{2+}-channel (Mantione et al., Biochem. Pharm., in press, 1987) by acidified extracts of rat antral stomach. Subsequently termed "antralin", this endogenous material was found to be a protein and to possess phospholipase A_2 (PLA_2)-like activity. We now report that "antralin" is PLA_2 as judged by both its enzymatic activity and amino acid sequence. Acidified extracts of rat antral stomach were applied to octadecylsilyl-silica cartridges (Sep-pak) and eluted with 80% acetonitrile/0.1% trifluoroacetic acid (TFA). The eluates were pooled and applied to a hydroxyapatite column and the protein eluted with a linear NaCl gradient (0-1M). Fractions were tested for PLA_2 activity with [^{3}H]phosphatidylcholine (labelled in the 2 fatty acid position) as substrate followed by heptane extraction of the radiolabelled arachidonic acid product. Enzymatic activity was observed in fractions eluted from 0.5 - 0.08M NaCl. Reversed phase HPLC was used for subsequent purification yielding a specific activity of approximately 100 umoles/mg/min, which represents a 500-1000 fold purification relative to the crude acidified extract. The enzyme was rechromatographed using HPLC to obtain highly purified enzyme for amino acid sequencing, antibody production and characterization of its catalytic properties. The complete amino acid sequence was determined by automatic Edman degradation of tryptic peptides and will be presented. Ionic requirements and substrate kinetics of the highly purified enzyme were characterized. Enzymatic activity was reduced in the absence of Ca^{2+}, but was abolished in the presence of EGTA, suggesting that PLA_2 possesses very high affinity for Ca^{2+}, and that Ca^{2+}/enzyme binding occurs even during purification. We are presently purifying brain PLA_2 using similar methods and studying the effect(s) of PLA_2 on a variety of neurotransmitter receptor-gated and voltage dependent ion channels.

415.8 IDENTIFICATION OF A KYNURENATE-LIKE SUBSTANCE IN HUMAN BRAIN TISSUE. M. Nakamura, W.A. Turski, W.O. Whetsell, Jr.[1] and R. Schwarcz. Maryland Psychiatric Research Center, Baltimore, MD 21228 and [1]Dept. Pathology, Vanderbilt University School of Medicine, Nashville, TN 37232.

Kynurenic acid (KYNA), a tryptophan metabolite known to be present in urine and peripheral tissues, has been shown to possess neuroinhibitory activity (Brain Res., 247, 184, 1982). Moreover, a deficiency of KYNA in the brain has been speculatively linked to the pathogenesis of human neurodegenerative disorders (Neurosci. Lett., 48, 243, 1984). However, the presence of KYNA in human brain tissue has as yet not been examined. Using a novel isolation procedure (established with the use of ^{3}H-KYNA), we have now purified a KYNA-like substance from post mortem human brain material and tentatively established its identity by several chromatographic methods.

Brains from individuals who died without neurological disease were homogenized (1:2; w/v) in distilled water. The homogenate was then boiled (10 min) and the pellet separated by centrifugation. After application of the supernatant to a Dowex AG 50W cation-exchange resin, the KYNA-fraction was eluted with distilled water. The eluate was then applied to a Seppak® C_{18} column and the KYNA-fraction obtained by adding solution containing 100mM acetic acid:methanol (50:50). The resulting eluate was lyophilized and taken up in water to be assessed in 5 different TLC systems (using cellulose or silica gel plates) or by HPLC (mobile phase: 50 mM ammonium acetate/5% methanol) on a 3 μm C_{18} reverse phase column.

Human brain contained a substance which in all systems behaved identically to ^{3}H-KYNA or non-radioactive KYNA. The following regional distribution was found to exist (data are expressed as pmol/mg tissue and are the mean ± S.E.M. of seven brains):

Cerebellum	0.14 ± 0.02
Frontal cortex	0.29 ± 0.03
Parietal cortex	0.39 ± 0.12
Globus pallidus	0.98 ± 0.27
Hippocampus	0.42 ± 0.11
Nucleus caudatus	1.58 ± 0.43
Thalamus	1.11 ± 0.34

These data are in good accordance with the regional distribution in human brain of KYNA's bioprecursor kynurenine (Neurochem. Res. 5, 223, 1980). However, additional (physico-chemical) methods are needed for the unequivocal identification of the isolated substance.

415.9 GAMMA-AMINOBUTYRIC ACID-INDUCED ENHANCEMENT OF 2-(^{125}I)-IODO-MELATONIN BINDING IN BRAIN MEMBRANES. L.P. Niles and D.S. Pickering*. Department of Neurosciences, McMaster University, Hamilton, Ontario, Canada L8N 3Z5.

Similarities in the psychopharmacological properties of the pineal hormone, melatonin, and the benzodiazepines suggest an interaction between this hormone and central GABAergic systems as previously reported for these drugs. This view is supported by our earlier findings that melatonin enhances gamma-aminobutyric acid (GABA) binding in vivo (1) and in vitro (2).

A reciprocal and functional interaction exists between the central binding sites for GABA and those for benzodiazepines. Thus, benzodiazepine agonists such as diazepam, enhance GABA binding while GABA, in turn, increases diazepam binding in synaptic membranes. In order to determine whether a similar reciprocal interaction occurs between the binding sites for GABA and those for melatonin, we have now examined the in vitro effects of GABA on the binding of the melatonin analog, 2-(^{125}I)-iodomelatonin ((^{125}I)MEL) in synaptosomal membranes from hamster brain. (^{125}I)MEL was synthesized as previously described (3) and purified by HPLC (4).

GABA, in concentrations of 10^{-9}-10^{-4}M, enhanced (^{125}I)MEL binding by 100-150% in cortical membranes. The GABA agonist, muscimol, also stimulated (^{125}I)MEL binding in brain membranes. This effect was blocked by the GABA receptor antagonist, bicuculline (10^{-5}M), indicating the specific involvement of $GABA_A$ receptors.

Preliminary competition and saturation binding experiments in the absence or presence of GABA (10^{-4}M) indicate that the enhancement of binding is due to a GABA-induced increase in the affinity of high-affinity sites.

415.10 MULTIPLE BINDING SITES FOR 2-(^{125}I)-IODOMELATONIN IN HAMSTER BRAIN. D.S. Pickering* and L.P. Niles (SPON: E. Werstiuk). Department of Neurosciences, McMaster University, Hamilton, Ontario, Canada L8N 3Z5.

In earlier binding studies with (^{3}H)melatonin, we observed shallow competition curves and low Hill coefficients which suggested the presence of multiple binding sites although Scatchard analysis indicated a single population of sites (1). Using an improved radioligand for melatonin binding sites, we have now re-examined the saturation binding characteristics of these sites in order to resolve this discrepancy. The radioligand, 2-(^{125}I)-iodomelatonin ((^{125})MEL), was synthesized as described by Vakkuri et al. (2), in 30-60% yields at specific activities ranging from 2000-2500 Ci/mmol. The label was purified by HPLC and nonradioactive 2-iodomelatonin was purified by silica gel column chromatography.

Adult (2-3 months old) male golden hamsters (M. auratus) were decapitated and brain tissues were rapidly dissected on ice. Synaptosomal membranes were prepared as previously reported (3) and used immediately in binding assays or frozen at -70°C before use.

Preliminary experiments using a radioligand range of 0.1-10 nM indicated a single high affinity site with a dissociation constant (kd) of 0.7-0.8 nM and a receptor concentration (Bmax) of about 20 fmol/mg protein. However, as full saturation was not achieved in these assays, we utilized a radioisotopic dilution assay to examine binding in the radioligand range of 0.1-100 nM. Specific binding was defined as that displaced by 10 μm 6-chloromelatonin.

Scatchard analysis of data yielded curvilinear plots which were resolved into two binding components using an iterative nonlinear least squares curve-fitting program. The binding parameters for the high affinity component were:- Kd_1 = 1.3 ± 0.1 nM and $Bmax_1$ = 26.6 ± 5 fmol/mg protein. Corresponding values for the low affinity sites were:- Kd_2 = 64 ± 5.1 nM and $Bmax_2$ = 250 ± 45 fmol/mg protein (n = 3).

The high affinity site is comparable to that (Kd = 3.8 nM) recently reported by Duncan et al. (4) using a similar radioligand in hamster brain. Further characterization of these sites is currently in progress.

415.11 MONOCLONAL ANTIBODY AE-2 STIMULATES FETAL BOVINE SERUM ACETYLCHOLINESTERASE HYDROLYSIS OF INDOPHENYL ACETATE. A. D. Wolfe*, C. A. Payne* and S. Bone*. (SPON: G. Mueller) Dept. of Applied Biochemistry, Walter Reed Army Inst. of Res., Washington, D. C., 20307-5100.

Fetal bovine serum acetylcholinesterase (FBS-AChE) hydrolyzes the neutral ester indophenyl acetate (IPA), in addition to acetylcholine (ACh), acetylthiocholine (ATC) and other esters typical of E.C. 3.1.1.7 enzymes. Differential effects of ligands on AChE ester hydrolysis have been reported and appear related to the catalytic function of the ligand binding site. For example, covalent binding of 2-chloro-N-(chloroethyl)-N-methyl-2-phenylethylamine (CMP) to bovine erythrocyte AChE inhibits hydrolysis of ATC but stimulates hydrolysis of IPA (O'Brien, R. D., Biochem. J., 113:713, 1969). This effect has been ascribed to CMP attachment to a nucleophilic enzyme site which either binds or influences the binding of electrophilic substrate substituents. AChE-CMP hydrolysis of IPA was characterized by a 1.5 fold increase in the maximal velocity (V_{max}) without change in the Michaelis-Menton constant (K_m). Recently, the monoclonal antibody AE-2 (Fambrough, D. M., Engel, A. G. and Rosenberry, T. L., Proc. Nat. Acad. Sci. U. S. A., 79:1078, 1982) was reported (Kopec, K. K., Gentry, M. K., Osborne, D. M., Ralston, J. S. and Doctor, B. P., Abstracts, 13th Int. Congr. Biochem., P. 391) to inhibit hydrolysis of ATC by FBS-AChE and the AE-2 binding site was located near the N-terminus between amino acid residues 22-82. We now wish to report that AE-2 also exhibits a differential effect on ATC and IPA hydrolysis with a pattern similar to that of CMP. A 4/1 molar ratio of AE-2 to FBS-AChE active site causes more than 75% inhibition of ATC hydrolysis but the rate of IPA hydrolysis is increased. The V_{max} for FBS-AChE hydrolysis of IPA in the presence of AE-2 was 1.23 (arbitrary units), whereas the V_{max} for IPA hydrolysis in the absence of AE-2 was .062, a ratio of approximately 20. In contrast, the Michaelis-Menton constant, K_m, remained unchanged (7 x 10^{-4} M). Incubation of FBS-AChE with graded concentrations of BW 284 C51, a specific AChE inhibitor, produced similar inhibition curves for hydrolysis of both ATC and IPA. In addition, pralidoxime chloride reversed the influence of AE-2 on both ATC and IPA hydrolysis. The present results, as well as those of O'Brien, indicate that different classes of ligands may bind to, obstruct, or change the conformation of nucleophilic AChE sites with results which depend upon the nature of the substrate.

415.12 ENDOGENOUS URIDINE AS A MODULATOR OF CEREBRAL EXCITATION. T. McCown, M.J. Rosner, R.A. Mueller, J.N. Ghia*, R.D. Hunt* and G.R. Breese. Departments of Surgery, Anesthesiology, Psychiatry and the BRSC, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.

CSF from ventriculostomy sites of head injury patients or neonatal subjects undergoing shunt revision was analyzed for xanthine, hypoxanthine, and uridine. As part of clinical management, ventricular CSF is removed to help decrease intracerebral pressure, in addition to numerous pharmacological manipulations of systemic perfusion pressure, mannitol, steroids, and other routine clinical care. Patients scheduled for lumbar subarachnoid blockade for surgical procedures served as controls. CSF was mixed with a solution of EHNA (an adenosine deaminase inhibitor) dipyridamole (to block adenosine uptake into cellular elements) and indomethacin (Gehrke CW, Kuo KC, Davis GE, and Suits RD: J. Chromatog 150:455-476, 1978) and stored at 4°C until analysis within several days. Analysis was via high pressure liquid chromatography (20 mM NH_4PO_4, pH 6.6 with 1% CH_3CN on C_{18} reversed phase column-U.V. detector at 2500A). Values are expressed as nmoles/ml of original CSF. Recovery was 85-90%.

Source	Uridine	Hypoxanthine	Xanthine
Head Injury	0.49**	3.88	5.99*
Adults (7)	±0.23	±0.55	±0.79
Hydrocephalic	2.57	6.45	10.7
Infants (3)	±0.82	±1.95	±3.3
Subarachnoid	4.13	3.31	3.21
Block (32)	±0.34	±0.26	±0.27

All values are Mean ± SEM of individual patient means expressed as nMoles/ml CSF ( ) = No. of patients. * $p < .05$ ** $p < 0.01$ relative to subarachnoid block subjects.

CSF uridine in head injury patients was only 12% that of normal subjects. Xanthine values were also significantly elevated ($p < .05$). Patients with elective shunt revision had uridine present at concentrations only 62% of normal adult lumbar fluid. The uridine concentration was not a function of red cell contamination in the CSF samples. A significant, though weak, positive correlation between xanthine and CSF lactate was also noted.

In rats, we have demonstrated that locally applied uridine (0.1 μmoles) significantly increases the threshold current necessary to initiate a wild running seizure from the inferior collicular cortex. Since uridine is an endogenous compound with anticonvulsant activity similar to that of GABA, and since it is reduced in head injury patients, the deficiency of CSF and possibly CNS uridine may contribute to post-traumatic cerebral excitation. It is presently unknown if the low uridine concentrations reflect decreased transport of the base into brain or increased utilization in brain.

415.13 ALTERATIONS IN BETA-ENDORPHIN LEVELS IN RESPONSE TO STRESS ARE MODULATED BY GONADAL STEROIDS. L.J. Forman and S. Estilow* Department of Medicine, UMDNJ-SOM, Camden, NJ 08103.

Castrated (CAST), and CAST gonadal steroid-replaced male and female rats, were exposed to acute (once for 45 min.) or chronic (45 min. each day for 15 consecutive days) immobilization stress. Immunoreactive beta-endorphin (IR-BE) levels in the plasma, anterior pituitary (AP), neurointermediate lobe of the pituitary (NIL) and the hypothalamus, were determined in these animals.

Acute stress increased plasma levels of IR-BE to the same extent in CAST male rats and CAST male rats replaced with testosterone proprionate (TP). TP potentiated the decrease in the concentration of IR-BE observed in CAST males in response to acute immobilization stress. Acute stress increased the concentration of IR-BE in the NIL of CAST male rats. This effect was abolished by treatment with TP. Exposure to chronic immobilization stress did not affect the concentration of IR-BE in the AP or the NIL of CAST males. By contrast, in rats treated with TP, chronic stress diminished the concentration of IR-BE in the AP and elevated the concentration of IR-BE in the NIL. Hypothalamic IR-BE levels in CAST and CAST TP-replaced animals were not influenced by acute or chronic stress.

Subjection to chronic stress resulted in a similar increase in plasma levels of IR-BE in CAST and CAST estradiol benzoate (EB)-replaced female rats. In CAST female rats, acute stress produced an increase in the concentration of IR-BE in the AP, which was attenuated by the administration of EB. Although IR-BE in the NIL was not influenced by acute stress in CAST females, exposure to acute stress resulted in an elevation in IR-BE levels in the NIL of CAST EB-treated rats. Chronic stress did not affect the concentration of IR-BE in the AP of CAST or CAST EB-replaced animals. Chronic stress did however, increase the concentration of IR-BE in the NIL of CAST females, which was potentiated by EB. The concentration of IR-BE in the hypothalamus of CAST and CAST EB-treated females was not affected by stress.

These data suggest that a) stress induced by immobilization affects IR-BE levels in the AP, NIL and plasma b) in male rats, testosterone modulates IR-BE levels in the AP and the NIL in response to acute and chronic stress and c) in female rats, estrogen influences the effects of acute stress on the AP and NIL, and the effects of chronic stress on the NIL alone. Hypothalamic IR-BE does not appear to be affected by acute or chronic stress, regardless of the gonadal steroid environment.

Supported by a grant from the American Osteopathic Association.

415.14 THE IDENTIFICATION OF CALCIUM BINDING PROTEINS IN RAT CORTEX AND AMMONIUM SULFATE FRACTIONS OF WHOLE RAT BRAIN. G.J. Creed*, W.E. Heydorn, and D.M. Jacobowitz, Laboratory of Clinical Science, NIMH, Bethesda, MD 20892

The essential role of calcium in cellular bioenergetics and synaptic transmission is well established. Identification of the calcium binding proteins involved yields insights into the mechanisms of calcium regulation of these events. Proteins from rat cortex and ammonium sulfate fractions of whole rat brain were separated by two-dimensional gel electrophoresis (2DE). The proteins were electroeluted onto nitrocellulose papers, which were then incubated in $^{45}Ca^{+2}$. The calcium binding proteins (CBP) were detected by autoradiography. Three proteins were consistently detected in rat cortex. The enrichment obtained with sequential 20% ammonium sulfate fractions, resulted in the detection of an additional four proteins. All seven CBP were acidic (pI's between 4.8 and 5.3) and of low molecular weight (M_r's between 12,500 and 27,500). Using the same methodology, but incubating with antisera in place of $^{45}Ca^{+2}$, we have previously reported the identification of two of these CBP as calmodulin and the B subunit of calcineurin. With appropriate antisera and comigration of pure proteins, the identifications of three more CBP have been ascertained. The protein (M_r 26,000, pI 5.0) detected in the 20%, 80%, and 100% fractions is the Vitamin D-dependent calcium binding protein. The protein (M_r 12,500, pI 5.2) detected in the S-100 fraction is parvalbumin. Finally, although it did not bind calcium in this system, the protein (M_r 22,000, pI 4.9) found solely in the S-100 fraction was identified as the S-100 protein. This protein also shows a monomeric form at the gel bottom (M_r 10,500). These results demonstrate that using 2DE, CBP are detectable. With enrichment, CBP normally in low concentration in the cell can be detected and identified.

415.15 **MODULATION OF [^{3}H]SPIROPERIDOL BINDING BY CHOLECYSTOKININ IN RAT STRIATUM.** M.A. Morency, J.S. Kajiura* and R.K. Mishra. Departments of Psychiatry and Neurosciences, Faculty of Health Sciences, McMaster University, Hamilton, Ontario, Canada, L8N 3Z5.

There is a striking overlap between the topographical distribution of dopamine (DA) and CCK in the mammalian brain. The functional significance of this close relationship between DA and CCK is not well understood. We examined the effects of CCK on brain DA-D_2 receptors in the rat striatum.

Male Sprague-Dawley rats (200-250 gm) were sacrificed by cervical dislocation, the brains removed, and the striata were dissected. Tissue was homogenized (Polytron setting 6, 20 sec) in 50 vol of ice-cold 50 mM Tris-HCl buffer (pH 7.4). The membrane suspension was then centrifuged twice at 50,000 g for 10 min. The final pellet was resuspended in assay buffer containing 50 mM Tris-HCl (pH 7.4), 0.1% ascorbic acid, 120 mM NaCl, 5mM KCl, 2 mM $CaCl_2$, and 1 mM $MgCl_2$. The tissue was then preincubated in the presence of 1.0 mg/ml bovine serum albumin, 0.1 mg/ml bacitracin and various concentrations of CCK peptides for time periods ranging from 1 to 60 min at 4°C. The preincubation was stopped by centrifugation (50,000 g for 10 min). The pellet was resuspended in assay buffer and analyzed for [^{3}H]spiroperidol binding. Receptor densities (B_{max}) and affinities (K_d) were determined by Scatchard analysis.

CCK_8 and desulfated CCK_8 dose-dependently modified the binding characteristics of the tritiated antagonist for DA-D_2 receptors in the striatum; a significant decrease in receptor density with a concomitant increase in the affinity of [^{3}H]spiroperidol binding sites was observed. Although these changes were observed with the 1 min preincubation, maximal effects of CCK peptides were achieved with the longer incubations. These results suggest a possible regulatory role for CCK in the striatum.

415.16 THE HIGH AFFINITY CANNABINOID SITE IN BRAIN: REGULATION BY NUCLEOTIDES, METAL IONS AND ASCORBATE.
Jeffrey S. Nye, Adele M. Snowman, Susan Voglmaier* and Solomon H. Snyder. Departments of Neuroscience and Pharmacology, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205, U.S.A.

The high affinity site in rat brain labelled by [^{3}H]5'-trimethylammonium delta-8-THC is an integral component of brain membranes that recognizes cannabinoids with inhibitory constants (K_i) in the nanomolar range (Nye et al. J.Pharm.Exp.Ther. 234: 784-791, 1985). To clarify its physiological role we studied the regulation of [^{3}H]TMA binding. The site is potently inhibited by the metal ions La^{3+} and Mn^{2+} with IC_{50}'s of 0.1 and 0.3 micromolar, respectively. Calcium, magnesium, barium, and strontium ions are inhibitory (IC_{50} = 200-500 micromolar), but significantly weaker. Ferrous, cuprous, and mercurous ions stimulate binding 2-3 fold at 1-5 micromolar, whereas ferric ion, the oxidized form, fails to stimulate and is inhibitory (IC_{50} = 100 micromolar). The halide ions F^-, Cl^-, Br^-, and I^- and the alkali metal ions K^+, Na^+, Rb^+ and Cs^+ are very weak inhibitors and have minimal effects at millimolar concentrations.

Ascorbate is also a stimulator of [^{3}H]TMA binding showing a maximal effect of 3-4 fold at 2 micromolar, whereas dehydroascorbate, the oxidized analog, is 10-20 fold weaker. The stimulation by ascorbate and cuprous ions depends upon the presence of oxygen, and does not result in covalent modification of the radioligand [^{3}H]TMA. At non-inhibitory concentrations Mn^{2+} is able to block the stimulation of ascorbate or cuprous ion. Thus ascorbic acid enhances [^{3}H]TMA binding via a mechanism which requires the presence of a metal ion and oxygen, suggesting that the [^{3}H]TMA site is linked to an unidentified enzymatic process.

Guanine and adenine nucleotides regulate the high affinity cannabinoid site. The non-hydrolyzable analogs of ATP and GTP, AMP-pNHp and GMP-pNHp, are inhibitors of [^{3}H]TMA binding at micromolar concentrations. The thiophosphate analogs, however, are potent stimulators of binding at 2 micromolar. Stimulation by ATP-gamma-S produces a large increase in the B_{max} and a reduction in the affinity of [^{3}H]TMA for its site. These effects suggest that the high affinity cannabinoid site may be regulated by an ATP hydrolyzing enzyme such as a protein kinase.

416.1 PRENATAL SEROTONIN SYNTHESIS IN THE BRAIN OF RATS AND FREE PLASMA L-TRYPTOPHAN IN NEWBORN HUMANS MALNOURISHED IN-UTERO. J. Hernández, G. Manjarréz*, G. Chagoya*. Lab. de Neurontogenia, Depto. Fisiología, Biofísica y Neurociencias, Centro de Investigación, I.P.N., México, D. F. 07000.

Plasma L-tryptophan (L-Trp) is known to be the precursor of brain serotonin (5-HT) synthesis through at least two possible mechanisms:a) regulation by unbound plasma L-Trp specifically transported through the BBB, which activates brain tryptophan-5-hydroxylase (T5-H);b) plasma L-Trp competing for transport through BBB with other neutral amino acids. It is known that early malnutrition is a condition that affects brain 5-HT metabolism, free plasma L-Trp, brain L-Trp and 5-HT content being increased postnatally. Among other possible relevant physiological roles of 5-HT, it has been recently suggested its participation in brain differentiation processes.

In the present study we report results concerning 5-HT metabolism in two group of small for date (SFD) human babies (gestational age ranging from 33 to 36 and from 38 to 42 weeks), who suffered intrauterine nutritional restriction. A complementary study in the brain of rat fetuses with two types of intrauterine deprivation, in which brain T5-H activity and 5-HT content were determined on days 17, 19 and 21 of gestation. The same parameters studied prenatally were followed in both species during the immediate postnatal period.

In the SFD babies the results were as follows: a) the free fraction of plasma L-Trp was significantly elevated; b) plasma neutral amino acids were not substantially modified in the 38 to 42 age group; c) the bound fraction of L-Trp and plasma proteins were significantly low, as compared to the same parameters in normally grown age-paires babies. In the fetal brain of intrauterine malnourished rats, L-Trp, activity of T5-H and 5-HT content, were significantly elevated, since day 17, as related to normal litter-mates. These alterations in 5-HT metabolism persisted during the early postnatal period in both species.

We conclude that brain serotonin synthesis is accelerated, not only in the postnatal period but also is the fetal differentiating brain of the rat with intrauterine malnutrition and that the observed elevation of the free fraction of plasma L-Trp in early malnourished SFD human babies suggest an increased transport of this amino acid to the brain with a possible enhancement of serotonin synthesis.

416.2 DISPARTIES IN THE EARLY PUP DEVELOPMENT AND MATERNAL BEHAVIOR RESULTING FROM DIFFERENT TRYPTOPHAN CONTENT OF DIET. M. Sakuma, Dept. of Biol. Sci.,Wayne St. Univ.,Detroit MI 48201, R.I.Peters*, Dept. of Biol. Sci.,Wichita St. Univ.,Wichita KA 67208, and L.M. Hryhorczuk*, Lafayette Clinic, Detroit MI 48207

Three groups of pregnant rats were fed a diet differing only in tryptophan content. Seven dams in group H recieved a diet containing 3% tryptophan; three dams in group M recieved 0.3% tryptophan diet; four dams in group F recieved 0.03% tryptophan diet. Mothers and pups were subjected to behavioral scoring on delivery day and subsequently every the other day till Day 21. Presently, data is reported for delivery day, one week and two weeks after parturition. The development of pup was evaluated with respect totwenty five items. Sixty pups and twelve pups of H group (60/80,12/80) showed flat and cruciform postures differing from those of M (21/31, 2/31) and F (8/52,4/52). Higher frequency of incisor eruption found in H group (29/66) than that of M (3/31) and no eruption was observed in F (0/52) group. Both H and F pups showed slowness in uprighting from spinal position than that of M pups,but F group showed lowest response to either tail hang or scruffing the neck (50% & 56% Of 55 pups), and lowest spontaneous cry than H and M groups. But F pups showed loud crying during tail pinch when compared with M and F groups. The behavior of dams corresponding these pups was evaluated with respect to fifteen items. On delivery day three out of seven in H dams failed to retrieve their pups 39/70), but three M and four F dams retrieved all pups. Four dams of F group showed no self grooming, whereas two of three in M and five of seven in H dams showed no self grooming. Above low frequencies in H pups appeared to be consist through one week after birth period. Two weeks following birth H pups still kept the flat posture, staggering during forward moving, falling from slope, no response found during one hind limb hang, and poor grasp associating less rearing. While two weeks of age in F pups exhibited the frequent sitting position and more rearing than H pups, meaning that their development was swayed toward to the controls by through one week of age period, excepting less growth of incisor height. On Day 7-8 of lactation, dams of all groups exhibited only one significant difference in that the number of retrieved pups appeared to be lower for the F dams than for the others. On Day 15-16 of lactation all dams failed to show the group difference in all items of maternal behaviors. Thus, Day 0, Day 7-8 and Day 15-16 confirmed the previous results concerning induced developmental lag in pups following the manipulation of mother rat's pregnancy by tryptophan diets (Sakuma,1986). Scince nursing behaviors of Day15-16 failed to show group difference, the findings of these days may exclude influences from dams on pup development suggesting the real developmental delay in both F and H groups compared with controls.

416.3 VISUAL ACUITY, ELECTRORETINOGRAMS, AND RETINAL MORPHOLOGY IN INFANT RHESUS MONKEYS DEPRIVED OF DIETARY TAURINE. M. Neuringer, H. Imaki*, J.A. Sturman, R.C. Moretz* & H.M. Wisniewski. Oregon Regional Primate Research Center, Beaverton, OR 97006 and New York State Institute for Basic Research in Developmental Disabilities, Staten Island, NY 10314.

Diets lacking the amino acid taurine lead to progressive photoreceptor degeneration in cats. Human infants and children maintained by taurine-free parenteral feeding show reduced plasma taurine levels and ophthalmoscopic and electroretinographic abnormalities which normalize when taurine is added to the infusate. Human infants fed low-taurine synthetic infant formulas have similarly low plasma taurine levels, but functional consequences have not been identified.

We are examining the effects of dietary taurine deprivation in rhesus monkeys. In a previous study, long-term feeding of a low-taurine formula resulted in reduced cone electroretinogram amplitudes and ultrastructural cone degeneration. The present study is following the course of visual, electroretinographic, and morphological retinal changes in young rhesus infants.

From birth until three months of age, rhesus monkeys were fed a taurine-free, soy protein-based human infant formula or the same formula supplemented with 70 µmoles/100 ml of taurine, the amount in monkey milk. At 8-12 weeks, plasma taurine levels were reduced by 50-65% in the taurine-deficient group, as they are in human infants fed similar formulas. Visual acuity was measured by the preferential looking method at 4, 8, & 12 weeks of age. Taurine-deprived infants had significantly poorer acuity at all ages. Ophthalmoscopic examinations revealed no significant refractive errors; therefore, the acuity impairment was due to retinal rather than optical factors. However, full-field electroretinograms at three months showed no changes in the amplitude or peak latency of rod- or cone-dominated responses. These results suggested that the central retina, which is critical for normal acuity, may be selectively affected by taurine deprivation. Examination of retinas by light and electron microscopy at three months demonstrated swelling and disorientation of cone outer segments, with extensive disorganization and vesiculation of disc membranes. These changes were most pronounced in the foveal region. Rod outer segments were also affected, but the changes were less severe. Abnormalities were also seen in photoreceptor inner segments and terminals and in pigment epithelial cells.

These results provide further evidence that dietary taurine is essential for normal retinal development in primates, and support the recommendation that taurine be added to human infant formulas at the same level found in human milk.

416.4 ALTERATIONS OF NEURAL DEVELOPMENT AND FUNCTION CAUSED BY NEONATAL NUTRITIONAL DEPRIVATION OR ENHANCEMENT. J.M. Bell, W.L. Whitmore*, K.L. Queen*, L. Orband-Miller* and T.A. Slotkin. Dept. of Pharmacology, Duke Univ. Med. Ctr., Durham, NC 27710.

Neural development and autonomic function were examined in neonatal rats whose nutritional status was manipulated by altering litter size to 5-6 pups (small litter) or 16-17 pups (large litter), as compared to a standard litter size of 10-11 pups. In order to evaluate biochemical mechanisms which operate to buffer the brain from growth retardation, comparisons were made between spared brain regions (cerebellum, cerebral cortrex, midbrain + brainstem), and a tissue which is not spared (heart): evaluations included assessment of ODC and the polyamines, which control macromolecule production during cellular replication and differentiation. Litter size manipulations were associated with shifts in cardiac ODC developmental patterns consistent with subsequent growth impairment in the nutritionally-deprived group whereas overnutrition was associated with a pattern which enhances growth. In contrast, there was a relative lack of nutritional alterations on brain ODC, thus providing an early indication of subsequent sparing of growth. Similar patterns were found for nutritional effects on polyamine levels: there was a predominance of early action on cardiac tissue, and a lack of effect on the most highly spared brain regions. However, the cerebellum, a brain region in which the principal microneurons develop predominantly postnatally (like cardiac muscle cells), displayed alterations of spermidine and spermine levels during the period in which granule cell replication and migration occurred. These data suggested that late-developing structures are more sensitive to nutritional status. To test this hypothesis, we examined peripheral sympathetic development which also occurs after birth. Nutritional deprivation was found to suppress development of sympathetic function, as shown by: (a) persistence of the immature non-neurogenic adrenomedullary catecholamine release in response to hypoxia and (b) a delay in the development of the centrally-mediated baroreflex response of cardiac sympathetics to hypotension. Because sympathetic input is thought to control growth of peripheral organs, the effect of nutritional status on β-receptor mediated cardiac hypertrophy was then examined. Animals raised in large litters showed impairment of the ability of isoproterenol to produce cardiac hypertrophy, suggesting a specific uncoupling of the receptors from growth of peripheral tissues. These results suggest that sparing of growth is not uniform throughout the nervous system, and that effects on neural development can participate in growth retardation and functional impairment in non-neural tissues. 416.5 EFFECTS OF UNDERNUTRITION ON GRANULAR CELLS OF THE DENTATE GYRUS OF HIPPOCAMPUS IN RATS OF THREE AGE GROUPS. L. Cintra, S. Díaz-Cintra and G. Padua*. Depto. de Fisiología, Instituto de Investigaciones Biomédicas, UNAM, México, D.F. 04510.

Previous studies had shown that the hippocampus may be affected by undernutrition in terms of cell reductions on fields CA1, CA2, CA4 and granular cells of the dentate gyrus. The aim of the present paper was the study of the effects of prenatally and postnatally undernutrition using an 8% caseín diet on the granular cells of the dentate gyrus in rats of 30, 90 and 220 days. Using a Golgi morphometric analysis we studied major and minor axis of the cell body, and the number of primary dendrites and dendritic density by the Sholl method and spine density in a 50 microns length of proximal, medial and terminal segments of principal dendrites, as well as, its linear extent. Our results showed in malnourished animals at 30 and 90 days, a significant reduction in the number of spines and dendritic density, however at 220 days, malnourished rats showed a significant increase of primary dendrites. Age related changes showed in malnourished rats a significant increase in the cell body and primary dendrites between 30 and 90 days. Between 90 and 220 days, control rats showed a significant reduction of major axes and significant increase of spines on the basal segment. Undernourished rats showed a significant reduction of major axes and significant increase of dendrites and total spine number between 90 and 220 days. These data shows a general reduction in the synaptic connections represented by the density of branches and dendritic spines, specially in the segments that receive inputs from the perforant path and aminergic brain stem nuclei.

416.6 THE EFFECTS OF PROTEIN DEPRIVATION ON PYRAMIDAL CELLS OF THE VISUAL CORTEX IN RATS OF 30, 90 AND 220 DAYS. S. Díaz-Cintra, L. Cintra and A. Ortega*. Depto. de Fisiología, Instituto de Investigaciones Biomédicas, UNAM, México, D.F. 04510.

The effects of postnatal undernutrition on pyramidal cells of layer V had been revealed that dendritic and spine density are importantly affected, as well as, the visual and motor deprivation affects the spine density on apical dendrites, where projects inespecific afferents. During the development, the layers V and I, mature on first order, followed by layers, VI, III, IV, and layer II. The cellular population of layer V has a prenatal development with postnatal maturation, however in the case of layer III, these mechanisms ocurrs later and probably are more affected by postnatal malnutrition. The aim of the present study was to use an 8% casein diet prenatally and postnatally in order to establish undernutrition in rats. At the ages of 30, 90 and 220 days their brains were processed with rapid-Golgi method and were applied a morphometric analysis on the cells size, the linear extent of apical dendrites and the number of dendritic spines in a 50 microns length in three segments: basal, medial and terminal. The results shown that undernutrition increased significantly the cell size at 30 days and decreased at 220 days on layer III, however layer V showed a significant reduction of cell size at 90 days, linear extent also was reduced at 90 and 220 days in layer V. The number of dendritic spines was significantly reduced at 30 days on medial segment however showed a significant increase at 220 days on terminal dendrites in layer V. Age related changes showed in control rats a significant reduction in the total spine number between 30 and 90 days on layer III, undernourished animals showed a significant increase in total spine number at 90 days in the same layer. In relation to changes between layers III and V, was observed that control animals had reduced number of spines on basal and terminal segment on apical dendrites of pyramidal cells of layer V at 30 and 220 days. Undernourished rats showed a significant reduction on the three segments at 30 days, and at 90 and 220 days the significant reduction was presented on basal segment, finally in control rats, the linear extent was longer on layer V. These results shown the great plasticity of visual area 17 to react to undernutrition and the age related changes. The reductions of different cellular parameters reveals an anatomical deficit of these area that probably affects the mechanisms of visuo-motor integration in undernourished rats.

416.7 ORAL FACTORS INFLUENCE BRAIN GROWTH IN ARTIFICIALLY REARED RAT PUPS. J. Diaz, E. Moore*, E. Ray* and D. Williams*. Department of Psychology, University of Washington, Seattle, WA 98195.

The procedure of rearing rat pups exclusively by direct gastric infusions of formula via chronic gastric fistulas, while useful in a variety of experimental paradigms, has reliably produced animals with smaller brains and larger visceral organs than their mother reared siblings. Oral factors involved in normal digestion and nutrient absorption has been recently described in the adult rat (Ramirez, 1985). In addition, the recent development of a chronic palate cannula for rat pups (Henning and Blake, 1987) has enabled direct testing of oral involvement in the brain growth of young animals. The purpose of the following study is to examine the possible role of oral factors in early brain development.

Eight day old Long-Evans rats were randomly assigned by weight to one of three conditions: 1) animals artificially reared by intragastric cannulas (AR, n=6); 2) animals artificially reared with intra-oral cannulas (PAL, n=5); and 3) animals that were mother reared (MR, n=7). The intraoral cannulas were placed lateral to the 3rd caudal palate ridge on the edge of the hard palate. After four days all the animals were sacrificed and their brains and visceral organs were removed and weighed.

A Repeated Measures Analysis of Variance indicated that the groups grew at different rates. The daily weight gains of the PAL animals were lower than the other two groups. Post hoc pair-wise comparisons further indicated that despite this poor weight gain, the absolute brain weights of the PAL animals were more like the mother reared animals than were the brain weights of the AR animals. However, the visceral organs of the PAL animals were larger than either mother reared or AR animals.

These data suggest that the brain deficits reliably seen following direct intragastric formula infusion may be due partially to the lack of appropriate oral events or factors. The reduced weight gains in the PAL animals presents a problem in the interpretation of these data. The increased visceral organ weights in the PAL animals raises additional concerns. Regardless of these limitations, the fact remains that infusing a milk formula intraorally results in animals with larger brains compared to animals that were infused with the same formula intragastrically. Whether these results may be mediated by lingual lipase, nerve growth factor release, the actual stimulation of swallowing and its possible initiation of gastric motility, or other factors remains to be determined. (Supported by NSF grant RII 8114919, and a grant from the Graduate School of the Univ. of Washington)

416.8 THE EFFECTS OF INFANT MALNUTRITION ON THE DEVELOPMENT OF EVOKED POTENTIALS. A.D. Kirsch*, George Washington University, Washington, D.C. 20037; A. Barnet, I. Weiss, Children's Hospital National Medical Center, Washington, D.C. 20037: J. Flinn, S. Lydick*, George Mason University, Fairfax, VA 22030.

Cortical evoked potentials (EPs) were recorded from 25 severly malnourished infants at admission to hospital, at discharge, and from age matched controls. The average age of the malnourished infants at admission was 174 days and the average age at discharge was 314 days. Auditory and visual evoked potentials (AEPs and VEPs) were recorded from the scalp at C_3, C_z, C_4 over left, right and central cortex and at O_1, O_2, O_z over left, right and central occipital cortex. We have previously reported an analysis of EPs recorded at C_3 and C_4 at admission. This analysis showed that, for EPs to click and patterned lights, the malnourished infants had significantly smaller EPs, with fewer peaks, than the controls, while AEPs to the child's name showed only a trend toward fewer peaks.

We report here that at discharge there were no significant differences in amplitude or number of peaks for the AEPs to click, and there were no significant differences in amplitude for the VEPs to patterned light, although there were fewer peaks ($p < .05$). However at discharge the EPs to name showed significant differences in amplitude ($p < .01$) and number of peaks ($p < .01$).

A frequency analysis of the VEPs to patterned light and the AEPs to name is consistent with these results. The power in three frequency ranges, 0-4, 4-8, 8-12, Hz has been examined. At admission the malnourished infants had significantly less power in all three frequency bands for the VEPs ($p < .01$). At discharge there was no differences in the 0-4 Hz or 8-12 Hz bands, with a tendency ($p < .1$) for lower power in the 4-8 Hz band. A preliminary analysis of the AEPs to name showed no significant differences at admission, but significant reductions in power at discharge ($p < .01$).

The results show that infant malnutrition affects the development of auditory and visual EPs. The EPs to clicks and patterned light improved during hospitalization. However, either because of malnutrition, or because of hospitalization the AEPs to name showed larger differences at discharge than at admission.
